In all that follows, we assume that rays normally propagate from left to right. The first optical system that is examined in more detail is the surface that separates two media with different indices of refraction.

7. CARTESIAN REFRACTING SURFACES

Spherical refracting surfaces do not provide a unique image of a point object, unless rays are restricted to make small angles with the optical axis. In order to obtain a unique image of a point object without imposing restrictions on the rays, the shape of the refracting surface must be changed. Referring to Fig. 9, the surface Σ is determined so that each ray that originated at O and refracted at P passes through I . Hence, the refracting surface Σ represents a perfect optical system according to the previous definition. The shape of Σ is obtained by applying Fermat's principle and requesting that for each point

Figure 8. Optical system and conjugate points.

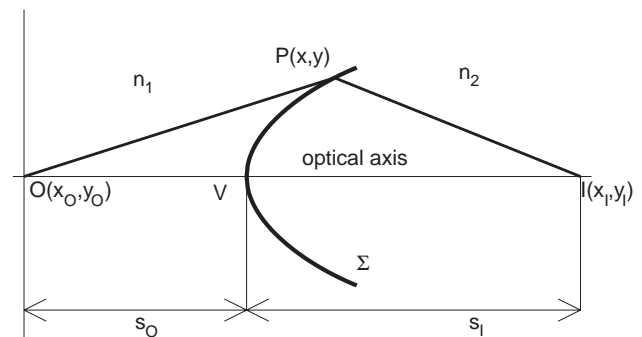

Figure 9. Geometry for a surface that refracts O into I . Note that the surface Σ is not spherical.

$P(x, y)$ on Σ , the path length $O \rightarrow P \rightarrow I$ be the same, i.e.:

$$\begin{aligned} & n_1 \sqrt{(x - x_0)^2 + (y - y_0)^2} \\ & + n_2 \sqrt{(x - x_I)^2 + (y - y_I)^2} \\ & = n_1 s_O + n_2 s_I \end{aligned} \tag{24}$$

This results in an algebraic curve of the fourth order, known as *Cartesian oval*, which is shown in Fig. 9. In practice, one would like to have the object and the image in the same medium and this is not accomplished by a single refracting surface. However, lenses provide a solution since rays passing through a lens undergo two refractions and the image appears outside the lens in the same medium of the object. Now the problem is to determine the appropriate shape of each refracting surface of the lens. Of particular interest are Cartesian refracting surfaces that refract rays from a point object into parallel rays. These parallel rays then will be refracted at the second surface of the lens to form the image. Figure 10a shows an ellipsoidal surface that refracts rays from O into parallel rays when $n_2 < n_1$, while Fig. 10b shows a hyperbolic surface that refracts rays from O into parallel rays when $n_2 > n_1$. It is important to understand that these surfaces provide perfect images only for object points O at very specific locations.

Most actual optical systems contain spherical reflecting and refracting surfaces because they are easy to manufacture. In order to obtain images from these systems, rays must be limited to make small angles with the optical axis. These rays are called *paraxial* and are the topic of the next section.

Figure 10. Cross sections of Cartesian refracting surfaces: (a) ellipsoidal surface that images O at infinity when $n_2 < n_1$; (b) hyperbolic surface that images O at infinity when $n_2 > n_1$.

8. PARAXIAL APPROXIMATION

Most optical systems contain spherical surfaces. When the centers of curvature of all these surfaces are aligned along an axis, the system is said to be *centered* and the axis is called the *optical axis*. If light rays travel almost parallel and at a short lateral distance from the optical axis, it is possible to make simplifications so that the laws of reflection and refraction applied to spherical surfaces take simpler forms. Approximations made assuming that rays are almost parallel to the optical axis are referred to as *paraxial approximations* or *Gaussian optics*. If an angle θ satisfies $|\theta| \ll 1$ because of the paraxial approximation, the following simplifications approximations are made

$$\sin \theta \simeq \tan \theta \simeq \theta, \cos \theta \simeq 1 \tag{25}$$

and, in particular, Snell's law becomes

$$n_1 \theta_1 = n_2 \theta_2 \tag{26}$$

8.1. Reflection at a Spherical Mirror

As a first application of the paraxial approximation, the reflection at a spherical mirror, shown in Fig. 11, is considered. To obtain the location of the image, at least two straight lines must be drawn. The first line goes from the tip P of the object to the center of curvature C because this line does not change direction on reflection. The second line is drawn from the tip P of the object to the vertex V , so that it is easy to determine the direction of the reflected ray. The intersection of these two lines determines the tip

Figure 11. Construction of the images for a concave and a convex spherical mirror.

Q of the image from which the whole virtual image is found. The locations of object and image are determined by using the paraxial approximation and the similarities between the triangles OPC , IQC and OPV , IQV , which yield

$$\frac{1}{s_O} + \frac{1}{s_I} = \frac{1}{f} \tag{27}$$

where f is the focal distance of the mirror, defined as

$$f = -\frac{R}{2} \begin{cases} > 0, & \text{concave mirror} \\ < 0, & \text{convex mirror} \end{cases} \tag{28}$$

The distances s_O and s_I are measured with a sign convention that assumes propagation of light from left to right. A real object (image) is located to the left of V and corresponds to a positive value for s_O (s_I). When the object (image) is virtual, it is located to the right of V and s_O (s_I) is negative. For this geometry, the lateral magnification of the image is

$$m = -\frac{s_I}{s_O} \tag{29}$$

where the negative sign used to obtain a positive number m , due to the sign convention on the distances.

8.2. Refraction at a Spherical Surface

A second application of the paraxial approximation is the refraction from a spherical surface, shown in Fig. 12. Similar to the reflection from a mirror, a minimum of two lines must be drawn to find the location of the image. The first line is traced from the tip P of the object to the center of curvature C , because this line is not deflected. The second line is drawn from the tip P of the object to the vertex V and then continues inside the medium n_2 with an angle θ_2 with respect to the normal at V . These two lines intersect at Q , which gives the location of the image. Application of the paraxial approximation and use of the similarity between triangles OPC and CIQ yields

$$\frac{n_1}{s_O} + \frac{n_2}{s_I} = \frac{n_2 - n_1}{R} \tag{30}$$

Figure 12. Construction of the image at a spherical refracting surface.

where the radius of curvature R is positive for a convex spherical surface. s_O and s_I are positive for real and negative for virtual object and images, respectively. The lateral magnification is given by

$$m = -\frac{n_1 s_I}{n_2 s_O} \tag{31}$$

8.3. The Thin Lens

The relationship just found for a spherical refractive surface may be used to obtain the equation of a *thin lens*, which is made of two spherical refractive surfaces that are separated by a negligible distance. Specifically, assuming that light propagates inside a medium of refractive index n_1 , crosses a refractive spherical interface with radius of curvature R_1 , enters a medium of index n_2 , crosses a spherical interface with radius of curvature R_2 and, finally, enters back into the medium with index n_1 , one obtains the *lensmaker* equation

$$\frac{1}{s_O} + \frac{1}{s_I} = \frac{1}{f} \tag{32}$$

where s_O and s_I are the object and image distances, respectively, which are measured from the plane of the thin lens. In the previous equation, the focal distance f is

$$\frac{1}{f} = \frac{n_2 - n_1}{n_1} \left(\frac{1}{R_1} - \frac{1}{R_2} \right) \tag{33}$$

The lensmaker equation also may be written in a form that emphasizes the curvatures of the wavefronts. In fact, referring to Fig. 13, a spherical wave that expands from O has a curvature, or *vergence*, $V = 1/s_O$ when it reaches the plane of the lens. The lens is characterized by a refracting power $P = 1/f$ that changes the curvature of the wavefront from V to $V' = 1/s_I$ when the wavefront enters the image space to the right of the lens. With these definitions, the alternative form of the lensmaker equation is

$$V + V' = P \tag{34}$$

and its terms have units of *diopeters*, i.e. the inverse of a length, when the distances are measured in meters.

When two or more thin lenses are attached together, their refractive powers add. So n thin lenses with focal

Figure 13. Interpretation of the lensmaker equation in terms of wavefront curvature.

distances f_1, \dots, f_n correspond to one thin lens with equivalent focal length f such that

$$\frac{1}{f} = \frac{1}{f_1} + \dots + \frac{1}{f_n} \quad (35)$$

or with a refractive power

$$P = P_1 + \dots + P_n \quad (36)$$

Many optical systems are designed, at least initially, using paraxial approximations. In fact, paraxial optics relationships are very useful in the analysis of optical systems with many elements, provided that these relationships are cast according to the method discussed in the next section.

9. RAY TRANSFER MATRICES

The analysis of a complex optical system may be carried out by the repeated application of the laws of geometric optics. However, this operation becomes cumbersome even for systems constituted only by a few elements. Fortunately, the paraxial approximation leads to a formalism that describes the passage of a ray through an optical system in terms of simple matrix multiplications. This formalism, known as *matrix optics*, is valid under the paraxial or Gaussian optics approximation and is limited to rays that travel in a single plane; hence it is applicable to systems that have a planar geometry or to meridional rays in circular symmetric systems.

Referring to Fig. 14, at any plane perpendicular to the optical axis, a ray is described by its position y and angle θ , so that the ray at the output plane z_2 is related to the ray at the input plane z_1 by the linear equations:

$$y_2 = Ay_1 + B\theta_1 \quad (37)$$

$$\theta_2 = Cy_1 + D\theta_1 \quad (38)$$

These two equations may be cast in matrix form as

$$\begin{bmatrix} y_2 \\ \theta_2 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} y_1 \\ \theta_1 \end{bmatrix} \quad (39)$$

Figure 14. Geometry for the matrix description of a ray.

Figure 15. Geometry for the translation matrix.

where the matrix with elements A, B, C, D is called *ray-transfer matrix* or *ABCD matrix*. We now are going to consider the ray transfer matrices for some optical systems.

1. *Translation Matrix.* The simplest optical system is the free space between two planes. Referring to Fig. 15, the matrix that describes the propagation is

$$M = \begin{bmatrix} 1 & L \\ 0 & 1 \end{bmatrix} \quad (40)$$

2. *Reflection at a Spherical Interface.* The geometry for the reflection at a spherical interface is described in Fig. 16, which corresponds to the matrix

$$M = \begin{bmatrix} 1 & 0 \\ \frac{2}{R} & 1 \end{bmatrix} \quad (41)$$

Note that the same sign convention applies to all angles both before and after reflection. Rays pointing upward are associated with positive angles while rays pointing downward are associated with negative angles.

3. *Reflection at a Planar Surface.* This matrix may be derived from the previous one in the limiting case that the

Figure 16. Geometry for the reflection from a spherical interface and sign convention for the angles.

curvature $R \rightarrow \infty$. In such a case, one obtains

$$M = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \tag{42}$$

4. *Refraction at a Spherical Interface.* The geometry for this case is given in Fig. 17, and the corresponding matrix is

$$M = \begin{bmatrix} 1 & 0 \\ \frac{n_1 - n_2}{Rn_2} & \frac{n_1}{n_2} \end{bmatrix} \tag{43}$$

5. *Refraction at a Plane Interface.* This is a special case that may be derived when the curvature $R \rightarrow \infty$, which yields

$$M = \begin{bmatrix} 1 & 0 \\ 0 & \frac{n_1}{n_2} \end{bmatrix} \tag{44}$$

6. *Thin-Lens Matrix.* The matrices reported above may be used to derive the ray transfer matrix for a thin lens. In fact, by considering the product of two matrices representing the refraction from a spherical surface, one obtains

$$M = \begin{bmatrix} 1 & 0 \\ \frac{n_2 - n_1}{R_2n_1} & \frac{n_2}{n_1} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ \frac{n_1 - n_2}{R_1n_2} & \frac{n_1}{n_2} \end{bmatrix} \tag{45}$$

$$= \begin{bmatrix} 1 & 0 \\ -\frac{1}{f} & 1 \end{bmatrix}$$

where the focal length f is given by (33). The thin-lens matrix is an example of an optical system that is studied

Figure 17. Geometry for the refraction from a spherical interface.

by cascading the matrices of simpler optical systems. In doing so, it is important to observe that if a ray passes through optical elements characterized by the matrices M_1, \dots, M_n , the overall transformation is represented by a matrix given by the product

$$M = M_n M_{n-1} \dots M_1, \tag{46}$$

Thus, the order of the matrices at the right hand side of the previous equation is inverse to the order followed by the ray to go through the elements of the system. One property of ray matrices is that their determinant is always equal to the ratio of the indices of refraction of the first and final media. This property may be used as a necessary condition to verify if a system matrix is computed correctly. Further details on matrix optics are found in the literature [1,8,10,14].

9.1. Cardinal Points of an Optical System

The characteristics of an optical system may be derived from the knowledge of its six *cardinal* points, which are illustrated in Fig. 18: two focal points F_1 and F_2 , two nodal points N_1 and N_2 , and two principal points Q_1 and Q_2 . *Focal points* are the locations where rays parallel to the optical axis converge. The intersections of rays entering the system with those leaving the system define the principal surfaces, which are usually spherical and centered on the object and the image. In the paraxial approximation, these surfaces are planes and are referred to as *principal planes*. Their intersections with the optical axis defines the *principal points*. *Nodal points* are located on the optical axis and have the property that a ray directed through one of them leaves the system from the other nodal point along a

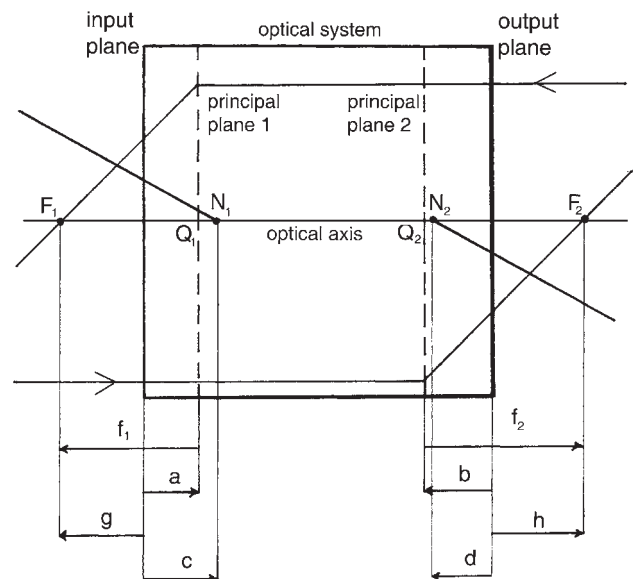

Figure 18. The six cardinal points of an optical system; the principal planes and distances relative to both input/output and principal planes.

direction parallel to the one of the first ray. The expressions “*first focal, principal, and nodal points*” refer to cardinal points defined by rays entering the system from the right. Conversely, “*second cardinal points*” are defined by rays entering the system from the left. The principal planes 1 and 2 are used as references to measure the distances within an optical system [15].

9.2. Meaning of Elements of ABCD Matrix

There are some interesting implications when the elements of the ray transfer matrix go to zero. Referring to (38), when $D = 0$, we obtain $\theta_2 = Cy_1$ regardless of θ_1 . So all rays that enter the system at y_1 will leave with the same angle θ_2 . Hence the input plane of a system with $D = 0$ is first focal plane.

When $A = 0$, from (37), $y_2 = B\theta_1$ hence input rays parallel to each other will leave the system passing by the point at y_2 . Therefore, the output plane of a system with $A = 0$ is the second focal plane of the system.

When $B = 0$, from (37), $y_2 = Ay_1$ so all rays entering the system at y_1 leave the system at y_2 . Hence the input and output planes are conjugate and $A = y_2/y_1$ represents the linear magnification.

When $C = 0$, from (38), $\theta_2 = D\theta_1$ so all rays parallel to the θ_1 direction will leave the system parallel to each other along θ_2 with an angular magnification $D = \theta_2/\theta_1$. Such a system is called *telescopic* because a telescope admits parallel rays and returns parallel rays.

The characteristics of an optical system are determined from its six cardinal points. Under the paraxial approximation, the elements of the ABCD matrix determine the characteristics of the system as well. Thus, there must be a relationship between the cardinal points and the ABCD matrix. This relationship is summarized in Table 1, where the symbols used for the distances are defined in Fig. 18.

Table 1. Relationship between Cardinal Points, Ray Matrix Elements, and Distances Shown in Fig. 18

Relative to Input and Output Reference Planes	
$g = \frac{D}{C}$	
$h = -\frac{A}{C}$	
$a = \frac{D - n_0/n_f}{C}$	
$b = \frac{1 - A}{C}$	
$c = \frac{D - 1}{C}$	
$d = \frac{n_0/n_f - A}{C}$	
Relative to Principal Planes	
$f_1 = g - a = \frac{n_0/n_f}{C}$	
$f_2 = h - b = -\frac{1}{C}$	

Figure 19. Geometry for the refraction from a spherical surface when the paraxial approximation is removed.

Let us now move away from paraxial rays and consider a general result, involving spherical surfaces, attributed to the German Ernst Abbe (1840–1905).

10. REFRACTION AT A SPHERICAL INTERFACE

Let us consider refraction from a spherical surface when the paraxial approximation is abandoned. Referring to Fig. 19, a small object near the axis is considered and its image is obtained by tracing two rays. The first ray, OC, passes through the center of curvature of the lens, so that it is not deflected. The second ray, OP is refracted and intersects the first ray at I. By simple considerations using the triangles OPC, PCI and the similarity between the triangles MOC, CNI one finds the following relationship

$$n_1 h_1 \sin \phi_1 = n_2 h_2 \sin \phi_2 \tag{47}$$

which is called the *Abbe sine condition*. In the paraxial approximation, the angles ϕ_1 and ϕ_2 are small so that the Abbe sine condition is simplified into

$$n_1 h_1 \phi_1 = n_2 h_2 \phi_2 \tag{48}$$

which is also known as the *Lagrange theorem*. For a centered optical system, with many refracting surfaces, the quantities $n_i h_i \sin \phi_i$ or, in the paraxial case, $n_i h_i \phi_i$ are invariant, which constitutes an important property. The Abbe sine condition is used in the one of Seidel’s aberrations.

11. ABERRATIONS

The paraxial approximation is valid for rays that travel very close to the axis of an optical system and leads to the formation of perfect images. In practical optical systems there are apertures, rays are not necessarily paraxial and departures from perfect images are observed. These departures are called *aberrations*, and practical optical systems are corrected to minimize aberrations so that images that are as close as possible to the ideal ones are obtained. To understand the origin of aberrations, let us consider an optical system that images a point source. Under the

paraxial approximation, the ideal wavefront at the exit pupil of an optical system is spherical and is obtained from linear expressions that result from the following trigonometric expansions

$$\begin{aligned} \sin x &= x - \frac{x^3}{3!} + \frac{x^5}{5!} + \dots + (-1)^n \frac{x^{2n+1}}{(2n+1)!} \\ \cos x &= 1 - \frac{x^2}{2!} + \frac{x^4}{4!} + \dots + (-1)^n \frac{x^{2n}}{(2n)!} \end{aligned} \tag{49}$$

when they are stopped at the first term. When higher order terms are included, aberrations appear. In particular, if the expansions (49) are stopped at terms of order no larger than x^3 , one obtains the third-order aberration theory originally developed by the German mathematician Ludwig Von Seidel (1821–1896). According to his theory, there are five aberrations for monochromatic illumination: *spherical aberration*, *coma*, *astigmatism*, *curvature of field* and *distortion*. If nonmonochromatic illumination is considered, the *chromatic aberration* is the sixth Seidel aberration. A further refined theory considers terms up to the order of x^5 , but for most practical applications Seidel theory is sufficiently accurate. The theory of aberrations is described, among others, elsewhere in the literature [9–11,13,15–19].

11.1. Third-Order Theory

Figure 20 shows a generic optical system that creates the actual wavefront S_2 and the ideal wavefront S_1 . The actual ray forms an image L along the optical axis and the image T in the plane of the ideal paraxial image, while the ideal ray forms an image at I . There are different ways to measure the aberration. One may refer to the longitudinal aberration LI , the transverse, or lateral aberration TI or the difference PQ of the wavefront position. Since most optical systems contain spherical surfaces, the aberrations of spherical surfaces are studied in great detail when the object is either a point along the optical axis or a point off the optical axis. For a point object O located on the optical axis, the aberration is measured as shown in Fig. 21 by the optical path difference between the shortest ray, OVI , and another ray refracted at P , OPI . The aberration according

Figure 20. Difference between the ideal wavefront S_1 and the actual wavefront S_2 and various measures for the aberration.

Figure 21. Geometry for the reflection at a spherical interface.

to the third-order theory, is given by the difference

$$a(P) = \overline{OCI} - \overline{OPI} = ch^4 \tag{50}$$

where c is a proportionality constant.

For an object point O located off axis, as shown in Fig. 22, the aberration measured as the difference between the shortest ray and another ray diffracted at P is given by

$$a(P) = \overline{OCI} - \overline{OPI} \tag{51}$$

However, all practical optical systems have an aperture or pupil or stop that is usually centered along the optical axis. Hence, a beam of rays out of O is not symmetrical with respect to OC because of the presence of the aperture. As a result of this lack of symmetry, the measure of the aberrations for points located off axis leads to four (additional) Seidel aberrations. Referring to Fig. 22, it is found that

$$\begin{aligned} a(P) &= C_{040}r^4 + C_{131}h_I r^3 \cos \theta + C_{222}h_I^2 r^2 \cos^2 \theta \\ &+ C_{220}h_I^2 r^2 + C_{311}h_I^3 r \cos \theta \end{aligned} \tag{52}$$

where the subscripts of the coefficients represents powers of h_I , r , $\cos \theta$, respectively. The terms that appear in (52)

Figure 22. Geometry for refraction of an off-axis point O by a spherical surface. The presence of a stop breaks the symmetry around the shortest ray OCI .

represent

$$\begin{aligned}
 S_1 &= C_{040}r^4 && \text{spherical aberration} \\
 S_2 &= C_{131}h_I r^3 \cos \theta && \text{coma} \\
 S_3 &= C_{222}h_I^2 r^2 \cos^2 \theta && \text{astigmatism} \\
 S_4 &= C_{220}h_I^2 r^2 && \text{curvature of field} \\
 S_5 &= C_{311}h_I^3 r \cos \theta && \text{distortion}
 \end{aligned}
 \tag{53}$$

Each one of these aberrations is described in the following as if they were the only aberration present.

11.2. Spherical Aberration

Spherical aberration is the variation of the focal length with the aperture and is the only aberration, among $S_1 - S_5$ indicated in (53), that does not depend upon h_I so it always exists. In particular, it may exist when combinations of spherical surfaces occur. Most optical instruments use parallel rays, so it is customary to measure, for comparison purposes, the aberration due to parallel rays. Figure 23 illustrates how spherical aberration results into different focal points F_0, F_1, F_2, F_3 depending on the diameter r of the zone of the lens where the beam of parallel rays is incident. The spherical aberration of a lens is reduced by changing the radii of curvature of the two spherical surfaces of the lens. In fact, since the focal length of the lens is given by (33), it is possible to change the values of the index of refraction n, R_1 and R_2 without altering the focal length f .

As an example, Fig. 24 shows lenses with the same focal length but different shape. The shape of a thin-lens may be characterized by the *Coddington shape factor*

$$\zeta = \frac{R_2 + R_1}{R_2 - R_1}
 \tag{54}$$

and by changing ζ the spherical aberration may be reduced but not completely eliminated. It is possible to completely eliminate spherical aberration from a single lens by aspherizing it. However, such an aspherized lens will be free from spherical aberrations only for a particular object distance, so such a process is justified for only a few special instruments.

Figure 23. Spherical aberration of a lens that produces different images depending on the diameter h of the zone of the lens.

Figure 24. Lenses with same focal length but different Coddington shape factors.

11.3. Coma

Coma is the variation of magnification with the aperture and is nonsymmetric with respect to the optical axis because it depends on $\cos \theta$. Figure 25 shows how this aberration affects a set of parallel rays that are refracted by a thin lens. The ray through the center of the lens V is focused at V' , while the rays through the edges of the lens P are focused at P' . Hence, the magnification is different depending on which part of the lens the rays go through.

More specifically, referring to Fig. 26, each ring-shaped area of the lens forms a so-called comatic circle. Within each ring-shaped zone of the lens, rays contribute to different parts of the comatic circle. For example, rays contained in the sagittal plane determine the top part of the comatic circle, whereas rays contained in the tangential plane determine the bottom of the comatic circle. Each comatic circle increases in radius as the radius of the originating zone on the lens increases. The superposition of all comatic circles, shown in the bottom right corner of Fig. 25, is a comet-like figure from which the name coma for this aberration is derived.

In Section 10, we saw that rays making wide angles with the optical axis must satisfy the Abbe sine condition (47). This relation may be rearranged to point out the lateral magnification as

$$\frac{h_2}{h_1} = -\frac{n_1 \sin \varphi_1}{n_2 \sin \varphi_2}
 \tag{55}$$

Figure 25. A set of parallel rays generates a superposition of comatic circles of different radii.

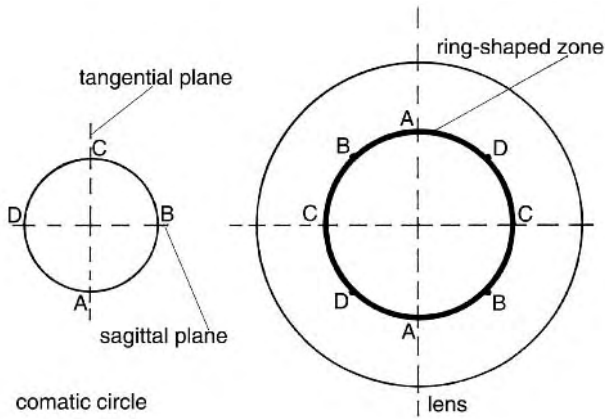

Figure 26. Detail of the contribution of a ring-shaped zone of a lens to the creation of a comatic circle. Rays through the tangential plane of the lens contribute to the bottom of the comatic circle, and rays through the sagittal plane of the lens contribute to the top of the comatic circle.

Hence, to prevent coma, the lateral magnification must be the same for all zones of a lens:

$$\frac{\sin \phi_1}{\sin \phi_2} = \text{const} \tag{56}$$

Similar to spherical aberration, coma may be reduced by changing the shape of a lens. In particular, it is possible to prove that coma is absent when

$$\zeta = \left(\frac{2n^2 - n - 1}{n + 1} \right) \frac{s_O - s_I}{s_O + s_I} \tag{57}$$

An optical system that is free of both spherical aberration and coma is called *aplanatic*.

11.4. Astigmatism

Astigmatism is explained with the help of Fig. 27 that shows an object point *O* and two beams of rays that are obliquely incident on the lens. The rays contained in the vertical, or tangential, plane *tt'* focus along the horizontal caustic line *T*, while the rays contained in the horizontal, or sagittal, plane *ss'* cross along the vertical caustic line *S*.

Figure 27. Formation of an astigmatic image. A fan of rays in the sagittal, or horizontal, *ss'* plane focuses along the vertical line *S*, while a fan of rays in the tangential, or vertical, plane *tt'* focuses along the horizontal line *T*.

Figure 28. Cross sections of the paraboloidal surfaces *S* and *T*.

Normally, the image of a point is a point, but, when astigmatism is present, the image takes the form of two separate lines. Between *T* and *S* the cross section of the beam is approximately circular and constitutes the *circle of least confusion* for the image of *O*. When the angle θ is varied, *S* and *T* describe curved surfaces that are paraboloids of revolution whose cross sections are indicated in Fig. 28. The amount of astigmatism is measured by the distance between these two surfaces along the chief ray (a ray that passes through the center of the aperture of an optical system). If the astigmatism is removed, the surfaces *S* and *T* coincide with each other and result into the *Petzval surface* (named after Joseph Max Petzval [1807–1891], a Hungarian optician and mathematician).

11.5. Curvature of Field

Even if the first three aberrations are removed, the image is formed on the curved Petzval surface and, hence, the focal surface is curved, which leads to the curvature of the field. This is understood by referring to Fig. 29, which shows the location of an ideal image *IQ* of the object *OP*. According to Fermat’s principle, for *IQ* to be an image, the distances *s_I* and *s_Q* must be identical. Since this cannot happen for an extended object *OP*, the image is formed along the curved surface *RS*. A simple way to obtain flattening of the image field is by means of a stop that prevents oblique chief rays from penetrating the lens center.

11.6. Distortion

This aberration is caused by a different lateral magnification for points located at different distances from the optical axis. The common shapes of distorted images are shown in Fig. 30, where part (a) represents the undistorted image of a wire mesh object; part (b) shows barrel distortion, which is characterized by a smaller magnification at the edges of the field; and part (c) shows pincushion distortion that is characterized by a greater magnification

Figure 29. Geometry for the formation of the image of an extended object that shows the curvature of field.

Figure 30. Example of distorted images. The correct image of a wire mesh object is shown in (a), while (b) represents an image affected by barrel distortion, and (c) depicts an image affected by pincushion distortion.

toward the edges of the field. As an example of an optical system that is free from distortion is the pinhole camera, shown in Fig. 31, for which

$$\frac{\tan \theta'}{\tan \theta} = \text{const} \tag{58}$$

11.7. Chromatic Aberration

The previous five aberrations occur for monochromatic light; when nonmonochromatic light is used, the variation of the index of refraction with the frequency of light causes chromatic aberration, which results in the creation of one image per color present in the illumination. Normally, the index of refraction is larger at higher frequencies, so that, for a thin lens, the focal distance (33) is shorter at higher frequencies. Figure 32a shows the variation in focal distance for the image of the same object that is illuminated with white light and located at large distance from the lens along the optical axis. The axial distance between the images *V* and *R* is the longitudinal chromatic aberration. There is also a lateral chromatic aberration, shown in Fig. 32b, for the image of an off-axis object. One of the simplest methods to correct chromatic aberration is to put in contact two lenses made of different materials and with different powers, as shown in the achromatic doublet of Fig. 32c. The powers are chosen with opposite sign and different magnitudes so that the net power is either

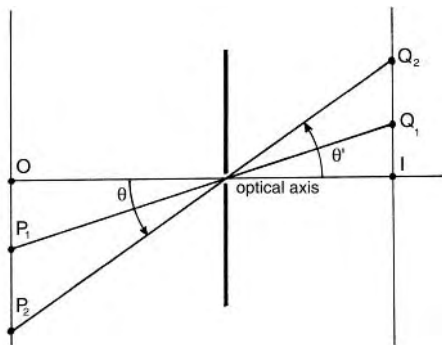

Figure 31. A pinhole camera provides a lateral magnification that is constant.

Figure 32. (a) Longitudinal chromatic aberration resulting from different focal distances for different colors for the images of an object located along the optical axis and at large distance from the lens; (b) lateral chromatic aberration for an object located off the optical axis; (c) achromatic doublet that removes chromatic aberration.

positive or negative. The materials and the shapes of the lenses are chosen so that the dispersion of one lens compensates for the dispersion of the other and, within a certain frequency interval, the doublet is not affected by chromatic aberration.

12. RELATIONSHIP BETWEEN GEOMETRIC OPTICS AND ELECTROMAGNETIC THEORY

12.1. Eikonal Equation

An elegant introduction to geometrical optics and its relationship to the electromagnetic theory is found in Refs. 2 and 12, from which part of the material contained in this section is based.

The German Gustav Kirchhoff (1824–1887) made the first significant effort to derive geometrical optics from a wave theory. He expressed mathematically the principle of Huygens, which resulted in the Kirchhoff–Huygens principle. Even though the Kirchhoff–Huygens principle contains some mathematical inconsistencies, it is remarkable that it is successful in so many applications. In particular, in 1882 Kirchhoff [20] showed that when the wavelength $\lambda \rightarrow 0$, the field given by the Kirchhoff integral in the presence of an obstacle approaches the prediction obtained from geometrical optics: the existence of a sharp transition

between dark and lit regions. Eventually, the point of view of geometric optics as a limiting case of the electromagnetic theory when $\lambda \rightarrow 0$ became accepted.

Sommerfeld and Runge [21] provided the most accepted argument to show the connection between geometric optics and electromagnetic theory. They assumed that a scalar function $u(x, y, z)$ represents the complex amplitude of a component of the electric field \mathbf{E} , which, in the monochromatic case, satisfies the Helmholtz scalar equation

$$\nabla^2 u(x, y, z) + k^2 u(x, y, z) = 0 \quad (59)$$

where ∇^2 is the laplacian operator, $k = k_0 n = \sqrt{\epsilon \mu} \omega / c = 2\pi / \lambda$ is the wavevector, ω is the angular frequency, and the medium is assumed to be linear, isotropic and described by a permittivity ϵ and a permeability μ , which may be functions of the position. Sommerfeld and Runge assumed that the functional form of $u(x, y, z)$ was a generalization of a plane wave

$$u(x, y, z) = A(x, y, z) e^{jk_0 \Psi(x, y, z)} \quad (60)$$

where A is the amplitude of u and $k_0 \Psi$ is the phase. In particular, $\Psi(x, y, z)$ is a real scalar called *eikonal function* and surfaces along which $\Psi(x, y, z) = \text{const}$ are the wavefronts of the electromagnetic field. It is also assumed that A and Ψ do not vary rapidly with changes in the position. When (60) is substituted into (59), it is obtained that

$$k_0^2 (n^2 - |\nabla \Psi|^2) A + \nabla^2 A + j k_0 (2\nabla \Psi \cdot \nabla A + A \nabla^2 \Psi) = 0 \quad (61)$$

which requires that both real and imaginary part be independently zero. The condition on the real part yields

$$|\nabla \Psi|^2 = n^2 + \left(\frac{\lambda}{2\pi}\right)^2 \frac{\nabla^2 A}{A} \quad (62)$$

In the limit of $\lambda \rightarrow 0$, the last term of the previous equation vanishes, which leaves the so-called eikonal equation:

$$|\nabla \Psi|^2 = n^2 \quad (63)$$

The eikonal equation is at the basis of geometric optics, and its solutions define the wavefronts. In the following, it is shown that the ray equation (16) may be obtained from the eikonal equation. For this purpose, let us observe that $\hat{\mathbf{t}} = \nabla \Psi / n$ defines a unit vector that is perpendicular to the surfaces $\Psi = \text{const}$ (because of the meaning of the gradient of Ψ) and consider a trajectory $\mathbf{r} = \mathbf{r}(s)$ that admits $\hat{\mathbf{t}}$ as its tangent unit vector, where s measures the length of the trajectory from an arbitrary point along it. Then, it is possible to write

$$n \hat{\mathbf{t}} = n \frac{d\mathbf{r}}{ds} = \nabla \Psi \quad (64)$$

from which ray trajectories could be derived from the knowledge of Ψ . With a few more steps, the dependence on Ψ is removed from the previous equation. In fact, the directional derivative along $\mathbf{r}(s)$ of the previous equation

yields

$$\begin{aligned} \frac{d}{ds} \left(n \frac{d\mathbf{r}}{ds} \right) &= \frac{d}{ds} (\nabla \Psi) = \frac{d\mathbf{r}}{ds} \cdot \nabla (\nabla \Psi) = \frac{\nabla \Psi}{n} \cdot \nabla (\nabla \Psi) \\ &= \frac{1}{2n} \nabla (|\nabla \Psi|^2) = \frac{1}{2n} \nabla n^2 = \nabla n \end{aligned} \quad (65)$$

So, finally, one obtains the ray equation (16) that was independently derived from Fermat's principle. Therefore, the path to point out the relationship between the electromagnetic theory and geometric optics occurs in three steps: (1) one shows that when $\lambda \rightarrow 0$ (high-frequency approximation) the description of the electromagnetic field provided by (60) leads to the eikonal equation (63); (2) one observes that the eikonal equation defines surfaces $\Psi = \text{const}$ that are perpendicular to the ray trajectories; and (3) the ray equation (16) is derived from the eikonal equation.

Classical geometric optics provides a description of light phenomena that is based only on the geometric concept of a ray. However, in order to use geometric optics to make quantitative statements, this theory needs to be extended to introduce the concepts of amplitude, phase, and polarization. These extensions are explored in the following two sections, which are based on Ref. 22.

12.2. Amplitude Relation

The notion of light intensity may be introduced into the classical geometric optics by imposing the conservation of the energy flux inside a tube of rays. For example, let us consider the isotropic spherical wavefront shown in Fig. 33, where two different cross sections of areas dA_0 and dA are located at some reference points $s=0$ and s , respectively. The radiation density S_0 at $s=0$ and S at s

Figure 33. Tube of rays for an isotropic spherical source. (Constantine A. Balanis, *Advanced Engineering Electromagnetics*, copyright ©1989 by John Wiley & Sons, Inc. This material is used by permission of John Wiley & Sons, Inc.)

are related by

$$S_0 dA = S dA \tag{66}$$

because it is assumed that no energy flows through the lateral side of the cylinder. For an electromagnetic wave in the far-zone field of the source, the relationship between the electric field $\mathbf{E}(\mathbf{r}, \theta, \varphi)$ and the radiation density $S(r, \theta, \varphi)$ is

$$S(r, \theta, \varphi) = \frac{1}{2\eta} |\mathbf{E}(r, \theta, \varphi)|^2 \tag{67}$$

Hence, combining the last two equations, one obtains

$$\frac{|\mathbf{E}|}{|\mathbf{E}_0|} = \sqrt{\frac{dA_0}{dA}} \tag{68}$$

The shape of the eikonal surface combined with this equation determines how the amplitude of the electric field changes between eikonal surfaces. As an example, let us consider the astigmatic eikonal surface, which is more general than a spherical one, shown in Fig. 34. For such a surface, the amplitude of the electric field on one surface relative to another varies according to [22]

$$\frac{|\mathbf{E}|}{|\mathbf{E}_0|} = \sqrt{\frac{dA_0}{dA}} = \sqrt{\frac{\rho_1 \rho_2}{(\rho_1 + s)(\rho_2 + s)}} \tag{69}$$

This equation reduces to

$$\frac{|\mathbf{E}|}{|\mathbf{E}_0|} = 1 \tag{70}$$

Figure 34. Astigmatic tube of rays. (Constantine A. Balanis, *Advanced Engineering Electromagnetics*, copyright © 1989 by John Wiley & Sons, Inc. This material is used by permission of John Wiley & Sons, Inc.)

for a plane wave, which corresponds to $\rho_1 = \rho_2 = \infty$. Equation (69) reduces to

$$\frac{|\mathbf{E}|}{|\mathbf{E}_0|} = \sqrt{\frac{dA_0}{dA}} = \sqrt{\frac{\rho_0}{\rho_0 + s}} \tag{71}$$

for a cylindrical wavefront, which corresponds to $\rho_1 = \rho_0, \rho_2 = \infty$. For a spherical wavefront, which corresponds to $\rho_1 = \rho_2 = \rho_0$, Eq. (69) becomes

$$\frac{|\mathbf{E}|}{|\mathbf{E}_0|} = \sqrt{\frac{dA_0}{dA}} = \sqrt{\frac{\rho_0}{\rho_0 + s}} \tag{72}$$

The relationship (69)–(72) define the correct way to relate to the amplitudes of the electric field at one surface relative to another, when the frequency ω is sufficiently large. However, these relationships do not include phase and polarization.

12.3. Phase and Polarization

Phase and polarization may be introduced into classical geometric optics using the approach of Luneburg [11] and Kline [23], which is referred to as *Luneburg–Kline high-frequency expansion*. According to their approach, when the frequency ω is sufficiently large, the electric field may be written using the following series:

$$\mathbf{E}(x, y, z, \omega) = e^{-j\beta_0 \Psi(x, y, z)} \sum_{m=0}^{\infty} \frac{\mathbf{E}_m(x, y, z)}{(j\omega)^m} \tag{73}$$

If we limit our attention only to solutions that (1) are of the first order (i.e., $m = 0$) and (2) take the form

$$\mathbf{E}(s) = e^{-j\beta_0 \Psi(s)} \mathbf{E}(s = 0) \tag{74}$$

we can prove [2] that for the geometry of Fig. 34

$$\mathbf{E} = \mathbf{E}_0 e^{-jk_0 \Psi(0)} \sqrt{\frac{\rho_1 \rho_2}{(\rho_1 + s)(\rho_2 + s)}} e^{-jk_0 s} \tag{75}$$

where $s = 0$ is the reference point. Equation (75) provides the extended geometric optics description of an electric field where the polarization comes from the vector \mathbf{E}_0 at an arbitrary reference point $s = 0$ along a trajectory described by a normal to the eikonal surface Ψ . The initial phase is given by $e^{-jk_0 \Psi(0)}$. The amplitude varies according to the square-root term, for an astigmatic wavefront, and the last exponential term accounts for the appropriate phase delay. When $s = -\rho_1$ or $s = -\rho_2$, Eq. (75) is singular because these are the locations of the two caustic lines shown in Fig. 34; hence this equation should not be used at caustics or very close to them.

13. APPLICATION OF GEOMETRIC OPTICS TO THE DESIGN OF ANTENNAS

The Cartesian surfaces described in Section 3 have properties that are exploited in the design of a class of antennas called *reflector antennas*. To understand how basic geometrical optics concepts are transferred to the operation of these antennas, let us refer to Fig. 35. In Section 3, we mentioned that rays emitted from a point source located at the focus F become parallel to the axis z after a reflection on the parabolic surface. Hence the circular wavefront out of F is transformed into a plane wavefront. The same conclusion may be obtained directly from the definition of a parabola. The parabola is the locus of points P that have the same distance from a straight line, the directrix d , and a point, the focus F , which yields

$$FP = GP \quad (76)$$

Consider the line MN , which is perpendicular to the axis z , and its intersection W with a ray reflected at P . One can write

$$FP + PW = FP + (GW - GP) = GW \quad (77)$$

Thus, since the path length $FP + PW$ is the same for all points P on the parabola, the line MN is a wavefront. Additionally, the image of the focus is the directrix because the wavefront at W appears to have originated at G .

In practice, the parabola shown in Fig. 35 must be terminated somewhere, such as at points A and B indicated in the figure. This geometry should be interpreted as the cross section of two antennas: the paraboloidal and the cylindrical parabolic reflectors. A paraboloid is obtained by the rotation of a parabola around its axis. If an isotropic source is located in the focus of the parabola, the portion of the spherical wavefront that is captured by the paraboloid is transformed into a plane wavefront. The cylindrical parabolic reflector has a line source located in the focus

Figure 35. A parabola.

and transforms a cylindrical wavefront into a plane wavefront. For both antennas, the power due to a source is concentrated mostly along the direction of the axis. For both antennas, the actual field received by an observer along the axis is the superposition of a plane wavefront and the direct field from the source. Improvements on the design of reflector antennas include the use of subreflectors. For example, in the Cassegrain design a hyperbolic subreflector faces the main parabolic reflector with the advantage of an overall more compact design because the feedpoint is moved closer to the vertex of the parabola [24]. Similar to optical elements with spherical surfaces, reflector antennas also are affected by aberrations.

Another result of geometric optics that finds application in the design of antennas is the Luneburg lens introduced in Section 5.4. In view of the relationship between electromagnetic theory and geometric optics, it is important to point out that many results from geometric optics are useful for the design of systems that operates at frequencies different from those of visible light. Such a perspective that unites optical principles with the design of microwave antennas are provided in Refs. 25 and 26.

14. EXTENSION OF GEOMETRIC OPTICS TO INCLUDE DIFFRACTION PHENOMENA

Ray tracing, which stems from geometric optics, is not only used for the design of optical systems but also has applications in other engineering fields. For example, many applications related to computer graphics are based on ray tracing [27], and software is available to write programs that exploit ray tracing [28].

The link between geometric optics and electromagnetic theory not only is a topic of academic interest but also proves useful in many engineering applications. Ray tracing is a very convenient way to simplify the complex problem of the propagation of a wavefront. In fact, many electromagnetic problems are simplified by making a high-frequency approximation that reduces the complex study of the propagation of a wavefront to the simpler ray tracing of the normal to the wavefronts. Electromagnetic problems that benefit from ray theories include the computation of radar cross sections and diffraction by objects and predictions of the path loss for radiocommunications [29].

The ray tracing that is derived from geometric optics is concerned only with the direction of propagation of the normal to the wavefront. For an electromagnetic application, other quantities such as polarization and the intensity associated with the wavefront are also important. While polarization is easily accounted for, a correct evaluation of the intensity requires an extension of geometric optics to account for diffraction. Hence many efforts have been devoted to the development of extensions to geometric optics [30]. Without going into the details of these extensions, which would be beyond the purpose of this article on geometric optics, only few of these efforts are mentioned. Keller [31] developed a theory that includes diffraction by formulating a generalization of Fermat's principle. Keller's geometric theory of diffraction (GTD) was later improved by uniform theories such as the

uniform theory of diffraction (UTD) of Kouyoumjian and Pathak [32,33] and the uniform asymptotic theory (UAT) of electromagnetic diffraction by Lee and Deschamps [34]. These theories may fail near caustics, so more recently Tiberio et al. [35] developed the incremental theory of diffraction (ITD), which avoids problems near caustics and presents other advantages.

1. INTRODUCTION

Silicon–germanium heterojunction bipolar transistors (HBTs) [1–3] extend the frequency limits of silicon-based technology. In the SiGe HBT, the base region is formed by an epitaxially grown SiGe layer between the adjacent silicon layers. Because of the lower bandgap of the base region also existing in the case of high base doping, a high emitter efficiency is achieved. This allows a HBT design with small base width and a low base series resistance. The heterojunction bipolar transistor was first suggested in 1957 by Kroemer [4]. A first suggestion for a SiGe-base heterojunction bipolar transistor (HBT) for high-frequency applications was made in 1977 [5]. SiGe technology has been pushed mainly as a commercial technology by IBM, DaimlerChrysler/TEMIC and Infineon. Commercially available HBTs exhibit f_T values greater than 50 GHz and f_{max} values in excess of 70 GHz, a minimum noise figure below 0.7 dB at 2 GHz, $1/f$ noise corner frequencies below 500 Hz, and a reliability comparable to Si devices [2]. Future trends in SiGe technology point toward the integration of more complex circuits, technology efforts to facilitate easier manufacturing and speed increase beyond $f_T = 200$ GHz [6]. The silicon–germanium heterojunction bipolar transistor enabled the breakthrough of silicon-based

MMIC (monolithic millimeter-wave integrated circuit) technology [1,6]. Amplifiers and tunable oscillators or with maximum operation frequencies beyond 80 GHz become feasible. Infineon's SiGe bipolar production technology B7HF is capable for high-volume production [7]. SiGe HBTs with transit frequencies f_T above 200 GHz and maximum oscillation frequencies of $f_{\max} = 338$ GHz already have been realized [8–11].

Also, the suitability of CMOS devices for RF applications continuously improves [3]. With 0.25- μm technology, f_T values are as high as 40 GHz and should double roughly every 3 years if trends continue [12,13]. A K-band traveling-wave amplifier as well as a 17-GHz traveling-wave oscillator have already been realized with CMOS devices [12]; 70-nm CMOS have cutoff frequencies reaching 150 GHz and an inverter gate delay time around 15 ps at a supply voltage of 1.5 V [14]. The short gate delay time makes CMOS circuits suitable for future broadband multimedia applications.

SiGe/Si-MODFETs (*modulation-doped field-effect transistors*) are high electron mobility transistors [15]. The material system GeSi is the only one that exhibits symmetric transport properties for complementary n- and p-channel devices. For both channel types an f_{\max} of 100 GHz has already been achieved. Silicon-germanium MODFETs have a significant high-frequency potential [16]. The introduction of SiGe allows the realization of n- and p-type hetero-FETs (MOSFETs), both with enhanced performance. Maximum oscillation frequencies of more than 100 GHz have been obtained with n- and p-MOSFETs.

A further improvement of the RF properties of silicon-based devices will result from the introduction of copper technology. As semiconductor devices are scaled down to the submicron region, interconnection losses are becoming a limiting factor. In submicrometer technology, copper interconnects will exhibit lower resistivity and better reliability than aluminium interconnects. Copper reduces line and via resistances by at least 50%, increases the maximum current density by a factor of 2.5–3.0, and maintains the same leakage current properties as the Al interconnects. The damascene process enables the fabrication of submicrometer copper interconnects [17,18].

New device concepts try to exploit unavoidable delay times and drift fields in heterojunction devices in order to generate a resonant behavior of the device at frequencies beyond the current gain cutoff frequency [19–21].

Silicon as a substrate for millimeter-wave monolithically integrated circuits was suggested in 1981 by RCA [22]. Since 1986 in the field of silicon *monolithic millimeter-wave integrated circuits* (SIMMWICs) there have been research activities at the former AEG-Telefunken Research Institute (now DaimlerChrysler Research Center) and at the Technische Universität München [23–29]. Up to now SIMMWICs for frequencies up to above 100 GHz already have been fabricated, and the suitability of silicon as the base material for monolithic integrated millimeterwave circuits has been successfully demonstrated. Monolithic integration of solid-state devices provides the possibility of low-cost production, improved reliability, small size and light weight, and easy assembly.

The linear passive parts of SIMMWICs may be realized in planar circuit technology. The fundamental transmission-line structures used SIMMWIC design are microstrip lines, slotlines, coplanar lines, coplanar striplines, and microshield lines. Based on these fundamental geometric structures, the planar circuit elements are designed. These planar circuit elements include transmission-line discontinuities, planar resonators and antennas as the basic structures.

In the frequency region above 60 GHz, SIMMWICs with dimensions of only a few millimeters may also include planar antenna structures. The integration of the antenna structures allows the direct coupling of SIMMWICs to the radiation field.

Monolithic integrated millimeterwave circuits based on silicon and SiGe will give new options for millimeter-wave sensor and communication applications. Compared with microwave-based systems, millimeter-wave-based systems offer the following advantages:

- Availability of broader frequency bands
- Higher gain and smaller dimensions of antennas
- Lower weight and smaller size of the components
- Higher resolution for sensor applications
- Atmospheric attenuation that may prevent interference between cells

A broad application of millimeter waves in sensors and communications has been hampered up to now because of the high costs of millimeter-wave components. This situation may change in the future with the availability of low-cost monolithic integrated components based on a silicon and SiGe technology.

2. SILICON AS THE BASE MATERIAL

Table 1 compares the data for Si and GaAs. At 90 GHz, the dielectric loss tangents of Si and GaAs are within the same order of magnitude, and for microwave circuits, silicon substrates with a specific resistance of $10,000 \Omega \cdot \text{cm}$ are available. For this material, the conductor losses due to the skin effect dominate the loss contributions of planar circuits, whereas the substrate losses in the silicon account only for a minor part. The electron mobility of GaAs is 6 times higher than the electron mobility of Si. This yields a correspondingly higher f_T value for bipolar transistors and field effect transistors. On the other hand, the

Table 1. Parameters of Si and GaAs

	Si	GaAs
Dielectric constant	$\epsilon_r = 11.7$	$\epsilon_r = 12.9$
Specific resistance	$> 10^4 \Omega \cdot \text{cm}$	$> 10^6 \Omega \cdot \text{cm}$
Dielectric loss		
Factor (90 GHz)	1.3×10^{-3}	0.7×10^{-3}
Thermal conditions	$1.45 \text{ W cm}^{-1} \text{ K}^{-1}$	$0.46 \text{ W cm}^{-1} \text{ K}^{-1}$
Electron mobility	$700 \text{ cm}^2/\text{V} \cdot \text{s}$	$4300 \text{ cm}^2/\text{V} \cdot \text{s}$
High field drift velocity	10^7 cm/s	$6 \cdot 10^6 \text{ cm/s}$
Density	2.33 g/cm^3	5.32 g/cm^3

high field drift velocity of Si and GaAs are in the same order. The thermal conductivity of silicon is 3 times higher than the thermal conductivity of GaAs. From this point of view, silicon is advantageous for power circuits. Silicon and germanium can be mixed in alloys with arbitrary mixing ratios because of their identical lattice structure and their similar lattice constants. The atoms are distributed statistically on free places and the lattice structure is maintained. The lattice constant a_{SiGe} can be calculated by the linear interpolation between the lattice constants a_{Si} of silicon (0.5431 nm) and a_{Ge} of germanium (0.5658 nm):

$$a_{\text{Si}_{1-x}\text{Ge}_x} = (1-x)a_{\text{Si}} + xa_{\text{Ge}} \quad (1)$$

For the realization of npn heterojunction bipolar transistors, the pseudomorphic growth of strained $\text{Si}_{1-x}\text{Ge}_x$ layers without misfit dislocations is of essential importance. Strained SiGe layers may be grown epitaxially on silicon substrate. If the thickness of the epitaxial layers is kept below a critical thickness, then the mismatch between the alloy and the silicon substrate is accommodated elastically. The strain grows with increasing lattice mismatch and germanium content [30,31]. The lattice mismatch is defined as

$$\eta = \frac{a_{\text{Si}_{1-x}\text{Ge}_x} - a_{\text{Si}}}{a_{\text{Si}}} \quad (2)$$

and the lattice mismatch between pure germanium and silicon is 4.2%.

Figure 1 shows that the energy gap of the alloy is dependent not only on the germanium content but also on the strain situation. The conduction band minima in unstrained silicon correspond to sixfold degenerate valleys located along {100} directions in k space. In case of strain, the sixfold degenerate conduction band valleys are separated and the four valleys oriented normal to the heterojunction are lowered in energy and the remaining two valleys are raised in energy. The overall bandgap shrinkage is increased over that of unstrained material with the same germanium content.

A unified SiGe/SIMMWIC technology uses this band-gap engineering to develop SiGe HBTs, MODFETs, and MOSFETs [28]. This unified technology also allows the fabrication of Schottky diodes, IMPATT diodes, and PIN diodes (Fig. 2).

3. ELECTRONIC DEVICES

3.1. SiGe-Base HBTs

Although silicon bipolar transistors with transient frequencies above 50 GHz are possible in principle, these devices would exhibit too high a base resistance and too low a breakdown voltage. A promising device for millimeter-wave applications is the SiGe base heterojunction bipolar transistor (HBT) [1]. The heterojunction bipolar transistor first has been suggested in 1957 by Kroemer [4]. A first suggestion for a SiGe-base HBT for high-frequency applications was made in 1977 [1,5]. Detailed investigations of

Figure 1. Energy gap in $\text{Si}_{1-x}\text{Ge}_x$ layers as a function of the Ge composition x .

the millimeterwave SiGe-base HBT have been presented [32–40].

In SiGe HBT, the base region is formed by an epitaxially grown SiGe layer between the adjacent silicon layers. With increased germanium content in the base, the band-gap of the base region is reduced. Because of the lower band gap of the base region also in the case of high base doping a high emitter efficiency is achieved. The base of a HBT can thus be more heavily doped than the base of a silicon bipolar transistor to reduce the base resistance without the negative impact on the current amplification. Figure 3 shows the cross section of a heterojunction bipolar transistor. The HBTs are fabricated using a self-aligned emitter–base structure together with selective epitaxial growth of the SiGe-base layer. Figure 4 shows a SiGe HBT embedded in a coplanar line crossing.

The effect of reduced barrier for the electron injection from the emitter into the base and the corresponding design freedom regarding the emitter and the base doping becomes evident if the current gain of a bipolar junction transistor is compared with the current gain of a heterojunction bipolar transistor. The current gain β of a conventional bipolar transistor is given by

$$\beta = \frac{D_{nE}N_Ew_E}{D_{pB}P_Bw_B} \quad (3)$$

where D_{nE} and D_{pB} are the diffusion constants of electrons and holes in the emitter and base regions respectively, N_E

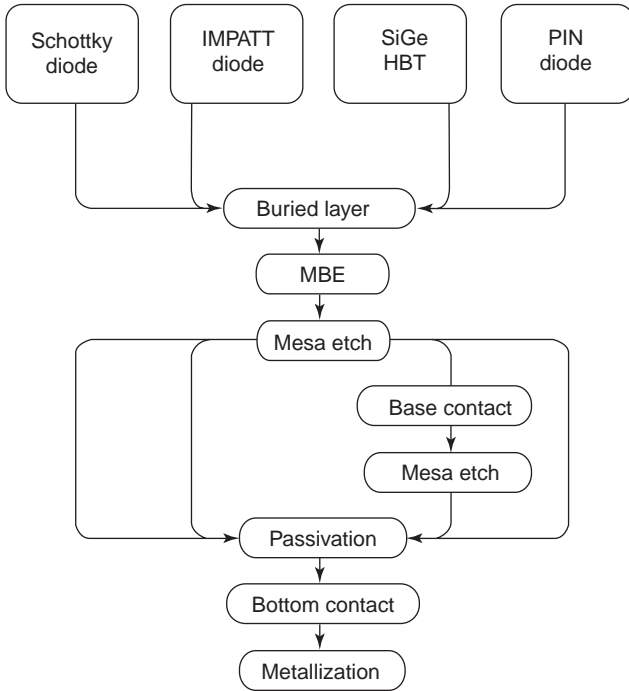

Figure 2. Technology.

Figure 4. SiGe-HBT in coplanar line crossing.

and P_B are the emitter and base doping concentrations, w_E is the emitter thickness, and w_B is the base thickness. For the HBT after Kroemer [4] the current gain β is given by

$$\beta = \frac{D_{nE} N_E w_E}{D_{pB} P_B w_B} e^{\Delta E/kT} \quad (4)$$

where ΔE is the bandgap difference between Si and SiGe. The exponential dependence of the minority carrier injection rate across the emitter–base barrier on the band gap difference yields for a Ge content of 20% a value of the exponential term of more than 1000. Thus a high base efficiency is obtained even in the case of a high emitter doping. Due to the high base doping, low base sheet resistances with base widths down to 10 nm are attainable. A typical high-frequency silicon bipolar transistor with a base width of less than 100 nm exhibits base sheet resistances in the order of 10 k Ω /□, whereas SiGe HBTs reach base sheet resistances as low as 1 k Ω /□ for a 20-nm-

Figure 3. Cross section of SiGe HBT.

doped base [28]. Therefore, a high current gain and a low base resistance are possible due to extremely low base width.

The unity current gain cutoff frequency f_T is given by [2]

$$f_T = [r_e(C_{eb} + C_{cb} + \tau_b + \tau_e + \tau_c)]^{-1} \quad (5)$$

where C_{eb} and C_{cb} are the emitter–base and collector–base depletion capacitances; τ_b , τ_e , and τ_c are the base, emitter, and collector transit times, respectively; and the emitter resistance r_e is given by

$$r_e = \frac{kT}{eI_c} \quad (6)$$

In bipolar junction transistors (BJTs), f_T is usually limited by the base transit time τ_b given by

$$\tau_{b,Si} = \frac{w_b^2}{2D_{nb}} \quad (7)$$

where D_{nb} is the electron diffusivity in the base region and w_b is the base width. In the SiGe HBT the Ge grading across the base decreases τ_b by [2]

$$\frac{\tau_{b,SiGe}}{\tau_{b,Si}} = \frac{2}{\tilde{\eta}} \frac{kT}{\Delta E_{g,Ge(grade)}} \left\{ 1 - \frac{kT}{\Delta E_{g,Ge(grade)}} \left[1 - e^{-\Delta E_{g,Ge(grade)}/kT} \right] \right\} \quad (8)$$

where the bandgap grading term $\Delta E_{g,Ge(grade)}$ is given by

$$\Delta E_{g,Ge(grade)} = \Delta E_{g,Ge(w_b)} - \Delta E_{g,Ge(0)} \quad (9)$$

and

$$\tilde{\eta} = \frac{D_{nb(SiGe)}}{D_{nb(Si)}} \quad (10)$$

The maximum oscillation frequency f_{max} of the HBT is given by

$$f_{max} = \sqrt{\frac{f_T}{8\pi C_{bc} r_b}} \tag{11}$$

where f_T is the transit frequency, r_b is the base resistance, and C_{bc} is the base collector capacity. In SiGe HBTs the lower bandgap allows for high base doping and therefore low base resistance. That increases f_{max} .

The fabrication of a heterojunction bipolar SiGe transistor with f_T values above 200 GHz has already been reported [1,8–11,28,35,41]. For most circuit applications, f_{max} is the more important parameter [1,28] and coplanar MMICs based on SiGe HBTs with f_{max} values as high as 338 GHz are under development [8,10,42–44].

For an efficient circuit design an accurate large-signal transistor model is required. Gummel and Poon introduced a bipolar transistor model based on a charge-control relation, derived from basic physical considerations, linking the dominant component of collector current, emitter and collector junction voltages, and base charge [45,46]. The equivalent circuit of the Gummel–Poon model is depicted in Fig. 5. The Gummel–Poon model is the basis for most advanced nonlinear BJT models; however, it is not suitable for reliable design of circuits operating at either high current densities or low voltages. Several authors proposed large-signal models for the SiGe heterojunction bipolar transistor [47–50].

The physics-based compact bipolar transistor model HICUM (high-current model) uses the small-signal parameters, such as the depletion capacitances and the transit times, as basic variables, which are described accurately as a nonlinear function of bias, temperature, and geometry. This results in continuously differentiable relations for charges and transfer current and accurate modeling of the large-signal switching behavior, including harmonic distortion at high frequencies [51,52]. A detailed description of the HICUM model can be found in Ref. 53. The so-called vertical bipolar intercompany (VBIC) model was developed as an industry standard to improve defi-

ciencies of the SPICE Gummel–Poon model that have become apparent over time because of the advances in BJT process technology. The VBIC model is still based on the Gummel–Poon formulation; however, it includes improved modeling of the Early effect, quasisaturation, substrate and oxide parasitics, avalanche multiplication, and temperature behavior [54]. A VBIC model for the analysis of two-tone intermodulation distortion behavior of SiGe HBTs takes into account all important effects for accurate modeling of large-signal behavior, including self-heating, weak-avalanche multiplication, quasisaturation effects, and all device capacitances [55].

The SGH (SiGe HBT) large-signal model combines elements of the VBIC and HICUM models [56,57]. Figure 6 shows the equivalent circuit of the SGH model. The SGH model accurately describes the SiGe HBT behavior up to 40 GHz. In the SGH model the transport current

$$I_{CC} = \frac{I_f - I_r}{q_b} \tag{12}$$

is related to the normalized stored charge q_b , given by

$$q_b = q_1 + q_2 \tag{13}$$

with

$$q_1 = \frac{Q_{p0} + HJE \cdot Q_{je} + HJC \cdot Q_{jc}}{Q_{p0}} \tag{14}$$

$$q_2 = \frac{Q_{f0} + HE \cdot Q_{fe} + HC \cdot f_c \cdot Q_{f0} + Q_{fb}}{Q_{p0}} \tag{15}$$

The coefficients HJE , HJC , HE , and HC , introduced similarly to the HICOM model parameters, are determined by parameter extraction. The empirical smoothing function f_c is given by

$$f_c = \left(\frac{V_{cc}}{VHC} \right)^{NHC} \tag{16}$$

where VHC and NHC are determined by parameter extraction. The default smoothing function is $f_c = 1$.

For an accurate simulation of the intermodulation performance of semiconductor devices, the modeling of the

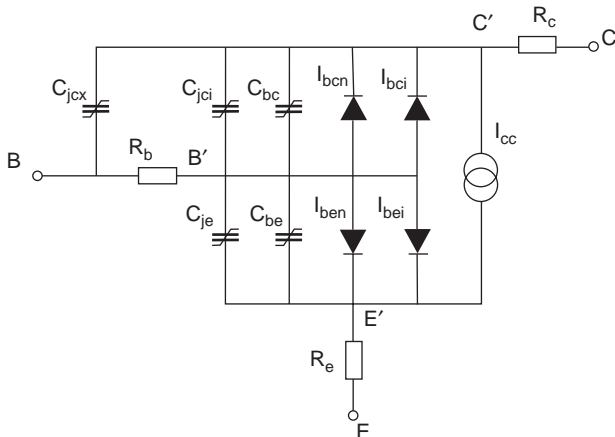

Figure 5. Gummel–Poon transistor model.

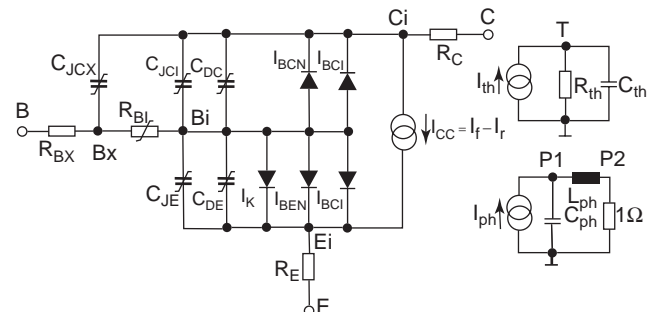

Figure 6. SiGe HBT large-signal equivalent circuit [56].

dynamic self-heating is required [58]. A method to extract the thermal time constants of HBTs from *S*-parameter data has been given by Sinnesbichler and Olbrich [59].

The noise figure of a bipolar transistor may be approximated by [60]

$$F = 1 + \frac{1}{R_s} \left[r_b + \frac{r_e}{2} + \left(\frac{1}{\beta} + \frac{f^2}{f_T^2} \right) \frac{r_b^2 + R_s^2}{2r_e} \right] \quad (17)$$

where *F* is the noise figure, *R_s* is the source impedance, and β is the current gain. The high *f_T* and the low base resistance of SiGe HBTs yield a low noise figure. SiGe HBT noise figures as low as 0.5 dB at 2 GHz, 0.9 dB at 10 GHz, and 2 dB at 20 GHz have been reported [61].

Low-frequency noise in active devices is a serious design constraint for millimeter-wave oscillator and mixer applications. Since the low-frequency noise is upconverted by the inherent nonlinearities of the active device, the low-frequency noise of the active device has to be minimized. The low-frequency noise in millimeter-wave Si/SiGe HBTs has been investigated [62–64]. For a SiGe HBT with an *f_T* of 43 GHz, Cressler et al. have reported a corner frequency of 373 Hz for the 1/*f* noise at a bias current of 2.25 μA [64]. However in real circuit applications, the bias currents are at least one order of magnitude higher. Usually the corner frequency increases proportional to the square of the bias current.

An accurate extraction method for the 1/*f* noise parameters of BJTs and FETs is presented in Ref. 65. Figure 7 shows the BJT equivalent circuit with input and output terminations and noise sources. Combining the nonlinear large-signal models with the noise models allows nonlinear noise modeling. This is a requirement for accurate phase noise modeling of oscillators.

3.2. Si/SiGe-Hetero FETs

Si/SiGe heterostructure technology may also be combined with Si CMOS technology [36,66]. Most of the Si/SiGe-hetero-FETs (MOSFETs) are of the modulation-doped type. These so-called MODFETs exhibit a thin quantum-well layer with a thickness of 5–30 nm. Within the quantum-well layer, a two-dimensional electron or hole gas with collision-free carriers exists. The n-quantum wells are Si layers, whereas the p-quantum wells are formed by SiGe

15 nm Si	Cap
40 nm Si _{0.7} Ge _{0.3}	Cap spacer
12 nm Si _{0.7} Ge _{0.3}	n ⁺ doping
10 nm Si _{0.7} Ge _{0.3}	spacer
25 nm Si	2 DEG (Si)
0.5 μm Si _{0.7} Ge _{0.3}	Buffer
1.5 μm Si _{1-x} Ge _x	X=0.3 X=0.05 Graded buffer
Si	Substrate

Figure 8. Layer structure of a n-type Si/SiGe-hetero FET.

layers. Figure 8 shows the layer structure of a n-type Si-channel Si/SiGe MOSFET.

The introduction of SiGe in field effect transistors allows the realization of n- and p-type hetero-FETs. Tensile-strained Si films on strain-relieved SiGe buffer layers enable the formation of electron quantum wells that exhibit enhanced electron mobilities. Compressively strained SiGe or even pure Ge layers can be used to create two-dimensional hole channels. The combination of n- and p-SiGe MOSFETs and a complementary circuit arrangement promises the realization of a novel hetero-CMOS generation [36,67]. This approach requires a proper SiGe buffer layer.

The epitaxial layers for n-type MODFETs—deposited on a high resistivity substrate—start with a relaxed buffer whose Ge content is linearly graded to 40–50%. The core of the layer structure is the 7–10-nm tensile-strained Si channel embedded into undoped Si_{1-x}Ge_x spacers that separate the carrier supply layers from the channel (Fig. 9a). Because of a Ge content of 40–50% in the SiGe layers, a high conduction band offset of 0.24 eV is achieved and the quantum well enables electron mobilities up to 2800 cm²/V·s [68]. Schottky or junction gates may be realized. The p-type MODFET employs a Ge channel (Fig. 9b). A double-sided doped Ge channel is on top of an artificial Si_{0.4}Ge_{0.6} substrate, accomplished by the compositionally graded strain relieved buffer. With the layer design values given in Fig. 9b, a 2D hole gas mobility of 1870 cm²/V·s is extracted from magnetic-field-dependent Hall measurements.

The RF performance is defined by *f_T* extrapolated from the current gain *h₂₁* and by *f_{max}* extrapolated from the maximum available gain or the unilateral gain. For n-Si channel MODFETs, *f_T* = 65 GHz and *f_{max}* = 120 GHz (non-deembedded still 110 GHz) for technologically relaxed gate lengths around 0.2 μm are reported [68,69]. For p-Ge

Figure 7. BJT equivalent circuit with noise sources [65].

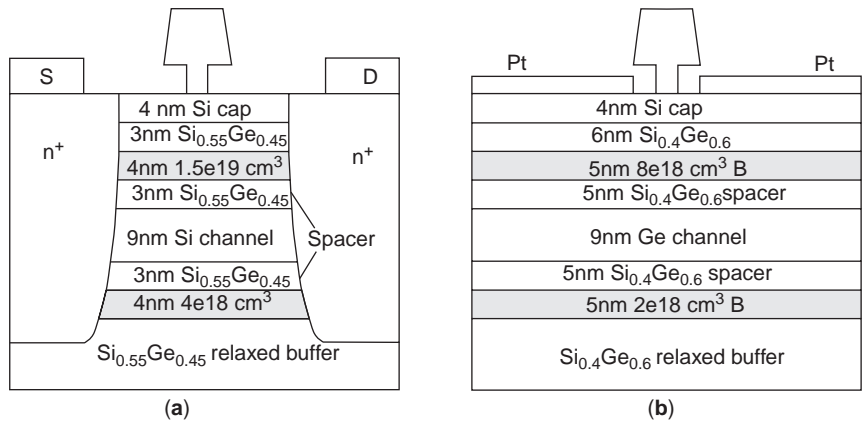

Figure 9. Layers of (a) n-type Si/SiGe MOD-FET and (b) p-type Ge channel MODFET.

channel MODFETs the f_T is up to 70 GHz and f_{max} values up to 135 GHz are reported [70,71].

The SiGe MOSFETs are still not yet optimized. Most of the MOSFET devices reported so far are mesalike. Preferably source and drain implantation is used. Pads are mostly arranged on field oxide, however, the cutoff frequencies of MOSFETs are already a factor of >2 above those of traditional Si MOSFETs, owing to their much higher mobilities. Furthermore the frequency level of n- and p-MOSFETs are very similar, which supports the potential of SiGe for the novel HCMOS generation.

3.3. Future Device Concepts

Future development of SiGe MMICs for operation up to 100 GHz stimulates the search for even faster transistors. A first approach might be to change the base SiGe profile from a box-shaped to a triangular curvature. A small improvement in f_{max} can be expected. However, due to a rough estimation, f_{max} values should be a factor of 5 higher than the operational frequency. Therefore, about 300 GHz f_{max} is required for 60-GHz SiGe MMICs. The pure HBT principle will not be sufficient to reach these frequencies. Improvements are expected from a transition to a metal base transistor or a camel-type transistor. Another promising concept was proposed by Luryi [19,20]: a transistor with an active behavior beyond the cutoff frequencies. The combination of a graded base layer enforcing coherent carrier transport and a base layer thickness designed to yield a transit-time-induced phase shift of $3\pi/2$ lead to a resonancelike behavior at elevated frequencies above f_{max} , the resonance phase transistor (RPT).

The overall phase of the collector current in a bipolar transistor is composed of an injection phase angle $\varphi = \varphi_E + \varphi_B$ with an emitter-base transit angle $\varphi_E = \omega\tau_E$ and $\varphi_B = \omega\tau_B$, respectively, and the drift delay $\theta = \omega\tau_C$ in the base-collector junction. At frequencies below the cutoff frequency, the phase delay of the collector current is less than $\sim 60^\circ$, as

$$\varphi + \theta = \varphi_E + \varphi_B + \theta = 2\pi f(\tau_E + \tau_B + \tau_C) \text{ for } f/f_T < 1 \quad (18)$$

In common transistor operation the phase of the collector current increases with decreasing current gain, taking a

maximum value around 60° at frequencies close to the cutoff frequency. However, at further increased phase delay, the output resistance of the transistor may become negative and result in renewed active behavior at higher frequencies. Such renewed active behavior was previously discussed on the basis of transit time effects using properly delayed injection of carriers into the base-collector space charge [19,20,72,73].

In SiGe four grading steps in a 200-nm base are suitable, considering the limitations given by the critical thickness and the germanium content as well as the requirements given by the energy steps to obtain coherent carrier transport [21]. After first experimental reports on the increase of the unilateral gain at frequencies larger than f_T [74], the RPT effect has been proven experimentally. A current amplification of 6.5 dB was measured at a frequency of $7 f_T = 40$ GHz for an RPT structure with a base layer thickness of 120 nm [75]. The measured current gain is depicted in Fig. 10.

Figure 10. Unilateral gain of a RPT test transistor deduced from S-parameter measurements between 100 MHz and 40 GHz.

A totally different approach to enhance the injection phase angle, proposed in 1998, uses counter-phase injection via resonant tunneling in a double barrier base structure [21]. The initial concept of resonance phase amplification using delayed injection basically subsists on keeping the base transport factor sufficiently high.

4. APPLICATIONS

Numerous examples of Si/SiGe-based monolithically integrated RF chips of high performance have been presented in the literature. A SiGe differential transimpedance amplifier with 50 GHz bandwidth for application as baseband amplifier in 40-Gbps (gigabits per second) Fiberoptic receivers already has been reported [76]. A monolithic integrated 40-Gbps clock and data recovery circuit with a 1 : 4 demultiplexer has also been realized in SiGe HBT technology [77] and a 40-Gbps 2 : 1 multiplexer and 1 : 2 demultiplexer, in 120 nm CMOS technology [78].

Monolithic integrated HBT oscillators with oscillation frequencies up to 74 GHz have been reported [79–81]. A 47-GHz MMIC SiGe HBT oscillator with an output power of 13.1 dBm, an efficiency of 13.6%, and a phase noise of -99.31 dBc/Hz at 100 kHz off carrier has already been realized [82]. The oscillator was realized on high-resistivity silicon ($\rho > 5000 \Omega \cdot \text{cm}$) in coplanar line technology. Applying the push–push principle, a hybrid SiGe HBT microstrip transmission-line oscillator with an output power of $+1$ dBm at 58 GHz and a single-sideband phase noise of -108 dBc/Hz at an offset frequency of 1 MHz [57,83] and a monolithic integrated 150 GHz SiGe HBT push–push VCO with -5 dBm output power at 150 GHz and 30 GHz tuning range [84] already have been realized. Figure 11 shows a 27 GHz SiGe HBT voltage-controlled oscillator in microstrip technology designed by DASA and fabricated by DaimlerChrysler Research. The oscillator exhibits an output power of $+1$ dBm and a SSB phase noise of -112 dBc/Hz at 1 MHz offset. In Fig. 12 a 38-GHz SiGe HBT harmonic mixer fabricated by DaimlerChrysler Research is depicted. A local oscillator input signal at 4.75 GHz is required. The conversion loss amounts 23 dB. The mixer

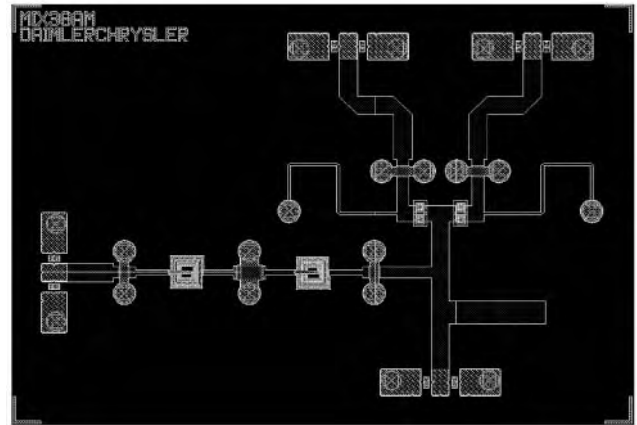

Figure 12. A 38-GHz SiGe HBT harmonic mixer. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

delivers an IF output signal at 1.33 GHz. The first active integrated K-band antenna on high-resistivity silicon substrate employing a Si/SiGe HBT has been presented [85,86]. Microstrip structures represent the resonating and radiating circuits. The HBT was mounted using the flip-chip technique. An output power of 20 dBm at 24 GHz has been achieved.

5. CONCLUSIONS

The performance of SiGe MMICs has to be viewed under the consideration of competing approaches, especially CMOS. K-band low-noise amplifiers using a $0.18\text{-}\mu\text{m}$ CMOS technology with operating frequencies of ≤ 24 GHz, a gain of > 12 dB, and a noise figure of 5.6 dB have been reported [87]. At 26 GHz still 8.9 dB of gain and a noise figure of 6.9 dB are obtained. The current consumption is 30 mA from a 1.8 V power supply. This results represent the highest operation frequencies reported for low-noise amplifiers in a standard CMOS process.

These results have to be compared with the latest SiGe device and circuit results. Cutoff frequencies are now approaching 400 GHz, and the circuit performance at W-band frequencies approaches or even exceeds that of III–V MMICs [81]. The most important advantage of SiGe MMIC concepts is probably the possible cointegration of low-noise, high current building blocks (e.g., oscillators) with CMOS circuits in order to realize complete single-chip solutions.

The availability of SiGe HBTs with transit frequencies above 200 GHz and even higher maximum oscillation frequencies [8–11] will allow the development of silicon-based monolithic integrated circuits for operation frequencies above 100 GHz. Areas of application include millimeter-wave communications and sensorics [88,89] and also mixed-digital/analog applications at millimeter-wave frequencies [90]. In digital fiberoptic receivers Schottky diode demultiplexers [91] in connection with SiGe HBT push–push oscillators for clock recovery may allow to realize electronic demultiplexers for bit rates of ≤ 160 Gbps in the future. Monolithic integrated millimeterwave sensors an communication front-end circuits may also include

antenna structures. An active SIMMWIC antenna for vehicular technology in the frequency range around 76.5 GHz already has been presented [92]. This active antenna acts as a transceiver and is well suited for low-cost integrated sensor systems for automotive applications.

GRATINGS, GRATING ANTENNAS

CHRISTOPHER T. RODENBECK
KAI CHANG
Texas A&M University
College Station, Texas

A *grating* is an array of parallel obstructions separated from one another at a distance comparable to a wavelength. When an electromagnetic wave is incident upon a grating, it scatters to one or more specific angles determined by the spacing of the grating and the frequency of the wave. Since this effect is a diffraction phenomenon, gratings are often also referred to as *diffraction gratings*.

One of the most important uses of the diffraction grating is as an antenna for millimeter-wave through optical frequencies. This type of diffraction grating is the primary focus of this article. In integrated optics, grating antennas are used to couple power into and out of dielectric waveguides. For millimeter-wave systems, grating antennas have received attention for several key advantages that they have in comparison with other

conventional microwave antennas. They have low radiation losses, they are inexpensive and easy to fabricate, and they are planar. There is also considerable interest in using grating antennas to implement low-cost beam steering at millimeter-wave frequencies.

This article examines gratings and grating antennas in a series of five sections. Each of these sections is presented in such a way that it may be read independently from the others. An overview of the historical development of diffraction gratings is presented. The fundamental principles behind grating diffraction are explained in a manner suitable for those with an RF/microwave background. A clear design procedure for grating antennas is offered, along with an extensive reference list for those interested in further study. Some of the latest and most impressive applications of millimeter-wave gratings are described. The article then concludes with a brief discussion of the future of this field.

1. HISTORICAL OVERVIEW

Despite its fundamental importance, the early origins of the diffraction grating are a remarkable tale of discovery and rediscovery. An intense period of research into optical technology had begun during the early 1600s following the invention of the telescope by the Dutch. During that century, the fundamental principles of refraction and diffraction were discovered and applied to numerous optical components such as lenses, mirrors, reflectors, slits, pinholes, etc. Gratings, however, were not invented until a much later date.

The first discovery of the diffraction grating occurred in Philadelphia in 1785. Francis Hopkinson, one of the signers of the Declaration of Independence, held a finely woven silk handkerchief up to a bright light and observed the interference pattern produced by the light passing through the fabric. Hopkinson consulted his friend David Rittenhouse, a self-trained physicist. Recognizing the phenomenon as a diffraction effect, Rittenhouse designed his own diffraction grating made of human hairs wound around two fine screws. He then used the device to measure the approximate wavelength of visible light. Hailing his invention in an American scientific journal, Rittenhouse exclaimed that “new and interesting discoveries may be made respecting the properties of this wonderful substance, light, which animates all nature in the eyes of man, and perhaps, above all things, disposes him to acknowledge the Creator’s bounty” [1–3].

Since few researchers of that era read American scientific journals, Thomas Young of London had the opportunity to re-invent the diffraction grating in 1803. Young used his invention to measure the wavelengths of the various visible colors, but his main objective was to lend support to his view that light is a wave rather than a particle. Opponents of the wave theory attacked Young’s work, labeling it as “destitute of every species of merit” [3,4]. The practical importance of Young’s invention was thus unfortunately lost amid the then viscous debate concerning the nature of light.

The grating would be discovered for the final time by Joseph von Fraunhofer in 1821. Fraunhofer had earlier established an optical company in Bavaria that produced optical components of the highest quality. After unexpectedly observing grating diffraction during an experiment, Fraunhofer built increasingly precise gratings, ultimately etching the profile of a grating directly onto the surface of a glass plate. Using this arrangement, Fraunhofer was able to separate visible light into the different colors and measure their wavelengths. Although his primary objective was to use the device to make precise optical measurements and thereby improve his company’s products, Fraunhofer did popularize additional uses for optical gratings, including chemical spectroscopy and astronomical observation [1–4]. After his death, the diffraction grating eventually became an indispensable component of optics. As one researcher put it in 1960, “It is difficult to point to another single device that has brought more important information to every field of science than the diffraction grating” [3].

The first use of gratings at radiofrequencies came during Heinrich Hertz’ revolutionary experiments in 1887–1891. Hertz used a narrowly spaced wire grating in order to test the polarization of his “electric waves” [5,6]. Shortly after Hertz’ death in 1894, Chandra Bose of Calcutta built an impressive 60-GHz transmitter and receiver. During these experiments, Bose used a diffraction grating to measure the wavelength of his millimeter-wave source [7]. Subsequent decades saw rapid progress in the area of RF/microwave antennas and arrays. Early researchers in this area were heavily influenced by their familiarity with the already well-known diffraction grating. This is not surprising since gratings and array antennas are both governed by the same fundamental principles of wave interference. In fact, the designation “grating lobe” is still commonly used to refer to the additional maxima emitted by an array of widely spaced antennas.

The first grating antennas were developed and popularized at optical frequencies during the 1970s. Researchers at IBM etched a grating profile along the surface of a dielectric waveguide and used the device to transmit and receive laser light [8]. Called a grating “coupler,” this optical antenna is used in integrated optics for coupling optical power into and out of dielectric waveguides. In 1977, Tatsuo Itoh demonstrated the first microwave grating antenna at 15 GHz [9]. Shortly afterward, a team of researchers at the U.S. Army Communications-Electronics Command presented the development of a 60-GHz grating antenna fabricated along a silicon dielectric waveguide [10–14]. The design established the grating antenna as a new kind of low-loss low-cost antenna for millimeter-wave frequencies. This work captured the interest of researchers worldwide. Progress was rapid and was aided by inherent similarities between grating antennas and earlier traveling-wave antennas designed at lower microwave frequencies [15–17]. With increasing contemporary interest in the commercial and military applications of millimeter waves, much of the early research on grating antennas is now receiving renewed attention. And what is more, new and exciting applications of this antenna continue to be developed and are beginning to find

Figure 1. A generalized reflection grating of periodicity d illuminated by a plane wave incident at the angle θ_i .

commercial success for a wide range of millimeter-wave applications.

2. FUNDAMENTAL PRINCIPLES

The early investigators who popularized gratings were able to grasp the underlying principles of grating diffraction even before those principles had been formalized. Grating diffraction can in fact be accurately explained by an analogy between light and sound [1]:

If a sudden sharp noise such as is made by clapping the hands together is reflected from a high flight of steps, the sound comes back to us as a musical note; in other words, the steps impress the element of periodicity upon the reflected disturbance, each step throwing off an echo wave.

Sound incident on the staircase scatters in different directions. Those directions are determined by the step spacing and by the wavelength of each tone. In the case of a grating, an electromagnetic wave incident on a periodic interface scatters in a direction determined by the grating spacing and frequency of the wave.

This section presents a brief description of the fundamental principles behind grating diffraction. The discussion draws on material found in the literature [3,18–21] and is crafted in a manner suited for those with an RF/microwave background.

To begin with, consider the generalized two-dimensional grating interface shown in Fig. 1. The structure is infinite and periodic in the x direction and is excited by a plane wave incident at the angle θ_i . Since the grating interface is periodic in x , this suggests that the scattered field can be expanded in terms of a Fourier series

$$F_s(x, z) = \left[\sum_{n=-\infty}^{\infty} F_n(z) e^{-j(2n\pi/d)x} \right] e^{-jk_0(\sin \theta_i)x} \quad (1)$$

where $F_n(z)$ is the unknown Fourier coefficient for the n th-space harmonic $e^{-j(2n\pi/d)x}$. The $e^{-jk_0(\sin \theta_i)x}$ term outside the expansion accounts for the phase distribution of the incident field along the surface of the grating interface. Bring-

ing that term within the expansion simplifies (1) to

$$F_s(x, z) = \sum_{n=-\infty}^{\infty} F_n(z) e^{-jk_{x,n}x} \quad (2a)$$

where

$$k_{x,n} = k_0 \sin \theta_i + \frac{2\pi n}{d} = k_0 \sin \theta_n \quad (2b)$$

and θ_n denotes the angle of radiation for the n th-space harmonic. Equation (2b) is the well-known “grating equation.” By convention, θ_i and θ_n are defined so that θ_i is positive in the reverse quadrant and θ_n is positive in the forward quadrant.

Since the scattered field must satisfy the Helmholtz equation

$$\nabla^2 F_s(x, z) + k_0^2 F_s(x, z) = 0 \quad (3)$$

it is possible to define

$$k_{z,n} = \pm \sqrt{k_0^2 - k_{x,n}^2} = k_0 \cos \theta_n \quad (4)$$

where the sign is chosen to satisfy the radiation condition. The wavevector for the scattered field can now be expressed in terms of the unit vectors \mathbf{u}_x and \mathbf{u}_z :

$$\mathbf{k}_n = k_{x,n} \mathbf{u}_x + k_{z,n} \mathbf{u}_z = k_0 \sin \theta_n \mathbf{u}_x + k_0 \cos \theta_n \mathbf{u}_z \quad (5)$$

The incident wavevector likewise has the following form:

$$\mathbf{k}_i = k_0 \sin \theta_i \mathbf{u}_x - k_0 \cos \theta_i \mathbf{u}_z \quad (6)$$

For a given incident angle θ_i and grating spacing d , it is possible to plot the incident and scattered wavevectors from (5) and (6) on an illustrative diagram. An example is shown in Fig. 2. The incident wavevector \mathbf{k}_i arrives at an angle θ_i , and the wavevector \mathbf{k}_0 scatters in an equal and opposite direction θ_0 . All the radiating wavevectors lie together on a unit circle of radius k_0 , with each vector pointing in its direction of radiation. All the nonradiating wavevectors lie outside this circle. These nonradiating or *evanescent* modes decay exponentially away from the

Figure 2. Diagram illustrating the incident and scattered wavevectors from a hypothetical reflection grating.

surface of the grating. What makes this diagram especially useful is that it gives the designer the ability to visualize how changing θ_i or d changes how many modes radiate and in which direction each radiates.

In the case of a grating antenna, the grating interface lies along the surface of a dielectric waveguide, and the grating is excited by the signal propagating within that waveguide. The grating equation (2b) should then be rewritten as

$$\text{Re}(k_{x,n}) = \text{Re}(k_{x,0}) + \frac{2\pi n}{d} = k_0 \sin \theta_n \quad (7)$$

where $k_{x,0}$ is the propagation constant within the dielectric waveguide. $k_{x,0}$ is actually a complex number with the imaginary part describing the rate of radiation along the antenna [21]. The imaginary part of $k_{x,0}$ is disregarded, however, when calculating the number and directions of the radiating space harmonics. Furthermore, the real part of $k_{x,0}$ is typically calculated with good accuracy as the propagation constant along the dielectric waveguide without any grating present.

A plot similar to Fig. 2 can be produced using (7) to determine the scattered wavevectors from the expression in (5). An example case is shown in Fig. 3. The fundamental wavevector \mathbf{k}_0 points in the positive direction along the ordinate axis with a magnitude equal to $\text{Re}(k_{x,0})$. Each radiating space harmonic lies on the unit circle and corresponds to a beam radiated by the antenna. Although

grating antennas are typically designed so that only the $n = -1$ beam radiates, this example shows two radiating beams. The $n = -1$ beam is radiating in the forward quadrant ($\theta > 0^\circ$) and the $n = -2$ beam, in the reverse quadrant ($\theta < 0^\circ$). This diagram can be useful for designing a grating so that a single main beam radiates in some desired direction.

3. ANTENNA DESIGN AND ANALYSIS

The grating antenna is a type of leaky-wave antenna. A leaky-wave antenna is essentially a waveguiding structure perturbed either continuously or periodically so that it leaks power all along its length [22]. In the case of a grating antenna, the waveguiding structure is a dielectric waveguide perturbed by a periodic grating placed along its surface. The conventional configuration is shown in Fig. 4. A periodic array of transverse strips is arranged along the surface of a dielectric waveguide, in this case a dielectric image line. The strips can be either metallic or dielectric. These strips form a grating that perturbs the signal traveling along the guide. If the antenna is designed correctly, the grating excites a single leaky mode above the surface of the guide to create a directive beam of radiation in the far field. The radiated beam is fan-shaped, with narrow beamwidth in the array-effect dimension.

The procedure for designing a grating antenna encompasses four key steps. This section provides a complete

Figure 3. Diagram illustrating the wavevectors along a hypothetical grating antenna.

Figure 4. Configuration of a conventional grating antenna.

description for each of those steps. Additional references are also provided for the reader who wishes to explore more advanced topics related to the design and analysis of this class of antenna.

Step 1. The aspect ratio and dielectric constant of the dielectric waveguide must be chosen so that only one mode can propagate within the guide over the antenna's desired frequency range. This requires that the designer calculate the propagation constants and cutoff frequencies within the guide for each potential dielectric waveguide design. There are several options for performing this sort of calculation. Rigorous methods are available [23], but they are not popular since they involve the solution of a large set of coupled, transcendental equations. For low-dielectric-constant guides, simple effective dielectric constant (EDC) methods can be used with good accuracy [23]. An especially accurate EDC method has been developed for dielectric image line [24]. For high-dielectric-constant guides, full-wave electromagnetic simulation should be used to determine the guided wavelength.

In general, greater antenna directivity can be achieved using a wide guide rather than a narrow guide of the same length. However, this factor must be balanced against other considerations, such as the available single-mode bandwidth in the guide and the mechanism used to feed the guide. Using a high-dielectric-constant material also has certain advantages, to be discussed later, but these too must be balanced against other considerations, such as the availability of high-dielectric-constant substrates with reasonably low loss in the chosen frequency range and by the undesirable dispersion in the guided and leaky modes

that can occur along high dielectric constant guides [25,26].

Step 2. The dielectric waveguide must be excited at the intended frequency of operation. This can be accomplished by directly integrating a signal source into the dielectric guide [27–32] or by manufacturing a transition between the dielectric guide and another type of transmission line. Although a waveguide transition is shown in Fig. 4, other transitions, including microstrip, CPW, and slot transitions, are also available [21,23,33–37]. In every case, the transition should be carefully designed to limit spurious radiation and surface-wave excitation, which have the potential to spoil an otherwise good antenna design by increasing the sidelobes above an acceptable level [22].

It is important to note that the method of excitation determines the polarization of the far-field radiation pattern. Dielectric waveguides can, in general, be excited so that one or both of two orthogonal degenerate fundamental modes propagate [23]. For a rectangular dielectric guide like the image line shown in Fig. 4, the primary field components under E -wave excitation are H_y , E_x , and E_z , and the antenna's E plane is located in the x - z plane. Under H -wave excitation, the primary field components are E_y , H_z , and H_x , and the H plane is located in the x - z plane. Using other conventions present in the literature, it is also possible to designate E -wave excitation along the guide in Fig. 4 as TM-to- z excitation or simply as TM excitation, as E_{mn}^z excitation, or as TE or "perpendicular-polarized" excitation (since the E field is "perpendicular" to the strips). Likewise, H -wave excitation can be referred to as TE-to- z , TE, E_{mn}^y , TM, or "parallel-polarized." For an

image line, E -wave excitation is generally preferred since the presence of the ground plane shorts out most of the power that could couple to the H -wave modes. Recent patents indicate that it may also be possible to intentionally excite both degenerate modes in a dielectric waveguide in order to create dual polarization or even circular polarization [38,39].

Step 3. The next step in the design process is to determine the periodic spacing between the grating strips. For thin

Figure 5. Array of periodic dielectric antennas designed for radiation in the broadside direction: (a) array configuration; (b) finished device for 65-GHz band. The element antennas are fed by a resonant slotted waveguide array with a horn transition. (From Solbach, [66], © 1985 EW Communications. Reprinted with permission of publisher from MSN & CT. All rights reserved.)

metal strips or thin dielectric strips, the presence of a grating along the dielectric guide has only a negligible effect on the propagation constant within the guide itself. In this case, the angle of radiation in the direction forward from broadside can be calculated at any given frequency of excitation as a simple function of the guide wavelength λ_g and strip spacing d

$$\theta_n = \arcsin\left(\frac{\lambda_0}{\lambda_g} + \frac{n\lambda_0}{d}\right), \left|\frac{\lambda_0}{\lambda_g} + \frac{n\lambda_0}{d}\right| \leq 1 \quad (7a)$$

where λ_0 is the free-space wavelength and n , the space harmonic ($0, \pm 1, \pm 2, \dots$), is chosen as -1 for single-beam operation [40]. In principle, the permissible range of values for θ_{-1} extends both forward and reverse of broadside, across the entire $\pm 90^\circ$ range. But as is the case with most planar antenna arrays, grating antennas do not radiate well beyond the $\pm 60^\circ$ range. There are other limitations as well. Bragg reflection occurs if $d = \lambda_g$ [9]. This prevents the antenna from radiating well for $\theta_{-1} = 0^\circ$ unless a more elaborate grating pattern [23,41,42] is used. In addition, it is difficult to achieve a sufficiently high effective relative dielectric constant along an image line or other open dielectric guide in order to prohibit appearance of the $n = -2$ grating lobe for increasingly positive values of θ_{-1} while still maintaining single-mode bandwidth along the guide. Unusually high dielectric constants ($\epsilon_r > 20$) are required, with associated tradeoffs in performance and implementation [25,26,43]. Choosing a main beam angle in the $\theta_{-1} > 0^\circ$ range is thus typically limited by the propagation of the $n = -2$ space harmonic.

Step 4. The final design step is to choose the strip widths and antenna length. The widths of the strips determine the rate of radiation along the antenna, and the antenna length determines how much power is left unradiated at the end of the antenna. Narrow strips radiate too little, leaving a substantial amount of power unradiated at the end of even a long antenna. Excessively wide strips radiate too much power during the first few strips, causing the effective aperture of the antenna to be too small and the sidelobes to be large [33]. In both cases, antenna efficiency can suffer. A popular compromise is to gradually increase the widths of the strips away from the input to the antenna.

Designing the strip widths can be done by experiment, by analysis, or even by rules of thumb. Several such rules of thumb are available in the literature. For the case of dielectric-strip gratings, perturbational analysis can be used to argue that $w = 0.5d$ is an optimal strip width [40,44]. In the case of a metal-strip grating, researchers determined by experiment that maximum radiation for a particular design occurred when $w = 0.4\lambda_g$ [33]. They then used this finding to formulate a very conservative empirical guideline for designing a tapered distribution of strip widths along their antenna.

Analytical approaches are generally preferred in antenna design. To analytically design a grating antenna

requires an analysis that is capable of relating the design parameters (viz., the strip width, interelement spacing, dielectric constant, etc.) to the radiation rate along the surface of the antenna. Once the radiation rate is known, the far-field pattern can easily be calculated using the spatial Fourier transform [40]. Unfortunately, calculating the radiation rate along a grating antenna is typically considered an involved process [21]. For the dielectric strip gratings commonly used in integrated optics, commercial software and curve fit models [45] are available. For metallic strip gratings, several rapid analytical procedures are available for the limiting cases of narrow strip gratings and narrow slot gratings. (See Refs. 17, 46, and 47 and the references cited in those papers.) Practical designs, however, typically use strips whose widths fall between those two limiting cases. Recently, a simple spectral-domain approach has been proposed that is capable of analyzing metal gratings composed of strips that are neither narrow nor wide [48]. Many more rigorous numerical methods are also available, with varying levels of rigor and computational effort for each approach. These methods include mode-matching techniques [49,50], waveguide models [51], rigorous network formulations [52], and full-wave simulation [53,54]. An excellent and timely overview of various approaches and their relative merits is provided in Ref. 3 for both metal and dielectric strip gratings. The reader is warned to investigate each approach since the literature does contain references to inaccurate and even erroneous approaches for analyzing grating antennas.

Experimental design can be a particularly expedient approach in the case of metal-strip gratings. Multiple sets of gratings can be etched onto a single thin dielectric film [55–57]. Thin dielectric films made from materials such as RT-Duroid have low loss at millimeter-wave frequencies

and can be easily etched using conventional photolithography. The film can then be extended across the surface of the dielectric guide, allowing the designer to rapidly test the radiation rate for each of the sets of grating strips. This information can then be used together with the spatial Fourier transform to determine a favorable distribution of strip widths in order to achieve a desired far-field pattern.

When the distribution of strip widths and the radiation rate along the antenna are being determined, the length of the antenna must also be chosen so that only a certain fraction of the input power remains unradiated at the end of the dielectric guide. If the amount of unradiated power is too large, antenna efficiency is low. For an antenna of length L , the total efficiency η can be expressed as

$$\eta = \int_0^L 2\alpha(x)e^{-2(\alpha(x) + \alpha_L)x} dx \quad (8)$$

where $\alpha(x)$ is the radiation rate along the grating and α_L accounts for conductor and dielectric losses [15]. If the radiation rate is uniform along the antenna and much larger than the loss factors, the efficiency can be approximated for design purposes as $1 - e^{-2\alpha_L L}$. If a substantial portion of the input power is to be left unradiated, the dielectric guide should be terminated in a matched load or with absorbing material, or else the wasted power will reflect from the end of the antenna and radiate as a sidelobe.

4. APPLICATIONS

The chief purpose of this section is not to present a comprehensive review of all applications of gratings and

Figure 6. A low-cost reconfigurable grating antenna.

grating antennas. Instead, the objective is to capture the reader's interest and identify the major applications of gratings. A special emphasis is given to antenna applications at millimeter-wave frequencies.

4.1. Array Antennas

Grating antennas are based on dielectric waveguide technology. Unlike printed-circuit transmission lines, dielectric waveguides exhibit low loss even at very high millimeter-wave frequencies. Unlike rectangular metal waveguides, dielectric waveguides are easily fabricated and compatible with mass production at frequencies through W band and beyond. Dielectric waveguides are thus ideal candidates for feeding millimeter-wave antenna arrays. Diffraction gratings are perhaps the most natural and inexpensive implementation of an array antenna to be based on this class of transmission line.

A conventional grating antenna is shown in Fig. 4. Many variations on this configuration are possible. The strips can be metal [10] or dielectric [40]. The strips can be replaced with slots, grooves, or cavities in the ground plane [23]. These strips, slots, and other perturbations don't necessarily have to be rectangular; they can also be circular. Their cross sections can be "blazed" or nonrectangular [3]. In addition, the perturbations can be made self-similar to allow broadside radiation [23,41]. If desired, the image line can also be replaced with another type of dielectric waveguide, such as insular image guide, nonradiative dielectric (NRD) guide, inverted-strip dielectric guide, or rectangular dielectric waveguide [23]. Gratings fabricated on circular dielectric waveguides can radiate omnidirectionally [58]. Gratings based on rotated strips can radiate circular polarization [59,60].

Several methods are available for increasing the gain of a grating antenna. The gain in the nonarray plane can be increased by embedding the dielectric guide within a trough [61] or flared trough [33] or by placing the guide in proximity to a parabolic reflector [39]. Pencil-beam radiation can be achieved by etching a two-dimensional grating on a surface-wave-excited dielectric slab [62–64]. This kind of grating is designated a "hologram" or "holographic antenna." This is a matter of nomenclature, however, since the standard grating antenna is itself a type of hologram. Other research has demonstrated unconventional circular and linear polarized pencil-beam antennas fed by NRD gratings [65]. Planar arrays of grating antennas can also be formed to increase the directivity of the beam [42]. One planar grating array, shown in Fig. 5, radiates a broadside beam at 65 GHz with a total efficiency, including the power divider and feed losses, of 27% [66].

4.2. Scanning Antennas

A wide array of consumer wireless applications are anticipated at millimeter-wave frequencies [48,55]. Many of these emerging applications require the ability to track a user or moving target. Unfortunately, conventional technology for steering and redirecting millimeter-wave

wireless signals is often prohibitively expensive for consumer applications. Rotating antennas use RF gimbal feeds that require precision machining and costly maintenance. Millimeter-wave phased arrays, on the other hand, are often exuberantly expensive, requiring exotic technologies and extensive supporting electronic equipment. In order to reduce the cost and broaden the commercial applications millimeter-wave frequencies, considerable research is currently directed at developing low-cost scanning antennas and phased arrays for the Ka band and above. Several approaches based on the grating arrays are under investigation, including

Figure 7. Electronically reconfigurable holographic antenna: (a) conducting regions formed on a silicon wafer; (b) corresponding far-field radiation pattern. (Courtesy of Dr. A. Fathy, University of Tennessee.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 8. A commercially available optically controlled grating antenna.

electromechanical, electronic, and electrooptic. Some of these approaches are also classified as “reconfigurable antennas” since the central tactic is often to provide beam steering by reconfiguring the aperture of the grating.

Figure 6 illustrates a simple scanning antenna that can be electromechanically reconfigured to provide low-cost millimeter-wave beam steering [67]. A thin movable dielectric film is extended across a stationary dielectric image line. Continuous metal grating strips are etched along the underside of the film, with the strips depicted as visible in the figure. The spacing between the metal strips varies linearly along the length of the film from d_{\max} to d_{\min} . Scrolling the film along the image line shifts the film in the y direction, steering a highly directive fan-shaped beam of radiation along the angle θ . As illustrated in the figure, the widths of the strips themselves are designed to increase away from the input to the guide in order to gradually perturb the signal as it is launched along the image line. The prototype configuration shown in Fig. 1 is able to achieve 53° beam steering at 35 GHz. An innovative, bidirectionally excited design achieves $\pm 50^\circ$ scanning across the complete 35–40 GHz range [48,57]. A key advantage of this approach is that the mechanical motion is inertialess and completely external to the millimeter-wave feed. Thin steel sheets may also be used. In either case, only a simple DC motor is required to spool the grating layer along the surface of the dielectric guide. Another electromechanical approach is to form a grating antenna from a spring coiled around a dielectric waveguide [68]. Flexing the spring provides beam steering. Several interesting electromechanically scanning grating antennas are now available commercially and are disclosed in a U.S. patent [39].

Other researchers are developing electronically scanned grating antennas by integrating PIN diodes into the grating structure. In Refs. 13 and 14, a PIN diode integrated into the sidewall of a grating antenna is used to modulate the propagation constant within the dielectric guide in order to steer the beam. In Ref. 69, PIN diodes are integrated into the grating strips themselves in order to switch the radiated beam between one of two scan states.

Most impressively, in Ref. 64, an array of PIN diodes are integrated onto the back of a silicon wafer in order to create a dynamically reconfigurable hologram. Holographic antennas are the two-dimensional analog of grating antennas. Figure 7 illustrates the conducting pattern formed by the PIN diodes on the silicon wafer and the corresponding far-field pattern.

Optical and ferroelectric scanning grating antennas are also a topic of investigation [70–75]. In many cases, however, the experimental results require improvement in order for the systems to find broad acceptance. Figure 8 illustrates the configuration of one design [74]. A circular dielectric waveguide is coupled to a semiconducting dielectric slab. Laser light illuminates the surface of the dielectric slab in order to create islands of conducting plasma on the surface. The spacing between these islands can be changed in order to steer the mainbeam angle of the radiated beam. Ferroelectric scanning grating antennas are also commercially available at frequencies from 10 to 76 GHz [75].

4.3. Other Applications

Many other uses for millimeter-wave gratings do exist. For example, on the circuit level gratings can be used as resonators for notch filters or for oscillators [9,76]. Closely spaced gratings are often used as polarizers in grid amplifiers [77]. In the far-field zone, millimeter-wave gratings are used for as spectrometry [7,78], spatial filtering and beam-shaping [79], spatial power combining and dividing [80–82], and remote beam control [83–85]. These applications for gratings are likely to increase in importance as millimeter-wave technology becomes more and more common.

5. CONCLUSION

Interest in millimeter-wave technology has been building steadily since the mid-1970s. Today, several applications have already become established; numerous others are quickly emerging. These new millimeter-wave wireless systems require inexpensive, mass-producible, low-loss

antenna arrays. Grating antennas meet these demands at frequencies up through the W band and beyond.

This article began with an examination of the historical background of gratings and grating antennas. The fundamental principles underlying their operation were clearly described, and an antenna design procedure was presented. The article ended with a survey of some of the most interesting applications to date for millimeter-wave gratings.

Acknowledgments

The authors wish to thank Prof. R. Nevels of Texas A&M University for graciously opening to them his extensive personal notes on periodic structures. They also kindly appreciate the assistance of Dr. A. Fathy at the University of Tennessee, of President H. Rutstein at Dorado International Corp., and of Ms. T. Quintana at Waveband Corp.

GREEN'S FUNCTION METHODS

JIAN-MING JIN
 WENG CHO CHEW
 University of Illinois at Urbana-
 Champaign

The Green's function method is a powerful techniques for solving boundary value problems. Green's function was named after George Green (1793–1841), who developed a general method to obtain solutions of Poisson's equation in potential theory. This method was described in an essay by Green entitled "On the application of mathematical analysis to the theories of electricity and magnetism," published in 1828.

To illustrate the Green's function method, consider the electric potential produced by a point electric charge q_1

placed at \mathbf{r}_1 in an unbounded homogeneous free space. It is well known from the elementary theory of electricity [1] that this potential at \mathbf{r} is given by

$$\phi_1(\mathbf{r}) = \frac{q_1}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_1|} \quad (1)$$

where $|\mathbf{r} - \mathbf{r}_1|$ denotes the distance between the points \mathbf{r} and \mathbf{r}_1 and ϵ is a constant called the *permittivity*. If there is another point charge q_2 placed at \mathbf{r}_2 , the potential produced by this charge is

$$\phi_2(\mathbf{r}) = \frac{q_2}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_2|} \quad (2)$$

The total potential produced by q_1 and q_2 is then the linear superposition of ϕ_1 and ϕ_2 :

$$\phi(\mathbf{r}) = \phi_1(\mathbf{r}) + \phi_2(\mathbf{r}) = \frac{q_1}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_1|} + \frac{q_2}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_2|} \quad (3)$$

If there are N point charges in the space, the total potential is given by

$$\phi(\mathbf{r}) = \sum_{i=1}^N \phi_i(\mathbf{r}) = \sum_{i=1}^N \frac{q_i}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_i|} \quad (4)$$

where Σ denotes the summation over all point charges and ϕ_i denotes the potential due to the i th point charge placed at \mathbf{r}_i . The procedure described above is known as the principle of linear superposition.

Next, consider the electric potential produced by a volume electric charge whose charge density is denoted by $\rho(\mathbf{r})$. To find the potential, we divide the volume of the charge into many small cubes. The charge within each small cube is then given by

$$q_i \approx \rho(\mathbf{r}_i)\Delta V_i \quad (5)$$

where \mathbf{r}_i denotes the center of the i th cube and ΔV_i denotes the volume of the cube. Since each cube is very small, it can be approximated as a point charge, whose potential is given by

$$\phi_i(\mathbf{r}) \approx \frac{q_i}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_i|} \approx \frac{\rho(\mathbf{r}_i)\Delta V_i}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_i|} \quad (6)$$

According to the principle to linear superposition, the total potential is then given by

$$\phi(\mathbf{r}) = \sum_{i=1}^N \phi_i(\mathbf{r}) \approx \sum_{i=1}^N \frac{\rho(\mathbf{r}_i)\Delta V_i}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_i|} \quad (7)$$

Clearly, the approximation improves as the volume is divided into smaller cubes. In the limit when $\Delta V_i \rightarrow 0$, Eq. (7) becomes exact. Hence, one obtains

$$\phi(\mathbf{r}) = \lim_{\Delta V_i \rightarrow 0} \sum_{i=1}^{\infty} \frac{\rho(\mathbf{r}_i)\Delta V_i}{4\pi\epsilon|\mathbf{r} - \mathbf{r}_i|} \quad (8)$$

which can be written in the integral form as

$$\phi(\mathbf{r}) = \int_V \frac{\rho(\mathbf{r}') dV'}{4\pi\epsilon|\mathbf{r} - \mathbf{r}'|} \tag{9}$$

where V denotes the volume of the electric charge.

The potential produced by a point source of unit strength is called *Green's function*. In the example above, the Green's function is

$$G(\mathbf{r}, \mathbf{r}') = \frac{1}{4\pi\epsilon|\mathbf{r} - \mathbf{r}'|} \tag{10}$$

and the total potential can then be written as

$$\phi(\mathbf{r}) = \int_V \rho(\mathbf{r}') G(\mathbf{r}, \mathbf{r}') dV' \tag{11}$$

It is clear that the Green's function method treats an arbitrary source for the potential as a linear superposition of weighted point sources. It then finds the potential as the corresponding linear superposition of the potentials produced by the point sources.

Obviously, once the Green's function corresponding to the potential due to a point source is found, the potential produced by an arbitrary distribution of sources can be obtained easily. Therefore, for a specific boundary value problem, instead of finding the potential for each new source encountered by solving Poisson's equation repeatedly, one can find the Green's function for that problem only once and obtain solutions to any sources by the principle of linear superposition. The procedure of finding Green's function is usually much simpler than finding the solution to an arbitrary source. To a large extent, a Green's function plays the same role as an impulse response of a linear circuit system. The system response to any input function can be determined by convolving the input function with the impulse response of the system. The Green's function method has since been expanded to deal with a large number of different partial-differential equations.

In electrodynamics, both the source (electric current density) and the response (electric or magnetic field) are vectors, each of which has three components. Since each component of an electric current density can produce all three components of the electric or magnetic field, one has nine Green functions that relate the response to the source. This unwieldiness can be alleviated by introducing the concept of the dyadic Green function. A dyadic Green function, which can be expressed as a 3×3 matrix, can be considered as a compact representation of the nine scalar Green's functions. The first use of dyadic Green's function was made by Julian Schwinger. The subject was also covered by Morse and Feshbach [2] in their well-known treatise on the methods of theoretical physics. A more comprehensive treatment of the dyadic Green functions in electromagnetic theory was presented by Tai [3], who has done much original work on this topic. In his well-known book, Tai derived dyadic Green's functions for variety of electromagnetic problems of practical importance.

Discussions on dyadic Green's functions can be found in Collin [4], Kong [5], and Chew [6].

As shall be shown later, the Green's function method not only provides a solution to many boundary value problems involving canonical geometries but also leads to integral equations for problems involving more complex geometries. These integral equations form the basis for a numerical solution of complex boundary value problems.

1. SCALAR GREEN'S FUNCTIONS

When both the source and response are scalar functions, the corresponding Green's function is also scalar and, hence, the name scalar Green's function.

1.1. The Delta Function

Since the Green's function method is based on the representation of an arbitrary source by the superposition of point sources, the mathematical representation of a point source will first be described. Consider an electric charge of unit strength located at point \mathbf{r}' . When the volume of the charge approaches zero, the charge density can be described by a function

$$\delta(\mathbf{r} - \mathbf{r}') = \begin{cases} \infty & \text{for } \mathbf{r} = \mathbf{r}' \\ 0 & \text{for } \mathbf{r} \neq \mathbf{r}' \end{cases} \tag{12}$$

Since the total charge remains at unity

$$\int_V \delta(\mathbf{r} - \mathbf{r}') dV = \begin{cases} 1 & \text{for } \mathbf{r}' \text{ in } V \\ 0 & \text{for } \mathbf{r}' \text{ not in } V \end{cases} \tag{13}$$

The function defined in Eqs. (12) and (13) is known as the *Dirac delta function*, named after P. A. M. Dirac. Clearly, given an arbitrary function $f(\mathbf{r})$, which is continuous at $\mathbf{r} = \mathbf{r}'$, we obtain

$$\int_V f(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') dV = \begin{cases} f(\mathbf{r}') & \text{for } \mathbf{r}' \text{ in } V \\ 0 & \text{for } \mathbf{r}' \text{ not in } V \end{cases} \tag{14}$$

This expression represents a volume source $f(\mathbf{r}')$ as a linear superposition of an infinite number of point sources $\delta(\mathbf{r} - \mathbf{r}')$.

In one dimension, the delta function can be considered as the limit of a function

$$\delta(x - x') = \lim_{\epsilon \rightarrow 0} u_\epsilon(x - x') \tag{15}$$

where $u_\epsilon(x - x')$ is called a *delta family*. It can be a rectangular function of width ϵ and height $1/\epsilon$, or a triangular function of width 2ϵ and height $1/\epsilon$, or a Gaussian function $e^{-(x-x')^2/2\epsilon^2}/\epsilon\sqrt{2\pi}$, all centered at $x = x'$. The important feature of the delta function is not its shape, but the fact that its effective width approaches zero, while its area remains

at unity, that is

$$\int_a^b \delta(x - x') dx = \begin{cases} 1 & \text{for } x' \text{ in } (a, b) \\ 0 & \text{for } x' \text{ not in } (a, b) \end{cases} \quad (16)$$

such that

$$\int_a^b f(x) \delta(x - x') dx = \begin{cases} f(x') & \text{for } x' \text{ in } (a, b) \\ 0 & \text{for } x' \text{ not in } (a, b) \end{cases} \quad (17)$$

The delta function so defined is not a function in the classical sense. For this reason, it is called a symbolic or generalized function [7].

Clearly, the delta function is a symmetric function

$$\delta(x - x') = \delta(x' - x) \quad (18)$$

The three-dimensional delta function in the rectangular, cylindrical, and spherical coordinate systems is related to the one-dimensional delta function by

$$\delta(\mathbf{r} - \mathbf{r}') = \delta(x - x') \delta(y - y') \delta(z - z') \quad (19)$$

$$\delta(\mathbf{r} - \mathbf{r}') = \frac{\delta(\rho - \rho') \delta(\phi - \phi') \delta(z - z')}{\rho} \quad (20)$$

$$\delta(\mathbf{r} - \mathbf{r}') = \frac{\delta(r - r') \delta(\theta - \theta') \delta(\phi - \phi')}{r^2 \sin \theta} \quad (21)$$

All of these above satisfy Eq. (13).

1.2. One-Dimensional Green's Function

To introduce the concept of Green's function in one dimension, consider an infinitely long transmission line with a distributed current source $K(x)$ (3), as illustrated in Fig. 1. Using Kirchhoff's voltage and current laws, one finds the relations between the voltage and current as

$$\frac{dV(x)}{dx} + (j\omega L + R)I(x) = 0 \quad (22)$$

$$\frac{dI(x)}{dx} + (j\omega C + G)V(x) = K(x) \quad (23)$$

where ω denotes the angular frequency and L , C , R , and G are the inductance, capacitance, resistance, and conduc-

Figure 1. An infinitely long transmission line excited by a distributed current source.

tance of the transmission line per unit length. Eliminating $I(x)$ in Eqs. (22) and (23), one obtains the differential equation for the voltage as

$$\frac{d^2V(x)}{dx^2} - \gamma^2V(x) = -(j\omega L + R)K(x) \quad (24)$$

where $\gamma^2 = (j\omega L + R)(j\omega C + G)$. Since the line is infinitely long, there is no reflected wave; hence, $V(x)$ satisfies the boundary conditions

$$\frac{dV(x)}{dx} + \gamma V(x) = 0 \quad \text{for } x \rightarrow \infty \quad (25)$$

$$\frac{dV(x)}{dx} - \gamma V(x) = 0 \quad \text{for } x \rightarrow -\infty \quad (26)$$

Since these boundary conditions are imposed when $|x| \rightarrow \infty$, they are also called *radiation conditions*.

Instead of solving for $V(x)$ directly from Eqs. (24)–(26), one can consider the solution of the following differential equation

$$\frac{d^2g_0(x, x')}{dx^2} - \gamma^2g_0(x, x') = -\delta(x - x') \quad (27)$$

where $g_0(x)$ satisfies the same radiation condition as $V(x)$. Since $g_0(x, x')$ is a point source response and $V(x)$ in Eq. (24) is due to the source $(j\omega L + R)K(x)$, according to the principle of linear superposition, $V(x)$ can be expressed as a convolution of $g_0(x, x')$ with $(j\omega L + R)K(x)$:

$$V(x) = \int_{-\infty}^{\infty} (j\omega L + R)K(x')g_0(x, x') dx' \quad (28)$$

It is evident that once we obtain $g_0(x, x')$, the voltage on the transmission line can be evaluated via a simple integration using Eq. (28).

To find $g_0(x, x')$, note that since

$$\frac{d^2g_0(x, x')}{dx^2} - \gamma^2g_0(x, x') = 0 \quad \text{for } x > x' \text{ or } x < x' \quad (29)$$

one has

$$g_0(x, x') = Ae^{-\gamma x} \quad \text{for } x > x' \quad (30)$$

$$g_0(x, x') = Be^{\gamma x} \quad \text{for } x < x' \quad (31)$$

where the radiation conditions in Eqs. (25) and (26) were used to determine the sign in front of γ . To determine the unknown coefficients A and B , consider Eq. (27). First, note that $g_0(x, x')$ must be continuous at $x = x'$, that is

$$g_0(x, x')|_{x=x'+0} = g_0(x, x')|_{x=x'-0} \quad (32)$$

where $x = x' + 0$ stands for the right-hand side of x' and $x = x' - 0$ stands for the left-hand side of x' since a discontinuity in $g_0(x, x')$ at $x = x'$ would result in a derivative on $\delta(x - x')$ on the left-hand side of Eq. (27). Next, integrate Eq. (27) over the region from $x' - \varepsilon$ to $x' + \varepsilon$ and in the limit

when $\varepsilon \rightarrow 0$

$$\left. \frac{dg_0(x, x')}{dx} \right|_{x=x'+0} - \left. \frac{dg_0(x, x')}{dx} \right|_{x=x'-0} = -1 \tag{33}$$

Applying these two conditions to Eqs. (30) and (31), one finds

$$g_0(x, x') = \frac{1}{2\gamma} e^{-\gamma(x-x')} \text{ for } x > x' \tag{34}$$

$$g_0(x, x') = \frac{1}{2\gamma} e^{\gamma(x-x')} \text{ for } x < x' \tag{35}$$

or, more compactly

$$g_0(x, x') = \frac{1}{2\gamma} e^{-\gamma|x-x'|} \tag{36}$$

This is the Green function for the infinitely long transmission line.

1.3. Two- and Three-Dimensional Green's Function

Consider the electric and magnetic fields produced by a time-harmonic electric source whose current density is denoted by $\mathbf{J}(\mathbf{r})$ and charge density is denoted by $\rho(\mathbf{r})$. These fields satisfy Maxwell's equations given by (1)

$$\nabla \times \mathbf{E}(\mathbf{r}) = -j\omega\mathbf{B}(\mathbf{r}) \tag{37}$$

$$\nabla \times \mathbf{H}(\mathbf{r}) = j\omega\mathbf{D}(\mathbf{r}) + \mathbf{J}(\mathbf{r}) \tag{38}$$

$$\nabla \cdot \mathbf{D}(\mathbf{r}) = \rho(\mathbf{r}) \tag{39}$$

$$\nabla \cdot \mathbf{B}(\mathbf{r}) = 0 \tag{40}$$

and the constitutive relations given by $\mathbf{B} = \mu\mathbf{H}$ and $\mathbf{D} = \varepsilon\mathbf{E}$, where μ is the magnetic permeability and ε is the electric permittivity. Again, assume that the space is homogeneous. Taking the curl of Eq. (37), one has

$$\nabla \times \nabla \times \mathbf{E}(\mathbf{r}) = -j\omega\mu\nabla \times \mathbf{H}(\mathbf{r}) \tag{41}$$

Using Eq. (38) in Eq. (41), one obtains

$$\nabla \times \nabla \times \mathbf{E}(\mathbf{r}) - k^2\mathbf{E}(\mathbf{r}) = -j\omega\mu\mathbf{J}(\mathbf{r}) \tag{42}$$

where $k^2 = \omega^2\mu\varepsilon$. Since $\nabla \times \nabla \times \mathbf{E} = \nabla(\nabla \cdot \mathbf{E}) - \nabla^2\mathbf{E}$, Eq. (42) can be written as

$$\nabla^2\mathbf{E}(\mathbf{r}) + k^2\mathbf{E}(\mathbf{r}) = j\omega\mu\mathbf{J}(\mathbf{r}) + \frac{1}{\varepsilon}\nabla\rho(\mathbf{r}) \tag{43}$$

where Eq. (39) has been applied. Similarly, one obtains the equation for \mathbf{H} as

$$\nabla^2\mathbf{H}(\mathbf{r}) + k^2\mathbf{H}(\mathbf{r}) = -\nabla \times \mathbf{J}(\mathbf{r}) \tag{44}$$

Equations (43) and (44) are inhomogeneous Helmholtz wave equations.

If one uses ϕ to represent each component of \mathbf{E} or \mathbf{H} in a Cartesian coordinate system, then ϕ satisfies the inhomogeneous Helmholtz equation

$$\nabla^2\phi(\mathbf{r}) + k^2\phi(\mathbf{r}) = -f(\mathbf{r}) \tag{45}$$

where $\phi(\mathbf{r})$ propagates in an infinite unbounded space, there is no reflected wave. Hence, $\phi(\mathbf{r})$ satisfies the radiation condition

$$r\left(\frac{\partial\phi}{\partial r} + jk\phi\right) = 0 \text{ for } r \rightarrow \infty \tag{46}$$

where r represents the radial variable in spherical coordinates. Instead of solving for $\phi(\mathbf{r})$ directly from Eqs. (45) and (46) for each $f(\mathbf{r})$, one first finds its Green function, which is the solution of the following partial-differential equation

$$\nabla^2G_0(\mathbf{r}, \mathbf{r}') + k^2G_0(\mathbf{r}, \mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}') \tag{47}$$

subject to the radiation condition in Eq. (46). If G_0 can be found, using the principle of linear superposition, one obtains

$$\phi(\mathbf{r}) = \int_V G_0(\mathbf{r}, \mathbf{r}')f(\mathbf{r}')dV' \tag{48}$$

where V is the support of $f(\mathbf{r})$, which is the volume having nonzero $f(\mathbf{r})$.

To find G_0 , we introduce a new coordinate system with its origin located at \mathbf{r}' . Thus, the problem has a spherical symmetry with respect to this point. Equation (47) then becomes

$$\frac{1}{r_1^2} \frac{d}{dr_1} \left[r_1^2 \frac{dG_0(\mathbf{r}_1, 0)}{dr_1} \right] + k^2G_0(\mathbf{r}_1, 0) = -\delta(\mathbf{r}_1) \tag{49}$$

where $\mathbf{r}_1 = \mathbf{r} - \mathbf{r}'$. When $r_1 \neq 0$, Eq. (49) can be written as

$$\frac{d^2[r_1G_0(\mathbf{r}_1, 0)]}{dr_1^2} + k^2r_1G_0(\mathbf{r}_1, 0) = 0 \tag{50}$$

which has a well-known solution

$$r_1G_0(\mathbf{r}_1, 0) = Ae^{-jkr_1} \text{ or } G_0(\mathbf{r}_1, 0) = A \frac{e^{-jkr_1}}{r_1} \tag{51}$$

The sign in the exponent is chosen such that Eq. (51) satisfies the radiation condition in Eq. (46). To determine the unknown coefficient A , substitute Eq. (51) into Eq. (49) and integrate over a small sphere centered at $\mathbf{r}_1 = 0$ with its radius $\varepsilon \rightarrow 0$. The result is $A = (4\pi)^{-1}$. Therefore

$$G_0(\mathbf{r}_1, 0) = \frac{e^{-jkr_1}}{4\pi r_1} \tag{52}$$

and in the original coordinates, it becomes

$$G_0(\mathbf{r}, \mathbf{r}') = \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \quad (53)$$

Following the same procedure, one can obtain the two-dimensional Green function for the Helmholtz equation as

$$G_0(\rho, \rho') = \frac{1}{4j} H_0^{(2)}(k|\rho - \rho'|) \quad (54)$$

where $\rho = x\hat{x} + y\hat{y}$ and $H_0^{(2)}(k|\rho - \rho'|)$ is the zeroth-order Hankel function of the second kind.

When one deals with the static electric field, Maxwell's equations for $\mathbf{E}(\mathbf{r})$ reduce to

$$\nabla \times \mathbf{E}(\mathbf{r}) = 0 \quad \text{and} \quad \nabla \cdot \mathbf{E}(\mathbf{r}) = \frac{\rho(\mathbf{r})}{\varepsilon} \quad (55)$$

These two equations can be solved conveniently by introducing the electric potential $\phi(\mathbf{r})$, which is defined as

$$\mathbf{E}(\mathbf{r}) = -\nabla\phi(\mathbf{r}) \quad (56)$$

The first equation in Eq. (55) is automatically satisfied because of the identity $\nabla \times \nabla\phi(\mathbf{r}) \equiv 0$. Substituting Eq. (56) into the second equation in Eq. (55), one obtains

$$\nabla^2\phi(\mathbf{r}) = -\frac{\rho(\mathbf{r})}{\varepsilon} \quad (57)$$

This equation is Poisson's equation, which can be considered as a special case of Eq. (45) with $k=0$.

Using the procedure described in this section, one obtains the three-dimensional Green function for Poisson's equation as

$$G_0(\mathbf{r}, \mathbf{r}') = \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|} \quad (58)$$

and the two-dimensional Green function as

$$G_0(\rho, \rho') = -\frac{1}{2\pi} \ln|\rho - \rho'| \quad (59)$$

1.4. Classification of Green's Functions

The Green functions derived above are for the infinite unbounded space where no other objects are present. They are called the *free-space Green's functions* and are denoted by the subscript 0. When the region of interest is bounded, one then has to consider boundary conditions for Green's function. Different boundary conditions lead to different Green's functions. For this reason, Green's functions are classified into three categories: Green's functions of the first, second, and third kind [3].

Green's function of the first kind, denoted by G_1 , satisfies the Dirichlet boundary condition, that is

$$G_0(\mathbf{r}, \mathbf{r}') = 0 \quad \text{for } \mathbf{r} \text{ on } S \quad (60)$$

where S denotes the boundary of the problem. For a half-space with an infinite ground plane coincident with the $z=0$ plane, the Green's function of the first kind for Poisson's equation is given by

$$G_0(\mathbf{r}, \mathbf{r}') = G_0(\mathbf{r}, \mathbf{r}') + G_0(\mathbf{r}, \mathbf{r}'_i) = \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|} - \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'_i|} \quad (61)$$

where $\mathbf{r}'_i = \mathbf{r}' - 2z'\hat{z} = x'\hat{x} + y'\hat{y} - z'\hat{z}$. This result can be derived conveniently using the method of images. It is easy to see that the Dirichlet boundary condition is satisfied by $G_1(\mathbf{r}, \mathbf{r}')$ in the $z=0$ plane.

The Green's function of the second kind, denoted by G_2 , satisfies the Neumann boundary condition, that is

$$\frac{\partial G_2(\mathbf{r}, \mathbf{r}')}{\partial n} = 0 \quad \text{for } \mathbf{r} \text{ on } S \quad (62)$$

where S denotes the boundary of the problem and $\partial/\partial n$ denotes the normal derivative. For a half space with an infinite magnetic (symmetry) plane coincident with the $z=0$ plane, the Green's function of the second kind for Poisson's equation is given by

$$G_2(\mathbf{r}, \mathbf{r}') = G_0(\mathbf{r}, \mathbf{r}') + G_0(\mathbf{r}, \mathbf{r}'_i) = \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|} + \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'_i|} \quad (63)$$

where \mathbf{r}'_i is the same as the one in Eq. (61). It satisfies the Neumann boundary condition in the $z=0$ plane.

The Green's function of the third kind is defined for problems involving two or more media. It can be denoted as $G^{(ij)}(\mathbf{r}, \mathbf{r}')$, where i indicates the medium where the field point \mathbf{r} is located and j indicates the medium where the source point \mathbf{r}' is located. Consider, for example, a potential problem involving two half-spaces. The upper half-space (medium 1) above $z=0$ has a permittivity of ε_1 , and the lower half-space (medium 2) has a permittivity of ε_2 . The Green's function for Poisson's equation is given by (8)

$$G^{(11)}(\mathbf{r}, \mathbf{r}') = G_0(\mathbf{r}, \mathbf{r}') - \frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2 + \varepsilon_1} G_0(\mathbf{r}, \mathbf{r}'_i) = \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|} - \frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2 + \varepsilon_1} \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'_i|} \quad (64)$$

and

$$G^{(21)}(\mathbf{r}, \mathbf{r}') = \frac{2\varepsilon_2}{\varepsilon_2 + \varepsilon_1} G_0(\mathbf{r}, \mathbf{r}') = \frac{2\varepsilon_2}{\varepsilon_2 + \varepsilon_1} \frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|} \quad (65)$$

Exchanging ε_1 and ε_2 in $G^{(11)}$ and $G^{(21)}$, one obtains the expressions for $G^{(22)}$ and $G^{(12)}$, respectively. This method

of obtaining the Green's functions of the third kind works only for Poisson's equation, but not for the Helmholtz equation because the standard image method is not applicable to the Helmholtz equation in this case.

1.5. Eigenfunction Expansion

In addition to the conventional method described earlier, another general method for deriving Green's functions is the method of Ohm-Rayleigh or the method of eigenfunction expansion [3]. In this section, one rederives the Green functions in Eq. (36) and Eq. (53) to illustrate the process of the Ohm-Rayleigh method.

Consider first the solution of Eq. (27). Expand $g_0(x, x')$ in terms of a Fourier integral

$$g_0(x, x') = \int_{-\infty}^{\infty} A(h)e^{ihx}dh \tag{66}$$

The e^{ihx} , which is the solution of the homogeneous differential equation $d^2\psi(x)/dx^2 + h^2\psi(x) = 0$, is called the *eigenfunction* and h^2 is the corresponding *eigenvalue*. Therefore, Eq. (66) can be considered as the eigenfunction expansion of $g_0(x, x')$. To determine $A(h)$, substitute Eqs. (66) into Eq. (27) and note that

$$\delta(x - x') = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{jh(x-x')}dh \tag{67}$$

This yields

$$A(h) = \frac{e^{-jh x'}}{2\pi(h^2 + \gamma^2)} \tag{68}$$

Hence, we obtain

$$g_0(x, x') = \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{e^{jh(x-x')}}{h^2 + \gamma^2} dh \tag{69}$$

This is known as the *spectral representation* of $g_0(x, x')$. The integral in this equation can be evaluated using Cauchy's residue theorem [9]. For this, one needs to form a closed contour for the integral in Eq. (69). In order to satisfy the boundary conditions in Eqs. (25) and (26), for $x - x' > 0$ the infinite integration path must be closed in the upper half-plane and for $x - x' < 0$ the infinite path must be closed in the lower half-plane, as shown in Fig. 2. The application of Cauchy's residue theorem yields

$$g_0(x, x') = \frac{1}{2\gamma} \begin{cases} e^{-\gamma(x-x')} & \text{for } x > x' \\ e^{\gamma(x-x')} & \text{for } x < x' \end{cases} \tag{70}$$

which is the same as Eqs. (34) and (35).

Next, consider the solution of Eq. (47). First expand $G_0(\mathbf{r}, \mathbf{r}')$ in terms of Fourier integrals

$$G_0(\mathbf{r}, \mathbf{r}') = \int_{-\infty}^{\infty} A(\mathbf{h})e^{i\mathbf{h}\cdot\mathbf{r}}d\mathbf{h} \tag{71}$$

Figure 2. Locations of the two poles in the complex plane and the closed contours for integration.

where $\mathbf{h} = h_x\hat{x} + h_y\hat{y} + h_z\hat{z}$. The $e^{i\mathbf{h}\cdot\mathbf{r}}$, which is the solution of the homogeneous partial differential equation $\nabla^2\psi(\mathbf{r}) + h^2\psi(\mathbf{r}) = 0$, is called the *eigenfunction* and $h^2 = |\mathbf{h}|^2$ is the corresponding *eigenvalue*. Again, Eq. (71) can be considered as the eigenfunction expansion of $G_0(\mathbf{r}, \mathbf{r}')$. Substituting Eq. (71) into Eq. (47), and noting that

$$\delta(\mathbf{r} - \mathbf{r}') = \frac{1}{(2\pi)^3} \int_{-\infty}^{\infty} e^{i\mathbf{h}\cdot(\mathbf{r}-\mathbf{r}')}d\mathbf{h} \tag{72}$$

one finds

$$A(\mathbf{h}) = \frac{e^{-j\mathbf{h}\cdot\mathbf{r}'}}{(2\pi)^3(h^2 - k^2)} \tag{73}$$

Therefore

$$G_0(\mathbf{r}, \mathbf{r}') = \frac{1}{(2\pi)^3} \int_{-\infty}^{\infty} \frac{e^{i\mathbf{h}\cdot(\mathbf{r}-\mathbf{r}')}}{h^2 - k^2}d\mathbf{h} \tag{74}$$

This is the spectral representation of the three-dimensional Green function. To evaluate the spectral integral, let

$$h_x = h \sin \theta \cos \varphi, \quad h_y = h \sin \theta \sin \varphi, \quad h_z = h \cos \theta \tag{75}$$

so that

$$d\mathbf{h} = h^2 \sin \theta dh d\theta d\varphi \tag{76}$$

Furthermore, because of the spherical symmetry of G_0 with respect to the point \mathbf{r}' , the value of G_0 is independent of the direction of $\mathbf{r} - \mathbf{r}'$. Therefore, one can choose an arbitrary $\mathbf{r} - \mathbf{r}'$ for the evaluation of G_0 . If one chooses the direction of $\mathbf{r} - \mathbf{r}'$ to coincide with the z direction, Eq. (74)

may be written as

$$\begin{aligned}
 G_0(\mathbf{r}, \mathbf{r}') &= \frac{1}{(2\pi)^3} \int_0^\infty \int_0^\pi \int_0^{2\pi} \frac{e^{jh \cos \theta |\mathbf{r}-\mathbf{r}'|}}{h^2 - k^2} h^2 \sin \theta \, dh \, d\theta \, d\varphi \\
 &= \frac{j}{(2\pi)^2 |\mathbf{r}-\mathbf{r}'|} \int_0^\infty [e^{-jh|\mathbf{r}-\mathbf{r}'|} - e^{jh|\mathbf{r}-\mathbf{r}'|}] \frac{h \, dh}{h^2 - k^2} \\
 &= \frac{j}{(2\pi)^2 |\mathbf{r}-\mathbf{r}'|} \int_0^\infty \frac{h e^{-jh|\mathbf{r}-\mathbf{r}'|}}{h^2 - k^2} \, dh \quad (77)
 \end{aligned}$$

This integral can now be evaluated using Cauchy's residue theorem. The integral has two poles: one at $h = k$ and the other at $h = -k$. Although the problem considered here is lossless, treat it as a limiting case of lossy problem for which k has a small negative imaginary part. Consequently, the pole at $h = k$ is on the lower side of the real axis and the pole at $h = -k$ is on the upper side of the real axis. In order to satisfy the radiation condition in Eq. (46), the infinite integration path must be closed in the lower half-plane, as shown in Fig. 3. Applying Cauchy's residue theorem, one obtains

$$G_0(\mathbf{r}, \mathbf{r}') = \frac{e^{-jk|\mathbf{r}-\mathbf{r}'|}}{4\pi |\mathbf{r}-\mathbf{r}'|} \quad (78)$$

which is the same as Eq. (53).

Finally, note that, although the process of the Ohm-Rayleigh method is more involved than the conventional method, it is more general and can be used to find Green's functions in many problems.

1.6. Green's Functions in a Bounded Region

As can be seen in the preceding section, the spectrum (eigenvalue) for infinite-space problems is continuous and, as a result, the spectral representation of the Green function involves spectral integrals. When the region of interest is finite, the spectrum will be discrete. To demonstrate this fact, consider a grounded rectangular cavity of dimension $a \times b \times d$, depicted in Fig. 4. The Green's function for Poisson's equation satisfies the partial differential

Figure 3. Locations of the two poles in the complex plane and the closed contour for integration.

Figure 4. A grounded rectangular cavity.

equation

$$\nabla^2 G_1(\mathbf{r}, \mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}') \quad (79)$$

and the Dirichlet boundary condition

$$G_1(\mathbf{r}, \mathbf{r}') = 0 \quad \text{for } \mathbf{r} \text{ on cavity walls} \quad (80)$$

This Green's function can be derived in a number of different ways, such as the conventional method, the method of images, and the Ohm-Rayleigh method. Here, the Ohm-Rayleigh method is employed. First, consider the solution of

$$\nabla^2 \psi + h^2 \psi = 0 \quad (81)$$

subject to the condition in Eq. (80). Using the method of separation of variables, one finds

$$\psi_{mnp} = \sin \frac{m\pi x}{a} \sin \frac{n\pi y}{b} \sin \frac{p\pi z}{d} \quad (82)$$

which is the eigenfunction of Eq. (81) with eigenvalue $h^2 = (m\pi/a)^2 + (n\pi/b)^2 + (p\pi/d)^2$. This can be used to expand G_1 :

$$G_1(\mathbf{r}, \mathbf{r}') = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \sum_{p=1}^{\infty} A_{mnp} \sin \frac{m\pi x}{a} \sin \frac{n\pi y}{b} \sin \frac{p\pi z}{d} \quad (83)$$

Substituting this expression into Eq. (79), one has

$$\begin{aligned}
 \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \sum_{p=1}^{\infty} A_{mnp} h^2 \sin \frac{m\pi x}{a} \sin \frac{n\pi y}{b} \sin \frac{p\pi z}{d} \\
 = \delta(x - x') \delta(y - y') \delta(z - z') \quad (84)
 \end{aligned}$$

The coefficient A_{mnp} can be determined by multiplying both sides by $\sin(m'\pi x/a)$, $\sin(n'\pi y/b)$, and $\sin(p'\pi z/d)$ and

integrating over x, y and z . The result is

$$G_1(\mathbf{r}, \mathbf{r}') = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \sum_{p=1}^{\infty} \frac{8}{abd h^2} \sin \frac{m\pi x}{a} \sin \frac{m\pi x'}{a} \sin \frac{n\pi y}{b} \sin \frac{n\pi y'}{b} \sin \frac{p\pi z}{d} \sin \frac{p\pi z'}{d} \tag{85}$$

The triple summation can be reduced to a double summation using the formula [4]

$$\sum_{p=1}^{\infty} \frac{1}{h^2} \sin \frac{p\pi z}{d} \sin \frac{p\pi z'}{d} = \frac{d}{2k_c \sinh k_c d} \sinh k_c z_{<} \sinh k_c (d - z_{>}) \tag{86}$$

where $k_c = \sqrt{(m\pi/a)^2 + (n\pi/b)^2}$, $z_{<} = z$ when $z < z'$, and $z_{<} = z'$ when $z' < z$, and $z_{>} = z$ when $z > z'$, and $z_{>} = z'$ when $z' > z$. As a result, Eq. (85) becomes

$$G_1(\mathbf{r}, \mathbf{r}') = \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{4}{ab} \sin \frac{m\pi x}{a} \sin \frac{m\pi x'}{a} \sin \frac{n\pi y}{b} \sin \frac{\sinh k_c z_{<} \sinh k_c (d - z_{>})}{k_c \sinh k_c d} \tag{87}$$

Next, consider the problem of a parallel-plate waveguide, which is finite in the y direction and infinite in the x and z directions, as shown in Fig. 5. Assuming that the source is uniform in the z direction, Green's function of the first kind for the Helmholtz equation satisfies the partial-differential equation

$$\nabla^2 G_1(\rho, \rho') + k^2 G_1(\rho, \rho') = -\delta(\rho - \rho') \tag{88}$$

and the boundary conditions

$$G_1(\rho, \rho') = 0 \text{ for } y = 0, b \tag{89}$$

Figure 5. A parallel-plate waveguide.

and the radiation conditions

$$\frac{\partial G_1(\rho, \rho')}{\partial x} + jk G_1(\rho, \rho') = 0 \text{ for } x \rightarrow \infty \tag{90}$$

$$\frac{\partial G_1(\rho, \rho')}{\partial x} - jk G_1(\rho, \rho') = 0 \text{ for } x \rightarrow -\infty \tag{91}$$

The eigenfunction for this problem is found as

$$\psi_n(h_x) = e^{jh_x x} \sin \frac{n\pi y}{b} \tag{92}$$

from which G_1 can be expanded as

$$G_1(\rho, \rho') = \int_{-\infty}^{\infty} \sum_{n=1}^{\infty} A_n(h_x) e^{jh_x x} \sin \frac{n\pi y}{b} dh_x \tag{93}$$

Substituting this expression into Eq. (88), one obtains

$$\int_{-\infty}^{\infty} \sum_{n=1}^{\infty} A_n(h_x) \left[k^2 - h_x^2 - \left(\frac{n\pi}{b} \right)^2 \right] e^{jh_x x} \sin \frac{n\pi y}{b} dh_x = -\delta(x - x') \delta(y - y') \tag{94}$$

The coefficient $A_n(h_x)$ can be determined by multiplying both sides by $e^{jh_x x} \sin(n\pi y/b)$ and integrating over x and y . The result is

$$G_1(\rho, \rho') = \frac{1}{\pi b} \int_{-\infty}^{\infty} \sum_{n=1}^{\infty} \left[h_x^2 + \left(\frac{n\pi}{b} \right)^2 - k^2 \right]^{-1} e^{jh_x(x-x')} \sin \frac{n\pi y}{b} \sin \frac{n\pi y'}{b} dh_x \tag{95}$$

Using Cauchy's residue theorem, one can evaluate the spectral integral in a similar manner to that for the transmission line case, yielding

$$G_1(\rho, \rho') = \frac{1}{b} \sum_{n=1}^{\infty} \frac{1}{\gamma_x} e^{-\gamma_x |x-x'|} \sin \frac{n\pi y}{b} \sin \frac{n\pi y'}{b} \tag{96}$$

where $\gamma_x = \sqrt{(n\pi/b)^2 - k^2}$.

1.7. Scalar Integral Equations

Originally, Green's function methods were developed for finding the general solution of a boundary value problem whose Green function can be derived. For many practical problems, the Green function cannot be derived. As a result, one must resort to a numerical method for the solution of the problem. One such numerical method is based on an integral equation derived using the Green's function method.

To demonstrate the formulation of integral equations, consider the problem of a scalar wave produced by a source $f(\mathbf{r})$ in the presence of an arbitrarily shaped object immersed in an infinite medium, as illustrated in Fig. 6. Exterior to the object, the wavefunction $\phi(\mathbf{r})$ satisfies the inhomogeneous Helmholtz equation in Eq. (45) and the

Figure 6. An object occupying volume V_0 .

radiation boundary condition in Eq. (46). Since the object has an arbitrary shape, no closed-form Green function can be found for this problem. However, one can establish an integral equation for this problem using the free-space Green function given in Eq. (53), which is the solution of Eq. (47) under the condition in Eq. (46).

First, multiply Eq. (45) with G_0 , Eq. (47) with ϕ , and integrate the difference of the resultant equations over the entire exterior volume, yielding

$$\begin{aligned} & \int_{V_\infty} [G_0(\mathbf{r}, \mathbf{r}') \nabla^2 \phi(\mathbf{r}) - \phi(\mathbf{r}) \nabla^2 G_0(\mathbf{r}, \mathbf{r}')] dV \\ &= - \int_{V_s} G_0(\mathbf{r}, \mathbf{r}') f(\mathbf{r}) dV + \int_{V_\infty} \phi(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') dV \end{aligned} \quad (97)$$

where V_∞ denotes the infinite space exterior to the object and V_s denotes the support of $f(\mathbf{r})$. Applying the second scalar Green's theorem (1)

$$\int_V (a \nabla^2 b - b \nabla^2 a) dV = \int_S \left(a \frac{\partial b}{\partial n} - b \frac{\partial a}{\partial n} \right) dS \quad (98)$$

where S denotes the surface enclosing V , one obtains

$$\begin{aligned} & \int_{S_0 + S_\infty} \left[G_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r})}{\partial n} - \phi(\mathbf{r}) \frac{\partial G_0(\mathbf{r}, \mathbf{r}')}{\partial n} \right] dS \\ & - \int_{V_\infty} \phi(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') dV \\ &= - \int_{V_s} G_0(\mathbf{r}, \mathbf{r}') f(\mathbf{r}) dV \end{aligned} \quad (99)$$

where S_0 denotes the surface of the object and S_∞ denotes a spherical surface with a radius approaching infinity. Since both G_0 and ϕ satisfy Eq. (46), the surface integral over S_∞ vanishes. Consequently, one has

$$\begin{aligned} & \int_{S_0} \left[G_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r})}{\partial n} - \phi(\mathbf{r}) \frac{\partial G_0(\mathbf{r}, \mathbf{r}')}{\partial n} \right] dS \\ & - \int_{V_\infty} \phi(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') dV = - \int_{V_s} G_0(\mathbf{r}, \mathbf{r}') f(\mathbf{r}) dV \end{aligned} \quad (100)$$

where the normal unit vector on S_0 points toward the interior of the object. Using Eq. (14), one obtains

$$\begin{aligned} & \int_{S_0} \left[G_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r})}{\partial n} - \phi(\mathbf{r}) \frac{\partial G_0(\mathbf{r}, \mathbf{r}')}{\partial n} \right] dS \\ & + \int_{V_s} G_0(\mathbf{r}, \mathbf{r}') f(\mathbf{r}) dV \\ &= \begin{cases} \phi(\mathbf{r}') & \text{for } \mathbf{r}' \text{ in } V_\infty \\ 0 & \text{for } \mathbf{r}' \text{ in } V_0 \end{cases} \end{aligned} \quad (101)$$

where V_0 denotes the volume of the object. Exchanging \mathbf{r} and \mathbf{r}' and using the symmetry property of G_0 [i.e., $G_0(\mathbf{r}', \mathbf{r}) = G_0(\mathbf{r}, \mathbf{r}')$], one has

$$\begin{aligned} & \int_{S_0} \left[G_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r})}{\partial n'} - \phi(\mathbf{r}) \frac{\partial G_0(\mathbf{r}, \mathbf{r}')}{\partial n'} \right] dS' \\ & + \int_{V_s} G_0(\mathbf{r}, \mathbf{r}') f(\mathbf{r}') dV' \\ &= \begin{cases} \phi(\mathbf{r}) & \text{for } \mathbf{r} \text{ in } V_\infty \\ 0 & \text{for } \mathbf{r} \text{ in } V_0 \end{cases} \end{aligned} \quad (102)$$

Equation (102) is an important result, which has several implications. First, notice that when the object is absent, the surface integral vanishes. Hence

$$\phi(\mathbf{r}) = \int_{V_s} G_0(\mathbf{r}, \mathbf{r}') f(\mathbf{r}') dV' \quad (103)$$

which is the same as Eq. (48). This may be called the *incident field impinging on the object* and be denoted as $\phi^{\text{inc}}(\mathbf{r})$. Second, when there is no source in V_∞ , Eq. (102) become

$$\phi(\mathbf{r}) = \int_{S_0} \left[G_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r}')}{\partial n'} - \phi(\mathbf{r}') \frac{\partial G_0(\mathbf{r}, \mathbf{r}')}{\partial n'} \right] dS' \quad (104)$$

for \mathbf{r} in V_∞ . Since there is no source in V_∞ , the field on S_0 must be produced by the source inside S_0 . This equation indicates that the field in a source-free region can be calculated by applying knowledge of the potential and its normal derivative on the surface enclosing the region. This is the mathematical representation of the well-known Huygens' principle for a scalar wave.

Equation (102) also provides the foundation to establish an integral equation for ϕ and $\partial\phi/\partial n$ on the surface of the object. If the object is impenetrable with a hard surface where ϕ satisfies the boundary condition

$$\phi(\mathbf{r}) = 0 \quad \text{for } \mathbf{r} \text{ on } S_0 \quad (105)$$

Eq. (102) becomes

$$\begin{aligned} \phi^{\text{inc}}(\mathbf{r}) + \int_{S_o} \mathbf{G}_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r}')}{\partial \mathbf{n}'} dS' \\ = \begin{cases} \phi(\mathbf{r}) & \text{for } \mathbf{r} \text{ in } V_\infty \\ 0 & \text{for } \mathbf{r} \text{ in } V_o \end{cases} \end{aligned} \quad (106)$$

Applying this equation on S_o , one obtains

$$\int_{S_o} G_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r}')}{\partial n'} dS' = -\phi^{\text{inc}}(\mathbf{r}) \text{ for } \mathbf{r} \text{ on } S_o \quad (107)$$

which is the integral equation for $\partial\phi/\partial n$ on S_o .

If the object is impenetrable with a soft surface where ϕ satisfies the boundary condition

$$\frac{\partial \phi(\mathbf{r})}{\partial n} = 0 \text{ for } \mathbf{r} \text{ on } S_o \quad (108)$$

Eq. (102) becomes

$$\begin{aligned} \phi^{\text{inc}}(\mathbf{r}) \\ - \int_{S_o} \phi(\mathbf{r}') \frac{\partial G_0(\mathbf{r}, \mathbf{r}')}{\partial n'} dS' = \begin{cases} \phi(\mathbf{r}) & \text{for } \mathbf{r} \text{ in } V_\infty \\ 0 & \text{for } \mathbf{r} \text{ in } V_o \end{cases} \end{aligned} \quad (109)$$

Applying this equation on S_o , one obtains

$$\frac{1}{2} \phi(\mathbf{r}) + \int_{S_o} \phi(\mathbf{r}') \frac{\partial G_0(\mathbf{r}, \mathbf{r}')}{\partial n'} dS' = \phi^{\text{inc}}(\mathbf{r}) \text{ for } \mathbf{r} \text{ on } S_o \quad (110)$$

where \int denotes the integral excluding the contribution from the singular point, which is known as the *principal-value integral*. This result is obtained as follows. The integral over S_o in Eq. (109) is divided into an integral over a small circular disk with center at \mathbf{r} plus the remaining integral, which is represented as a principal-value integral in the limit as the area of the isolated disk approaches zero. If \mathbf{r} approaches S_o from the outside, the integral over the vanishingly small disk can be evaluated to give $-\phi(\mathbf{r})/2$. If \mathbf{r} approaches S_o from the inside, the integral gives $\phi(\mathbf{r})/2$. In either case, one obtains Eq. (110), which is the integral equation for ϕ on S_o .

If the object is penetrable and homogeneous, apply Eq. (102) on S_o to obtain

$$\begin{aligned} \frac{1}{2} \phi(\mathbf{r}) - \int_{S_o} [G_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r}')}{\partial n'} - \phi(\mathbf{r}') \frac{\partial G_0(\mathbf{r}, \mathbf{r}')}{\partial n'}] dS' \\ = \phi^{\text{inc}}(\mathbf{r}) \text{ for } \mathbf{r} \text{ on } S_o \end{aligned} \quad (111)$$

To solve for ϕ and $\partial\phi/\partial n$ on S_o , another equation is needed, which can be derived by considering the interior of the object. The wavefunction inside the object satisfies the Helmholtz equation

$$\nabla^2 \phi(\mathbf{r}) + \tilde{k}^2 \phi(\mathbf{r}) = 0 \quad (112)$$

where \tilde{k} characterizes the property of the object. Multiplying this equation by the Green function for unbounded space filled with material characterized by \tilde{k}

$$\tilde{G}_0(\mathbf{r}, \mathbf{r}') = \frac{e^{-j\tilde{k}|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \quad (113)$$

and applying a similar derivation as before, one has

$$\begin{aligned} - \int_{S_o} \left[\tilde{G}_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r}')}{\partial n'} - \phi(\mathbf{r}') \frac{\partial \tilde{G}_0(\mathbf{r}, \mathbf{r}')}{\partial n'} \right] dS' \\ = \begin{cases} 0 & \text{for } \mathbf{r} \text{ in } V_\infty \\ \phi(\mathbf{r}) & \text{for } \mathbf{r} \text{ in } V_o \end{cases} \end{aligned} \quad (114)$$

When this is applied on S_o , one obtains the second integral equation

$$\begin{aligned} \frac{1}{2} \phi(\mathbf{r}) + \int_{S_o} \left[\tilde{G}_0(\mathbf{r}, \mathbf{r}') \frac{\partial \phi(\mathbf{r}')}{\partial n'} - \phi(\mathbf{r}') \frac{\partial \tilde{G}_0(\mathbf{r}, \mathbf{r}')}{\partial n'} \right] \\ \cdot dS' = 0 \text{ for } \mathbf{r} \text{ on } S_o \end{aligned} \quad (115)$$

which can be used together with Eq. (111) for a numerical solution of ϕ and $\partial\phi/\partial n$ on S_o .

If the object is penetrable and inhomogeneous, the wavefunction still satisfies Eq. (112); however, \tilde{k} now is a function of \mathbf{r} . In this case, one can write Eqs. (45) and (112) in one equation:

$$\nabla^2 \phi(\mathbf{r}) + k^2 \phi(\mathbf{r}) = -f(\mathbf{r}) - [\tilde{k}^2(\mathbf{r}) - k^2] \phi(\mathbf{r}) \quad (116)$$

Multiplying this equation by G_0 and integrating over the infinite volume, one obtains

$$\begin{aligned} \phi(\mathbf{r}) - \int_{V_o} [\tilde{k}^2(\mathbf{r}') - k^2] G_0(\mathbf{r}, \mathbf{r}') \phi(\mathbf{r}') dV' \\ = \int_{V_s} G_0(\mathbf{r}, \mathbf{r}') f(\mathbf{r}') dV' \end{aligned} \quad (117)$$

This is the integral equation that can be used to solve for ϕ in V_o . Unlike the previous integral equations, this equation involves the volume integral. For this reason, it is often referred to as the *volume integral equation*, whereas the previous ones are often referred to as the *surface integral equations*. Integral equations for more complicated objects may involve both volume and surface integrals [10].

2. DYADIC GREEN'S FUNCTIONS

When both the source and response are vector functions, the corresponding Green function is a dyad; hence, the term, *dyadic Green function*.

2.1. Definition of Dyad

A dyad, denoted by $\bar{\mathbf{D}}$, is formed by two vectors:

$$\bar{\mathbf{D}} = \mathbf{A}\mathbf{B} \quad (118)$$

This entity by itself does not have any physical interpretation as a vector. However, when it acts on another vector, the result becomes meaningful. The major role of a dyad is that its scalar product with a vector produces another vector of different magnitude and direction. For example, its anterior scalar product with vector \mathbf{C} yields

$$\mathbf{C} \cdot \bar{\mathbf{D}} = (\mathbf{C} \cdot \mathbf{A})\mathbf{B} \quad (119)$$

which is a vector. Its posterior scalar product with vector \mathbf{C} yields

$$\bar{\mathbf{D}} \cdot \mathbf{C} = \mathbf{A}(\mathbf{B} \cdot \mathbf{C}) \quad (120)$$

which is also a vector. Apparently, the resulting vectors in Eqs. (119) and (120) are different. In addition to the two scalar products, there are two vector products. The anterior vector product is defined as

$$\mathbf{C} \times \bar{\mathbf{D}} = (\mathbf{C} \times \mathbf{A})\mathbf{B} \quad (121)$$

and the posterior vector product is defined as

$$\bar{\mathbf{D}} \times \mathbf{C} = \mathbf{A}(\mathbf{B} \times \mathbf{C}) \quad (122)$$

Clearly, these products are dyads.

The dyad defined in Eq. (118) is a special entity, since it contains only six independent components, three in each of the two vectors. A more general dyad, also called a tensor, is defined as

$$\bar{\mathbf{D}} = \mathbf{D}_x \hat{x} + \mathbf{D}_y \hat{y} + \mathbf{D}_z \hat{z} \quad (123)$$

where \mathbf{D}_x , \mathbf{D}_y , and \mathbf{D}_z are vectors. Therefore, Eq. (123) can be expressed as

$$\begin{aligned} \bar{\mathbf{D}} = & D_{xx} \hat{x}\hat{x} + D_{yx} \hat{y}\hat{x} + D_{zx} \hat{z}\hat{x} + D_{xy} \hat{x}\hat{y} + D_{yy} \hat{y}\hat{y} + D_{zy} \hat{z}\hat{y} \\ & + D_{xz} \hat{x}\hat{z} + D_{yz} \hat{y}\hat{z} + D_{zz} \hat{z}\hat{z} \end{aligned} \quad (124)$$

which contains nine independent components.

A special dyad is called the unit dyad or identity dyad, defined as

$$\bar{\mathbf{I}} = \hat{x}\hat{x} + \hat{y}\hat{y} + \hat{z}\hat{z} \quad (125)$$

It is evident that

$$\mathbf{C} \cdot \bar{\mathbf{I}} = \bar{\mathbf{I}} \cdot \mathbf{C} = \mathbf{C} \quad (126)$$

2.2. Free-Space Dyadic Green's Functions

Consider the electric and magnetic fields produced by an electric current source $\mathbf{J}(\mathbf{r})$ in an unbounded space. Maxwell's equation for this problem are given in Eqs. (37)–(40),

which lead to Eq. (42), reproduced here as

$$\nabla \times \nabla \times \mathbf{E}(\mathbf{r}) - k^2 \mathbf{E}(\mathbf{r}) = -j\omega\mu \mathbf{J}(\mathbf{r}) \quad (127)$$

This is the vector wave equation, which is the analog of the scalar Helmholtz wave equation. It describes electromagnetic wave phenomena that are very pervasive in modern technologies, such as in communication, microwave, and computer chip technologies.

Just as in the scalar case, one can derive a dyadic Green function $\bar{\mathbf{G}}_{e0}$, whose end result is to relate $\mathbf{E}(\mathbf{r})$ and $\mathbf{J}(\mathbf{r})$ by

$$\mathbf{E}(\mathbf{r}) = -j\omega\mu \int_V \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \quad (128)$$

where V is the support of the current $\mathbf{J}(\mathbf{r})$. Using Eq. (128) in Eq. (127), one obtains

$$\begin{aligned} & -j\omega\mu \int_V \nabla \times \nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \\ & + j\omega\mu k^2 \int_V \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \\ & = -j\omega\mu \mathbf{J}(\mathbf{r}) = -j\omega\mu \int_V \bar{\mathbf{I}}\delta(\mathbf{r} - \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \end{aligned} \quad (129)$$

For arbitrary $\mathbf{J}(\mathbf{r})$, this could be satisfied only if

$$\nabla \times \nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') - k^2 \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') = \bar{\mathbf{I}}\delta(\mathbf{r} - \mathbf{r}') \quad (130)$$

where $\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')$ is the dyadic Green function of the electric type that relates vector field \mathbf{E} to vector current \mathbf{J} .

Taking the curl of Eq. (128) and using Maxwell's equations, one obtains

$$\begin{aligned} \mathbf{H}(\mathbf{r}) &= \int_V \nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \\ &= \int_V \bar{\mathbf{G}}_{m0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \end{aligned} \quad (131)$$

where $\bar{\mathbf{G}}_{m0}(\mathbf{r}, \mathbf{r}') = \nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')$ is the dyadic Green's function of the magnetic type. It satisfies the equation

$$\nabla \times \nabla \times \bar{\mathbf{G}}_{m0}(\mathbf{r}, \mathbf{r}') - k^2 \bar{\mathbf{G}}_{m0}(\mathbf{r}, \mathbf{r}') = \nabla \times [\bar{\mathbf{I}}\delta(\mathbf{r} - \mathbf{r}')] \quad (132)$$

Therefore, the task of finding the dyadic Green function of the electric type is reduced to the task of solving Eq. (130). Equation (130) can be made less difficult by taking the posterior scalar product with an arbitrary vector \mathbf{a} , yielding

$$\nabla \times \nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} - k^2 \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} = \mathbf{a}\delta(\mathbf{r} - \mathbf{r}') \quad (133)$$

Recognizing that $\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a}$ represents a vector, one may use the vector identity $\nabla \times \nabla \times \mathbf{A} = \nabla(\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A}$ to find

$$\begin{aligned} & -\nabla^2 \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} - k^2 \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} \\ & = \mathbf{a}\delta(\mathbf{r} - \mathbf{r}') - \nabla[\nabla \cdot \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a}] \end{aligned} \quad (134)$$

Taking the divergence of Eq. (133) and making use of the fact that $\nabla \cdot (\nabla \times \mathbf{A}) \equiv 0$, it can be seen that

$$\nabla \cdot \overline{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} = -\frac{1}{k^2} \nabla \cdot [\mathbf{a} \delta(\mathbf{r} - \mathbf{r}')] \quad (135)$$

Using this in Eq. (134), one obtains

$$\begin{aligned} \nabla^2 \overline{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} + k^2 \overline{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} = \\ - \left(1 + \frac{\nabla \nabla \cdot}{k^2} \right) [\mathbf{a} \delta(\mathbf{r} - \mathbf{r}')] \end{aligned} \quad (136)$$

By making use of the fact that

$$\nabla^2 G_0(\mathbf{r}, \mathbf{r}') + k^2 G_0(\mathbf{r}, \mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}') \quad (137)$$

and the fact the $1 + \nabla \nabla \cdot / k^2$ is a linear operator that commutes with ∇^2 , it can be deduced that

$$\overline{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} = \left(1 + \frac{\nabla \nabla \cdot}{k^2} \right) [\mathbf{a} G_0(\mathbf{r}, \mathbf{r}')] \quad (138)$$

Writing this as

$$\overline{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} = \left(\overline{\mathbf{I}} + \frac{\nabla \nabla}{k^2} \right) G_0(\mathbf{r}, \mathbf{r}') \cdot \mathbf{a} \quad (139)$$

and since \mathbf{a} is an arbitrary vector, one deduces that

$$\overline{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') = \left(\overline{\mathbf{I}} + \frac{\nabla \nabla}{k^2} \right) G_0(\mathbf{r}, \mathbf{r}') \quad (140)$$

The free-space dyadic Green function of the magnetic type can be derived as

$$\begin{aligned} \overline{\mathbf{G}}_{m0}(\mathbf{r}, \mathbf{r}') &= \nabla \times \overline{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') = \nabla \times [\overline{\mathbf{I}} G_0(\mathbf{r}, \mathbf{r}')] \\ &= \nabla G_0(\mathbf{r}, \mathbf{r}') \times \overline{\mathbf{I}} \end{aligned} \quad (141)$$

This is the explicit representation of the dyadic Green's function in terms of the scalar Green's function $G_0(\mathbf{r}, \mathbf{r}')$. It is to be noted that the aforementioned relationship between the dyadic Green function and the scalar Green function $G_0(\mathbf{r}, \mathbf{r}')$ is valid only for a homogeneous unbounded space such as a free space. Such a relation does not hold true in a cavity, waveguide, or half-space. For example, the dyadic Green's functions for a half-space (above $z = 0$) are given by [3]

$$\begin{aligned} \overline{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}') &= \left(\overline{\mathbf{I}} - \frac{\nabla \nabla'}{k^2} \right) [G_0(\mathbf{r}, \mathbf{r}') \\ &- G_0(\mathbf{r}, \mathbf{r}'_i)] + 2\hat{z}\hat{z}G_0(\mathbf{r}, \mathbf{r}'_i) \end{aligned} \quad (142)$$

and

$$\overline{\mathbf{G}}_{m2}(\mathbf{r}, \mathbf{r}') = \nabla G_0(\mathbf{r}, \mathbf{r}') \times \overline{\mathbf{I}} + \nabla G_0(\mathbf{r}, \mathbf{r}'_i) \times \overline{\mathbf{I}}_i \quad (143)$$

where $\mathbf{r}'_i = x'\hat{x} + y'\hat{y} - z'\hat{z}$ and $\overline{\mathbf{I}}_i = -\overline{\mathbf{I}} + 2\hat{z}\hat{z}$. It can be verified that $\overline{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}')$ and $\overline{\mathbf{G}}_{m2}(\mathbf{r}, \mathbf{r}')$ satisfy the boundary

conditions

$$\hat{z} \times \overline{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}') = 0 \text{ for } z = 0 \quad (144)$$

and

$$\hat{z} \times \nabla \times \overline{\mathbf{G}}_{m2}(\mathbf{r}, \mathbf{r}') = 0 \text{ for } z = 0 \quad (145)$$

respectively. For this reason, $\overline{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}')$ is called the "electric-type dyadic Green function of the first kind" and $\overline{\mathbf{G}}_{m2}(\mathbf{r}, \mathbf{r}')$ is called the "magnetic-type dyadic Green's function of the second kind". The classification of dyadic Green's functions is similar to that of scalar Green's functions.

2.3. Eigenfunction Expansion

As in the scalar case, the Ohm-Rayleigh method or the method of eigenfunction expansion is a general method to derive dyadic Green function [3]. For vector problems, the eigenfunctions are vector functions, known as vector wavefunctions. There are three kinds of vector wavefunctions [1], defined by

$$\mathbf{L}(\mathbf{r}) = \nabla \psi(\mathbf{r}) \quad (146)$$

$$\mathbf{M}(\mathbf{r}) = \nabla \times [c\psi(\mathbf{r})] \quad (147)$$

$$\mathbf{N}(\mathbf{r}) = \frac{1}{\kappa} \nabla \times \mathbf{M}(\mathbf{r}) \quad (148)$$

where \mathbf{c} is a vector called the "pilot vector" and ψ satisfies that homogeneous Helmholtz wave equation

$$\nabla^2 \psi(\mathbf{r}) + \kappa^2 \psi(\mathbf{r}) = 0 \quad (149)$$

It can be shown that, \mathbf{L} , \mathbf{M} , and \mathbf{N} satisfy the vector equations

$$\nabla^2 \mathbf{L}(\mathbf{r}) + \kappa^2 \mathbf{L}(\mathbf{r}) = 0 \quad (150)$$

$$\nabla \times \nabla \times \mathbf{M}(\mathbf{r}) - \kappa^2 \mathbf{M}(\mathbf{r}) = 0 \quad (151)$$

$$\nabla \times \nabla \times \mathbf{N}(\mathbf{r}) - \kappa^2 \mathbf{N}(\mathbf{r}) = 0 \quad (152)$$

and \mathbf{M} can be expressed in terms of \mathbf{N} as

$$\mathbf{M}(\mathbf{r}) = \frac{1}{\kappa} \nabla \times \mathbf{N}(\mathbf{r}) \quad (153)$$

Since $\nabla \times \mathbf{L}(\mathbf{r}) = \nabla \times \nabla \psi(\mathbf{r}) = 0$, \mathbf{L} is the irrotational vector wavefunction. Since $\nabla \cdot \mathbf{M}(\mathbf{r}) = 0$ and $\nabla \cdot \mathbf{N}(\mathbf{r}) = 0$, \mathbf{M} and \mathbf{N} are the solenoidal vector wavefunctions.

For a rectangular waveguide illustrated in Fig. 7, ψ is given by

$$\psi_{mn}(h, \mathbf{r}) = \left\{ \begin{array}{l} \cos k_x x \cos k_y y \\ \sin k_x x \sin k_y y \end{array} \right\} e^{-jhz} \quad (154)$$

Figure 7. A rectangular waveguide.

where $k_x = m\pi/a$ and $k_y = n\pi/b$. The vector wavefunctions \mathbf{L} , \mathbf{M} , and \mathbf{N} are given by

$$\mathbf{L}_{\sigma mn}^e(h, \mathbf{r}) = \nabla \psi_{\sigma mn}^e(h, \mathbf{r}) \quad (155)$$

$$\mathbf{M}_{\sigma mn}^e(h, \mathbf{r}) = \nabla \times [\hat{\mathbf{z}} \psi_{\sigma mn}^e(h, \mathbf{r})] \quad (156)$$

$$\mathbf{N}_{\sigma mn}^e(h, \mathbf{r}) = \frac{1}{\kappa} \nabla \times \nabla \times [\hat{\mathbf{z}} \psi_{\sigma mn}^e(h, \mathbf{r})] \quad (157)$$

where the pilot vector is $\mathbf{c} = \hat{\mathbf{z}}$. This causes \mathbf{M} to be transverse to $\hat{\mathbf{z}}$.

The vector wavefunctions are always orthogonal to each other. For those in a rectangular waveguide, it can be shown

$$\int_V \mathbf{U}_{\sigma mn}^e(h, \mathbf{r}) \cdot \mathbf{V}_{\sigma' m' n'}^e(-h', \mathbf{r}) dV = 0 \quad (158)$$

where $\mathbf{U}, \mathbf{V} = \mathbf{L}, \mathbf{M}, \mathbf{N}$, except when $\mathbf{U}_{\sigma mn}^e(h, \mathbf{r}) = \mathbf{V}_{\sigma mn}^e(h, \mathbf{r})$. They form a complete set and, therefore, can be employed to expand any vector functions.

The electric-type dyadic Green's function of the first kind satisfies the equation

$$\nabla \times \nabla \times \bar{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}') - k^2 \bar{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}') \equiv \bar{\mathbf{I}} \delta(\mathbf{r} - \mathbf{r}') \quad (159)$$

and the boundary condition

$$\hat{\mathbf{n}} \times \bar{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}') = 0 \quad \text{on the waveguide walls} \quad (160)$$

It is clear that only \mathbf{L}_{omn} , \mathbf{M}_{emn} , and \mathbf{N}_{omn} satisfy Eq. (160) and, therefore, can be used to expand $\bar{\mathbf{G}}_{e1}$:

$$\begin{aligned} \bar{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}') = & \int_{-\infty}^{\infty} \sum_{m,n} [\mathbf{L}_{omn}(h, \mathbf{r}) \mathbf{A}_{omn}(h) + \mathbf{M}_{emn}(h, \mathbf{r}) \mathbf{B}_{emn}(h) \\ & + \mathbf{N}_{omn}(h, \mathbf{r}) \mathbf{C}_{omn}(h)] dh \end{aligned} \quad (161)$$

Substituting this expansion into Eq. (159), one obtains

$$\begin{aligned} & \int_{-\infty}^{\infty} \sum_{m,n} \{-k^2 \mathbf{L}_{omn}(h, \mathbf{r}) \mathbf{A}_{omn}(h) \\ & + (\kappa^2 - \kappa'^2) [\mathbf{M}_{emn}(h, \mathbf{r}) \mathbf{B}_{emn}(h)] \\ & + \mathbf{N}_{omn}(h, \mathbf{r}) \mathbf{C}_{omn}(h)\} dh = \bar{\mathbf{I}} \delta(\mathbf{r} - \mathbf{r}') \end{aligned} \quad (162)$$

Taking the anterior scalar product of Eq. (162) with $\mathbf{L}_{om'n'}$ ($-h'$, \mathbf{r}), $\mathbf{M}_{em'n'}$ ($-h'$, \mathbf{r}), and $\mathbf{N}_{om'n'}$ ($-h'$, \mathbf{r}), respectively, integrating over the entire volume of the waveguide, and applying the orthogonal relation in Eq. (158), one can find

$$\mathbf{A}_{omn}(h) = -\frac{k_{cmn}^2}{k^2 \kappa'^2} C_{mn} \mathbf{L}_{omn}(-h, \mathbf{r}') \quad (163)$$

$$\mathbf{B}_{emn}(h) = \frac{1}{\kappa^2 - \kappa'^2} C_{mn} \mathbf{M}_{emn}(-h, \mathbf{r}') \quad (164)$$

$$\mathbf{C}_{emn}(h) = \frac{1}{\kappa^2 - \kappa'^2} C_{mn} \mathbf{N}_{omn}(-h, \mathbf{r}') \quad (165)$$

where $k_{cmn}^2 = k_x^2 + k_y^2$ and $C_{mn} = (2 - \delta_0) / (\pi a b k_{cmn}^2)$ with $\delta_0 = 1$ when $m = 0$ or $n = 0$ and $\delta_0 = 0$, where m and n are nonzero. Therefore

$$\begin{aligned} \bar{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}') = & \int_{-\infty}^{\infty} \sum_{m,n} C_{mn} \left\{ -\frac{k_{cmn}^2}{k^2 \kappa'^2} \mathbf{L}_{omn}(h, \mathbf{r}) \mathbf{L}_{omn}(-h, \mathbf{r}') \right. \\ & + \frac{1}{\kappa^2 - \kappa'^2} [\mathbf{M}_{emn}(h, \mathbf{r}) \mathbf{M}_{emn}(-h, \mathbf{r}') \\ & \left. + \mathbf{N}_{omn}(h, \mathbf{r}) \mathbf{N}_{omn}(-h, \mathbf{r}') \right\} dh \end{aligned} \quad (166)$$

Through some mathematical manipulations and the application of Cauchy's residue theorem [3], one can simplify Eq. (166) as

$$\begin{aligned} \bar{\mathbf{G}}_{e1}(\mathbf{r}, \mathbf{r}') = & -\frac{1}{k^2} \hat{\mathbf{z}} \hat{\mathbf{z}} \delta(\mathbf{r} - \mathbf{r}') - \frac{j}{ab} \sum_{m,n} \frac{2 - \delta_0}{k_{cmn}^2 k_{gmn}} \\ & [\mathbf{M}_{emn}(\pm k_{gmn}, \mathbf{r}) \mathbf{M}_{emn}(\pm k_{gmn}, \mathbf{r}) \mathbf{M}_{emn}(\mp k_{gmn}, \mathbf{r}') \\ & \mathbf{N}_{omn}(\pm k_{gmn}, \mathbf{r}) \mathbf{N}_{omn}(\mp k_{gmn}, \mathbf{r}')] \quad z \geq z' \end{aligned} \quad (167)$$

where $k_{gmn} = \sqrt{k^2 - k_{cmn}^2}$.

In addition to the method described above, Tai [3] proposed the method of $\bar{\mathbf{G}}_m$, in which $\bar{\mathbf{G}}_m$ is derived first and $\bar{\mathbf{G}}_e$ is then derived from $\nabla \times \bar{\mathbf{G}}_m = \bar{\mathbf{I}} \delta(\mathbf{r} - \mathbf{r}') + k^2 \bar{\mathbf{G}}_e$. Since $\bar{\mathbf{G}}_m$ is completely solenoidal, its expansion requires only \mathbf{M} and \mathbf{N} and, therefore, the derivation becomes simpler.

The Ohm-Rayleigh method can be used to derive a variety of dyadic Green's functions. Table 1 lists the problems for which the dyadic Green's functions have been derived.

Table 1. Problems with Available Dyadic Green Functions

Geometry of Problem	References
Parallel-plate waveguide	3

2.4. Vector Integral Equations

Consider the problem of the electric and magnetic fields produced by an electric current source $\mathbf{J}(\mathbf{r})$ in the presence of an arbitrarily shaped object immersed in an infinite homogeneous medium (see Fig. 6). Exterior to the object, the electric field satisfies the vector wave equation in Eq. (127), and the radiation condition at infinity is given by

$$r[\nabla \times \mathbf{E}(\mathbf{r}) + jk\hat{\mathbf{r}} \times \mathbf{E}(\mathbf{r})] = 0 \text{ for } r \rightarrow \infty \quad (168)$$

Multiplying Eq. (127) by $\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')$, Eq. (130) by $\mathbf{E}(\mathbf{r})$, and integrating the difference of the resultant equations over the exterior region, one obtains

$$\begin{aligned} & \int_{V_\infty} \{[\nabla \times \nabla \times \mathbf{E}(\mathbf{r})] \cdot \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') - \mathbf{E}(\mathbf{r}) \cdot [\nabla \times \nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')]\} dV \\ &= -j\omega\mu \int_{V_s} \mathbf{J}(\mathbf{r}) \cdot \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') dV - \int_{V_\infty} \mathbf{E}(\mathbf{r}) \cdot \bar{\mathbf{I}}\delta(\mathbf{r} - \mathbf{r}') dV \end{aligned} \quad (169)$$

where V_∞ denotes the infinite space exterior to the object and V_s denotes the support of $\mathbf{J}(\mathbf{r})$. Applying the vector dyadic Green's second identity [27]

$$\begin{aligned} & \int_V [(\nabla \times \nabla \times \mathbf{A}) \cdot \bar{\mathbf{D}} - \mathbf{A} \cdot (\nabla \times \nabla \times \bar{\mathbf{D}})] dV \\ &= \int_S [(\hat{\mathbf{n}} \times \mathbf{A}) \cdot (\nabla \times \bar{\mathbf{D}}) + (\hat{\mathbf{n}} \times \nabla \times \mathbf{A}) \cdot \bar{\mathbf{D}}] dS \end{aligned} \quad (170)$$

where V is a volume enclosed by S , one has

$$\begin{aligned} & \int_{S_0 + S_\infty} \{[\hat{\mathbf{n}} \times \mathbf{E}(\mathbf{r})] \cdot [\nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')] \\ &+ \hat{\mathbf{n}} \times \nabla \times \mathbf{E}(\mathbf{r}) \cdot \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')\} dS \\ &= -j\omega\mu \int_{V_s} \mathbf{J}(\mathbf{r}) \cdot \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') dV - \int_{V_\infty} \mathbf{E}(\mathbf{r}) \delta(\mathbf{r} - \mathbf{r}') dV \end{aligned} \quad (171)$$

where S_0 denotes the surface of the object, S_∞ denotes a large spherical surface whose radius approaches infinity, and $\hat{\mathbf{n}}$ is the normal unit vector pointing away from V_∞ . Since both $\mathbf{E}(\mathbf{r})$ and $\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')$ satisfy the radiation condition, the surface integral over S_∞ vanishes. As a result, we obtain

$$\begin{aligned} & - \int_{S_0} \{[\hat{\mathbf{n}} \times \mathbf{E}(\mathbf{r})] \cdot [\nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')] \\ &+ [\hat{\mathbf{n}} \times \nabla \times \mathbf{E}(\mathbf{r})] \cdot \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')\} dS \\ &- j\omega\mu \int_{V_s} \mathbf{J}(\mathbf{r}) \cdot \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') dV = \begin{cases} \mathbf{E}(\mathbf{r}') & \text{for } \mathbf{r}' \text{ in } V_\infty \\ 0 & \text{for } \mathbf{r}' \text{ in } V_0 \end{cases} \end{aligned} \quad (172)$$

which can also be written as

$$\begin{aligned} & - \int_{S_0} \{[\nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')] \cdot [\hat{\mathbf{n}}' \times \mathbf{E}(\mathbf{r}')] \\ &- j\omega\mu \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot [\hat{\mathbf{n}}' \times \mathbf{H}(\mathbf{r}')] \} dS' \\ &- j\omega\mu \int_{V_s} \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' = \begin{cases} \mathbf{E}(\mathbf{r}) & \text{for } \mathbf{r} \text{ in } V_\infty \\ 0 & \text{for } \mathbf{r} \text{ in } V_0 \end{cases} \end{aligned} \quad (173)$$

where V_0 denotes the volume of the object.

Similar to Eq. (102) in the scalar case, Eq. (173) is an important result, which has several implications. First, notice that when the object is absent, the surface integral vanishes. Hence

$$\mathbf{E}(\mathbf{r}) = -j\omega\mu \int_{V_s} \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \quad (174)$$

where is the same as Eq. (128). This can be regarded as the incident field and denoted as $\mathbf{E}^{\text{inc}}(\mathbf{r})$. Second, when there is no source in V_∞ , Eq. (173) becomes

$$\begin{aligned} \mathbf{E}(\mathbf{r}) = & - \int_{S_0} \{[\nabla \times \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')] [\hat{\mathbf{n}}' \times \mathbf{E}(\mathbf{r}')] \cdot -j\omega\mu \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \\ & \cdot [\hat{\mathbf{n}}' \times \mathbf{H}(\mathbf{r}')] \} dS' \end{aligned} \quad (175)$$

for \mathbf{r} in V_∞ . Since there is no source in V_∞ , the field on S_0 must be produced by the source inside S_0 . This equation indicates that the field in a source-free region can be calculated from knowledge of the tangential electric and

magnetic fields on the surface enclosing the region. This is the mathematical representation of the well-known Huygens' principle for a vector field.

Equation (173) also provides the foundation to establish an integral equation for $\hat{n} \times \mathbf{E}$ and $\hat{n} \times \mathbf{H}$ on the surface of the object. If the object is a perfect conductor, $\hat{n} \times \mathbf{E}(\mathbf{r}) = 0$ for \mathbf{r} on S_o . Consequently, Eq. (173) becomes

$$\mathbf{E}(\mathbf{r}) = \mathbf{E}^{\text{inc}}(\mathbf{r}) + j\omega\mu \int_{S_o} \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot [\hat{n}' \times \mathbf{H}(\mathbf{r}')] dS' \quad (176)$$

for \mathbf{r} in V_∞ . Substituting this into $\hat{n} \times \mathbf{E}(\mathbf{r}) = 0$ for \mathbf{r} on S_o , we obtain an integral equation, which can be solved for $\hat{n} \times \mathbf{H}(\mathbf{r})$.

If the object is a homogeneous body, one can derive another integral representation for the field inside S_o using the unbounded-space dyadic Green's function for the interior medium. When this and Eq. (173) are applied at S_o , one obtains two integral equations, which can be solved for $\hat{n} \times \mathbf{E}(\mathbf{r})$ and $\hat{n} \times \mathbf{H}(\mathbf{r})$.

If the object is an inhomogeneous dielectric body, the electric field satisfies the vector wave equation

$$\nabla \times \nabla \times \mathbf{E}(\mathbf{r}) - \tilde{k}^2(\mathbf{r})\mathbf{E}(\mathbf{r}) = -j\omega\mu\mathbf{J}(\mathbf{r}) \quad (177)$$

This can be written as

$$\begin{aligned} \nabla \times \nabla \times \mathbf{E}(\mathbf{r}) - k^2\mathbf{E}(\mathbf{r}) &= -j\omega\mu\mathbf{J}(\mathbf{r}) + [\tilde{k}^2(\mathbf{r}) \\ &- k^2]\mathbf{E}(\mathbf{r}) \end{aligned} \quad (178)$$

Multiplying Eq. (177) by $\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')$ and integrating the resultant equation over the entire space, one obtains

$$\mathbf{E}(\mathbf{r}) = \mathbf{E}^{\text{inc}}(\mathbf{r}) + \int_{V_o} \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot [\tilde{k}^2(\mathbf{r}') - k^2]\mathbf{E}(\mathbf{r}') dV' \quad (179)$$

This is the mathematical representation of the volume equivalence principle. It provides a volume integral equation that can be solved for $\mathbf{E}(\mathbf{r})$.

We note that the formulation described in this section can be repeated for the magnetic field in a similar manner. As a result, different integral equations exist for the same problem, which provide different approaches to the solution of the problem.

2.5. Singularity of the Dyadic Green's Function

As shown in Eq. (128), the electric field produced by the current \mathbf{J} in an unbounded space can be written as

$$\mathbf{E}(\mathbf{r}) = -j\omega\mu \int_V \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \quad (180)$$

where $\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')$ is defined by Eq. (140). Many electromagneticists have tried to fathom the meaning of Eq. (180). Strictly speaking, the integral does not converge because of the $1/|\mathbf{r} - \mathbf{r}'|$ singularity in $G_0(\mathbf{r}, \mathbf{r}')$. After being operated upon by the double ∇ operator in Eq. (140), $\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')$

contains terms of the form $1/|\mathbf{r} - \mathbf{r}'|^3$, rendering the integral in Eq. (180) ill-defined. A remedy to this is to rewrite Eq. (180) as

$$\mathbf{E}(\mathbf{r}) = -j\omega\mu \left(\bar{\mathbf{I}} + \frac{\nabla\nabla}{k^2} \right) \cdot \int_V G_0(\mathbf{r}, \mathbf{r}') \mathbf{J}(\mathbf{r}') dV' \quad (181)$$

This equation is well defined for all \mathbf{r} and \mathbf{r}' , but lacks the compactness of Eq. (180).

Equation (180) can be made meaningful in a generalized function sense. To this end, one defines $\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}')$ as a generalized function

$$\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') = PV\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') - \frac{\bar{\mathbf{L}}\delta(\mathbf{r} - \mathbf{r}')}{k^2} \quad (182)$$

where PV implies the invocation of a principal volume integral whose value depends on the shape of the principal volume chosen. For the sake of uniqueness, $\bar{\mathbf{L}}$ also depends on the shape of the principal volume. A principal volume integral is defined as

$$\begin{aligned} \int_V PV\bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' &= PV \int_V \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \\ &= \lim_{V_\delta \rightarrow 0} \int_{V-V_\delta} \bar{\mathbf{G}}_{e0}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}') dV' \end{aligned} \quad (183)$$

where V_δ is the exclusion volume. Unfortunately, even though the integral above converges, its value is nonunique in the sense that it depends on the shape of V_δ . The nonuniqueness in the first term of Eq. (182) is rectified by the choice of a shape-dependent $\bar{\mathbf{L}}$. The volume of $\bar{\mathbf{L}}$ in Eq. (182) for various exclusion volumes is given by [28–33].

$$\bar{\mathbf{L}} = \frac{\bar{\mathbf{I}}}{3} \text{ for spheres and cubes} \quad (184)$$

$$\bar{\mathbf{L}} = \hat{z}\hat{z} \text{ for disks perpendicular to the } z \text{ axis} \quad (185)$$

$$\bar{\mathbf{L}} = \frac{\hat{x}\hat{x} + \hat{y}\hat{y}}{2} \text{ for needles parallel to the } z \text{ axis} \quad (186)$$

To understand how these $\bar{\mathbf{L}}$ values are derived, one can start with the classically legitimate Eq. (181) and split the integral into two terms with the definition of a principal volume integral:

$$\begin{aligned} \mathbf{E}(\mathbf{r}) &= -j\omega\mu \lim_{V_\delta \rightarrow 0} \left(\bar{\mathbf{I}} + \frac{\nabla\nabla}{k^2} \right) \cdot \int_{V-V_\delta} G_0(\mathbf{r}, \mathbf{r}') \mathbf{J}(\mathbf{r}') dV' \\ &\quad - j\omega\mu \lim_{V_\delta \rightarrow 0} \left(\bar{\mathbf{I}} + \frac{\nabla\nabla}{k^2} \right) \cdot \int_{V_\delta} G_0(\mathbf{r}, \mathbf{r}') \mathbf{J}(\mathbf{r}') dV' \end{aligned} \quad (187)$$

In the first term, $V_\delta > 0$ and hence, it is legitimate to exchange the order of differentiation and integration so that it becomes the first term of Eq. (182). In the second term in Eq. (187), the term that does not allow the exchange of the order of integration and differentiation is the term involving the $\nabla\nabla$ operator. Focusing on it more carefully, one has

$$\begin{aligned} & \lim_{V_\delta \rightarrow 0} \nabla\nabla \cdot \int_{V_\delta} G_0(\mathbf{r}, \mathbf{r}') \mathbf{J}(\mathbf{r}') dV' \\ &= \lim_{V_\delta \rightarrow 0} \nabla \left[\int_{V_\delta} G_0(\mathbf{r}, \mathbf{r}') \nabla' \cdot \mathbf{J}(\mathbf{r}') dV' \right. \\ & \quad \left. - \int_{S_\delta} \hat{\mathbf{n}}' \cdot \mathbf{J}(\mathbf{r}') G_0(\mathbf{r}, \mathbf{r}') dS' \right] \end{aligned} \quad (188)$$

To arrive at this, one has made use of the fact that $\nabla G_0(\mathbf{r}, \mathbf{r}') = -\nabla' G_0(\mathbf{r} - \mathbf{r}')$, and $[\nabla' G_0(\mathbf{r}, \mathbf{r}') \cdot \mathbf{J}(\mathbf{r}')] = \nabla' \cdot [G_0(\mathbf{r}, \mathbf{r}') \mathbf{J}(\mathbf{r}')] - G_0(\mathbf{r}, \mathbf{r}') \nabla' \cdot \mathbf{J}(\mathbf{r}')$. Using Gauss' theorem on the term involving $\nabla' \cdot [G_0(\mathbf{r}, \mathbf{r}') \mathbf{J}(\mathbf{r}')]$ finally gives rise to Eq. (188). The first integral on the right-hand side of Eq. (188) vanishes since if $\mathbf{J}(\mathbf{r}')$ is regular, $\nabla' \cdot \mathbf{J}(\mathbf{r}') = \rho(\mathbf{r}')/j\omega$ is also regular and the integral is finally proportional to V_δ . In the second integral, S_δ is the surface bounding V_δ . Hence, $\hat{\mathbf{n}}' \cdot \mathbf{J}(\mathbf{r}')$ is the surface charge on S_δ due to the sudden truncation of $\mathbf{J}(\mathbf{r}')$ within the volume V_δ . This integral gives the potential observed within V_δ due to this surface charge, and it is non zero even when $V_\delta \rightarrow 0$. The gradient (outside the brackets) in turn yields the field generated by this surface charge. In other words, surface charges of opposite polarities on the wall of an infinitesimally small volume always generate a finite field within the small volume. This fact is also intimately related to the scale invariant nature of the Laplace equation which is Maxwell's equations at low frequency.

GROUND PENETRATING RADAR

DAVID J. DANIELS
ERA Technology
Surrey, United Kingdom

1. INTRODUCTION

Ground penetrating radar (GPR) is a nondestructive measurement technique, which uses electromagnetic waves to locate targets or interfaces buried within a visually opaque substance or Earth material.

GPR is also termed *ground probing, surface penetrating* (SPR), or subsurface radar. A GPR transmits a regular sequence of low-power packets of electromagnetic energy into the material or ground, and receives and detects the weak reflected signal from the buried target. The energy is in the form of either a very short-duration impulse, a sweep over a range of frequencies, radiation of noise over a defined band, or a pseudorandom coded sequence of pulses. Most GPR systems, which all need to comply with the relevant national and international regulations regarding radio transmitters, operate within the range of frequencies from 10 MHz to 10 GHz and can have a bandwidth of several GHz. GPR systems are a special class of ultra-wideband (UWB) radar systems. The typical average radiated power is in the order of a thousandth of a watt. The receiver is highly sensitive and can detect reflected signals of less than one millionth, of one millionth, of a watt. The topic of radar system design is covered in many texts, and useful information relating to GPR will be found in several texts [1–7].

The buried target can be a conductor, a dielectric, or combinations of both. The surrounding host material can be soil, Earth materials, wood, rocks, ice, fresh water, or manmade (synthetic) materials such as concrete or brick. A typical GPR achieves a range of up to a few meters, but some special systems can penetrate up to hundreds of meters or even kilometers. A few GPR systems have been operated from aircraft and from satellites to image geologic features buried beneath the Sahara Desert as well as measuring the depth of the (Earth's) Moon and features on Mars or comets.

The range of the GPR in the ground is limited because of the absorption that the signal undergoes, while it travels, on its two-way path, through the ground material. GPR works well through materials such as granite, dry sand, snow, ice, and freshwater, but will not penetrate certain clays that are high in salt content or saltwater because of the high absorption of electromagnetic energy of such materials. In air, the GPR signal travels at the speed of light, but is slowed down in ground materials by their dielectric constant; hence true range needs calibrating for each material. GPR will not penetrate metal because of the latter's conductivity.

There are now a number of commercially available equipments, and the technique is gradually developing in scope and capability. GPR has also been used successfully to provide forensic information in the course of criminal investigations, detect buried mines, survey roads,

detect utilities, measure geophysical strata, and in other applications. Many GPR systems are handheld, but systems can be used on vehicles for rapid survey, by means of an array of antennas. Other GPR systems are designed to be inserted into boreholes to provide images of the intervening rock. Typical GPR system attributes are given in Table 1.

Most GPR systems use separate, human-portable, transmit and receive antennas, which are placed on the surface of the ground and moved in a known pattern over the surface of the ground or material under investigation, and an image can be generated, in real time, on a display either in gray scale or in color. By systematically surveying the area in a regular grid pattern, a radar image of the ground can be built up. GPR images are displayed either as two-dimensional representations, using horizontal (x or y) and depth (z) axes or a horizontal plane representation (x , y) at a given depth (z) or as a three-dimensional reconstruction. GPR data may be classified as *A scan*, *B scan*, or *C scan* depending on the plane of image. *A scan* is a measurement at a single fixed point in space and is displayed in amplitude (y) and range (x). *B scan* is a representation usually in grayscale or color-coded image intensity of a plane (x , z or y , z) of scan, while *C scan* represents a horizontal plane (x , y) at a given depth (z). Alternatively, the GPR may be designed to provide an audible warning of target presence.

The radar image is very different from an optical image because the wavelengths of the illuminating radiation are similar in dimension to those of the target. This results in a much lower definition in the GPR image and one that is highly dependent on the propagation characteristics of the ground. The beam pattern of the antenna is widely spread in the dielectric, and this degrades the spatial resolution of the image, unless corrected. Refraction and anisotropic characteristics of the ground may also distort the image. For some longer-range systems, synthetic aperture techniques processing techniques are used to optimise the resolution of the image.

Unprocessed GPR images often show “bright spots” caused by multiple internal reflections as well as a distortion of the aspect ratio of the image of the target caused by variations in the velocity of propagation. Symmetric targets, such as spheres or pipes, cause migration of the reflected energy to a hyperbolic pattern. GPR images can be processed to compensate for these effects, and this is usually carried out offline. A GPR can be designed to detect specific targets such as interfaces in roads, pipes, and

Table 1. Characteristics of GPR System

Pulse Duration (ns)	Center Frequency (mHz)	Target Depth (m)	Depth Resolution (m)
0.5	2000	<0.25	0.025
1.0	1000	<0.5	0.05
2.0	500	<1.0	0.1
4.0	250	<2.0	0.2
8.0	125	<4.0	0.4
16.0	63	<8.0	0.8
32.0	31	<16.0	1.6

cables and localized objects such as cubes, spheres, and cylinders. GPR is capable of detecting features many hundreds of years old; hence a prospective site should remain unexcavated, prior to survey, so as to preserve its information and aid interpretation of the GPR image.

2. PHYSICS OF PROPAGATION

2.1. Introduction

Maxwell's equations are the foundation for the consideration of the propagation of electromagnetic waves. In free space the magnetic susceptibility and electric permittivity are constants; that is, they are independent of frequency and the medium is not dispersive. In a dielectric with zero loss tangent, no losses due to attenuation are encountered and hence there is no consideration of the attenuation, which occurs in real dielectric media.

If an alternating electric field is applied to a material, the individual molecules will be induced to rotate in an oscillatory manner about an axis through their centers, the inertia of the molecules preventing them from responding instantaneously. Similar translational effects can occur. The polarization produced by an applied field (such as a propagating radar wave) is closely related to the thermal mobility of the molecules and is, therefore, strongly temperature-dependent. In general, the relaxation time (which may be expressed as a relaxation frequency) depends on activation energy, the natural frequency of oscillation of the polarized particles, and temperature. Relaxation frequencies vary widely between different materials.

For example, maximum absorption occurs at very low frequencies in ice (10^3 Hz), whereas it takes place in the microwave region in water (10^6 – 10^{10} Hz); thus the effects of this phenomenon can have a direct bearing on the dielectric properties of materials at the frequencies employed by surface penetrating radars, especially if moisture is present within a material. There are a number of other mechanisms that cause a separation of positively and negatively charged ions resulting in electric polarization. These mechanisms can be associated with ionic atmospheres surrounding colloidal particles (particularly clay minerals), absorbed water and pore effects, as well as interfacial phenomenon between particles. The general form of the model that describes the frequency dependence of such systems is the Debye [8] relaxation equation

$$\epsilon' - i\epsilon'' = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + i\omega\tau}$$

where

- ϵ' = real part of the dielectric permittivity
- ϵ'' = imaginary part of the dielectric permittivity
- ϵ_∞ = high-frequency limiting value of the permittivity
- ϵ_s = low-frequency limiting value of the permittivity
- ω = radian frequency ($= 2\pi f$)
- τ = relaxation time constant

The frequency of maximum movement and loss occurs at $\omega = 1/\tau$.

In general, single relaxations are rarely observed in natural systems. Instead, there are distributions of relaxations corresponding to distributions of size scales that influence movement of charge. There are several equations describing such distributed systems, with the most common experimental observations in agreement with the model from Cole and Cole [9]

$$\epsilon' - i\epsilon'' = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + (i\omega\tau)^\alpha}$$

where α describes the breadth of the time constant distribution, from a single relaxation, $\alpha=1$, to an infinitely broad distribution, $\alpha=0$, with a common process. Different polarization processes may be described by a series of Cole–Cole equations with different values of α and other parameters.

The electromagnetic properties of a buried target must be different from those of the surrounding soil or material, and this means that to a first order its relative dielectric constant should be significantly lesser or greater than the host soil. Typically, most soils exhibit a relative dielectric constant, which ranges between 2 and 25. Freshwater has a relative dielectric constant of approximately 80. It should be noted that the ground and surface are quite likely to be inhomogeneous and contain inclusions of other rocks of various size as well as manmade debris. This suggests that the signal to clutter performance of the sensor is likely to be an important performance factor. Clutter may be regarded as any radar return that is not associated with the intended target and needs to be carefully defined.

2.2. Attenuation

Electromagnetic waves propagating through natural media experience losses, to both the electric (E) and magnetic (H) fields. This causes attenuation of the original electromagnetic wave. Plane waves are good approximations to real waves in many practical situations. More complicated electromagnetic wavefronts can be considered as a superimposition of plane waves, and this method may be used to gain an insight into more complex situations. For most soils of interest in ground penetrating radar the magnetic response is weak and need not be considered as a complex quantity, unlike the permittivity and conductivity. However, in certain soil types such as those derived from volcanic rocks or otherwise high in iron content, full consideration of the magnetic properties is necessary. In the case of lossy dielectric materials, both conduction and dielectric effects cause absorption of electromagnetic radiation.

The electromagnetic material properties that describe such a coupled system are in the complex propagation constant or circular wavenumber

$$\gamma = ik = \alpha + i\beta$$

where

- γ = propagation constant
- k = circular wavenumber
- α = attenuation constant (Np/m) (nepers per meter)
- $k^2 = \omega(\mu' - i\mu'')(\omega(\epsilon' - i\epsilon'') + i\sigma)$
- β = phase constant (rads/m)

with

$$\alpha = \omega \sqrt{\frac{(\mu'\epsilon' - \mu''(\epsilon'' + \frac{\sigma}{\omega}))^2 + (\mu''\epsilon' + \mu'(\epsilon'' + \frac{\sigma}{\omega}))^2}{2}}$$

$$\beta = \omega \sqrt{\frac{(\mu'\epsilon' - \mu''(\epsilon'' + \frac{\sigma}{\omega}))^2 + (\mu''\epsilon' + \mu'(\epsilon'' + \frac{\sigma}{\omega}))^2 + (\mu'\epsilon' - \mu''(\epsilon'' + \frac{\sigma}{\omega}))}{2}}$$

The field at a distance z from the source is given by

$$E(z, t) = E_0 e^{-\alpha z} e^{j(\omega t - \beta z)}$$

The wavelength λ in the medium is given in meters, and the frequency f is expressed in hertz:

$$\lambda = \frac{2\pi}{\beta} = \frac{v}{f}$$

The losses in such systems are described in terms of tangents of loss angles δ between fields and fluxes:

$$\tan \delta_e = \frac{\epsilon''}{\epsilon'} + \frac{\sigma}{\omega\epsilon'}$$

The electrical loss tangent represents the sum of the charge transport and polarization relaxation losses, and the phase angle between electric field and current density. The skin depth or attenuation length is $1/\alpha(\text{m})$; the distance electromagnetic energy travels while being attenuated by $1/e$ in amplitude. This distance is known as the *skin depth* d and provides an initial guide to the useful penetration depth of a ground penetrating radar system, although in some media the useful range may be greater.

In a lossy conducting dielectric the parameters associated with susceptibility can be rearranged to give

$$\alpha = \omega \sqrt{\left(\frac{\mu\epsilon'}{2} \left(\sqrt{1 + \left(\frac{\epsilon'}{\epsilon''}\right)^2} - 1\right)\right)}$$

$$\beta = \omega \sqrt{\left(\frac{\mu\epsilon'}{2} \left(\sqrt{1 + \left(\frac{\epsilon'}{\epsilon''}\right)^2} + 1\right)\right)}$$

and where the losses are low, then

$$\tan \delta_e = \frac{\sigma}{\omega\epsilon'}$$

This article has not considered the electromagnetic and magnetic loss tangent, and these may need to be considered in special cases.

It can be seen from the expressions above that the attenuation constant of a material is, to a first order, linearly related (in dB/m) to frequency. It is not sufficient to consider only the low-frequency conductivity when attempting to determine the loss tangent over the frequency range 10^7 – 10^{10} Hz. In the case of a material that is dry and relatively lossless, it may be reasonable to consider that $\tan \delta$

is constant over that frequency range. However, for materials that are wet and lossy such an approximation is invalid. There are, nevertheless, a number of other factors, that influence the effective penetration depth, notably the strength of reflection from the target sought, and the degree of clutter suppression of which the system is capable.

A first-order estimate of the various contributions to signal loss can be carried out using the standard radar range equation, although this is only applicable for far-field conditions and thus has restrictions:

$$P_r = \frac{P_t A G \sigma k}{(4\pi R^2)^2} e^{-\alpha 2R}$$

where

- P_t = transmitted power in watts
- P_r = received power in watts
- A = antenna gain
- G = antenna effective aperture
- R = range in meters
- σ = target radar cross section
- k = calibration coefficient

The cumulative losses include the transmission coefficients into the ground, the spreading losses describe the R^{-4} losses for a target of 1 m^2 , and the attenuation losses are for a soil with a ϵ_r of 9 and $\tan \delta$ of 0.1. Fixed losses include the transmission losses into the soil and the reflection loss from the target. In Fig. 1 the first meter (1 m) has not been plotted, as the radar range equation is not an accurate model in this range and the purpose of the explanation is to provide a basic introduction to first-order signal estimation.

2.3. Velocity

The velocity of propagation of electromagnetic waves in free space is approximately $3 \times 10^8 \text{ m/s}$ ($2.997925 \times 10^8 \text{ m/s}$),

Figure 1. Graph of the typical losses encountered at 100 MHz by a GPR probing into the ground. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

but slows in a material depending on its relative permittivity and relative magnetic permeability. The velocity of propagation of electromagnetic waves in a soil with a value for ϵ_r of 9 would be slowed to 1.10^8 m/s. The time to a target at a range of 1 m is therefore 20 ns, and GPR systems operate at time ranges between a few nanoseconds up to 200 ns, although some systems for probing through ice may use ranges up to several tens of milliseconds.

In general, it is not possible to make a reliable estimate of propagation velocity or relative permittivity in a medium from a single measurement without trial holing or other supplementary information. Even in the case where a measurement is carried out at one location, it is often found that significant variations in velocity will occur within comparatively short distances from the original location. This can lead to significant errors in the estimation of depths of reflectors. One procedure that overcomes this limitation is known as *common-depth-point surveying*, which utilizes two antennas in bistatic operation at a number of transmit and receive positions. The velocity of propagation is also slowed by $\tan \delta$ and ϵ_r and assumes $\mu_r = 1$ and is given by

$$v = c \frac{\epsilon'}{2\epsilon_0} \sqrt{\left(\sqrt{1 + \left(\frac{\epsilon'}{\epsilon''}\right)^2} - 1 \right)}$$

It is also possible to derive velocity from multiple measurements scanning over a target, but this works well only in relatively uncluttered situations where the media has no anisotropic characteristics.

2.4. Reflection

In any estimation of received signal level it is necessary to consider the coefficients of reflection and transmission, as the wave passes through the dielectric to the target and Snell's laws describe the associated angles of incidence, reflection, transmission, and refraction. Where lossy materials are involved, complex angles of refraction may occur, unlike the simple classical case, and polarization and the Stoke's matrix may also be required for oriented high-aspect-ratio features such as pipes, wires, and fractures. The intrinsic impedance η of a medium is the relationship between the electric field E and the magnetic field H and is a complex quantity given by

$$\eta = \sqrt{\frac{-j\omega\mu}{\sigma - j\omega\epsilon}}$$

At the boundary between two media, some energy will be reflected and the remainder transmitted. The reflected field strength is described by the reflection coefficient r

$$r = \frac{\eta_2 - \eta_1}{\eta_2 + \eta_1}$$

where η_1 and η_2 are the impedances of media 1 and 2, respectively.

The reflection coefficient has a positive value when $\eta_2 > \eta_1$, such as where an air-filled void exists in a dielectric material. The effect on a pulse waveform is to change the phase of the reflected wavelet so that targets with relative dielectric constants different from those of the host material show different phase patterns of the reflected signal. However, the propagation dielectric of the host material, and the geometric characteristics of the target and its dielectric parameters affect the amplitude of the reflected signal.

2.5. Polarization

A complete description of the radar scattering cross section of a target includes a description of its polarization scattering characteristics. The polarizing properties of targets are described by the Stokes parameters, and the polarization coordinates can be represented on the Poincaré sphere. All of these are well described in standard texts. In summary, these descriptions allow the state of an electromagnetic wave to be described in terms of linear, elliptical, and circular polarization (left-handed or right-handed). It is well known that linear targets as depolarizing features and a linearly polarized crossed dipole antenna rotated about an axis normal to a linear target produces a sinusoidal variation in received signal. However, the null points are a distinct disadvantage because the operator is required to make two separate, axially rotated measurements at every point to be sure of detecting pipes at unknown orientations. An attractive technique is to radiate a circularly polarized wave, which automatically rotates the polarized vector in space and hence removes the direction of signal nulls.

2.6. Dispersion

The frequency-dependent nature of the dielectric properties of the material causes the phase velocity of the component frequencies of a wideband signal to suffer differential propagation values. Hence, there will be variation in the velocity of propagation with frequency. Dielectrics exhibiting this phenomenon are termed *dispersive*. In this situation, the different frequency components within a broadband radar pulse would travel at slightly different speeds, causing the pulse shape to change with time. However, the propagation characteristics of octave band radar signals remain largely unaffected by dispersion. In many instances, the potential variation in the velocity of wave propagation over the frequency range of interest is small and will be ignored.

2.7. Clutter

A major difficulty for operation of GPR systems is the presence of clutter within the material. *Clutter* is defined as sources of unwanted reflections that occur within the effective bandwidth and search window of the radar and present as spatially coherent reflectors. The definition of clutter depends heavily on the intended target. The operator of a GPR system searching for pipes may classify the interfaces between road layers as clutter, whereas the operator of a system measuring road layer thickness might

consider pipes and cables as sources of clutter. Careful definition and understanding are critically important in selecting and operating the best system and processing algorithms. Clutter can completely obscure the buried target and a proper understanding of its source and impact on the radar is essential.

2.8. Depth Resolution

Normally the range, or in the case of GPR, the depth resolution, of a radar is defined by considering the case of targets with identical radar scattering cross sections. In the case of Gaussian pulses, resolution can be achieved at pulse separations between 1.25 and 1.5 of the pulsewidth and can be defined by the Rayleigh criteria for resolution. Essentially, range resolution is defined by the bandwidth of the received signal. A receiver bandwidth in excess of 500 MHz and typically 1 GHz is required to provide a typical resolution of 5–20 cm, depending on the relative permittivity of the material.

When a number of features may be present, a signal having a larger bandwidth is required to be able to distinguish between the various targets and to show the detailed structure of a target. In this context it is the bandwidth of the received signal that is important, rather than that of the transmitted wavelet. The material acts a lowpass filter that modifies the transmitted spectrum in accordance with the electrical properties of the propagating medium. There are some applications of subsurface radar, such as road layer thickness measurement, where the feature of interest is a single interface. Under such circumstances, it is possible to determine the depth sufficiently accurately by measuring the elapsed time between the leading edge of the received wavelet provided the propagation velocity is accurately known.

Although a greater depth resolution is achieved in wetter materials for a given transmitted bandwidth, Earth materials with significant water content tend to have higher attenuation properties. This characteristic reduces the effective bandwidth, tending to balance out the change so that within certain bounds the resolution is approximately independent of loss within the propagating material.

Where interfaces are spaced more closely than a half-wavelength, the reflected signal from one interface will become convolved with that from the other. In such circumstances, some form of deconvolution processing would be required in order to recognize the responses from the individual interfaces and to enable them to be characterized and traced. Such processing is seldom carried out during standard commercial radar surveys.

It should be noted that the Rayleigh criteria for range resolution are less appropriate for the case of a weak target adjacent to strong target. For example, if the amplitude of the weak target is -20 dB relative to that of the strong target, different criteria are needed. Thus the resolution at the -20 dB amplitude level may be a more relevant criterion on which to assess the merits of competing system designs. This is because of the need to detect targets of low radar cross section in close proximity to targets of high radar cross section.

It can be shown [10] that for equivalent main 3 dB bandwidths, a radar design using a time-domain, direct receiver has a considerably better resolution at the -20 dB level than does a frequency-domain radar. This is primarily because the receiver of the frequency-domain radar cross-correlates the received signal. In essence, resolution has been achieved at the expense of signal-to-noise ratio, but this may not be so relevant to attenuation-limited operation.

2.9. Plan Resolution

The plan resolution of a subsurface radar system is important when localized targets are sought and when there is a need to distinguish between more than one at the same depth. Where the requirement is for location accuracy, which is primarily a topographic surveying function, the system requirement is less demanding.

The *plan resolution* is defined by the characteristics of the antenna and the signal processing employed. In general, to achieve an acceptable plan resolution, one must employ a high-gain antenna. This necessitates transmission of a sufficiently large aperture at the lowest frequency. To achieve small antenna dimensions and high gain therefore requires the use of a high carrier frequency, which may not penetrate the material to sufficient depth. When selecting equipment for a particular application, it is necessary to compromise between plan resolution, size of antenna, the scope for signal processing, and the ability to penetrate the material. Plan resolution improves as attenuation increases, provided there is sufficient signal to discriminate under the prevailing clutter conditions. In low-attenuation media the resolution obtained by the horizontal scanning technique is degraded, but under these conditions the use of advanced signal processing techniques becomes feasible and synthetic aperture techniques can dramatically increase the plan resolution. These techniques typically require measurements to be made using transmitter/receiver pairs at a number of antenna positions to generate a synthetic aperture or focus the image. Unlike conventional radars, which generally use a single antenna, most ground penetrating radar systems use separate transmit and receive antennas in what has been termed a *bistatic mode*.

3. PROPERTIES OF MATERIALS

Determination of the dielectric properties of Earth materials remains largely experimental. Rocks, soils, and concrete are complex materials composed of many different minerals in widely varying proportions, and their dielectric parameters may differ greatly even within materials, that are nominally similar. Most Earth materials contain moisture, usually with some measure of salinity. Since the relative permittivity of water is in the order of 80, even small amounts of moisture cause a significant increase of the relative permittivity of the material. A large number of workers have investigated the relationships between the physical, chemical, and mechanical properties of materials and their electrical and in particular microwave properties. In general, they have sought to develop

Figure 2. Real and imaginary dielectric losses plotted as a function of frequency for a typical Earth material with specified fractions of water, sand, silt, and clay. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

suitable models to link the properties of the material to its electromagnetic parameters. Such models provide a basis for understanding the behavior of electromagnetic waves within these media. The real and imaginary dielectric losses as a function of frequency can be plotted over a wide frequency range, and a typical result is shown in Fig. 2.

Information on the geologic properties of Earth soils can be found in the *Digital Soil Map of the World and Derived Soil Properties CD* © published by the Food and Agriculture Organisation of the United Nations. This enables the 10 map sheets of the world to be classified in terms of parameters such as pH, organic carbon content,

carbon/nitrogen ratio, clay mineralogy, soil depth, soil moisture capacity, and soil drainage class. Such information is useful in assessing the potential of RF techniques and particularly GPR for particular geographic regions.

There are two benefits to understanding soil properties in relation to GPR. (1) to understand the applicability of GPR to particular soils and hence the possibility of using GPR to detect buried targets such as pipe, cables, and landmines and (2) to use GPR to characterise soils and soil properties.

GPR can provide a detailed map of the subsurface, which, combined with traditional soil survey methods, can provide information on the type, lateral extent, and depth of the soil; the water table; and the layering and features of the soil and hence its local geology and history.

Since the mid-1970s GPR has been used in the united states by the Department of Agriculture–Natural Resources Conservation Service (USDA-NRCS) as a quality control tool for soil mapping and investigations. The use of GPR in soil survey activities has provided information about the soil resource that would have been unobtainable by other means or would have been uneconomic to obtain. An example of the results of this work is shown in Fig. 3.

4. GPR SYSTEMS

The choice of system design is to a large extent governed by the type of target, the resolution required, and the anticipated ground attenuation and clutter. The depth range of the radar system is likely to be primarily defined by the soil attenuation, once a particular frequency range has

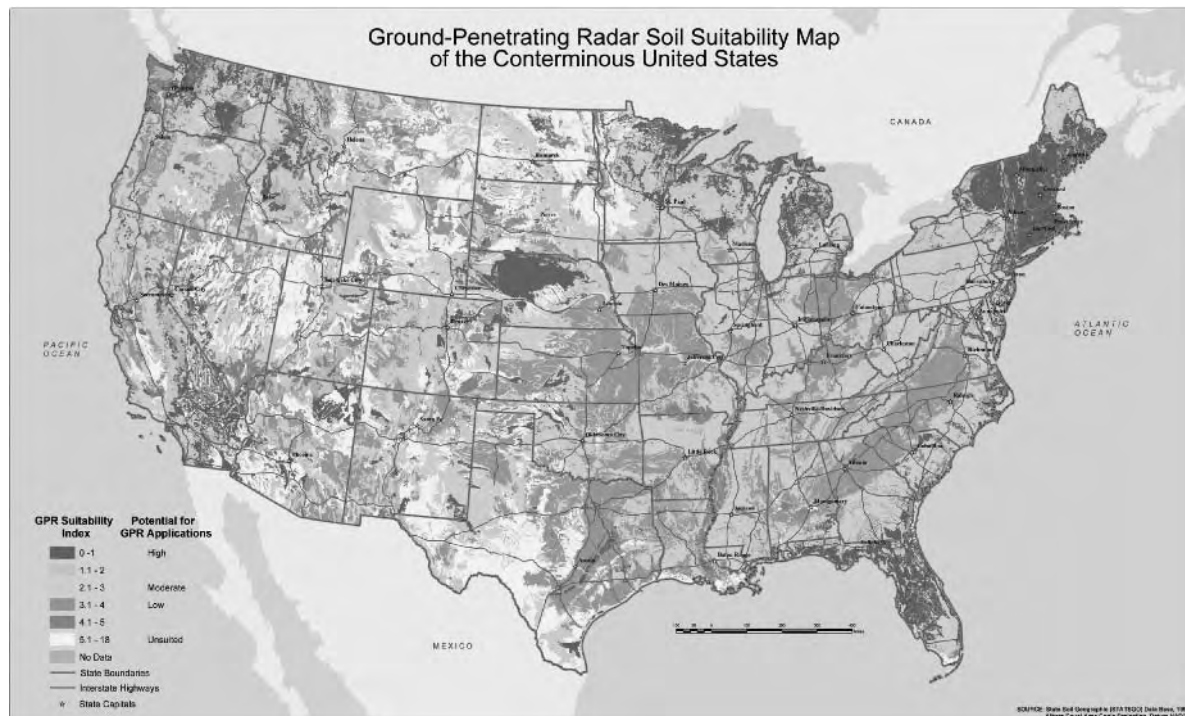

Figure 3. Soil suitability map for GPR applications in the United States. (Courtesy of USDA-NRCS.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

been chosen. However, it can be shown that considerable variations (10–30 dB) in the sensitivity of competing system designs actually translate to relatively small changes in depth performance in lossy soils.

The selection of a suitable waveform for transmission, at least in terms of resolution, can be considered a function of the duration of the complex envelope of the measured signal. The output from most ultrawideband radar systems can be compared in terms of a time-domain representation of the waveform. Almost all types of radar can be assessed not just by their signal-to-noise and signal-to-clutter ratios but also by comparing their inherent range sensitivity. Such a procedure reveals the characteristics that control radar performance. The design of a GPR system is defined by the modulation technique and time-domain, frequency-domain, and noise-domain radar designs are most likely to be encountered.

The frequency-domain, matched-filter, radar receiver provides an optimum linear processing of radar in the presence of noise. The radar signal is processed by a receiver that cross-correlates the received waveform with a suitably time-delayed version of the transmitted waveform. The output results in a compressed pulse in which the amplitude of the latter and its position in delay time is related to the target radar characteristic. This type of receiver is widely used to process chirp, stepped-frequency, coded, and noise waveforms, and the design of such waveforms is extensively described in the literature. Time-domain radar systems are simpler in design and use a sampling receiver to downconvert the radar signals from the nanosecond timeframe to a millisecond timeframe that is easier to postprocess. However, a real disadvantage of the sampling receiver is its limited dynamic range and high noise floor.

A key parameter for most radar systems is the mean power. For portable, close-in radars the capacity of the power sources limits the radiated power. The frequency-domain radar transmits, on a repetitive basis, a nominally constant amplitude signal whose frequency increases in a linear progression from the lowest to the highest values. However, shaping of the envelope of the radiated signal reduces the mean power compared with the instantaneous peak value. The time-domain radar transmits, on a repetitive basis, a short-duration impulse. Consequently the peak power is significantly greater than the mean power. This is not the case with noise radar, whose radiated power per unit bandwidth is optimally low compared with the frequency-domain and time-domain designs.

5. MODULATION TECHNIQUES

There are three basic modulation techniques: time-domain, frequency-domain, and noise-coded radar.

5.1. Time-Domain Radar

Most commercially available ground probing radar systems use short pulses or impulses such as the Ricker wavelet shown in Fig. 4. The high-speed sequential sampling approach used to acquire RF waveforms produces a low SNR because the spectrum of the sampling pulse is a

Figure 4. Ricker wavelet (amplitude vs. time).

poor match for that of the received pulse. In general, the dynamic range of the sampling receiver is typically 60 dB, without time varying gain, and with time varying gain is equivalent to 90 dB or more. Signal averaging can increase the effective sensitivity by the amount of averaging, and this can be typically 10–30 dB. The overall dynamic range is set largely by the ratio of the mean power to the effective receiver sensitivity and can extend up to 150 dB. The antennas that can be used are limited to linear phase designs such as resistively loaded dipoles, TEM horns, or impulse radiating antennas (IRAs) unless the dispersive properties of the antenna used are compensated by suitable post-processing filtering.

5.2. Frequency-Domain Radar

The main potential advantages of the frequency-domain radar are the wider dynamic range, lower noise figure, and higher mean powers that can be radiated. There are two main types of frequency-domain radar: frequency-modulated carrier wave (FMCW) and stepped-frequency carrier wave (SFCW). FMCW radar transmits a continuously changing carrier frequency by means of a voltage-controlled oscillator (VCO) over a chosen frequency range on a repetitive basis as shown in Fig. 5. The received signal is mixed with a sample of the transmitted waveform and results in a difference frequency that is related to the phase of the received signal; hence its time delay and hence range of the target. The difference frequency or intermediate frequency (IF) must be derived from an I/Q mixer pair if the information equivalent to a time-domain representation is required, as a single-ended mixer provides only the modulus of the time-domain waveform. The FMCW radar system is particularly sensitive to certain parameters. In particular, it requires a high degree of linearity of frequency sweep with time to avoid spectral widening of the IF and hence degradation of system resolution. An assessment of the sensitivity of sidelobe level to linearity was made by Dennis and Gibbs [11], who showed the ratio of sidelobe to peak level was dependent on the sweep linearity. Practically the effect of a nonlinearity of a few percent is to cause significant sidelobes.

Figure 5. Typical FMCW transmitted swept waveform (amplitude vs. time).

The SFCW radar transmits a series of incremental frequencies and stores the received IF signal to then carry out a fast Fourier transform (FFT) reconstruction of the time-domain equivalent waveform. The SFCW has found many applications, and the impact of mobile communications technology has had a significant impact on reducing the cost of radar components for this design. Two forms of the synthesized radar can be considered. The first and simplest system is stepped-frequency continuous-wave radar. The second form is more complex in that each individual frequency is appropriately weighted in amplitude and phase prior to transmission. Normally the radar is calibrated to establish a reference plane for measurement as well as to reduce the effect of variations in the frequency characteristics of components and antennas.

A much wider class of antenna is available for use by the designer of frequency-domain radars. The sensitivity of the receiver is much better than the time-domain equivalent, simply by virtue of its lower bandwidth and hence lower thermal noise. Typically, a sensitivity of 120 dBm is found, and a system dynamic range of 180 dB is feasible. However, the FMCW ground probing radar system is particularly sensitive to certain parameters. In particular, it requires a high degree of linearity of frequency sweep with time to avoid spectral widening of the IF and hence degradation of the system resolution.

The main potential advantages of a stepped-frequency or FMCW ground probing radar are its ability to adjust the range of frequencies of operation to suit the material and targets and electromagnetic environment under investigation if the antenna has an adequate passband of frequencies. It can radiate a higher mean power level per spectral line, and its ability to integrate the received signal level improves the system sensitivity. The calibration of the radar does, of course, depend on stable system characteristics and antenna parameters that are invariant with the spacing of the front surface and the antenna. Although on first consideration frequency-domain radars should offer a sensitivity superior to that of time-domain radars, because of their lower receiver bandwidth and, hence thermal noise, both the type of receiver and the range sidelobes of the radiated spectrum may result in an equivalent or worse sensitivity in terms of range resolution as discussed above.

5.3. Noise or PseudoRandom Coded Radar

More recently, work has been carried out on noise modulation and pseudorandom coded modulation techniques for

GPR. The main advantage of these methods is that the energy transmitted is spread more evenly over the spectrum than with any other modulation method, and hence the likelihood of interference to other users of the spectrum is minimized. In addition, the chances of other users of, say, mobile phones interfering with the GPR operator are also reduced. The mean power is the lowest of any of the modulation schemes, and this is helpful in meeting regulatory requirements.

The transmitted signal has noiselike characteristics, and the received signal is cross-correlated with a sample of the transmitted signal. The range of the target is given by the time position of the cross-correlated signal and the amplitude by the peak of the cross-correlated signal. Control of the cross-correlation sidelobes is vital to achieve good range resolution, and the sidelobes are affected by the antenna and system characteristics as well as the duration and randomness of the transmitted waveform. Further information is given by Narayan et al. [12] and Sachs et al. [13].

6. ANTENNAS

In the ultrawideband case the radar antennas are considered in terms of their transfer function rather than their gains or effective apertures. In many cases separate transmit and receive antennas are used; hence their transfer functions may not be identical. The type of antenna that is used with ultrawideband radar has an important role in defining the performance of the radar.

The types of antenna that are useful to the designer of ultrawideband radar fall into two groups: dispersive antennas and nondispersive antennas. However, in principle, all antennas are dispersive to some extent. Examples of dispersive antennas that have been used in ultrawideband radar are the exponential spiral, the Archimedean spiral, the logarithmic planar antenna, the Vivaldi antenna, slot antennas, and the exponential horn. The impulse response of this class of antenna is extended, and generally results in a "chirp" waveform if the input is an impulse. Examples of nondispersive antennas are the TEM horn; the bicone; the bowtie; the resistive, lumped-element loaded antenna; and the continuously, resistively loaded antenna. The input voltage driving function to the terminals of the antenna in an impulse radar is typically a Gaussian pulse, and this requires the impulse response of the antenna to be extremely short, mainly to prevent the antenna from distorting the input function and generating

time sidelobes. These time sidelobes would obscure targets that are close in range to the target of interest; in other words, the resolution of the radar can become degraded if the impulse response of the antenna is significantly extended.

Element antennas are characterized by linear polarization, low directivity, and relatively limited bandwidth unless either end loading or distributed loading techniques are employed, in which case bandwidth is increased at the expense of radiation efficiency. Horn antennas have found most use with FMCW ultrawideband radars where the generally higher frequency of operation and relaxation of the requirement for linear phase response permit the consideration of this class of antenna. FMCW ultrawideband radars have used an offset paraboloid fed by a ridged horn. This arrangement was designed to focus the radiation into the ground at a slant angle to reduce the level of the reflection from the ground. Care needs to be taken in such arrangements to minimize the effect of back- and sidelobes from the feed antenna, which can easily generate reflection from the ground surface.

One method of radiating circular polarization is to use an equiangular spiral antenna. The dispersive nature of this type of antenna causes an increase in the duration of the transmitted waveforms, and the radiated pulse takes the form of a “chirp” in which high frequencies are radiated first, followed by the low frequencies. This effect, however, may be compensated by a “spiking” filter, which may take the form of a conventional matched filter or a more sophisticated filter such as Wiener filter.

7. SIGNAL AND IMAGE PROCESSING

The most basic GPR data record is an *A* scan, and an example is shown in Fig. 6. An *A* scan provides an amplitude–time record of a single measurement over a target. Only amplitude range information is plotted. Ground penetrating radar is generally used in such a way as to generate a sequence of *A* scans related to the survey position on the ground surface. This sequence can be termed a *B* scan, and an example is shown in Fig. 7. This effectively

Figure 6. Typical example of GPR *A* scan (amplitude/time-modeled data).

Figure 7. Typical example of *B* scan (y, z axis, gray scale image of modeled data).

represents on one axis (z) depth and the orthogonal axis (x or y) linear position. The amplitude of the signal may be shown as a series of overlapping signals or alternatively a “wiggle plot” (borrowed from the seismic terminology) or a grayscale coded intensity plot or a pseudocolor image. In the modeled example shown, the hyperbolic spreading of the target spatial response can be seen. As shown in Fig. 8, a *C* scan consists of a plan view (x, y plane over a defined range of depth z).

As the antennas generally used for surface penetrating radars have a poor directivity, the pattern of the reflected waveform in the *B* scan represented the spatial convolution of the antenna pattern with the point source of the target. This pattern may be deconvolved using any of the following processes: synthetic aperture processing, conjugate gradient methods, and reverse time migration. Many of these techniques work well on isolated targets such as pipes, which have well defined geometric boundaries. The situation is more difficult with stratified layers and, of course, anisotropic materials. When a focused image of the buried object is created, whether as a *B* or *C* scan (area at a particular range of depths), it is necessary to interpret

Figure 8. Typical example of *C* scan (x - y plane at defined z -range color image of modeled data of buried landmines). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the radar image as being generated by a physical structure. This is not always easy in the case of a cluttered image, and a great deal still depends on the field experience of the operator.

Automated methods based on standard image processing methods (mask filtering), image matching, and similar methods, as well as methods based on neural networks, have been investigated. The variability of ground conditions, as well as the physics of EM wave propagation and reflection, must be carefully taken into account in generating pattern libraries. For example, the depth image of a void is always apparently smaller than the void's physical size; corner reflectors of any reasonable size generate large, apparently discontinuous reflection images; and conductive targets, which reverberate by means of stored energy, create extended-depth images. The image of a buried target generated by a subsurface radar will not, of course, correspond to the target's geometric representation. The fundamental reasons for this are related to the ratio of the wavelength of the radiation and the physical dimensions of the target. In most cases for surface penetrating radar, the ratio is close to unity. This compares very differently with an optical image, which is obtained with wavelengths such that the ratio is considerably greater than unity. In ground penetrating radar, applications, the effect of combinations of scattering planes, for example, the corner reflector, can cause "bright spots," in the image and variations in the velocity of propagation can cause dilation of the aspect ratio of the image. While many images can be focused to reduce the effect of antenna beamspeading, regeneration of a geometric model is a much more complex procedure and is rarely attempted.

The general objective of signal processing as applied to ground penetrating radar is to present either an image that can readily be interpreted by the operator or to classify the target return with respect to a known test

Figure 9. GPR data from reinforced-concrete roadway taken with 1-GHz SPR radar system at 50-ns time window and 3 m horizontal distance. (Courtesy of ERA Technology.) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

procedure or template. While much work has been carried out on 3D SAR processing, there is a tendency for this to be restricted to situations where the customer is prepared to pay for the additional information.

The general processing problem encountered in dealing with ground penetrating radar data is in the widest sense the extraction of a localized wavelet function from a time series that displays time-domain characteristics very similar to those of the wavelet. This time series is generated by signals from the ground and other reflecting surfaces, as well as internally from the radar system. Unlike conventional radar systems in which the target can generally be regarded as being in motion compared with the clutter, in the ground penetrating radar case, the target and the clutter are spatially fixed and the radar antenna is moved with respect to the environment.

It is assumed that data are recorded to an adequate resolution and bandwidth. Most antennas used in surface penetrating applications have a limited low-frequency response and tend to act as highpass filters effectively differentiating the applied impulse, hence creating a wavelet. In the case of antennas operated in close proximity to the ground, the antenna characteristics may vary as a result of changes in the ground surface electrical parameters. Any processing scheme that relies on invariant antenna parameters should take into account the mode of operation of the antennas and the degree of stability that is practically realizable. This is a particular issue for GPR and needs careful attention to reduce the effect of antenna-ground surface interaction.

Alternative methods of processing are associated with identifying target resonances using singularity expansion methods (SEMs) to evaluate the target response. Early research using Prony methods encountered difficulties due to the ill-conditioned nature of natural frequency extraction from noisy data.

Some of the ancillary requirements of an operational subsurface radar system need to be considered. There is a need for an accurate, small-scale, low-cost position referencing system for use with radar for subsurface survey techniques. It is important that data can be related to a true geographic reference particularly when filed on digital mapping systems and used to define areas of safe working. It is necessary to provide some means of scanning the antenna. Obviously a basic approach is the

handheld device, but this places some limitations on the signal processing strategies.

Another consideration is the plane of polarization of the electromagnetic energy. For targets with one large area dimension such as a pipe, the radar cross-scattering section will be larger when the polarization vector is in line with the pipe. This means that any area that is surveyed with, say, parallel dipoles must be surveyed in orthogonal directions to ensure that no targets are missed. The same principle also relates to crossed dipole antennas.

8. APPLICATIONS

8.1. Introduction

It is possible to provide only a brief summary of the wide variety of the applications for GPR, which has in some cases become an established and routine method of subsurface investigation. In other applications, such as borehole detection, the technique is under development, whereas in others, such as mine detection, basic research is being carried out, although some equipment is now being used in field trials. GPR, in the hands of an expert, provides a safe and noninvasive method of conducting speculative searches without the need for unnecessary disruption and excavation.

GPR has significantly improved the efficiency of the exploratory work that is fundamental to the construction and civil engineering industries, the police and forensic sectors, security/intelligence forces, and archaeological surveys.

GPR has been very successfully used in forensic investigations. The most notorious cases are in the United Kingdom in 1994, when the gravesites, under concrete and in the house of Fred West, of the victims of the serial murderer, were pinpointed. In Belgium, the gravesites of the victims of the pedophile Dutroux were detected in 1996.

Archaeological applications of GPR have been varied, ranging from attempts to detect the Ark to the exploration of Egyptian (see Fig. 10) and North American Indian sites as well as castles and monasteries in Europe. The quality of the radar image can be exceptionally good, although correct understanding normally requires joint interpretation by the archaeologists and radar specialists see (Fig. 11).

Abandoned antipersonnel landmines and unexploded ordnance are a major hindrance to the recovery of many countries from war. Their effect on the civilian population is disastrous, and major efforts are being made by the international community to eliminate the problem. Most detection is done with metal detectors, which respond to the large amount of metallic debris in abandoned battlefield areas and hence have difficulty in detecting the minimum metal or plastic, mine. GPR technology is being applied to this problem as a means of reducing the false-alarm rate and providing improved detection of low-metal-content mines. An example of data gathered from a 4-m wide GPR 32-channel array is shown in Fig. 12.

GPR has been used for surveying many different types of geologic strata ranging from exploration of the Arctic

Figure 10. GPR system in use for archaeological surveying in Saqqara, Egypt. (Courtesy of ERA Technology.)

and Antarctic icecaps and the permafrost regions of North America, to mapping of granite, limestone, marble, and other hard rocks as well as geophysical strata.

The thickness of the various layers of a road can be measured using radar techniques. The great advantage is that this method is nondestructive and high-speed (>40 km/h) and can be applied dynamically to achieve a continuous profile or rolling map. The accuracy of calibration tends to reduce as a function of depth because of the attenuation characteristics of the ground. The accuracy may be quite high (i.e., a few millimeters) for the surface wearing course but will degrade to centimeters at depths of 1 m. An example is shown in Fig. 9.

While most GPR systems are used in close proximity to the ground, airborne systems have been able to map ice formations and glaciers, and penetrate through forest canopy. Airborne GPR, processed using synthetic aperture techniques, has been used to detect buried metallic mines from a height of several hundred meters. In addition, the SIR-C satellite SAR radar has imaged buried artefacts in desert conditions, and the JPL Website <http://southport>.

jpl.nasa.gov/sir-c/ is an important source of radar imagery.

A list of the applications is given below, and the reader can find further information from the literature and publications referenced:

- Archaeological investigations
- Bridge deck analysis
- Borehole inspection
- Building condition assessment
- Contaminated-land investigation
- Detection of buried mines (antipersonnel and antitank)
- Evaluation of reinforced concrete
- Forensic investigations
- Geophysical investigations
- Medical imaging
- Pipes and cable detection
- Planetary exploration
- Rail track and bed inspection
- Remote sensing from aircraft and satellites
- Road condition survey
- Security applications
- Snow, ice, and glaciers
- Timber condition
- Tunnel linings
- Wall condition

Readers are encouraged to review the applications described in the following sources.

9. REGULATION

All countries require that GPR systems be properly regulated and operated in accordance with national and international requirements. Users should consult with their national authorities to determine the regulatory environment.

Within the European Union (EU) there are two main considerations governing the use of ground penetrating radar (GPR): (1) the use of the equipment as a deliberate radiofrequency radiator and (2) usage as equipment that must satisfy the EMC requirements of the EU. The ETSI regulatory body is in the process of drafting specifications, and information can be found at <http://www.etsi.org> that will cover the use of such equipment as a deliberate radiofrequency radiator. Planned legislation and an ETSI product specification at some undefined time in the future means that this equipment will eventually need to conform to the R&TTE directive. In the short term until a new product specification is introduced and formally published in the *Official Journal of the European Communities*, the EMC directive should be applied. All equipment, including ultrawideband radar or ground probing radar, must be CE marked to demonstrate that it satisfies the relevant directives of the European Union. The CE mark may be applied only when the requirements of all other relevant EU directives, such as safety, have also been demonstrated.

In the United States the FCC Website <http://www.fcc.gov/aboutus.html> provided the following information in February 2002:

Feb 2002 Washington, D.C.—The Federal Communication Commission (FCC) adopted today a First Report and Order that permits the marketing and operation of certain types of new products incorporating ultra-wideband (“UWB”)

technology. UWB technology holds great promise for a vast array of new applications that have the potential to provide significant benefits for public safety, businesses and consumers in a variety of applications such as radar imaging of objects buried under the ground or behind walls and short-range, high-speed data transmissions.

UWB devices operate by employing very narrow or short duration pulses that result in very large or wideband transmission bandwidths. With appropriate technical standards, UWB devices can operate using spectrum occupied by existing radio services without causing interference, thereby permitting scarce spectrum resources to be used more efficiently. This First Report and Order (“Order”) includes standards designed to ensure that existing and planned radio services, particularly safety services, are adequately protected. The FCC will act vigorously to enforce the rules and act quickly on any reports of interference.

The standards adopted today represent a cautious first step with UWB technology. These standards are based in large measure on standards that the National Telecommunications and Information Administration (“NTIA”) believes are necessary to protect against interference to vital federal government operations. Since there is no production UWB equipment available and there is little operational experience with the impact of UWB on other radio services, the Commission chose in this First Report and Order to err on the side of conservatism in setting emission limits when there were unresolved interference issues. The Commission intends within the next six to twelve months to review the standards for UWB devices and issue a further notice of proposed rule making to explore more flexible standards and address the operation of additional types of UWB operations and technology.

Ground Penetrating Radar Systems: GPR’s must be operated below 960 MHz or in the frequency band 3.1–10.6 GHz. GPR’s operate only when in contact with or within close proximity of, the ground for the purpose of detecting or obtaining the images of buried objects. The energy from the GPR is intentionally directed down into the ground for this purpose. Operation is restricted to law enforcement, fire and rescue organizations, to scientific research institutions, to commercial mining companies, and to construction companies.

It is understood that waivers have been granted to certain operators and the FCC are in the process of reviewing the policy announced in 2002. In February 2003 the following announcement was made:

In response to the petitions, the Commission amended the rules to facilitate the operation of through-wall imaging systems by law enforcement, emergency rescue and firefighter personnel in emergency situations; eliminated the requirement that GPR’s and wall imaging systems operate with their – 10 dB bandwidths below 960 MHz or above 3.1 GHz; specified the limitations on who may operate ground penetrating radar (GPR) systems and wall imaging systems and for what purposes; eliminated the requirement for non-hand held GPR’s to employ a dead man switch; clarified the coordination requirements for imaging devices; and clarified the rules regarding emissions produced by digital circuitry used by UWB transmitters.

For more information, see <http://www.g-p-r.com/>.

10. SUMMARY

Advances in the performance and design of lightweight and compact GPR radar sensors have been significant since the mid-1990s because of the impact of the telecommunications industry and availability of affordable high-power computing; the volume of published papers and conferences, some devoted entirely to GPR, has risen considerably since then. Inevitably there have been some claims for GPR capability that are simply outside the realms of known physics and unfortunately have been accepted by some sections of the media. Tuley et al. [14] give an excellent review of one such claim. There has also been some duplication of basic research. However, developments in the field of noise and pseudorandom coded [15] modulation techniques together with better signal and image processing algorithms as well as spinoff from improved microwave technology originating from the telecommunications industry will have a significant impact on GPR in the future.

It is reasonable to conclude that GPR is now an established branch of science. It has links to electronic engineering, mathematics, signal processing, geophysics, civil engineering, structural engineering, archaeology, forensic science planetary exploration, as well as unexploded ordnance (UXO) clearance and mining. GPR has achieved academic recognition as well as commercial impact and seems set to continue its impact into all branches of human activity where buried objects are sought.

GUIDED ELECTROMAGNETIC WAVES

WILLIAM T. JOINES
Duke University

Closed-form solutions for TEM, TM, and TE waves in guiding structures are obtained from Maxwell's equations. Propagation parameters, frequency ranges, broadbanding techniques, and design examples are presented. Dielectric waveguides for microwave and optical frequencies are also presented.

1. MAXWELL'S EQUATIONS

Maxwell's equations in differential form, as determined from Faraday's, Ampere's, and Gauss' laws, respectively, are

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (1)$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \quad (2)$$

$$\nabla \cdot \mathbf{D} = \rho \quad (3)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (4)$$

In these equations, \mathbf{E} is the electric field intensity in V/m, \mathbf{H} is the magnetic field intensity in A/m, $\mathbf{D} = \epsilon \mathbf{E}$ is the electric flux density in C/m², ϵ is the electric permittivity in F/m, $\mathbf{J} = \sigma \mathbf{E}$ is the conduction current density in A/m², σ is the electrical conductivity in S/m, ρ is electric charge density in C/m³, $\mathbf{B} = \mu \mathbf{H}$ is the magnetic flux density in Wb/m² (or tesla) and μ is the magnetic permeability in H/m.

2. PROPAGATING SINE WAVES AND THE WAVE EQUATION

For signals oscillating sinusoidally in time it is convenient to represent the time variation as $e^{j\omega t}$. Thus, the electro-

magnetic fields are expressed as $\mathbf{E}(x, y, z, t) = \mathbf{E}(x, y, z)e^{j\omega t}$, and $\mathbf{H}(x, y, z, t) = \mathbf{H}(x, y, z)e^{j\omega t}$. Substituting these expressions into the differential form of Maxwell's equations given in (1)–(4) yields the sinusoidal steady-state form as

$$\nabla \times \mathbf{E} = -j\omega\mu\mathbf{H} \quad (5)$$

$$\nabla \times \mathbf{H} = (\sigma + j\omega\epsilon)\mathbf{E} \quad (6)$$

$$\nabla \cdot \mathbf{D} = \rho \quad (7)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (8)$$

where the last two equations are unchanged since no time derivative is involved.

A wave equation for \mathbf{E} and \mathbf{H} is derived by taking the curl of both sides of (5) and (6), and then using the vector identity

$$\nabla \times \nabla \times \mathbf{E} = \nabla(\nabla \cdot \mathbf{E}) - \nabla^2 \mathbf{E} \quad (9)$$

Thus, from (5), (6), and (9), we obtain

$$\nabla \times \nabla \times \mathbf{E} = -j\omega\mu(\nabla \times \mathbf{H}) \quad (10)$$

and

$$\nabla(\nabla \cdot \mathbf{E}) - \nabla^2 \mathbf{E} = -j\omega\mu(\sigma + j\omega\epsilon)\mathbf{E} \quad (11)$$

If in the region of interest, $\rho = 0$, and $\epsilon \neq \epsilon(x, y, z)$, then from (7), $\nabla \cdot \mathbf{E} = 0$, and (11) takes a convenient form of the wave equation as

$$\nabla^2 \mathbf{E} = j\omega\mu(\sigma + j\omega\epsilon)\mathbf{E} = \gamma^2 \mathbf{E} \quad (12)$$

A similar procedure, starting with the curl of both sides of (6), yields an identical equation involving \mathbf{H} as

$$\nabla^2 \mathbf{H} = j\omega\mu(\sigma + j\omega\epsilon)\mathbf{H} = \gamma^2 \mathbf{H} \quad (13)$$

In (12) and (13), we obtain

$$\gamma = \sqrt{j\omega\mu(\sigma + j\omega\epsilon)} = \alpha + j\beta \quad (14)$$

where γ is the propagation constant, α is the attenuation constant, and β is the phase constant, all expressed per unit length.

Solutions to the wave equations for \mathbf{E} and \mathbf{H} may be obtained most conveniently by separation of variables, as shown in the next section.

3. SOLUTIONS FOR TEM, TM, AND TE WAVES [1,2]

Allowing all polarizations of \mathbf{E} in rectangular coordinates, (12) may be expressed as

$$\nabla^2(E_x\hat{x} + E_y\hat{y} + E_z\hat{z}) = \gamma^2(E_x\hat{x} + E_y\hat{y} + E_z\hat{z}) \quad (15)$$

where \hat{x} , \hat{y} , and \hat{z} are unit vectors. Thus, a typical term is

$$\nabla^2 E_z = \gamma^2 E_z \quad (16)$$

Substituting the separated-variable solution $E_z(x, y, z) = X(x)Y(y)Z(z)$ into (16), and dividing by XYZ , produces the result

$$\frac{1}{X} \frac{d^2 X}{dx^2} + \frac{1}{Y} \frac{d^2 Y}{dy^2} + \frac{1}{Z} \frac{d^2 Z}{dz^2} = \gamma^2 = -k_x^2 - k_y^2 - k_z^2 \quad (17)$$

From (17), it will be convenient to let

$$k_z^2 = -(\gamma^2 + k_x^2 + k_y^2) = -\Gamma^2 \quad (18)$$

or

$$\Gamma = \sqrt{\gamma^2 + k_x^2 + k_y^2} \quad (19)$$

where the propagation constants k_x , k_y , and Γ are to be determined.

Equating terms in (17) yields three ordinary differential equations that have the implied solutions indicated in the following:

$$\frac{d^2 X}{dx^2} + k_x^2 X = 0 \rightarrow X(x) = A_1 \cos k_x x + B_1 \sin k_x x \quad (20)$$

$$\frac{d^2 Y}{dy^2} + k_y^2 Y = 0 \rightarrow Y(y) = A_2 \cos k_y y + B_2 \sin k_y y \quad (21)$$

$$\frac{d^2 Z}{dz^2} - \Gamma^2 Z = 0 \rightarrow Z(z) = A_3 e^{-\Gamma z} + B_3 e^{\Gamma z} \quad (22)$$

We express a sinusoidally time-varying, z -polarized wave propagating in the $+z$ direction as

$$E_z(x, y, z, t) = E_z(x, y, z)e^{j\omega t} = X(x)Y(y)e^{j\omega t - \Gamma z} \quad (23)$$

and all the other components of E and H are expressed in a similar form.

In (23), in order to produce the term $e^{j(\omega t - |\Gamma|z)}$ necessary for wave propagation to occur, Γ must be imaginary. Taking the dielectric material through which the wave propagates to be perfect ($\sigma = 0$), then $\gamma^2 = j\omega\mu(\sigma + j\omega\epsilon) = -\omega^2\mu\epsilon$. The propagation condition is

$$\Gamma = \sqrt{\gamma^2 + k_x^2 + k_y^2} = j\sqrt{\omega^2\mu\epsilon - k_x^2 - k_y^2} = j\beta_g \quad (24)$$

and wave propagation occurs if β_g (the phase constant of the wave-guiding structure) is real. At $\beta_g = 0$, no propagation occurs, which defines a cutoff frequency

$$f_c = \frac{\omega_c}{2\pi} = \frac{1}{2\pi\sqrt{\mu\epsilon}} \sqrt{k_x^2 + k_y^2} \quad (25)$$

Substituting (25) into (24) yields

$$\Gamma = j\sqrt{\omega^2\mu\epsilon - \omega_c^2\mu\epsilon} = j\omega\sqrt{\mu\epsilon} \sqrt{1 - \left(\frac{f_c}{f}\right)^2} = j\beta_g \quad (26)$$

These parameters will be examined further for different wave-guiding structures.

All of the field solutions, expressed in the form $XYe^{-\Gamma z}$, satisfy the wave equation, and the solutions must also satisfy the boundary conditions imposed by the guiding structure. For guided waves, the basic wave types are transverse electromagnetic (TEM) waves, transverse magnetic (TM) waves, and transverse electric (TE) waves. For propagation guided in the z direction, a TEM wave has components of \mathbf{E} and \mathbf{H} that are perpendicular (or transverse) to the z axis, and thus by definition, $E_z = H_z = 0$. A TM wave has components of \mathbf{H} perpendicular to the z axis, but by definition, $H_z = 0$. A TE wave has components of \mathbf{E} perpendicular to the z axis, but by definition, $E_z = 0$. These wave types and polarizations are illustrated in Fig. 1, where the TE and TM waves are guided by reflecting rays at specific angles (θ) between the parallel metal plates at $x = 0$ and $x = a$.

The guiding structures may take on a variety of forms, but two important ones are diagramed in Fig. 2: Fig. 2a is a parallel-plate transmission line with plate separation a and width w ; Fig. 2b is a rectangular waveguide with inside width a and height b . Within the parallel-plate line depicted in Figs. 1 and 2a, a TEM wave can propagate at all frequencies, and TM and TE waves can propagate at all frequencies above a certain cutoff frequency (f_c) that will be determined later. Within the closed structure of the rectangular waveguide, TM and TE waves can propagate at all frequencies above their cutoff frequencies (f_c differs for TM and TE waves in the closed waveguide), but TEM waves cannot exist within the closed waveguide.

Figure 1. Waves guided between parallel metal plates spaced a distance a apart: (a) TEM waves— $\mathbf{E} = E_x\hat{x}$, $\mathbf{H} = H_y\hat{y}$, $E_z = 0$; (b) TM waves— $\mathbf{E} = -E_x\hat{x} - E_z\hat{z}$, $\mathbf{H} = -H_y\hat{y}$, $H_z = 0$; (c) TE waves— $\mathbf{E} = E_y\hat{y}$, $\mathbf{H} = -H_x\hat{x} - H_z\hat{z}$, $E_z = 0$.

Figure 2. Two important structures for guiding waves: (a) parallel-plate line of width w and spacing a ; (b) closed rectangular waveguide of inside width a and height b .

3.1. Transverse Electromagnetic (TEM) Waves

To show that TEM waves cannot exist, and therefore propagate, within the rectangular waveguide, proceed to solve for a propagating wave as if one may exist. Assume solutions of the form $XYe^{-\Gamma z}$ for E_x , E_y , H_x , and H_y , take $E_z = H_z = 0$ by definition, and substitute the assumed solutions into Maxwell's curl equations. First, $\nabla \times \mathbf{E} = -j\omega\mu\mathbf{H}$ yields

$$0 + \Gamma E_y = -j\omega\mu H_x \quad (27)$$

$$-\Gamma E_x + 0 = -j\omega\mu H_y \quad (28)$$

$$\frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} = 0 \quad (29)$$

and $\nabla \times \mathbf{H} = (\sigma + j\omega\epsilon)\mathbf{E}$ yields

$$0 + \Gamma H_y = (\sigma + j\omega\epsilon) E_x \quad (30)$$

$$-\Gamma H_x + 0 = (\sigma + j\omega\epsilon) E_y \quad (31)$$

$$\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} = 0 \quad (32)$$

where the common term $e^{-\Gamma z}$ has been canceled in each equation.

From (27), (28), (30), and (31), we obtain

$$-\frac{E_y}{H_x} = \frac{E_x}{H_y} = \frac{j\omega\mu}{\Gamma} = \frac{\Gamma}{\sigma + j\omega\epsilon} \quad (33)$$

Therefore, $\Gamma^2 = j\omega\mu(\sigma + j\omega\epsilon) = \gamma^2$, and $k_x = k_y = 0$, which allows no variation of \mathbf{E} and \mathbf{H} in the x - y plane. Thus, boundary conditions cannot be satisfied within the closed structure, and TEM waves cannot exist.

Since $\Gamma^2 = \gamma^2$ for TEM waves, the wave equations for E_x and H_y within the parallel-plate transmission line are

$$\frac{d^2 E_x}{dz^2} = \gamma^2 E_x \quad \text{and} \quad \frac{d^2 H_y}{dz^2} = \gamma^2 H_y \quad (34)$$

If $w \gg a$ for the parallel-plate line, then E_x and H_y represent uniform fields between the plates. By applying Faraday's law between the conducting plates, and Ampere's law around the plates, the fields are related to the voltage

and current at any point z by

$$E_x = \frac{V(z)}{a} \quad \text{and} \quad H_y = \frac{I(z)}{w} \quad (35)$$

Thus, $V(z)$ and $I(z)$ also satisfy the wave equation, and for waves propagating in the $+z$ direction they have the solutions

$$V(z) = Ae^{-\gamma z} \quad \text{and} \quad I(z) = \frac{A}{Z_0} e^{-\gamma z} \quad (36)$$

where A is a constant and Z_0 is the characteristic impedance of the transmission line. As in (33), since $E_x/H_y = \eta$, the intrinsic impedance of the material between the plates, it is easily determined from foregoing relations that

$$Z_0 = \frac{V(z)}{I(z)} = \frac{E_x a}{H_y w} = \frac{a}{w} \eta = \frac{a}{w} \sqrt{\frac{j\omega\mu}{\sigma + j\omega\epsilon}} \quad (37)$$

for the parallel-plate line considered here.

3.2. Transverse Magnetic (TM) Waves

Returning to the rectangular waveguide of width a and height b , since $H_z = 0$ by definition for TM waves, select $E_z = XYe^{-\Gamma z}$ as a solution that cannot vanish if a solution does exist. Assuming solutions of the form $XYe^{-\Gamma z}$ for E_x , E_y , H_x , and H_y , substitute the assumed solutions into Maxwell's curl equations. First, $\nabla \times \mathbf{E} = -j\omega\mu\mathbf{H}$ yields

$$\frac{\partial E_z}{\partial y} + \Gamma E_y = -j\omega\mu H_x \quad (38)$$

$$-\Gamma E_x - \frac{\partial E_z}{\partial x} = -j\omega\mu H_y \quad (39)$$

$$\frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} = 0 \quad (40)$$

and $\nabla \times \mathbf{H} = (\sigma + j\omega\epsilon)\mathbf{E}$ yields

$$0 + \Gamma H_y = (\sigma + j\omega\epsilon)E_x \quad (41)$$

$$-\Gamma H_x + 0 = (\sigma + j\omega\epsilon)E_y \quad (42)$$

$$\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} = (\sigma + j\omega\epsilon)E_z \quad (43)$$

The common term $e^{-\Gamma z}$ has been canceled in each equation.

From (41) and (42)

$$-\frac{E_y}{H_x} = \frac{E_x}{H_y} = \frac{\Gamma}{\sigma + j\omega\epsilon} = Z_0 \quad (44)$$

which defines Z_0 as the characteristic impedance of TM waves in the rectangular waveguide. Using this definition of Z_0 , and the curl equations, all the field components may be expressed in terms of the one-component solution E_z .

Substituting (42) into (38) and using (44), we obtain

$$H_x = \frac{\partial E_z / \partial y}{\Gamma Z_0 - j\omega\mu} \quad (45)$$

Substituting (41) into (39) and using (44), we obtain

$$H_y = \frac{-\partial E_z / \partial x}{\Gamma Z_0 - j\omega\mu} \quad (46)$$

The remaining components are

$$E_x = Z_0 H_y, \quad E_y = -Z_0 H_x, \quad \text{and} \quad H_z = 0 \quad (47)$$

Again, the assumed solution for E_z is

$$E_z = XYe^{-\Gamma z} = (A_1 \cos k_x x + B_1 \sin k_x x) \times (A_2 \cos k_y y + B_2 \sin k_y y) e^{-\Gamma z} \quad (48)$$

and the boundary conditions are that $E_z = 0$ on each wall of the waveguide. Letting $E_z(0, y) = 0$ and $E_z(x, 0) = 0$ requires that $A_1 = 0$ and $A_2 = 0$. The remaining sinusoidal terms will satisfy the conditions $E_z(a, y) = 0$ and $E_z(x, b) = 0$ if

$$k_x = \frac{m\pi}{a} \quad \text{and} \quad k_y = \frac{n\pi}{b} \quad (49)$$

where m and n are integers, including zero. Thus, the solution for E_z is

$$E_z(x, y, z, t) = E_{mn} \sin \frac{m\pi x}{a} \sin \frac{n\pi y}{b} e^{-\Gamma z} e^{j\omega t} \quad (50)$$

Depending on the choice of integers m and n , different cross-sectional field patterns may occur in the x - y plane. These different modes are designated by TM_{mn} . Observe from (50) that the TM_{23} mode (for example) has two half-sine-wave variations in the x direction and three half-sine-wave variations in the y direction. The lowest-order mode that can propagate is the TM_{11} , since the TM_{10} and the TM_{01} modes render $E_z = 0$ in (50).

In (50), as stated earlier, wave propagation occurs if Γ is imaginary. Taking the dielectric material (usually air) filling the waveguide to be perfect ($\sigma = 0$), then $\gamma^2 = j\omega\mu(\sigma + j\omega\epsilon) = -\omega^2\mu\epsilon$, and

$$\begin{aligned} \Gamma &= \sqrt{\gamma^2 + k_x^2 + k_y^2} \\ &= j\sqrt{\omega^2\mu\epsilon - \left(\frac{m\pi}{a}\right)^2 - \left(\frac{n\pi}{b}\right)^2} = j\beta_g \end{aligned} \quad (51)$$

Thus, wave propagation occurs at frequencies above the cutoff frequency

$$f_c = \frac{\omega_c}{2\pi} = \frac{1}{2\pi\sqrt{\mu\varepsilon}} \sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2} \quad (52)$$

$$= v \sqrt{\left(\frac{m}{2a}\right)^2 + \left(\frac{n}{2b}\right)^2}$$

The cutoff frequency of the TM_{11} (lowest-order) mode is

$$f_c = \frac{v}{2a} \sqrt{1 + \left(\frac{a}{b}\right)^2} \quad (53)$$

Note that if the dimension b approaches infinity, and the parallel sides remain a distance a apart, the cutoff frequency for all TM modes in (52) becomes

$$f_c = \frac{mv}{2a} \quad (54)$$

3.3. Transverse Electric (TE) Waves

For TE waves within the rectangular waveguide of width a and height b , since $E_z = 0$ by definition, select $H_z = XYe^{-\Gamma z}$ as a solution that cannot vanish if a solution does exist. Assuming solutions of the form $XYe^{-\Gamma z}$ for E_x , E_y , H_x , and H_y , substitute the assumed solutions into Maxwell's curl equations. First, $\nabla \times \mathbf{E} = -j\omega\mu\mathbf{H}$ yields

$$0 + \Gamma E_y = -j\omega\mu H_x \quad (55)$$

$$-\Gamma E_x + 0 = -j\omega\mu H_y \quad (56)$$

$$\frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} = -j\omega\mu H_z \quad (57)$$

and $\nabla \times \mathbf{H} = (\sigma + j\omega\varepsilon)\mathbf{E}$ yields (assuming $\sigma = 0$ for a perfect dielectric medium)

$$\frac{\partial H_z}{\partial y} + \Gamma H_y = j\omega\varepsilon E_x \quad (58)$$

$$-\Gamma H_x - \frac{\partial H_z}{\partial x} = j\omega\varepsilon E_y \quad (59)$$

$$\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} = 0 \quad (60)$$

The common term $e^{-\Gamma z}$ has been canceled in each equation.

The characteristic impedance of TE waves is defined from (55) and (56) as

$$-\frac{E_y}{H_x} = \frac{E_x}{H_y} = \frac{j\omega\mu}{\Gamma} = Z_0 \quad (61)$$

Using this definition of Z_0 in (58) and (59) yields

$$\frac{\partial H_z}{\partial y} = j\omega\varepsilon E_x - \frac{\Gamma E_x}{Z_0} = \left(j\omega\varepsilon - \frac{\Gamma}{Z_0}\right) E_x \quad (62)$$

$$\frac{\partial H_z}{\partial x} = -j\omega\varepsilon E_y + \frac{\Gamma E_y}{Z_0} = -\left(j\omega\varepsilon - \frac{\Gamma}{Z_0}\right) E_y \quad (63)$$

For the rectangular waveguide under consideration, $E_x = 0$ at $y = 0$ and $y = b$, and $E_y = 0$ at $x = 0$ and $x = a$. Thus, from (62) and (63), we obtain

$$\frac{\partial H_z}{\partial y} = 0 \quad \text{at } y = 0 \quad \text{and } y = b \quad (64)$$

and

$$\frac{\partial H_z}{\partial x} = 0 \quad \text{at } x = 0 \quad \text{and } x = a \quad (65)$$

are appropriate boundary conditions since H_z cannot vanish if a solution exists.

Applying the boundary conditions to the assumed solution

$$H_z = XYe^{-\Gamma z} = (A_1 \cos k_x x + B_1 \sin k_x x) \times (A_2 \cos k_y y + B_2 \sin k_y y) e^{-\Gamma z} \quad (66)$$

yields

$$H_z = H_{mn} \cos \frac{m\pi x}{a} \cos \frac{n\pi y}{b} e^{-\Gamma z} \quad (67)$$

where $k_x = m\pi/a$, $k_y = n\pi/b$, and m and n are integers corresponding to the mode variations in the x - y plane.

The remaining components of the TE waves are obtained as follows: From (62), we obtain

$$E_x = \frac{\frac{\partial H_z}{\partial y}}{j\omega\varepsilon - \frac{\Gamma}{Z_0}} = \frac{-k_x H_{mn} \cos k_x x \sin k_y y e^{-\Gamma z}}{j\omega\varepsilon - \frac{\Gamma}{Z_0}} \quad (68)$$

From (63)

$$E_y = \frac{\frac{\partial H_z}{\partial x}}{-j\omega\varepsilon + \frac{\Gamma}{Z_0}} = \frac{k_x H_{mn} \sin k_x x \cos k_y y e^{-\Gamma z}}{j\omega\varepsilon - \frac{\Gamma}{Z_0}} \quad (69)$$

From (61)

$$H_x = -\frac{E_y}{Z_0} \quad (70)$$

and

$$H_y = \frac{E_x}{Z_0} \quad (71)$$

If $a > b$ for the rectangular waveguide, the mode of lowest order is the TE_{10} , which has the cutoff frequency $f_c = v/2a$ and the field components

$$H_z = H_{10} \cos \frac{\pi x}{a} e^{-\Gamma z} \quad (72)$$

$$E_y = -j\eta \frac{2a}{\lambda} H_{10} \sin \frac{\pi x}{a} e^{-\Gamma z} = E_{10} \sin \frac{\pi x}{a} e^{-\Gamma z} \quad (73)$$

$$H_x = -\frac{E_y}{Z_0} \quad (74)$$

$$E_x = H_y = E_z = 0 \quad (75)$$

The cutoff frequency of the TE_{10} mode is

$$f_c = \frac{v}{2a} \sqrt{m^2 + n^2 \left(\frac{a}{b}\right)^2} = \frac{v}{2a} \quad (76)$$

Again, TE and TM waves share the same general expressions for propagation constant (Γ) and cutoff frequency (f_c), as expressed in Eqs. (24), (25), (51), and (52). For the two wave types, Γ and f_c differ in the choice of the integer mode numbers m and n . However, if the dimension b goes to infinity, creating a parallel-plate waveguide, then Γ and f_c are the same for both TE and TM waves. The characteristic impedance differs for the two wave types, as $Z_0 = \Gamma/(j\omega\epsilon) = \eta\sqrt{1 - (f_c/f)^2}$ for TM waves, and $Z_0 = j\omega\mu/\Gamma = \eta/\sqrt{1 - (f_c/f)^2}$ for TE waves, where $\eta = \sqrt{\mu/\epsilon}$ is the intrinsic impedance of the medium filling the guide. Thus, as frequency is increased from f_c to ∞ , Z_0 increases from 0 up to η for TM waves and decreases from ∞ down to η for TE waves.

For $f < f_c$, Γ is real, and the propagation term $e^{j\omega t - \Gamma z}$ from the wave equation becomes $e^{j\omega t - \alpha_g z}$, or

$$\Gamma = \omega\sqrt{\mu\epsilon}\sqrt{(f_c/f)^2 - 1} = \alpha_g \quad (77)$$

At operating frequencies below cutoff for the waveguide, the waves are attenuated by the factor α_g as they evanesce or diffuse along the guide in the z direction with no real wave propagation occurring. A waveguide below cutoff may be used as an attenuator. For example, if $f = 10$ GHz and $f_c = 13.12$ GHz (corresponding to $a = 0.45$ in. or 11.43 mm in an air-filled, TE_{10} waveguide), then $\alpha_g = 1.78$ Np/cm, or 15.46 dB/cm. Thus, the length is adjusted to yield a desired attenuation.

For $f < f_c$, the characteristic impedances are imaginary, as $Z_0 = \Gamma/(j\omega\epsilon) = -j\eta\sqrt{(f_c/f)^2 - 1}$ for TM waves, and $Z_0 = j\omega\mu/\Gamma = j\eta/\sqrt{(f_c/f)^2 - 1}$ for TE waves. This puts the transverse components of \mathbf{E} and \mathbf{H} 90° out of time phase, and tells us once again that time-average power cannot be transferred as a propagating wave. Thus, energy transfer along the guide is by evanescence or diffusion.

4. INTERPRETING Z_0 FOR TEM, TM, AND TE WAVES

Taking the propagation medium to be a lossless dielectric ($\sigma = 0$), the intrinsic impedance of the medium is $\eta = \sqrt{\mu/\epsilon}$. For TEM waves propagating in the z direction, the characteristic impedance is

$$Z_0 = \frac{V(z)}{I(z)} = \eta F(g) = \frac{E_x}{H_y} F(g) \quad (78)$$

where, as in Fig. 2a, the geometry function $F(g) = a/w$ for two parallel conducting strips of width w , separation a , and $w \gg a$; and $F(g) = (1/2\pi) \ln(b/a)$ for a coaxial line, if a is the inner conductor radius and b is the inner radius of the outer conductor.

For TM waves guided in the z direction, the characteristic impedance is

$$\begin{aligned} Z_0 &= \frac{\Gamma}{j\omega\epsilon} = \frac{j\omega\sqrt{\mu\epsilon}}{j\omega\epsilon} \sqrt{1 - \left(\frac{f_c}{f}\right)^2} \\ &= \eta \sqrt{1 - \left(\frac{f_c}{f}\right)^2} \end{aligned} \quad (79)$$

From a raypath diagram of the guided TM wave, as in Fig. 1b, Z_0 may also be determined as

$$Z_0 = \frac{E_x}{H_y} = \frac{E \sin \theta}{H} = \eta \sin \theta = \eta \sqrt{1 - \cos^2 \theta} \quad (80)$$

But, $\beta_z = \beta \sin \theta$ and $\beta_x = \beta \cos \theta$, and Z_0 becomes

$$Z_0 = \eta \frac{\lambda}{\lambda_z} = \eta \sqrt{1 - \left(\frac{\lambda}{\lambda_x}\right)^2} = \eta \sqrt{1 - \left(\frac{f_c}{f}\right)^2} \quad (81)$$

where $\lambda_z = \lambda_g$ is the wavelength along the direction of propagation or the wavelength along the guide, and $\lambda_x = \lambda_c$ is the cutoff wavelength.

For TE waves guided in the z direction, the characteristic impedance is

$$Z_0 = \frac{j\omega\mu}{\Gamma} = \frac{j\omega\mu}{j\omega\sqrt{\mu\epsilon}\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} = \frac{\eta}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} \quad (82)$$

From a raypath diagram of the guided TE wave, as in Fig. 1c, Z_0 may also be determined as

$$Z_0 = -\frac{E_y}{H_x} = \frac{E}{H \sin \theta} = \frac{\eta}{\sin \theta} = \frac{\eta}{\sqrt{1 - \cos^2 \theta}} \quad (83)$$

Again, $\beta_z = \beta \sin \theta$ and $\beta_x = \beta \cos \theta$, and Z_0 for TE waves becomes

$$Z_0 = \eta \frac{\lambda_z}{\lambda} = \frac{\eta}{\sqrt{1 - \left(\frac{\lambda}{\lambda_x}\right)^2}} = \frac{\eta}{\sqrt{1 - \left(\frac{f_c}{f}\right)^2}} \quad (84)$$

Table 1. Comparison Equations and Properties of TM, TE, and TEM Waves

TM Waves	TE Waves	TEM Waves
$H_z = 0$	$E_z = 0$	$E_z = H_z = 0$
$\Gamma = \sqrt{-\omega^2 \mu \epsilon + k_x^2 + k_y^2}$	$\Gamma = \sqrt{-\omega^2 \mu \epsilon + k_x^2 + k_y^2}$	$\gamma = \sqrt{-\omega^2 \mu \epsilon} = j\omega \sqrt{\mu \epsilon}$
$f_c = \frac{v}{2\pi} \sqrt{k_x^2 + k_y^2}$	$f_c = \frac{v}{2\pi} \sqrt{k_x^2 + k_y^2}$	$f_c = 0$
$\lambda_c = \frac{v}{f_c} = \frac{2\pi}{\sqrt{k_x^2 + k_y^2}}$	$\lambda_c = \frac{v}{f_c} = \frac{2\pi}{\sqrt{k_x^2 + k_y^2}}$	$\lambda_c = \infty$
$\beta_g = \sqrt{\omega^2 \mu \epsilon - (k_x^2 + k_y^2)}$	$\beta_g = \sqrt{\omega^2 \mu \epsilon - (k_x^2 + k_y^2)}$	$\beta = \omega \sqrt{\mu \epsilon}$
$\beta_g = \frac{2\pi}{\lambda} \sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}$	$\beta_g = \frac{2\pi}{\lambda} \sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}$	$\beta = \frac{2\pi}{\lambda}$
$\lambda_g = \frac{2\pi}{\beta_g} = \frac{\lambda}{\sqrt{1 - (\lambda/\lambda_c)^2}}$	$\lambda_g = \frac{2\pi}{\beta_g} = \frac{\lambda}{\sqrt{1 - (\lambda/\lambda_c)^2}}$	λ
$Z_0 = \frac{\Gamma}{j\omega \epsilon} = \eta \sqrt{1 - (\lambda/\lambda_c)^2}$	$Z_0 = \frac{j\omega \mu}{\Gamma} = \frac{\eta}{\sqrt{1 - (\lambda/\lambda_c)^2}}$	η
$v_g = \frac{\omega}{\beta_g}$	$v_g = \frac{\omega}{\beta_g}$	$v = \frac{\omega}{\beta}$
$Z(z) = Z_0 \frac{Z_L + jZ_0 \tan \beta_g z}{Z_0 + jZ_L \tan \beta_g z}$	$Z(z) = Z_0 \frac{Z_L + jZ_0 \tan \beta_g z}{Z_0 + jZ_L \tan \beta_g z}$	$Z(z) = Z_0 \frac{Z_L + jZ_0 \tan \beta z}{Z_0 + jZ_L \tan \beta z}$

and again, $\lambda_z = \lambda_g$ is the wavelength along the guide, and $\lambda_x = \lambda_c$ is the cutoff wavelength.

For convenient reference, selected equations, properties and parameters of waveguiding structures are collected in Table 1 and 2.

5. FREQUENCY BANDWIDTH OF WAVEGUIDES

As discussed in earlier sections, waveguides operate at frequencies above a specific cutoff frequency, and they may be subject to higher-order modes (higher than the funda-

Table 2. Features of Some Commercially Available Rectangular Waveguides

Figure 3. (a) The cutoff frequency of TE₁₀-mode waveguide is lowered by increasing the width a ; (b) the waveguide in (a) is folded for a more compact structure, and the new equivalent width is a' ; (c) a double-ridged version of (b), imaged along the horizontal bisector, has the same operating frequencies and bandwidth as in (b).

mental mode). Single-mode propagation is necessary for efficient transmission and detection of signal information on the carrier wave, and, of course, more information may be sent if the bandwidth is as large as possible. These restrictions may be troublesome at times, but there are ways to avoid most of the trouble.

5.1. Lowering the Cutoff Frequency of Waveguides

The bandwidth of a rectangular waveguide operating in the TE₁₀ mode is generally taken to be $1.25f_c \leq f \leq 1.90f_c$, where $f_c = v/2a$ is the TE₁₀-mode cutoff frequency. This is the choice because $f_1 = 1.25f_c$ is a convenient distance above $f = f_c$ (where $Z_0 = \infty$) and $f_2 = 1.90f_c$ is conveniently less than $f = 2f_c$ (where the first higher-order mode, TE₀₂, occurs if $2b < a$). Thus, the operating bandwidth is $f_2 - f_1 = 0.65f_c$.

To increase the bandwidth, we first lower the cutoff frequency of the TE₁₀ mode waveguide by increasing the wide dimension a in $f_c = v/2a$, as in Fig. 3a. To accommodate a large increase in the width a , the waveguide is folded such that the width is now $2b$ and the height is $(a + 2s)/2$, as in Fig. 3b.

In Fig. 3, the dotted path a' is longer than a because of the fringing capacitance across the gap s . The fringing capacitance is [3]

$$C_f = \epsilon \frac{4}{\pi} \ln \left(\coth \frac{\pi s}{2b} \right) \quad (85)$$

which is equivalent to a length increase given by

$$C_f = \epsilon \frac{2\Delta a}{b} \quad (86)$$

Thus

$$a' = a + 2\Delta a = a + \frac{4b}{\pi} \ln \left(\coth \frac{\pi s}{2b} \right) \quad (87)$$

In (87), if $s = 0.2b$ and $b = 0.5a$, then $a' = 1.715a$, and the resulting lower cutoff frequency for the TE₁₀ mode is $f'_c = v/2a' = f_c/1.715 = 0.583f_c$. The lower operating frequency is $f'_1 = 1.25f'_c = 0.729f_c$. The upper operating frequency remains the same at $f'_2 = f_2 = 1.90f_c$, since the electric field of the TE₂₀ mode is zero across the gap s and little or no fringing capacitance occurs to increase the pathlength. Thus, the new operating bandwidth is $f'_2 - f'_1 = (1.90 - 0.729)f_c = 1.171f_c$, rather than $0.65f_c$.

Example 1. Given $a = 12.5$ cm, $b = 0.5a = 6.25$ cm, and $s = 0.2b = 1.25$ cm, determine the operating frequencies and bandwidth for exclusive TE₁₀ mode operation in (a) the rectangular waveguide and (b) the folded rectangular waveguide in Fig. 3b.

Solution: (a) For the rectangular waveguide

$$f_c = \frac{v}{2a} = \frac{3 \times 10^8}{0.25} = 1200 \text{ MHz} \quad (88)$$

$$f_1 = 1.25f_c = 1500 \text{ MHz} \quad (89)$$

$$f_2 = 1.90f_c = 2280 \text{ MHz} \quad (90)$$

$$\text{BW} = f_2 - f_1 = 780 \text{ MHz} \quad (91)$$

(b) For the folded rectangular waveguide in Fig. 3b, we obtain

$$f'_c = \frac{v}{2a'} = 0.583f_c = 700 \text{ MHz} \quad (92)$$

$$f'_1 = 1.25f'_c = 875 \text{ MHz} \quad (93)$$

$$f'_2 = f_2 = 1.90f_c = 2280 \text{ MHz} \quad (94)$$

$$\text{BW} = f'_2 - f'_1 = 1405 \text{ MHz} \quad (95)$$

The folded waveguide considered here is more commonly known as a single-ridged waveguide with a ridge thickness approaching zero ($t \cong 0$). A double-ridged version using the same configuration (same operating frequencies and bandwidth as in Fig. 3b) is shown in Fig. 3c. More commonly used relative dimensions are shown in Figs. 4a and 4b for single-ridged and double-ridged waveguides, respectively [4]. Another variation on the same theme is the T-septum waveguide, single and double, as shown in Figs. 4c and 4d [5–7].

6. DIELECTRIC WAVEGUIDES

An electromagnetic wave is guided by a dielectric material [8] of permittivity ϵ_1 surrounded by another dielectric material of permittivity ϵ_2 , where $\epsilon_1 > \epsilon_2$, as illustrated in

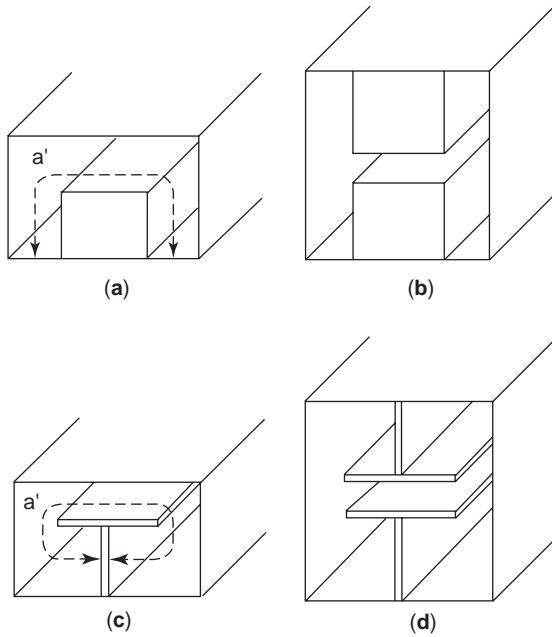

Figure 4. More commonly used relative dimensions for (a) a single-ridged waveguide and (b) a double-ridged waveguide. Other variants are (c) the single T-septum waveguide and (d) the double T-septum waveguide.

Fig. 5a and the top view along the propagation direction in Fig. 5c. If θ is the angle of the guided ray to the interface normal, and ϕ is the angle to the normal interface of any ray that transmits into material 2, then by Snell's law of refraction

$$\sqrt{\epsilon_1} \sin \theta = \sqrt{\epsilon_2} \sin \phi \quad (96)$$

Requiring $\phi = 90^\circ$ for total internal reflection yields

$$\theta = \sin^{-1} \sqrt{\frac{\epsilon_2}{\epsilon_1}} \triangleq \theta_c \quad (97)$$

Thus, with $\epsilon_1 > \epsilon_2$, the wave is guided along material 1 for all angles $\theta \geq \theta_c$. While most of the guided wave is in material 1, part of the wave protrudes into material 2 and propagates along the interface.

For TE waves, $E_x = 0$, $E_z = 0$, and

$$\mathbf{E} = \hat{y}E_y(x)e^{-j\beta z} = \hat{y}E_y(x, z) \quad (98)$$

where $\beta = \omega\sqrt{\mu\epsilon_e}$ is the propagation constant of the guided wave that propagates through an effective permittivity that has the range: $\epsilon_2 \leq \epsilon_e \leq \epsilon_1$. Note that $\partial\mathbf{E}/\partial z = -j\beta\mathbf{E}$, and $\partial\mathbf{E}/\partial y = 0$, but $\partial\mathbf{E}/\partial x \neq 0$, since the permittivity changes along the x dimension. Substituting these specifications into Maxwell's curl equations yields

$$\frac{\partial E_y}{\partial x} = -j\omega\mu H_z \quad (99)$$

Figure 5. (a) Dielectric waveguide of permittivity ϵ_1 surrounded by permittivity ϵ_2 , where $\epsilon_1 > \epsilon_2$ and $2d \ll h$; (b) electric field distributions along x for the first two even modes (cosine terms) and the first two odd modes (sine terms)—as in Fig. 6, the phase angle from center to edge $\beta_{1x}d$ in increasing mode order is $0 < \beta_{1x}d < \pi/2$, $\pi/2 < \beta_{1x}d < \pi$, $\pi < \beta_{1x}d < 3\pi/2$, and $3\pi/2 < \beta_{1x}d < 2\pi$; (c) a TE wave guided in the z direction between the sides $2d$ apart.

and

$$j\beta E_y = -j\omega\mu H_x \quad (100)$$

from $\nabla \times \mathbf{E} = -j\omega\mu\mathbf{H}$, and

$$-j\beta H_x - \frac{\partial H_z}{\partial x} = j\omega\epsilon E_y \quad (101)$$

from $\nabla \times \mathbf{H} = j\omega\epsilon\mathbf{E}$.

Substituting (99) and (100) into (101) yields

$$\frac{\partial^2 E_y}{\partial x^2} = (\beta^2 - \omega^2 \mu \epsilon) E_y \quad (102)$$

which is valid in both material 1 and material 2 and has the general solution

$$E_y = A_i e^{-\sqrt{\beta^2 - \omega^2 \mu \epsilon} x} \quad (103)$$

Thus, in material 1 ($\epsilon_1 > \epsilon_2$), we obtain

$$\begin{aligned} E_y &= A_i e^{-\sqrt{\beta^2 - \omega^2 \mu \epsilon_1} x} = A_i e^{-j \sqrt{\omega^2 \mu \epsilon_1 - \beta^2} x} \\ &= A_i e^{-j \beta_{1x} x} = A \cos \beta_{1x} x + B \sin \beta_{1x} x \end{aligned} \quad (104)$$

where

$$\beta_{1x}^2 = \omega^2 \mu \epsilon_1 - \beta^2 = \beta_1^2 - \beta^2 \quad (105)$$

The $\cos \beta_{1x} x$ and $\sin \beta_{1x} x$ solutions in (104) allow harmonic modes of the propagating wave across the x dimension in material 1. In material 2 ($\epsilon_2 < \epsilon_1$)

$$E_y = A_i e^{-\sqrt{\beta^2 - \omega^2 \mu \epsilon_2} x} = C e^{-\alpha_2 x} \quad (106)$$

where

$$\alpha_2^2 = \beta^2 - \omega^2 \mu \epsilon_2 = \beta^2 - \beta_2^2 \quad (107)$$

which shows that E_y decreases exponentially in the x direction.

Tangential components of E and H must be continuous across the interface between materials 1 and 2, and this condition is used to determine additional characteristics of the propagating modes. Equating E_y terms at $x = d$, and using the $E_y = A \cos \beta_{1x} x$ solution from (104), we obtain

$$A \cos \beta_{1x} d = C e^{-\alpha_2 d} \quad (108)$$

or

$$C = A e^{\alpha_2 d} \cos \beta_{1x} d \quad (109)$$

Thus, in material 2 at $x \geq d$, we have

$$\begin{aligned} E_y &= (A e^{\alpha_2 d} \cos \beta_{1x} d) e^{-\alpha_2 x} \\ &= (A \cos \beta_{1x} d) e^{-\alpha_2 (x-d)} \end{aligned} \quad (110)$$

Equating $H_{1z} = H_{2z}$ at $x = d$ by using $\partial E_y / \partial x = -j \omega \mu H_z$ as given by (99), we obtain

$$H_{1z} = \frac{1}{-j \omega \mu} \frac{\partial}{\partial x} (A \cos \beta_{1x} x) = \frac{\beta_{1x} A}{j \omega \mu} \sin \beta_{1x} x \quad (111)$$

$$H_{2z} = \frac{1}{-j \omega \mu} \frac{\partial}{\partial x} (C e^{-\alpha_2 x}) = \frac{\alpha_2 C}{j \omega \mu} e^{-\alpha_2 x} \quad (112)$$

and at $x = d$

$$\begin{aligned} \beta_{1x} A \sin \beta_{1x} d &= \alpha_2 C e^{-\alpha_2 d} \\ &= \alpha_2 (A e^{\alpha_2 d} \cos \beta_{1x} d) e^{-\alpha_2 d} \end{aligned} \quad (113)$$

or

$$\tan \beta_{1x} d = \frac{\alpha_2}{\beta_{1x}} \quad (114)$$

is obtained for the choice $E_y = A \cos \beta_{1x} x$ in material 1. If the equally valid $E_y = B \sin \beta_{1x} x$ had been chosen as the solution in material 1, the result of matching tangential fields at $x = d$ would have been

$$\tan \beta_{1x} d = -\frac{\beta_{1x}}{\alpha_2} \quad (115)$$

The electric field distributions along the x dimension for the first four modes, two even (cosine terms), and two odd (sine terms), are shown in Fig. 5b. Note the corresponding phase angle $\beta_{1x} d$ from center to edge for each mode as listed in the caption for Fig. 5b. These phase angles and the propagating modes that are allowed may be determined by graphically solving the transcendental eigenvalue equations $\tan \beta_{1x} d = \alpha_2 / \beta_{1x}$ and $\tan \beta_{1x} d = -\beta_{1x} / \alpha_2$.

From the expressions defined earlier, $\alpha_2^2 = \beta^2 - \omega^2 \mu \epsilon_2$ and $\beta_{1x}^2 = \omega^2 \mu \epsilon_1 - \beta^2$, express

$$\frac{\alpha_2}{\beta_{1x}} = \sqrt{\frac{\omega^2 \mu (\epsilon_1 - \epsilon_2)}{\beta_{1x}^2} - 1} \quad (116)$$

Next, define and then substitute the term

$$\begin{aligned} V &\triangleq \sqrt{\omega^2 \mu (\epsilon_1 - \epsilon_2) d^2} = \omega d \sqrt{\mu \epsilon_0} \sqrt{\epsilon_{1r} - \epsilon_{2r}} \\ &= \frac{\omega d}{c} \sqrt{\epsilon_{1r} - \epsilon_{2r}} = \frac{2\pi d}{\lambda_0} \sqrt{\epsilon_{1r} - \epsilon_{2r}} \end{aligned} \quad (117)$$

to obtain

$$\tan \beta_{1x} d = \frac{\alpha_2}{\beta_{1x}} = \sqrt{\left(\frac{V}{\beta_{1x} d}\right)^2 - 1} \quad (118)$$

for the even modes, and

$$\tan \beta_{1x} d = -\frac{\beta_{1x}}{\alpha_2} = \frac{-1}{\sqrt{\left(\frac{V}{\beta_{1x} d}\right)^2 - 1}} \quad (119)$$

Figure 6. First and last terms of (118) and (119) plotted against $\beta_{1x}d$ for the case when $V = 6$. For this value of V , two even modes and two odd modes are allowed to propagate.

for the odd modes. The operating frequency and the parameters of the dielectric waveguide set the value of V (called the *normalized frequency*). The first and last terms of (118) and (119) are plotted against $\beta_{1x}d$, and the particular points of the curves give the allowed modes and the particular value of $\beta_{1x}d$ for that mode. An example is plotted in Fig. 6 for the case when $V = 6$. For this value of V , two even modes and two odd modes are allowed to propagate. Observe from the plot that if $V < 3\pi/2$, only three modes could propagate (two evens and one odd). Also, if $V < \pi/2$, only one mode could propagate (the lowest-order even mode).

Example 2. A dielectric sheet of thickness $2d = 0.002$ m and permittivity $\epsilon_1 = 3.25\epsilon_0$ is surrounded by air ($\epsilon_2 = \epsilon_0$). (a) Over what range of operating frequencies will no more than three modes propagate? (b) Over what range of operating frequencies will only one mode propagate?

Solution:

$$V = \frac{2\pi fd}{c} \sqrt{\epsilon_{1r} - \epsilon_{2r}}$$

$$= \frac{2\pi f \cdot 0.001}{3 \times 10^8} \sqrt{3.25 - 1} = \pi f \times 10^{-11}$$

(a) For $\pi f \times 10^{-11} < 3\pi/2$, three modes propagate in the range $f < 150$ GHz.

(b) For $\pi f \times 10^{-11} < \pi/2$, only one mode propagates in the range $f < 50$ GHz.

As indicated earlier, β , the propagation constant of waves or modes that are guided in the z direction, lies within the range $\beta_2 \leq \beta \leq \beta_1$, where $\beta_1 = \omega\sqrt{\mu_0\epsilon_1}$ and $\beta_2 = \omega\sqrt{\mu_0\epsilon_2}$. Also, the raypaths of guided waves may have θ angles that lie within the range $\theta_c \leq \theta \leq 90^\circ$, where $\theta_c = \sin^{-1} \sqrt{\epsilon_2/\epsilon_1}$ is the angle of the critical ray and $\theta = 90^\circ$ is the angle of the axial ray. So, how do the angles of the raypaths relate to the propagation constant of modes or waves? From the raypath diagram in Fig. 5c, the propa-

gation constant of modes guided in the z direction is

$$\beta = \beta_1 \sin \theta = \omega\sqrt{\mu_0\epsilon_1} \sin \theta \tag{120}$$

For axial rays ($\theta = 90^\circ$)

$$\beta = \beta_1 = \omega\sqrt{\mu_0\epsilon_1} \tag{121}$$

This is the largest value of β , and it occurs at the highest operating frequency of a particular mode, since β is directly proportional to frequency.

For rays at $\theta = \theta_c$, we obtain

$$\beta = \omega\sqrt{\mu_0\epsilon_1} \sqrt{\frac{\epsilon_2}{\epsilon_1}} = \omega\sqrt{\mu_0\epsilon_2} = \beta_2 \tag{122}$$

This is the smallest value of β , and it occurs at the lowest operating frequency of a particular mode. Also, at $\theta = \theta_c$ where $\beta = \beta_2$, we have from (105)

$$\beta_{1x}^2 = \omega^2 \mu \epsilon_1 - \beta^2 = \omega^2 \mu \epsilon_1 - \omega^2 \mu \epsilon_2 \tag{123}$$

or

$$\beta_{1x} = \omega\sqrt{\mu\sqrt{\epsilon_1 - \epsilon_2}} = \frac{V}{d} \tag{124}$$

Thus, rays at $\theta = \theta_c$ within a particular mode have $\beta_{1x}d = V$, which is at the point of extinction or cutoff for the mode. The relationships discussed above are indicated on the plot of β versus radian frequency ω in Fig. 7. Note from the plot that at a single operating frequency, many different modes may be propagating, and the highest-order modes have ray paths at $\theta = \theta_c$, while the lowest-order modes have axial rays ($\theta = 90^\circ$).

Example 3. (a) A dielectric waveguide has $\epsilon_{1r} = 2.34$, $\epsilon_{2r} = 2.28$, $d = 5 \mu\text{m}$ and $f = 318.31$ THz, which yields a normalized frequency of $V = (\omega d/c)\sqrt{\epsilon_{1r} - \epsilon_{2r}} = 8.22$. The

Figure 7. Plot of β versus radian frequency ω . Note from the plot that at a single operating frequency, many different modes may be propagating, and the highest-order modes have raypaths near the critical angle, while the lowest-order modes are nearly axial.

eigenvalues of each propagating mode are $\beta_{1x}d = 1.400, 2.491, 4.179, 5.543, 6.865, \text{ and } 8.045$. Find the propagation angle (θ to the interface normal) for each mode. (b) Is the raypath of the highest-order mode near the critical angle ($\theta = \theta_c$) or near the axial angle ($\theta = 90^\circ$)?

Solution: The propagation constant along a ray path within the waveguide is

$$\beta_1 = \omega\sqrt{\mu_0\epsilon_1} = \frac{\omega\sqrt{\epsilon_{1r}}}{c} = \frac{1.02 \times 10^7}{\text{m}} \quad (125)$$

The propagation constant along the x direction is $\beta_{1x} = \beta_1 \cos \theta_1$, where from the data, we have

$$\beta_{1x} = \frac{0.28, 0.498, 0.8358, 1.1086, 1.373, 1.609 \times 10^6}{\text{m}} \quad (126)$$

Thus

$$\theta = \cos^{-1} \frac{\beta_{1x}}{\beta_1} = 88.43^\circ, 87.20^\circ, 85.30^\circ, 83.76^\circ, 82.26^\circ, 80.92^\circ \quad (127)$$

Observe that the highest-order mode is near the critical angle, $\theta_c = \sin^{-1} \frac{1.51}{1.53} = 80.72^\circ$, and the lowest-order mode is nearly axial (90°).

Example 4. (a) A dielectric waveguide has $\epsilon_{1r} = 2.19$ and $\epsilon_{2r} = 2.16$. For single-mode propagation at the following wavelengths (in air), $\lambda_0 = 1.3, 1.4, 1.5, 1.6 \mu\text{m}$, the eigenvalues are $\beta_{1x}d = 0.9336, 0.9027, 0.8734, 0.8456$, respectively. Find the propagation angle (θ to the interface normal) for each wavelength if $d = 1.89 \mu\text{m}$. (b) Is the shortest wavelength closest to the critical ray ($\theta = \theta_c$) or to the axial ray ($\theta = 90^\circ$)?

Solution: The normalized frequency (V) in the order of increasing wavelength (in μm) is

$$V = \frac{2\pi d}{\lambda} \sqrt{\epsilon_{1r} - \epsilon_{2r}} = \frac{2.042}{\lambda_0} \quad (128)$$

$$= 1.5708, 1.4586, 1.3613, 1.2763$$

Using this result, the eigenvalue at each wavelength is found by solving

$$\tan \beta_{1x}d = \sqrt{\left(\frac{V}{\beta_{1x}d}\right)^2 - 1} = \sqrt{\left(\frac{2.042}{\lambda\beta_{1x}d}\right)^2 - 1} \quad (129)$$

to yield $\beta_{1x}d = 0.9336, 0.9027, 0.8734, 0.8456$, and $\beta_{1x} = (0.4940, 0.4776, 0.4621, 0.4474) \times 10^6/\text{m}$. At each wavelength, $\beta_1 = 2\pi\sqrt{\epsilon_{1r}}/\lambda_0 = 7.1532, 6.6422, 6.1994, 5.8119 \times 10^6/\text{m}$.

Thus

$$\theta = \cos^{-1} \frac{\beta_{1x}}{\beta_1} = 86.04^\circ, 85.88^\circ, 85.72^\circ, 85.58^\circ \quad (130)$$

in the order of increasing wavelength. Note that the shortest wavelength is closest to the axial ray ($\theta = 90^\circ$), and the longest wavelength is closest to the critical ray ($\theta = \theta_c = 83.34^\circ$).

GUNN OR TRANSFERRED-ELECTRON DEVICES AND CIRCUITS

HERIBERT EISELE
University of Leeds
Leeds, United Kingdom

1. GENERAL

Among all solid-state microwave devices, transferred-electron devices (TEDs), often called *Gunn devices*, are quite unique in that they utilize specific bulk-material properties of certain semiconductors. They are unipolar devices and, generally, do not exhibit the distinctive diode characteristic of p-n (positive-negative) junctions as seen, for example, in other two-terminal microwave devices such as impact ionization avalanche transit-time (IMPATT) or tunnel injection transit-time (TUNNETT) diodes. Originally, TED structures and circuits were developed for both

amplifier and oscillator applications. However, rapid progress in high-speed and high-frequency three-terminal devices with excellent noise performance has practically been eliminating TEDs from all low-noise preamplifier applications up to the high-millimeter-wave frequencies. Additionally, oscillators or amplifiers with three-terminal devices continue to reach higher and higher frequencies and offer similar or even higher radiofrequency (RF) output power levels and direct-current (DC)-to-RF conversion efficiencies compared to the most powerful two-terminal devices such as IMPATT diodes. TEDs in oscillator applications are characterized by low-noise and medium-RF output power P_{RF} . Therefore, they are well suited for local oscillators in sensitive heterodyne receivers and for transmitters at operating frequencies above 30 GHz.

2. PRINCIPLES OF OPERATION

The transferred-electron effect only depends on a specific band structure of the semiconductor material and, therefore, is present in the bulk material. Several materials, mainly in groups III–V and II–VI compound semiconductors and listed in Table 1 [1–3] exhibit such a band structure. These semiconductor materials have more than one energy minimum (i.e., valley in the conduction band) and meet the following criteria, which were proposed independently by Ridley and Watkins [4] as well as Hilsum [5] (RWH):

1. At least two valleys must be present in the conduction band.
2. The minimum (minima) of the upper valley(s) must be several times the thermal energy of electrons above the minimum of the lowest (= main) valley in the conduction band for electrons to reside initially in the lowest valley.
3. The energy difference (ΔE) between the minimum (minima) of the upper valley(s) and the minimum of the main valley in the conduction band must be less

than the energy bandgap E_g to avoid the onset of significant impact ionization in such a device.

4. The transfer of electrons from one conduction band valley to another must require much less time than one period of the intended operating frequency.
5. The effective masses and densities of states in the upper valley(s) must be considerably higher than in the main valley. As a consequence of the higher effective masses, mobilities in the upper valley(s) must be much lower than in the main valley.

For the principles of operation, a homogeneous bulk semiconductor material and a simplified band structure as shown in Fig. 1 are assumed. Electrons at low energies initially reside in the main valley of the conduction band, where a low effective mass corresponds to a high mobility μ_1 . When electrons acquire more energy (e.g., under an electric field \mathcal{E}), most of them still remain in the main valley if $\mathcal{E} < \mathcal{E}_{th}$, where \mathcal{E}_{th} is referred to as the *threshold electric field*. As electrons acquire even more energy (for $\mathcal{E} > \mathcal{E}_{th}$), many of them are scattered (“transferred”) into the upper valley, where a higher effective mass corresponds to a lower mobility μ_2 [1]. For an electric field \mathcal{E} , assumed to be constant in the bulk material, an average electron velocity v_{avg} and average mobility μ_{avg} can be defined as

$$v_{avg} = \frac{n_1\mu_1 + n_2\mu_2}{n_1 + n_2} \mathcal{E} = \mu_{avg} \mathcal{E} \tag{1}$$

where n_1 and n_2 denote the number of electrons in the lower and upper valleys, respectively. Since n_1 decreases and n_2 increases, v_{avg} decreases as shown in Fig. 2. At large energies [i.e., high electric fields ($\mathcal{E} \gg \mathcal{E}_{th}$)], most of the electrons are transferred to the upper valley and $n_1 \ll n_2$. Therefore, after reaching the minimum value, the average drift velocity again increases for higher electric fields. The decrease in the average drift velocity for $\mathcal{E} > \mathcal{E}_{th}$ generates a region of negative differential

Figure 1. Simplified energy-band diagram for a direct two-valley semiconductor showing electron transfer: (a) electron distribution for $\mathcal{E} < \mathcal{E}_{th}$; (b) electron distribution for $\mathcal{E} > \mathcal{E}_{th}$; (c) electron distribution for $\mathcal{E} \gg \mathcal{E}_{th}$.

mobility μ_{diff} with

$$\mu_{diff} = \frac{dv_{avg}}{d\mathcal{E}} \quad (2)$$

If electrons in the upper valley reach a region where the electric field \mathcal{E} drops below \mathcal{E}_{th} , they lose energy and significantly more of them are scattered back to the main valley.

James B. Gunn was the first to observe current oscillations experimentally in bulk GaAs and InP [6,7], which were subsequently explained by this transferred-electron effect [8]. As a result, the term *Gunn device* quickly became common for this type of device. Out of more than 10 semiconductor materials known for the transferred-electron effect, only GaAs and InP have so far found widespread use in system applications. GaAs and InP have three valleys in the conduction band, and at the doping concentrations required for operation at millimeter-wave frequencies, high-field mobilities are considerably lower than the low-field mobilities. As a consequence of two upper valleys and additional scattering mechanisms, the electron drift velocity v monotonically decreases for electric fields above \mathcal{E}_{th} . Figure 3 shows simplified band structure diagrams for GaAs and InP, and Fig. 4 their respective velocity–electric field profiles. Table 2 [9–11] summarizes the relevant material characteristics of GaAs and InP. The finite time it takes for electrons to gain or lose energy in an electric field causes a fundamental physical frequency limit in these devices. This frequency limit

Figure 2. Velocity–electric field profile for the two-valley semiconductor of Fig. 1.

was originally thought to be approximately 100 and 200 GHz [9–11] for TEDs based on the GaAs and InP material systems, respectively. However, more recent theoretical and experimental work indicates a significantly higher frequency limit in InP-based TEDs.

Except for some rare conditions in devices at lower microwave frequencies, the bulk negative differential mobility alone does not cause a static negative differential resistance (NDR) to be used for RF power generation. A mechanism based on the negative differential mobility results in a dynamic negative resistance as shown next. In a region of bulk semiconductor material under uniform conditions (doping concentration N_D , electric field \mathcal{E} , average differential mobility μ_{diff}), any space charge inhomogeneity $Q_S(x,t)$ traveling at the velocity v grows or decays following an exponential law that can be derived from Maxwell's equations:

$$Q_S(x,t) = Q_S(x - vt, 0) \exp\left(-\frac{t}{\tau}\right) \quad (3)$$

where

$$\tau = \frac{\epsilon_s}{\sigma} = \frac{\epsilon_s}{qN_D\mu_{diff}} \quad (4)$$

Figure 3. Simplified band diagram for the three-valley semiconductor materials GaAs and InP.

Figure 4. Velocity–field profile for the three-valley semiconductor materials GaAs and InP.

where, q denotes the elementary charge; σ and ϵ_s denote specific conductivity and dielectric constant of the material, respectively. At low electric fields \mathcal{E} , where $\mu_{\text{diff}} > 0$, the charge inhomogeneity decays with $\tau = \tau_D$, the dielectric relaxation time, and at higher electric fields, where $\mu_{\text{diff}} < 0$, a charge inhomogeneity can grow. This charge inhomogeneity reaches a significant level only if the growth factor for the maximum traveled distance l , the length of the active region of the device, is very large. Therefore the condition

$$\frac{l}{v|\tau|} = \frac{lqN_D|\mu_{\text{diff}}|}{\epsilon_s v} > 1 \tag{5}$$

must be satisfied, which corresponds to

$$N_D l > 1 \times 10^{12} \text{ cm}^{-2} \tag{6}$$

for both GaAs and InP.

Figure 5. Carrier concentrations and electric field profile for a dipole domain.

Typical Gunn devices at millimeter-wave frequencies have $N_D l$ products between $1 \times 10^{12} \text{ cm}^{-2}$ and $3 \times 10^{12} \text{ cm}^{-2}$, and doping concentrations N_D in the active region exceed 10^{15} cm^{-3} . For $N_D > 10^{15} \text{ cm}^{-3}$, space charge inhomogeneities typically grow into so-called dipole domains where accumulation and depletion layers are lumped together. Figure 5 shows the carrier distribution and electric-field profile for such a dipole domain under uniform conditions. Electrons in the low-field region travel at a constant v_T for a constant electric field \mathcal{E}_1 . Electrons in region a are accelerated by the higher electric field until they reach region b , where they are transferred to the upper valley and slow down to be trapped in this accumulation region. Electrons in region c lose energy and are transferred back to the lower valley. Their average velocity now is higher than the average velocity in region b , thus region c is depleted of electrons. After a domain forms at the cathode, grows, and propagates through the active region, the voltage drop across the domain increases and, under a constant bias voltage, lowers the voltage drop outside the domain. This voltage drop is equivalent to a reduction in the electric field \mathcal{E}_1 outside the domain and generally prevents formation of new domains in the active region. It also limits the growth of the existing domain because fewer electrons are trapped in the accumulation layer or escape the depletion layer. Domains reaching the anode collapse and induce a current flow in the external circuit. A phase difference occurs between this current flow and the applied RF voltage and, at the right frequency, this phase difference corresponds to a dynamic negative resistance and causes RF power generation in an appropriate RF circuit.

Distinct modes of operation have been investigated and described for TEDs at microwave frequencies [12].

However, as is shown next, at millimeter-wave frequencies finite intervalley transfer and domain formation times reach a significant fraction of the RF cycle. In such a case, domains form, grow, and suppress formation of new domains, but may never reach the stable state before they reach the anode as described above. Therefore, modes get blurred, and devices generally operate in a near transit-time mode, where the operating frequency f_{op} is given by

$$\frac{1}{T} = f_{op} = \frac{v_T}{l} \quad (7)$$

The effective transit velocity $v_T = v(\mathcal{E}_1) = v_D(\mathcal{E}_h)$ can be determined from Butcher's equal-area rule [13], which is

$$\int_{\mathcal{E}_1}^{\mathcal{E}_h} [v(\mathcal{E}) - v_D] d\mathcal{E} = 0 \quad (8)$$

for a constant diffusion coefficient throughout the active region and is illustrated in Fig. 6.

If the operating frequency f_{op} differs somewhat from Eq. (7), the domain reaches the anode prematurely or is delayed. Similar to the operation of transit-time diodes, the current pulse from the collapsing domain still causes a negative resistance and generates RF power. Therefore, operation over a broad bandwidth can be achieved. Additionally, higher bias voltages increase electric fields in the device, and higher electric fields reduce the domain velocity v_D , as seen in Fig. 6. At higher electric fields, electrons also acquire the energy for intervalley transfer over a shorter distance as is described in more detail in a subsequent section. Consequently, the portion of the active region where domains form and travel is increased. Lower v_D and longer domain travel distance correspond to a lower optimum f_{op} .

Figure 7 gives an overview of typical structures and schematic doping profiles for TEDs that yielded (Figs. 7a, 7b, 7d, 7e) or are expected to yield (Fig. 7c) excellent RF performance in oscillators. The three-zone flat-doping and the two-zone flat-doping structures were the first to be exploited because they are easy to grow in more classical growth systems such as liquid-phase or vapor-phase epitaxy (LPE or VPE). The three-zone flat-doping structure [14] consists of the n^- -doped active region sandwiched between the highly doped n^+ regions for the ohmic contacts. Since low-ohmic alloyed contacts can be formed on

Figure 6. Equal-area rule for TEDs.

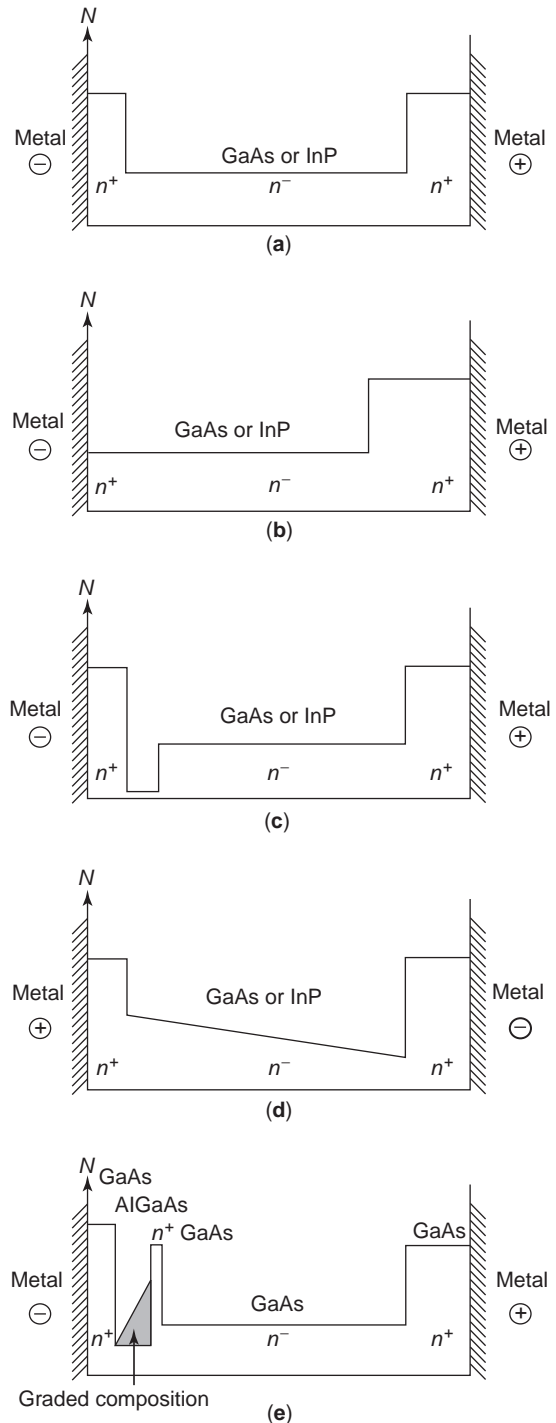

Figure 7. Different device structures for TEDs: (a) three-zone flat doping; (b) two-zone flat doping; (c) three-zone flat doping with cathode notch; (d) three-zone graded doping; (e) heterojunction barrier cathode.

n -type GaAs and InP, the highly doped region on the cathode side can be omitted and just a two-zone, flat-doping structure needs to be grown by VPE or LPE.

The advent of advanced growth techniques such as molecular-beam epitaxy (MBE), metallorganic chemical vapor deposition (MOCVD), metallorganic molecular-beam

epitaxy (MOMBE), and chemical-beam epitaxy (CBE) has allowed more complicated structures to be grown. Using these growth techniques, graded-doping profiles and heterojunction barriers as shown in Fig. 7 can be incorporated into the device structures and suitably tailored to optimize device performance at a particular frequency or to extend the frequency limit of TEDs. Computer simulations [11,15,16] have revealed that in a three-zone flat-doping structure, “cold” electrons with low energies enter the active region from the contact zone at the cathode and require some time to acquire enough energy before they transfer to the upper valley. The results of such Monte Carlo simulations [16] at a frequency of 95 GHz are illustrated in Fig. 8 for a three-zone flat-doping structure in InP with a doping of $1 \times 10^{16} \text{ cm}^{-3}$ in the active region. The finite-energy relaxation times, which are shown in Fig. 9 as a function of the electron energy in GaAs and InP,

create a huge so-called “dead space” at the beginning of the 1.7- μm -long active region. As can be seen from Fig. 8c, the average energy E of electrons within the dead space does not reach the threshold energy E_{th} for intervalley transfer, and electrons reside mostly in the main valley. Therefore, the differential mobility remains positive, and space charge inhomogeneities are prevented from growing, which is illustrated in Fig. 8b with insignificant electron accumulation within the dead space. As a consequence, the resistance of the device $R(x)$ [i.e., the real part of $\mathbf{Z}(x)$] as a function of the position x

$$\mathbf{Z}(x) = R(x) + j\mathbf{X}(x) = \frac{\int_0^x \mathcal{E}(x') dx'}{\frac{A}{l} \int_0^x \mathbf{J}(x') dx'} \quad (9)$$

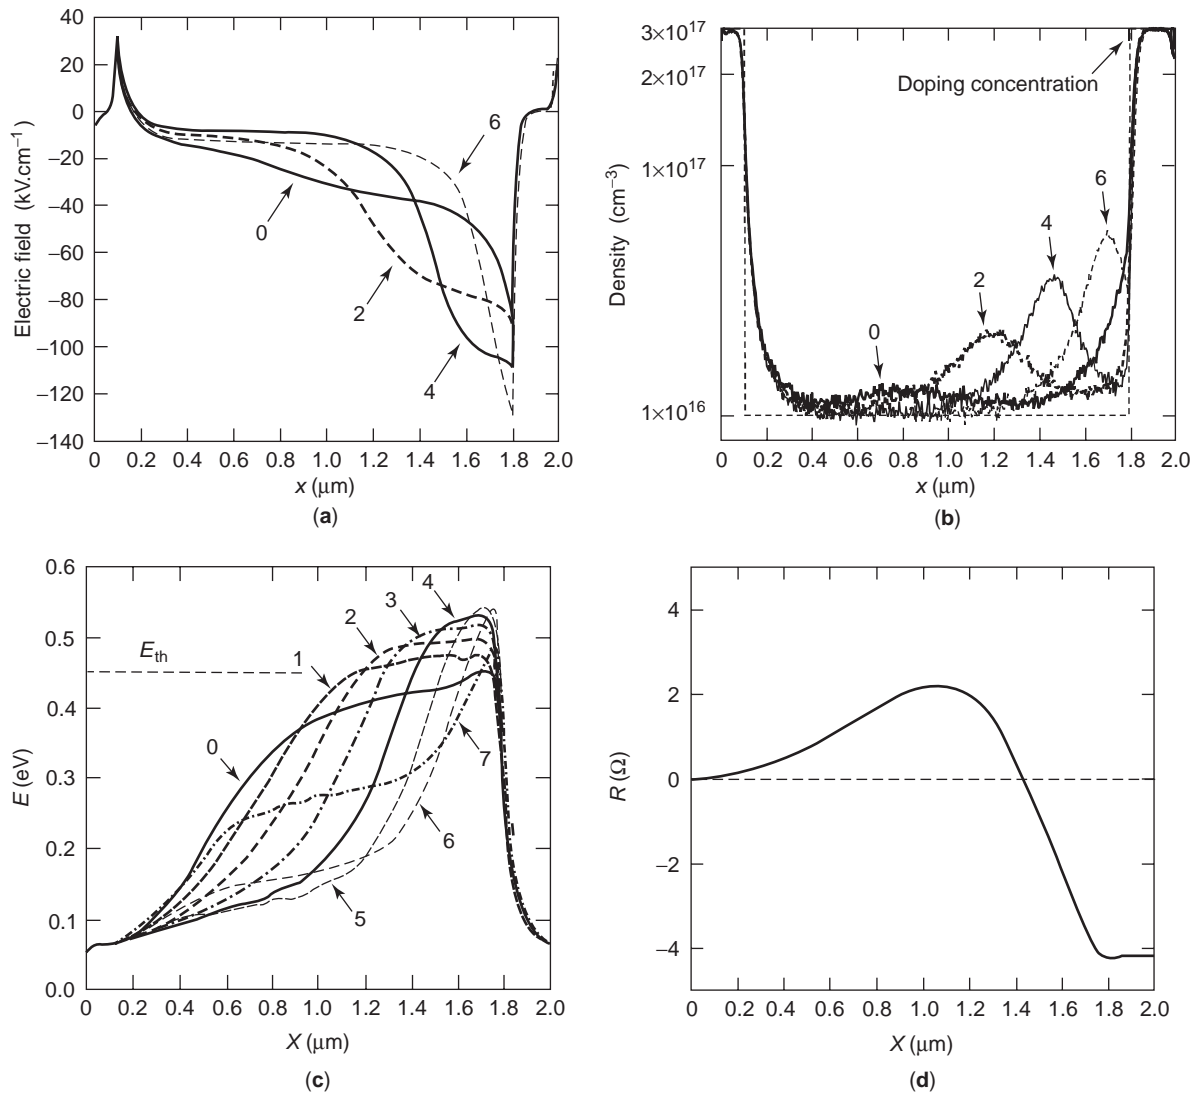

Figure 8. Evolution of (a) electric field, (b) electron density, (c) average electron energy E , and (d) diode resistance R against position x (active region 0.1–1.8 μm): $f = 95 \text{ GHz}$, $V_{\text{rf}} = 1.0 \text{ V}$, $V_{\text{bias}} = 5.0 \text{ V}$, $I_{\text{bias}} = 474 \text{ mA}$, $T = 500 \text{ K}$. The graphs in parts (a), and (b) show the electric field and the electron density, respectively, at $\omega t = n\pi/4$, $n = 0, 2, 4, 6$, and part (c) shows the electron energy profile at $\omega t = n\pi/4$, $n = 0 \dots 7$, during one RF cycle.

Figure 9. Energy relaxation times τ_e in GaAs and InP against electron energy E . (After Rolland et al. [15].)

remains positive for a large fraction of the active region and contributes to losses in this dead-space region, whereas a negative resistance contributes to the RF power generation only for a small fraction of the active region. In Eq. (9), A and J , denote the device area and total current density, respectively. In addition to this dead-space region, the peak electric field occurs near the anode, and, at a high DC bias, the electric field may reach values for the onset of avalanche breakdown. The energy-dependent energy relaxation times of Fig. 9 lead to effective transfer time constants as shown in Table 2 for GaAs and InP. Fundamental frequency limits of 100 GHz for GaAs and 200 GHz for InP TEDs were originally estimated from these effective transfer time constants and considered hard limits. However, in subsequent sections, some solutions that help reduce the dead-space region or have been demonstrated to extend the useful frequency range even far beyond these fundamental frequency limits are presented and discussed.

3. FABRICATION TECHNOLOGIES

TEDs are characterized by low to medium DC-to-RF conversion efficiencies ranging from approximately more than 15% down to less than 1%. As a consequence, most of the DC input power P_{DC} , namely, $P_{DC} - P_{RF}$, needs to be dissipated as heat in the device. In most cases, one of the metal contacts near the active region of the device also acts as the heatsink; therefore, TEDs for millimeter-wave frequencies generally are mesa-type devices. Additionally, operation at these frequencies requires thin devices to reduce losses in the substrate resulting from the skin effect. The integrated heatsink technology is the most widespread for devices at millimeter-wave frequencies. To reduce losses in the substrate, most of it needs to be removed during fabrication.

In early fabrication technologies, vapor-phase epitaxy (VPE) provided the layer structures. As a first step in processing, a few small holes (or grooves) across the sample

were etched through the epitaxial layers down into the substrate. An appropriate depth of the holes was chosen to gauge the thickness during substrate removal. The advent of more advanced growth techniques, such as MBE, MOMBE, MOCVD, and CBE, allows the incorporation of a lattice-matched, stop-etch layer between the substrate and the epitaxial layers of the device. This way, the substrate is completely removed, and precise control of the mesa height and, consequently, the device diameter is achieved. Fabrication technologies for substrateless devices on integral heatsinks or on diamond heatsinks for better heat removal have been developed and described in the literature. Selective etching technologies in the GaAs and InP material systems [16–18] employ as etch-stop layers lattice-matched $\text{Ga}_x\text{Al}_{1-x}\text{As}$ ($x < 0.4$) and $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ layers, respectively. Improved yield, reproducibility, and performance characterize these substrateless devices.

Figure 10 summarizes the basic steps of these fabrication technologies. The batch fabrication of InP TEDs on integral heatsinks serves as an example [16]. In the first step, the metallization for the n-ohmic contact (Ni/Ge/Au/Ti/Au) is evaporated or sputtered onto the surface. A thick gold layer is then electroplated onto this metallization to form the integral heatsink. The sample is mounted on a carrier to provide additional mechanical support and protect the heatsink during the subsequent processing steps. The substrate is removed in a selective etchant of diluted hydrochloric acid [16], which does not attack the $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ etch-stop layer. Good ohmic contacts can be formed on n-type InP or, with lower specific contact resistance ρ_c , on n-type $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. Therefore, this $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ layer need not be removed, but may be etched away selectively in a standard solution of phosphoric or sulfuric acid, hydrogen peroxide, and water as indicated in Fig. 10. Such a solution does not attack InP. A photolithography step defines the openings on this InP surface (or $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ surface if left in place), where the metallization (Ni/Ge/Au/Ti/Au) for the other n-ohmic contacts on the second heavily n^+ -doped layer is deposited. Excess metal outside the contacts is lifted off with the photoresist and, using another photolithography step, the contacts are selectively electroplated with several micrometers of gold to form a good bonding pad. The contact pad acts as a mask when the mesa of the diode is etched in a nonselective etch. After the sample has been removed from the carrier, the contacts are annealed, and the sample is diced into individual diodes. Diodes are then mounted in packages for appropriate RF circuits.

4. DEVICE PACKAGES, OSCILLATOR CIRCUITS, AND RF PERFORMANCE

Figure 11a shows a typical TED package. It consists of a gold-plated threaded copper puck (which can be screwed into the RF circuit), an alumina ring, and a top lid for a hermetic seal. The device is soldered or thermocompression-bonded onto a pedestal inside the ring, and gold straps are then thermocompression-bonded onto the device and the top metallization of the alumina ring. The height and diameter of the ring depend on the operating

Figure 10. Steps in the fabrication of InP TEDs on integral heatsinks: (a) Island definition, N-ohmic evaporation and gold plating of heatsink ($\approx 20\ \mu\text{m}$); (b) substrate thinning, etch-stop layer removal, and second N-ohmic evaporation; (c) gold plating of ohmic contacts; (d) final devices after annealing and mesa etch. (After Kamoua et al. [16].)

frequency as well as the device, and typical values are given in Fig. 11a. This type of package is used up to frequencies of 94 GHz, and its parasitic elements can be approximated by lumped elements as illustrated in Fig. 11b. Different ribbon configurations are chosen to minimize the influence of the parasitic inductance L_p , which is the highest for just one gold strap across and the lowest for the “star” configuration. The useful frequency range of the package can be extended to 140 GHz and higher if the alumina ring is replaced by a quartz ring for a lower parasitic capacitance C_p . However, new devices for frequencies above 100 GHz are still being developed, and, for research purposes, a low-parasitic open package with two or four standoffs at the highest millimeter- and up to submillimeter-wave frequencies is also often employed [18,19].

The heat-flow resistance R_{th} from the active layer of the device to the package causes an average temperature increase ΔT_{op} in the active layer

$$\Delta T_{op} = R_{th}(P_{DC} - P_{RF}) \tag{10}$$

Too high an active layer temperature degrades the RF performance as well as the device reliability and lifetime [11]. A larger valley separation of 0.53 eV in InP than in GaAs (see Fig. 3) reduces the temperature dependence of

the transfer mechanism as well as the temperature-dependence of the effective transit velocity v_T (see Table 2). As a result, DC-to-RF conversion efficiencies and oscillation frequencies are generally less temperature-dependent in InP Gunn devices. However, the higher threshold electric field of 10.5 kV/cm in InP (see Table 2) requires higher bias voltages than those applied at GaAs devices of the same length. Therefore, RF power levels are thermally limited at low microwave frequencies, where long active regions need to be used. As a further consequence, InP TEDs are more likely to benefit from reduced heat-flow resistances [11]. Figure 12 compares the estimated [20] heat-flow resistances of W-band (75–110 GHz) and D-band (110–170 GHz) InP Gunn devices on integral and diamond heatsinks as well as some measured values for devices on integral heatsinks [21–23]. Examples of how significantly diamond heatsinks improve the RF performance of both GaAs and InP Gunn devices are provided in the sections on device structures.

Many different circuit configurations for oscillators with TEDs have been investigated. At millimeter-wave frequencies, waveguide circuits are quite common. Although excellent results were reported from a few transferred-electron oscillators (TEO) in microstrip circuits [10,11,24–26], the vast majority of the state-of-the-art results were obtained in waveguide circuits. These results, summarized in Fig. 13, include the performance of different

Figure 11. (a) Hermetically sealed package for millimeter-wave TEDs; (b) equivalent circuit of the parasitic elements.

device structures as illustrated in Fig. 7. Examples for the RF performance of individual device structures are given in the subsequent sections. An overview of typical configurations for waveguide circuits [27,28] is shown in Fig. 14. Examples of oscillator circuits using coaxial lines at microwave frequencies can be found in Ref. 1.

5. DEVICE STRUCTURES

5.1. Ohmic Cathode Contacts

TEDs with ohmic contacts on both heavily n-doped regions of the structure of Fig. 7a (flat-doping profile) are the simplest structure, easy to fabricate, but characterized by low DC-to-RF efficiencies. These devices are typically operated in a full-height waveguide cavity with a resonant cap on top of the device package, and this configuration is illustrated in Fig. 14e. Modifications of this configuration include the use of a reduced-height waveguide or a mechanism for adjusting the position of the resonant cap and the device package with respect to the bottom of the waveguide. Fundamental-mode operation of Gunn devices in a reduced-height postcoupled waveguide cavity was reported up to millimeter-wave frequencies, for instance, for a GaAs Gunn device at 84 GHz [29] and an InP Gunn device at 126 GHz [30]. RF power levels (and corresponding DC-to-RF conversion efficiencies) of 420 mW (6%) at 35 GHz [19], 280 mW at 45 GHz [19], 150 mW at 60 GHz, and 110 mW (2.8%) at 70 GHz [31] were reported from flat-profile GaAs Gunn devices in the fundamental mode.

A sharp decline in the DC-to-RF conversion efficiencies of devices operating in the fundamental-mode presages the abovementioned frequency limits for GaAs or InP Gunn devices. However, this frequency limit can be extended by the extraction of higher harmonics from the inherently nonlinear Gunn device. Second-harmonic power extraction has proved most successful in a slightly

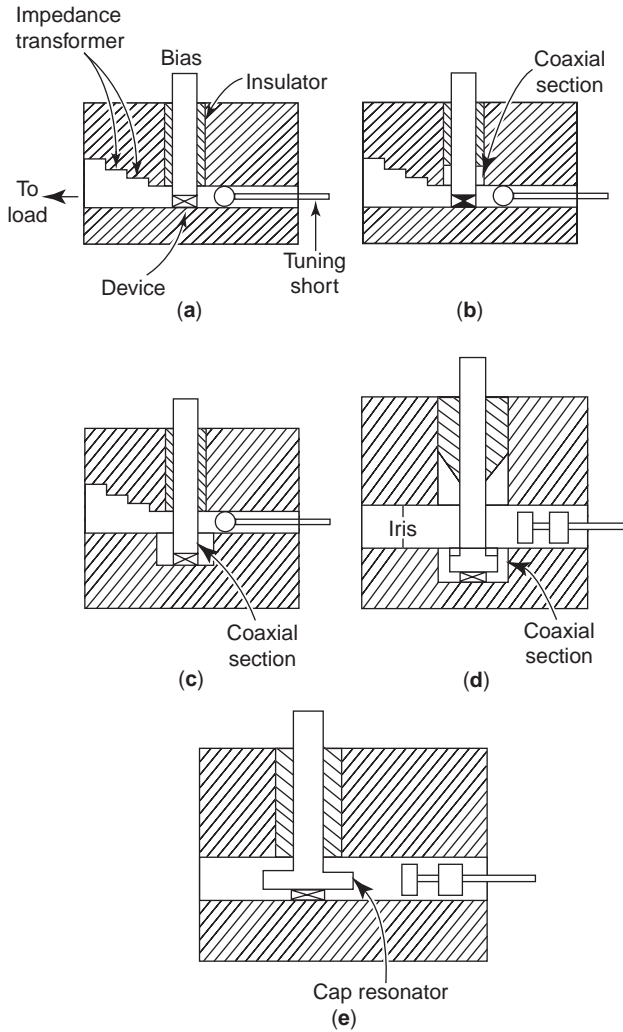

Figure 14. Examples of waveguide circuits for TED oscillators. (After Kuno [27].)

modified version of a resonant-cap, full-height waveguide cavity. The size of the waveguide is appropriate for the second-harmonic frequency, but impedes wave propagation at the fundamental frequency. If in such a circuit the fringe capacitance of the cap and the device capacitance together resonate with the inductance of the bias post (see Fig. 14e) at half the output frequency, this signal cannot propagate, and the termination of the device is almost purely reactive at the fundamental frequency. This reactive termination causes a large voltage swing in the device and, as a result, strong nonlinear operation. A cap of appropriate size together with the coaxial post provides impedance matching into the waveguide at the second-harmonic frequency, and a waveguide backshort at one side of the cavity provides power tuning. The resonant circuit at the fundamental frequency is decoupled from the load, which corresponds to Q values typically higher than those in fundamental-mode operation. As results, reduced frequency pulling with load changes or improved frequency stability may be observed. However, more complicated circuits with precise mechanical dimensions are

necessary if wide-range frequency tuning is to be implemented. As an example for second-harmonic power extraction, RF power levels (and DC-to-RF conversion efficiencies) of 123 mW (3.1%) at 83 GHz, 96 mW (2.7%) at 94 GHz were measured with GaAs Gunn devices [31].

The advantages of InP can be clearly seen at millimeter-wave frequencies with short active regions where lower inertial energy time constants lead to a much higher fundamental frequency limit. RF power levels (and corresponding DC-to-RF conversion efficiencies) of 200 mW (5%) at 80 GHz and 150 mW (3.5%) at 94 GHz [22] in the fundamental mode as well as 7 mW at 180 GHz and 3.2 mW at 206 GHz [32] in a second-harmonic mode were reported from similar flat-doping InP Gunn devices on integral heatsinks.

RF power stability against package temperature typically ranges from -0.02 to -0.06 dB/°C as quoted by various manufacturers for commercially available GaAs Gunn devices (see also Ref. 11). Conversely, values of around -0.013 dB/°C [11] or as low as -0.005 dB/°C [21,22] were reported from InP Gunn devices.

The more complex structures of Figs. 7c–7e also employ ohmic cathode contacts at the anode and cathode, but device characteristics and RF performance are discussed separately in subsequent sections.

5.2. Current-Limiting Cathode Contacts

A partially annealed ohmic contact significantly reduces the typical Schottky barrier height of metals on the semiconductors GaAs and InP (0.6–0.9 eV), but still leaves a small barrier (<200 meV). If such a contact is formed on the cathode side of the two-zone structure (see Fig. 7b) and is reverse-biased, this barrier causes a high-field region at the cathode contact of the device under bias. Electrons injected over this barrier enter the active region at a higher energy and, under this high electric field, transfer faster into the upper valleys. This faster transfer reduces the dead space. The shallow Schottky barrier also limits the current flow into the active region at the cathode. Thermionic emission and thermionic field emission contribute to the current flow, and, in this case, the current density J_c as a function of the voltage V_c across the barrier can be approximated by

$$J_c(V_c) = J_r \left\{ \exp\left(-\frac{qV_c}{rkT}\right) - \exp\left[\frac{(1-r)qV_c}{kT}\right] \right\} \quad (11)$$

where $J_r = A^*T^2 \exp(-q\phi_{Bn}/kT)$ is the saturation current; k , T , r , A^* , and $q\phi_{Bn}$ denote the Boltzmann constant, absolute temperature, ideality factor, effective Richardson constant, and effective barrier height on n-type material, respectively [1]. Current limiting as a boundary condition at the cathode causes the electrons in the active region of the device to approximate the current valley condition [15,33] for a saturated electron velocity v_s and a doping concentration N_D

$$\int_0^T J(t) dt = J_0 = N_D q v_s \quad (12)$$

with large space charge waves superimposed on an almost constant electric field throughout the active region [15]. This mode of operation yields high RF power levels in the fundamental mode as well as a second-harmonic mode. Corresponding DC-to-RF conversion efficiencies are typically the highest reported to date. RF power levels (and DC-to-RF conversion efficiencies) of more than 500 mW (15%) at 35 GHz, more than 350 mW (13%) at 44 GHz and 380 mW (10.6%) at 57 GHz [19,34] in the fundamental mode as well as 175 mW (7%) at 94 GHz and 65 mW (2.6%) at 138 GHz [23,35] in a second-harmonic mode were achieved using this technology. These devices are on integral heatsinks, and still higher RF power levels are expected from devices on diamond heatsinks. Devices on integral heatsinks with high RF power levels are also commercially available.

Equation (11) expresses the strong temperature dependence that is inherent in the current flow through a shallow Schottky barrier in the reverse direction [1]. However, the high-efficiency mode reduces DC input requirements and provides higher RF impedance levels. As a consequence, larger device diameters can be used, which have lower heat-flow resistances (see Fig. 12). In turn, lower heat-flow resistances R_{th} entail lower active-layer temperatures T_{op} [see Eq. (10)]. The typical temperature increase ΔT_{op} remains below 100 K at maximum RF output power [23,34], and low operating active-layer temperatures ensure reliability and excellent temperature stability over wide temperature ranges of -30 to $+70^\circ\text{C}$ for devices at 56 GHz [34] and 94 GHz [34,35] as well as of 0 – 50°C for devices at 140 GHz [23]. The temperature-dependent performance of a D-band InP Gunn device in Fig. 15 serves as an example.

5.3. Graded Active Region

A doping profile with a lower doping concentration N_D at the cathode and a linear grading toward a higher N_D at the anode as shown in Fig. 7d decreases the peak electric field near the anode to a large extent and increases the electric field near the cathode [16]. Both effects are beneficial to the device operation, and enhance the DC-to-RF conversion efficiency as well as the RF output power of the device. A lower electric field near the anode reduces the power dissipation in this region and also allows higher bias voltages without the onset of impact ionization and avalanche breakdown. A higher electric field near the cathode causes a larger fraction of the electrons to transfer to the upper valleys over a shorter distance, which is equivalent to a shorter dead-space region. This is illustrated in Fig. 16, which compares domain formation in a flat-profile (Fig. 16a) and a graded-profile (Fig. 16b) TED structure, both with a $1.0\text{-}\mu\text{m}$ -long active region. Accumulation domains form in the flat-profile structure, whereas dipole domains form in the graded-profile structure. A higher fraction of electrons in the upper valleys slightly lowers the average electron velocity throughout the active region; as a consequence, the graded-profile structure operates at lower current densities compared to a flat-profile structure of a similar (average) doping concentration. In fact, a lower average electron velocity and shorter dead

Figure 15. Measured RF performance of a D-band InP Gunn device against ambient temperature. (After Crowley et al. [23].)

space may somewhat decrease the optimum operating frequency f_{op} for the same device length l . However, more efficient device operation extends the upper frequency limit and allows shorter active regions. Similar to the three zone structures of Fig. 7a, the structures with graded-doping profiles have ohmic contacts at anode and cathode; therefore, they are easy to fabricate. They were investigated in both InP and GaAs material systems.

RF power levels (and DC-to-RF conversion efficiencies) of 345 mW (6.8%) at 31.2 GHz and 325 mW (6.6%) at 34.9 GHz from devices on integral heatsinks [36] and 210 mW (3.5%) around 60 GHz from devices on diamond heatsinks [37] were achieved in the GaAs material system. The devices on diamond heatsinks showed operating active-layer temperatures below 150°C and fundamental-mode operation up to 84 GHz (33 mW and 1.7%) [38]. Devices from InP material with properly designed [16,39] graded-doping profiles yielded the highest RF power levels reported for any Gunn device to date. Fundamental-mode operation was demonstrated up to 165 GHz, and RF power levels that exceeded 310 mW at 82 GHz [40], 200 mW at 103 GHz, 130 mW around 132 GHz, 80 mW at 152 GHz, and 25 mW at 163 GHz [41] were obtained from devices on diamond heatsinks [30]. As an example, DC-to-RF conversion efficiencies exceeded 4% at 82 GHz [39,40] and 2.3% between 102 and 132 GHz [42].

As illustrated in Fig. 17, the InP Gunn devices on diamond heatsinks allow single-mode operation over a wide range of DC input power levels. Excellent tuning behavior was also observed, which can be expected from operation in the fundamental mode. This tuning behavior over a range of more than 4.5 GHz is shown in Fig. 18 for the device of Fig. 17 near maximum DC bias. The oscillation frequency changes almost linearly with the position of the backshort, which is the only tuning element in this full-height waveguide resonant cap cavity (see Fig. 14e for a schematic). Improved DC-to-RF conversion efficiencies reduce the DC input power requirements for the same RF power levels, and, similar to devices with current-limiting

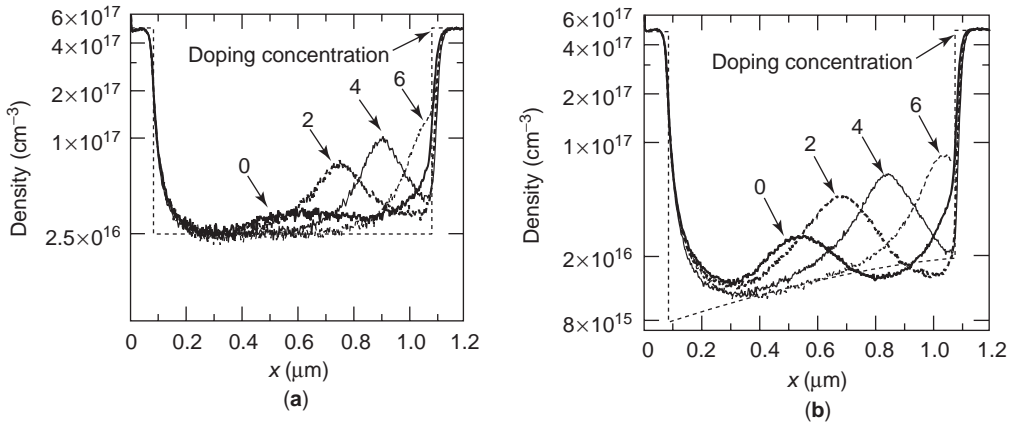

Figure 16. Evolution of electron density against position x (active region $0.1\text{--}1.1\ \mu\text{m}$) for a flat-profile (a) and graded-profile (b) TED structure at $f = 130\ \text{GHz}$ and $ot = n^{\pi/4}$, $n = 0, 2, 4, 6$, during one RF cycle.

cathode contacts, lower the operating active-layer temperatures, in particular on diamond heatsinks [30,38].

InP Gunn devices with a graded-doping profile yielded the highest RF power levels from any Gunn device not only in the fundamental mode but, for the same graded-doping profile, also in a second-harmonic mode. Examples are the RF power levels of 1.8 and 1.1 mW at second-harmonic frequencies of 280 GHz and 315 GHz, respectively [41,43] (see inset of Fig. 17 for the doping profile) as well as 34 mW at 193 GHz and 26 mW at 199 GHz [40,44]. When the graded-doping profile is optimized just for second-harmonic power extraction, even higher RF power levels of, for example, more than 3.5 mW around 300 GHz

are generated and, as indicated in Fig. 13, RF power generation is observed up to at least 325 GHz [40,45].

5.4. Injection over a Homo- or Heterojunction Barrier

Injection of electrons with an energy higher than that at thermal equilibrium (i.e., “hot” electrons) over a barrier reduces the dead space in the active region. Several concepts (e.g., planar-doped barrier, camel cathode, and heterojunction barriers) have been investigated in the GaAs/AlGaAs material system to improve efficiency, but also to eliminate cold-start problems in GaAs Gunn devices. Injection over a heterojunction barrier has proved the most

Figure 17. Bias-dependent RF characteristics of a D-band InP Gunn device (●: output power, +: oscillation frequency, ---: lines of constant efficiency). *Inset:* Nominal doping profile. (After Eisele and Haddad [30].)

Figure 18. Mechanical tuning characteristic for the D-band InP Gunn device of Fig. 17 close to maximum applied bias.

successful and was experimentally investigated in the AlGaAs/GaAs system with improved efficiencies and upper frequency limits [29,46]. Figure 19 shows the band diagrams of isotype heterojunctions in the lattice-matched GaAs/Al_xGa_{1-x}As and InP/In_xGa_{1-x}As_yP_{1-y} material systems. In both material systems, layers can be grown lattice-matched over a wide composition range and, thus, bandgap or conduction-band offset can be tailored suitably.

Linear composition grading from the GaAs to the wider-bandgap AlGaAs eliminates the first barrier, and the doping spike as shown in Fig. 7e at the beginning of the active region (GaAs) reduces or eliminates the notch at the interface from the AlGaAs layer to the GaAs region. At the proper bias level, “hot” electrons are now ballistically launched into the active region from an approximately 200-meV-high step in the conduction band. The optimization of such a design requires advanced simulation schemes, such as ensemble Monte Carlo techniques. Using a reduced-height post-coupled waveguide cavity (see Fig. 14b for a schematic) for the oscillator, an RF output power of 71 mW with a corresponding DC-to-RF conversion efficiency of 2.8% was measured in the fundamental mode at 77.6 GHz. Low-noise operation of such a Gunn device was achieved at least up to 84 GHz [29]. As a characteristic of fundamental-mode operation [30], a wide tuning bandwidth of more than 6 GHz was observed by simply adjusting the position of the backshort [29].

In contrast to the GaAs/AlGaAs material system, lattice-matched InGaAsP has a smaller bandgap than does InP as illustrated in Fig. 19. Therefore, electrons cannot be ballistically launched into the active region. However, a wide composition range in the InGaAsP material system can be grown lattice-matched to InP. This wide composition range allows a wide range in the bandgap and conduction-band offset to be implemented. As a consequence, the proper current-limiting injection at the cathode can be designed. Theoretical investigations predict a significant improvement in DC-to-RF conversion efficiencies at W-band and D-band frequencies [33,47] while preserving the higher frequency limit of InP compared to GaAs.

In summary, different schemes for “accelerating” electrons and transferring them faster to the upper valleys can be incorporated into a device design. Shorter transfer times reduce the dead space, improve the DC-to-RF conversion efficiency, and allow for a shorter active region to achieve a higher operating frequency. However, a reduced dead space effectively increases the transit time and actually lowers the optimum operating frequency f_{op} for an active region of the same length l . Finite valley transfer times still impose some physical upper frequency limit. Additionally, if electrons gain too much energy and/or the active region is too short, the long energy relaxation time prevents the electrons from losing enough energy to transfer back to the lower valley. No domains can form in such a structure, the dynamic resistance between the two device terminals remains positive for all frequencies, and no RF power is generated.

6. NOISE

The noise in the output spectrum of an oscillator consists of fluctuations in RF amplitude (AM noise) and oscillation frequency (FM noise). However, FM noise generally dominates in Gunn devices and can be described as effective frequency modulation Δf_{rms} versus frequency f_m off the oscillation frequency f_o . It corresponds to the noise-to-carrier ratio $N/C|_{FM}$ as, for example, seen on a spectrum analyzer

$$\left. \frac{N}{C} \right|_{FM} = \frac{\Delta f_{rms}^2}{2f_m^2} \quad (13)$$

To compare the noise performance of different oscillators, including those with other two-terminal devices on a more equitable basis, the FM noise measure M [48] is more appropriate

$$M = \frac{\Delta f_{rms}^2 Q^2}{f_o^2 k T_0 B} P_{RF} \quad (14)$$

Figure 19. Band diagram of isotype heterojunctions in GaAs/AlGaAs and InP/InGaAsP at zero bias. (After Friscourt et al. [33].)

where T_0 is the absolute temperature and B is the measurement bandwidth. The loaded Q factor of the oscillator circuit is determined in a waveguide setup as illustrated in Fig. 20a. The sweep oscillator injects a signal at the power level P_i into the oscillator under test (OUT), and the maximum continuous frequency range Δf_s over which the OUT remains injection-locked with the sweep oscillator is determined [48]:

$$Q = \frac{2f_o}{\Delta f_s} \left(\frac{P_i}{P_{RF}} \right)^{1/2} \tag{15}$$

An alternative is also shown in Fig. 20b. The signal from the OUT is reflected at a tunable low-loss short and injected back as P_i through the coupler into the OUT. If the position of the short is moved by more than half of the guide wavelength λ_g , the oscillation frequency continuously changes from a lower to an upper limit. This maximum tuning range (i.e., the self-injection locking range) is now Δf_s in Eq. (15).

Thermal noise of electrons is the dominant effect in Gunn devices. If a TED is designed (using subcritical $N_D l < 1 \times 10^{12} \text{ cm}^{-2}$) for and operated in the amplifier mode [1], the small-signal noise measure M approaches the asymptotic limit M_0

$$M_0 = \frac{qD}{k|\mu_{diff}|T_0} \tag{16}$$

where the ratio of the diffusion coefficient D and the differential mobility μ_{diff} is the crucial factor. InP shows an advantage of 142/72 (approximately 3 dB; see Table 2) over GaAs. If an equivalent differential mobility μ_{eff} is introduced for the oscillator mode (critical $N_D l > 1 \times 10^{12} \text{ cm}^{-2}$) with the device conductance per unit area G_D

$$\mu_{eff} = \frac{|G_D|}{qN_D} \tag{17}$$

the large-signal noise measure M can be defined as

$$M = \frac{qD}{k\mu_{eff}T_0} \tag{18}$$

The noise performance of Gunn devices near the carrier is dominated by flicker noise components with typical corner frequencies in the range of 100 kHz–1 MHz. As predicted by Eq. (13), the phase noise decreases by -20 dB per decade at higher off-carrier frequencies f_m . Table 3 summarizes typical results from GaAs and InP Gunn devices [24,29,30,39,41,44,49].

Although Eq. (18) predicts lower values of M for oscillators with InP Gunn devices, experimental results indicate little difference between the two. Figure 21 [50] compares the FM noise measure M of Gunn devices with that of other two-terminal devices in the frequency range of 75–155 GHz. This figure highlights the low-noise

Table 3. Phase Noise of Free-Running Oscillators using GaAs or InP Millimeter-Wave Gunn Devices

Material System	Phase Noise (dBc/Hz)	Off-Carrier Frequency (kHz)	Oscillation Frequency (GHz)	RF Output Power (mW)	Ref.
GaAs	< -80 ^a	100	77	>40 ^a	29
GaAs	-70	100	80	55	24
GaAs	-100	1,000	80	55	24
GaAs	-120	10,000	80	55	24
GaAs	-80	100	94	10	49
GaAs	-105	1,000	94	10	49
InP	-75	100	94	20	49
InP	-100	1,000	94	20	49
InP	< -110	500	81	126	39
InP	< -110	500	103	180	41
InP	< -108	500	132	120	30
InP	< -103	500	151	58	30
InP	< -94	500	199	19	44

^aReported as typical value, corresponding RF output power not mentioned.

characteristics of TEDs, where the large-signal FM noise measure of both GaAs and InP Gunn devices typically remains below 25 dB [11,24,30,49,51]. Some InP devices with current-limiting contacts show excess flicker noise components near the carrier frequency f_0 . Oscillators with Gunn devices in a second-harmonic mode yield lower values for the phase noise, but they yield similar values for the noise measure because much higher Q values are achieved in a circuit without a resistive load at the fundamental frequency.

Figure 21. Comparison of the FM noise measure M in free-running oscillators with different two-terminal devices at millimeter-wave frequencies of 75–155 GHz. (After Eisele and Haddad [50].)

7. FUTURE TRENDS

7.1. More Power and Higher Operating Frequencies with INP TEDs

Fundamental-mode operation up to 165 GHz was demonstrated with InP Gunn devices. Therefore, InP or InP with heterojunction barriers are promising material systems not only for device structures that exhibit improved performance in the fundamental mode at frequencies around or above 100 GHz but also for other device structures that generate significant RF power levels up to submillimeter-wave frequencies in a second-harmonic mode. In all these devices, proper heat management is one of the important factors, and employment of the appropriate diamond heat-sink technologies is mandatory for maximum RF output power as well as reliable long-term operation. Power-combining techniques [28,52] can be employed to increase the available RF power levels. As examples, four InP Gunn devices in a power-combiner circuit delivered an RF power of 260 mW to the load in CW operation at 98.6 GHz [11,53], and two devices each on diamond heatsinks yielded more than 300 mW at 103 GHz [42] or more than 125 mW at 152 GHz [41].

Structures with a flat-doping profile, ohmic contacts at cathode and anode, but with a doping notch near the cathode, were originally investigated for low-noise microwave and millimeter-wave amplifier applications [11], but have now emerged as quite promising candidates for efficient second-harmonic power extraction at J-band (220–325 GHz) frequencies and above [39,45]. Figure 22a compares the predicted RF performance of two different doping profiles in the active region of InP Gunn devices in a second-harmonic mode as shown in Fig. 22b [45]. In all simulations, the predicted operating temperatures were kept similar and below 420 K to ensure a fair comparison and, much more importantly, reliable long-term operation of fabricated devices on diamond heatsinks. The improvements are even more pronounced at frequencies above 300 GHz, where initial Monte Carlo simulation results indicate an improvement in RF output power by a factor of 2–3 compared to structures with a graded-doping profile. RF power levels of more than 7 mW at 360 GHz and 4.7 mW at 500 GHz are predicted for structures with a doping notch as opposed to 5 and 2.6 mW, respectively, for structures with a graded-doping profile at the same frequencies [45]. These performance improvements are attributed to a faster transfer of electrons to the upper valleys near the cathode and, as a comparison in Fig. 23 indicates, a rather flat electric field profile throughout most of the active region [39,45] of the structure with a notch in the doping profile.

7.2. New Material Systems

Wide-bandgap materials such as GaN and AlGaN are also regarded as promising for high-power Gunn devices. Favorable material parameters, for example, are higher critical electric fields for avalanche breakdown, higher thermal conductivities, higher permissible operating temperatures, and expected higher carrier drift velocities. However, high threshold electric fields E_{th} and

Figure 22. Comparison of predicted RF power level from InP Gunn devices with doping profiles optimized for second-harmonic power extraction.

consequently higher DC bias voltages may result in severe thermal limitations of the device performance [54]. Furthermore, major improvements in material quality or availability and in fabrication technologies are needed before devices for system applications can be developed.

7.3. Circuit Integration

Waveguide circuits are, in general, rugged, can dissipate heat easily, and offer high Q values. Therefore, they are the preferred circuits to obtain the maximum RF output power. However, they are bulky and in most cases must be machined, assembled, and tested individually, which prohibits low-cost mass production. Therefore, high-volume production for system applications such as wireless communication (high-speed data transmission) or collision avoidance radar in automobiles must be based on quite

different approaches. Both hybrid and monolithic integration were attempted with Gunn devices. Hybrid microstrip-line oscillators with InP Gunn devices exhibited excellent performance. RF power levels (with corresponding DC-to-RF conversion efficiencies) of 52 mW (3.5%) at 94 GHz [25], but also 40 mW (1.4%) at 81 GHz [11,24] and > 200 mW (>7.5%) around 35.5 GHz [10,35] were measured and are considered comparable to values from similar Gunn devices in waveguide circuits. Hybrid integration of a GaAs Gunn device for automotive applications at 77 GHz was also demonstrated [26]. The thermal conductivity of the semiconductor materials InP and GaAs is rather low (0.68 and 0.46 W cm⁻¹K⁻¹, respectively) when compared to metals or diamond (20 W cm⁻¹K⁻¹ at room temperature). Therefore, fully monolithic integration of low-efficiency Gunn devices at millimeter-wave frequencies encounters severe thermal

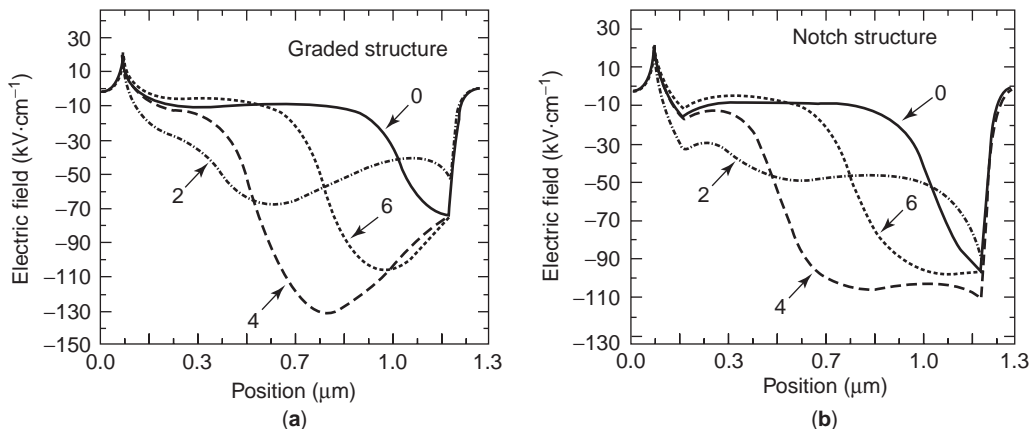

Figure 23. Evolution of electric field against position x (active region 0.1–1.2 μm) for a graded-profile (a) and a flat-profile with notch (b) TED structure at the fundamental frequency $f = 120$ GHz and $\omega t = n\pi/4$, $n = 0, 2, 4, 6$, during one RF cycle.

limitations. A summary of reports on integration of Gunn devices at frequencies up to approximately 68 GHz can be found elsewhere [28].

GYRATORS

DOUGLAS R. FREY
Lehigh University

1. DEFINITION

A *gyrator* is a nonreciprocal electrical network. It is capable of transforming signals or energy represented in terms of one electrical quantity, such as voltage or magnetic field, to another electrical quantity that may be of similar type or of a complementary type, such as current or electric field. Such networks are quite useful in electronic systems, since one often wishes to design systems with a limited set of component types or with restrictions regarding certain physical parameters.

2. HISTORICAL USAGE

Tellegen first proposed the idea of a gyrator in his original work in 1948 [1]. In this paper he explained that resistors, capacitors, inductors, and ideal transformers were the four basic circuit building blocks. However, these elements are all reciprocal and could, therefore, only be expected to go into the creation of reciprocal networks. *Reciprocal networks* are those networks whose impedance (or admittance) matrices are symmetrical. In order to realize nonreciprocal networks, one would need a nonreciprocal building block. Tellegen proposed such a network, calling it a gyrator. This name was given because the equations produced for an electrical network with a gyrator were identical to those of a mechanical gyrostatic network. As time went on other researchers [2–5] picked up on the idea and began to look for circuit realizations for this abstract functional block. In addition, over the years other systems, such as microwave circulators, have been recognized as being analogous to gyrators, which helps in the understanding of these systems.

3. THE BASICS OF TWO-PORT GYRATORS

3.1. Introduction to Two-Ports and Passivity

A gyrator is a special type of electrical two-port network. Electrical two-port networks are any circuits where one can identify two ports, or simply, two pairs of nodes to which one might consider the connection of two pairs of wires. One of the nodes at each port may be in common—for example, ground may be common to both ports. Additionally, a bipolar transistor may be considered a two-port, where port 1 is the base-emitter node pair, and port 2 is the collector-emitter node pair.

Except for trivial cases, every two-port possesses a mathematical description relating the port voltages, V_1 and V_2 , and associated port currents, I_1 and I_2 . Figure 1 shows the standard reference labeling for the voltages and currents of a two-port. Notice that the port currents are defined as flowing into the + voltage reference for each port. These sign conventions make the definition of power regarding a two-port more precise. Specifically, the power as a function of time $P(t)$ delivered to a two-port is given by $P(t) = V_1(t)I_1(t) + V_2(t)I_2(t)$, which is analogous to the definition in a one-port—that is, a two-terminal element. A two-port network is *lossless* when the average power $P(t)$ delivered to the network is zero. A network is called *passive* if the average power delivered to the network is positive. Active networks are those networks where $P(t)$ is negative on average. In general, the power delivered to a network can be positive or negative instantaneously, regardless of its passivity. For example, a capacitor in a resonant circuit alternately sinks and sources power instantaneously, despite its lossless average power consumption. Power can be defined just as easily in the frequency domain, again in a way analogous to one-ports. The Fourier transform of power $P(\omega)$ as a function of frequency is given by $P(\omega) = V_1(\omega)I_1(\omega)^* + V_2(\omega)I_2(\omega)^*$, where the * indicates complex conjugation.

The general description for a two-port is given by a relation between its port voltages and currents. One such description is the so-called y -parameter model given by

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} \Rightarrow \mathbf{I} = \mathbf{YV} \quad (1)$$

Equation (1) defines the port current and port voltage vectors, \mathbf{I} and \mathbf{V} , respectively, in addition to the y -parameter matrix, \mathbf{Y} . By inverting this vector equation, one relates the port voltages to the port currents with z parameters. Specifically

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} \Rightarrow \mathbf{V} = \mathbf{ZI} \quad (2)$$

Figure 1. Basic two-port model.

where Z is the z -parameter matrix for the two-port. Using models of the type shown in Eqs. (1) and (2), two-ports can be compared by their two-port parameters—for example, y parameters. Two-ports characterized by symmetric y -parameter matrices (equivalently z -parameter matrices) are called *reciprocal*. Networks possessing this reciprocity are not necessarily lossless, but can always be realized with reciprocal physical elements. Note that one-ports (two terminal elements) are always reciprocal. The concept of a two-port can be extended in an obvious way to N -ports by considering the voltage-current relationship measured using N pairs of terminals or, equivalently, N -ports.

3.2. Mathematical Two-Port Definition of a Gyrator

In the context of this discussion, a gyrator is simply a special case of a linear two-port. While there are many possible two-port descriptions, the most common way of writing the basic equations relating the port parameters in a gyrator is as follows:

$$I_2 = gV_1; \quad I_1 = -gV_2 \quad (3)$$

Using these equations it is simple to write the y -parameter two-port description for a gyrator as

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} 0 & -g \\ g & 0 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} \Rightarrow \mathbf{I} = \mathbf{YV} \quad (4)$$

This suggests that a gyrator can be implemented with voltage-controlled current sources, having gains of g and $-g$, respectively. By inverting the relations in Eq. (3), one obtains a gyrator formulation based on current-controlled voltage sources. Specifically

$$\mathbf{V} = \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} 0 & -r \\ r & 0 \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \mathbf{ZI}; \quad r = 1/g \quad (5)$$

where the z -parameter matrix Z is just the inverse of the y -parameter matrix \mathbf{Y} . Since it is most convenient to realize practical voltage-controlled current source networks, as opposed to current-controlled voltage source networks, the formulation in Eq. (4) is generally preferred. For theoretical purposes, of course, both formulations are useful. Using Eq. (4) it is simple to show that a gyrator is a lossless electrical network. Specifically, we obtain

$$\begin{aligned} P = \mathbf{V}^T \mathbf{I} &= \begin{vmatrix} V_1 & V_2 \\ I_1 & I_2 \end{vmatrix} = \begin{vmatrix} V_1 & V_2 \\ g & 0 \end{vmatrix} \begin{vmatrix} 0 & -g \\ g & 0 \end{vmatrix} \begin{vmatrix} V_1 \\ V_2 \end{vmatrix} \\ &= V_2 V_1 - V_1 V_2 = 0 \end{aligned} \quad (6)$$

The fact that gyrators are, in theory, lossless makes them attractive in filter synthesis, and this will become clear later.

3.3. Properties of Gytrators

Gytrators possess several properties that make these circuits interesting for use in electronics. A first property is that these two-ports are not reciprocal networks, since their y -parameter matrices are not symmetric. In fact, these matrices are skew symmetric. It is well known to circuit theorists that nonreciprocal networks cannot be realized with only passive components—that is resistors, capacitors, and inductors. This means that gytrators are strictly active networks that must, therefore, be realized with active components, such as transistors or operational amplifiers. Two-port gytrators have been given their own circuit symbol, which is shown in Fig. 2. The gyration constant, g is built into the symbol.

Perhaps the most important property of a gytrator is its ability to transform admittances into impedances. Specifically, when an admittance is connected to one port of a gytrator, the impedance looking into the other port is exactly a scaled version of that admittance. The derivation can be accomplished with the help of Fig. 3, where Z_{load} is the impedance attached to port 2, Y_{load} is its reciprocal—that is, the admittance attached to port 2—and Z_{input} is the impedance seen looking into port 1. We have

$$Z_{load} = \frac{V_2}{-I_2};$$

$$Z_{input} = \frac{V_1}{I_1} = \frac{I_2/g}{-gV_2} = \frac{1}{g^2} \frac{1}{Z_{load}} = \frac{1}{g^2} Y_{load}$$

The gyration constant g determines the scale factor, but the nature of the input impedance is determined by the admittance attached to port 2. Therefore, if a capacitor is attached to port 2, then we have

$$Z_{input} = \frac{1}{g^2} sC = sL_{eq}; \quad L_{eq} = \frac{C}{g^2}$$

This simple relation explains the vast majority of the gytrator’s popularity in electronic design. It shows that a capacitor can be used to replace an inductor in a circuit with the help of a gytrator. Since inductors are rarely desirable in electronic circuits operating below about 1 GHz, this idea is quite appealing. Capacitors and gytrators are conveniently realized within integrated circuits.

Filter synthesis based on the inductor simulation already described is usually done by starting with an RLC (resistor, inductor, capacitor) prototype, and replacing the inductors with capacitor–gytrator combinations. Consider the following example of a very simple second-order bandpass filter shown in Fig. 4. After replacing the inductor with a gytrator/capacitor combination, the filter is realized solely using RC (resistor, capacitor) passive elements, as shown in Fig. 5. Some original related work appears in

Figure 2. Electrical circuit symbol for a gytrator.

Figure 3. Reflecting load impedance with a gytrator.

Refs. 6 and 7. Furthermore, the filter can be tuned electronically if the gyration constant can be varied electronically. An electronically tunable filter using gytrators will be shown later.

A byproduct of the property under discussion is that series and parallel circuits may be interchanged with the help of a gytrator. Suppose one port, say, port 2, of a gytrator is loaded with a parallel combination of elements. The admittance of this combination is the sum of the admittances of each of the elements. At the other port, port 1, the input impedance will be a scaled version of this admittance; hence, a sum of impedances. Since the composite input impedance seen at port 1 is given by a sum of impedances, it must be equivalent to a series combination of elements. Therefore, the gytrator converts a parallel network into a series network. Using similar logic, it becomes clear that a series network connected to port 2 will be reflected as a parallel network looking into port 1 (these results are summarized next):

$$Y_{load} = \sum_{k=1}^N Y_k \Rightarrow Z_{input} = \frac{Y_{load}}{g^2}$$

$$= \sum_{k=1}^N \frac{Y_k}{g^2} = \sum_{k=1}^N Z_{in-k}$$

$$Z_{load} = \sum_{k=1}^N Z_k \Rightarrow Y_{input} \tag{9}$$

$$= \frac{1}{Y_{load}/g^2} = g^2 Z_{load}$$

$$= \sum_{k=1}^N g^2 Z_k = \sum_{k=1}^N Y_{in-k}$$

4. CIRCUIT REALIZATIONS FOR GYRATORS

4.1. The 2G_m Cell Realization

The realization of gytrators in electronic form is quite simple; however, as usual, different circuit realizations are

Figure 4. Bandpass filter.

Figure 5. Bandpass filter with inductor replaced by gyrator/capacitor.

preferable to others, depending on the application. To begin, consider the simplest generic realization consisting of a pair of transconductance amplifiers, as shown in Fig. 6. Each transconductance amplifier is assumed to have infinite input and output impedance, with an output current equal to the transconductance $G_m = g$, times the input voltage applied to the + and - terminals. The circuit shown in Fig. 6 satisfies the basic two-port relations for a gyrator, given by Eq. (3).

The circuit of Fig. 6 does not implement the most general form of a gyrator, since both ports of the gyrator realization in the figure have ground in common. Therefore, only ground-referenced impedances may be transformed as described elsewhere in this article. This limitation stems from the fact that the transconductors in Fig. 6 have single-ended outputs. If differential input/differential output transconductors are used, then a general floating gyrator realization is created—that is, a gyrator whose ports need not be referenced in any way to ground.

Unfortunately, the realization of fully differential gyrators is not easy. In general, this realization requires more circuitry and the management of common-mode signals. Figure 7 shows how a floating gyrator can be realized using single-ended transconductors; however, this circuit suffers from common-mode problems. An analysis of this structure yields the following results:

$$\begin{aligned}
 I_{2+} &= -gV_{1+}; \quad I_{2-} = -gV_{1-}; \quad I_{1+} = gV_{2+}; \quad I_{1-} = gV_{2-} \\
 \Rightarrow I_2 = I_{2+} &= -I_{2-} = -g(V_{1+} - V_{1-}) = -gV_1 \quad (10) \\
 I_1 = I_{1+} &= -I_{1-} = g(V_{2+} - V_{2-}) = gV_2
 \end{aligned}$$

The crucial assumption embodied in Eq. (10) is that + and - currents are equal and opposite one another. This can happen only if the + and - input voltages at the ports are exactly equal and opposite. Since this special case cannot be relied on in practice, additional circuitry must be added to deal with any common-mode current component. To do this compensation, more transconductors can be added to process the average voltage at each port. As

Figure 6. Realization of gyrator using transconductance amplifiers.

Figure 7. Floating-gyrator implementation.

one might expect, this additional circuitry is an unwelcome addition to the design. As a result, this idea is rarely found in practical designs.

There is an alternative for the simulation of a floating inductor using gyrators. A pair of gyrators is used with a grounded impedance Z_{load} as shown in Fig. 8. The equations describing this system are given by

$$\begin{aligned}
 I_2 &= gV_1; \quad I_1 = -gV_2; \quad I_4 = gV_3; \quad I_3 = -gV_4 \\
 V_{load} &= V_2 = V_3; \quad I_{load} = -(I_2 + I_3) \\
 V_{input} &= V_1 - V_4; \quad I_{input} = I_1 = -I_4 \\
 Z_{input} &= \frac{V_{input}}{I_{input}} = \frac{V_1 - V_4}{I_1} = \frac{I_2/g - I_3/(-g)}{-gV_2} \quad (11) \\
 &= \frac{1}{g^2} \frac{I_2 + I_3}{-V_2} = \frac{1}{g^2} \frac{I_{load}}{V_{load}} \\
 &= \frac{1}{g^2 Z_{load}} = \frac{1}{g^2} Y_{load}
 \end{aligned}$$

Clearly, if a grounded capacitor is used as the grounded load in Fig. 8, then a floating simulated inductor is realized. The obvious benefit of this realization is that it requires only single-ended transconductance amplifiers, configured as in Fig. 6, and a grounded internal load to obtain a floating input port. Observe that no common-mode problems exist with this realization since common-mode signals at the input port cause canceling currents at the grounded port. Even in practice, with unmatched gyrators, there is a negative-feedback effect regarding common-mode errors that is highly desirable. The network of Fig. 8 is the preferred realization of floating inductors using capacitors and gyrators. Reference 8 represents some original work in this area.

Figure 8. Floating-gyrator realization.

4.2. Realization with Operational Amplifiers

Gyrators may be realized with operational amplifiers; however, modifications must be made to account for the fact that these are voltage-controlled voltage sources. A voltage-controlled current source (VCCS) may be created using an op amp, as is well known, using the circuit of Fig. 9. A gyrator can then be realized with a second VCCS preceded by an inverter, recalling that the gains in different directions have opposite signs. A more clever variation of this idea is shown in Fig. 10, where only two op amps are required to implement the entire gyrator. Of course, this gyrator is ground-referenced as, for example, is the one in Fig. 6. Floating-gyrator structures can be implemented using the ideas stated, and similarly, a floating inductor may be synthesized via a pair of ground-referenced gyrators implemented with op amps and a grounded capacitor. References 6 and 7 give more discussion of the topics in the last two sections.

4.3. Other Realizations

Gyrators may be realized with any active circuitry that can implement either a VCCS or a CCVS (current-controlled voltage source). For example, a simple transistor-level realization for a gyrator appears in Fig. 11. $Q_1 - Q_3$ create a first transconductance amplifier, and Q_4 implements an inverting transconductance amplifier. The signal levels must be restricted with such an implementation due to the nonlinearity of the transistor junctions.

Alternatively, the transconductance amplifiers constituting the gyrator may be implemented using operational transconductance amplifiers (OTAs). OTAs are essentially bipolar differential pairs loaded with current sources in such a way as to create a nearly ideal transconductance amplifier. An example of an integrated version of an OTA is the LM3080 integrated circuit manufactured by National Semiconductor Corp. of Santa Clara, CA. An important feature of OTAs is that their transconductance can be tuned over a wide range by varying a control current. As a result, gyrators made using OTAs are electronically tunable. This is quite desirable in applications where one wishes to electronically tune a filter. An example of this capability is given later.

Of course, there are limitations imposed by the use of OTAs since these circuits are not ideal in practice.

Figure 9. VCCS realization using an op amp.

Figure 10. Gyrator realization using op amps.

Specifically, they suffer from finite input and output impedance, and these impedances vary as a function of the transconductance. As a result, the tuning range of OTA tuned filters can be limited. Furthermore, at higher frequencies the complexity of OTAs introduces an unwanted phase shift, which degrades the behavior of the gyrator, as well as compromising the usable tuning range. Finally, these circuits become quite nonlinear for inputs above a few tens of millivolts, which limits the dynamic range of the resulting filters.

5. FILTER REALIZATION USING GYRATORS

This section considers the general problem of filter synthesis based on gyrators. Basically, synthesis with gyrators involves either the substitution of inductors, in the practical case, or the partition of state equations.

5.1. Replacement of Inductors in Ladder Networks

The replacement of inductors in filters has already been implied. In this section, the idea is generalized. Consider the case where a prototype passive RLC filter has been specified. This is usually done, starting from a filter specification, using filter design tables or software to produce one of a variety of passive filter structures. Special cases will be considered in the discussion that follows. All other cases are obvious variations.

Figure 11. Transistor realization of a gyrator.

Figure 12. Doubly terminated passive ladder highpass filter.

The first case considered is that of a doubly terminated highpass RLC ladder network, shown schematically in Fig. 12. It is desirable to replace the grounded inductors with gyrator/capacitor combinations. Given the prototype design values for the inductors L_k , for $k = 1$ through N , one simply replaces each grounded inductor with one gyrator terminated with a capacitance C_k , given by the formula

$$C_k = g_k^2 L_k \quad (12)$$

where g_k represents the gyration constant for the k th gyrator. In practice, all gyration constants might be chosen to be equal for reasons of simplicity in the circuit design, and possibly for the purpose of optimizing noise and distortion performance. The resulting gyrator-based implementation is now an active filter containing $2N$ capacitors and N gyrators.

The doubly terminated lowpass filter structure obtained by swapping the positions of the inductors and the capacitors in the highpass filter of Fig. 12 is the dual-filter network to that shown previously. Again, each of the inductors can be replaced by a gyrator loaded by a capacitor, whose value is computed using Eq. (12). However, this time the gyrator structures will have to be the floating implementation described later. The complexity, in principle, of the final realization will equal that of the highpass example; however, each of the gyrators will require twice as much circuitry for its realization, therefore, the final circuit implementation will require considerably more circuitry as N gets larger.

A more complex filter variation is that of a bandpass RLC filter. A doubly terminated bandpass filter can be created starting from the highpass prototype of Fig. 12 by replacing each grounded inductor with a grounded parallel combination of a capacitor and inductor, and each series capacitor with a series combination of a capacitor and an inductor. The resulting filter is of order $4N$, instead of $2N$, as it must be to realize a bandpass equivalent. Again, gyrators may be used to replace each inductor, using methods like Eq. (12). Half of the inductors may be replaced using simple ground referenced gyrators, while the rest must be realized using the floating version.

An interesting final variation of this idea is demonstrated using the notch (bandstop) filter of Fig. 13. Here, the grounded inductor can be replaced by a gyrator and a grounded capacitor as outlined above. An alternative approach is to replace the grounded series LC (inductor, capacitor) combination using a gyrator loaded by a grounded parallel LC combination as shown in Fig. 14. Then replace the grounded inductor with another gyrator and a grounded

Figure 13. RLC notch filter.

capacitor. This is shown in Fig. 15. While this idea may seem to be wasteful in terms of component count, it shows how to exploit the property described elsewhere in this article regarding the conversion of series impedances combinations to parallel impedance combinations. In addition, this circuit has practical value since the pair of gyrators now allows two parameters to be tuned in this active filter realization. Specifically, the filter design equations are given as follows:

$$\begin{aligned} \frac{V_{out}}{V_e} = H(s) &= \frac{s^2 + \omega_0^2}{s^2 + (\omega_0/Q)s + \omega_0^2}; \\ \omega_0 &= \frac{1}{\sqrt{LC}}; \quad Q = \frac{1}{R} \sqrt{\frac{L}{C}} \\ C &= g_1^2 L_p = \frac{g_1^2}{g_2^2} C_L; \\ L &= \frac{1}{g_1^2} C_p \Rightarrow \omega_0 = \frac{g_2}{\sqrt{C_L C_p}} \\ Q &= \frac{g_2}{R g_1^2} \sqrt{\frac{C_p}{C_L}} \end{aligned} \quad (13)$$

Using this result, it is easy to see that both the notch frequency ω_0 and the sharpness of the notch, proportional to Q , can be controlled independently using only the gyration constants, g_1 and g_2 . Using an OTA implementation of the gyrators as discussed elsewhere, this tuning is relatively simple.

5.2. Synthesis Based on Gyrators

Clearly, the inductor replacement strategy described above could be applied in reverse to replace capacitors with inductors; however, this is not a good option in practical cases. This is because capacitors are easier to realize at frequencies below 1 GHz_z, and capacitors are of generally higher quality than inductors in this range of

Figure 14. Gyrator-based parallel-to-series conversion.

frequencies. Although inductors may be of greater interest at very high frequencies, the use of gyrators at very high frequencies is limited by the nonideal behavior of the active circuitry used to realize them. It is of interest to note here that, as with any active circuit, there is excess phase shift introduced by the transconductors at high frequencies, causing the gyrators to take on complex gyration constants at high frequencies, as suggested later in the article. Furthermore, the finite output impedance of the transconductors limits there available DC gain. The net result of these effects is to cause simulated inductors to exhibit a reduced Q at both the low and high end of the frequency spectrum. In some situations this may introduce instability; however, this can be compensated for by careful design.

Another option exists for the generic design of active filters using gyrators. This option can be exercised by casting the equations for a given filter in the G_m - C format. This is done by writing the state equations for the desired filter in the standard form

$$\frac{d}{dt} \mathbf{x} = \mathbf{A}\mathbf{x} + \mathbf{b}u; \quad y = \mathbf{c}^T \mathbf{x} + du; \tag{14}$$

$$H(s) = \frac{y}{u} = \mathbf{c}^T (s\mathbf{I} - \mathbf{A})^{-1} \mathbf{b} + d$$

where $\mathbf{x} = (x_1, x_2, \dots, x_N)^T$

where the input u and the output y are assumed scalars, \mathbf{x} is the $(N \times 1)$ -state vector, \mathbf{A} is the N by N state matrix, \mathbf{b} and \mathbf{c}^T are N dimensional vectors, and d is a scalar. Now assume that the input, u , is a voltage, and let each of the state variables x_k be equated to the voltage v_k on some grounded capacitor C_k . The derivative of this voltage, times the capacitance value, is equal to the current in the respective capacitor. Using this idea the state equations may be converted into current equations of the form

$$C \frac{d}{dt} \mathbf{v} = \mathbf{i}_C = \mathbf{C}\mathbf{A}\mathbf{v} + \mathbf{C}\mathbf{b}u = \mathbf{G}_m \mathbf{v} + \mathbf{g}_{m0}u$$

$$\Rightarrow \begin{array}{c} C_1 \dot{v}_1 \\ C_2 \dot{v}_2 \\ \vdots \\ C_N \dot{v}_N \end{array} = \begin{array}{c} i_{C1} \\ i_{C2} \\ \vdots \\ i_{CN} \end{array} \tag{15}$$

$$= \begin{array}{cccc|c} g_{m11} & g_{m12} & \cdots & g_{m1N} & v_1 \\ g_{m21} & g_{m22} & \cdots & g_{m2N} & v_2 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ g_{mN1} & g_{mN2} & \cdots & g_{mNN} & v_N \end{array} + \begin{array}{c} g_{m01} \\ g_{m02} \\ \vdots \\ g_{m0N} \end{array} u$$

where $C = \text{diag}(C_1, C_2, \dots, C_N)$

Figure 15. Replacement of series LC with two gyrators and two capacitors.

where the dot above a variable denotes time differentiation. The realization of a filter based on these equations produces a filter composed of grounded capacitors, with transconductance amplifiers bridging between the capacitor nodes and the input. The class of G_m - C filters, sometimes referred to as “OTA- C filters”, is based exclusively on this formulation.

A gyrator-based synthesis is possible by partitioning the G_m matrix into symmetric and skew symmetric matrices. The idea is best described by an example. Suppose that a second-order version of the g_m - C formulation is given. The G_m matrix can always be decomposed as follows

$$G_m = \begin{array}{cc|c} g_{m11} & g_{m12} & \\ \hline g_{m21} & g_{m22} & \end{array} = G_{m1} + G_{m2} \tag{16}$$

$$= \begin{array}{cc|c} g_{m11} & g_{m12} + g & \\ \hline g_{m21} - g & g_{m22} & \end{array} + \begin{array}{cc|c} 0 & -g & \\ \hline g & 0 & \end{array}$$

where the off-diagonal elements of G_{m1} are equal, making this a symmetric matrix. Clearly, G_{m2} is a skew symmetric matrix. With this partitioning of the transconductance matrix, it is possible to realize the system in Eq. (16) using one reciprocal two-port, characterized by G_{m1} , and a second two-port, characterized by G_{m2} , that is a gyrator. Figure 16 shows the realization associated with this decomposition assuming a single input term in Eq. (15) and a special case for the output—that is, $g_{m02} = 0$ and $y = x_1 = v_1$. The reciprocal two-port can often be realized only with resistors, but in general may require active circuitry.

This special case considered can be further explained with a specific example. Suppose the second order system of Eq. (16) is the bandpass filter described with the

Figure 16. Generic synthesis of a second order G_m - C filter.

following state space description:

$$\begin{aligned} \begin{vmatrix} \dot{x}_1 \\ \dot{x}_2 \end{vmatrix} &= \begin{vmatrix} -\omega_0/Q & -\omega_0 \\ \omega_0 & 0 \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \end{vmatrix} \\ &+ \begin{vmatrix} \omega_0 \\ 0 \end{vmatrix} u; \quad y = \begin{vmatrix} 1 & 0 \end{vmatrix} \begin{vmatrix} x_1 \\ x_2 \end{vmatrix} \\ H(s) &= \begin{vmatrix} 1 & 0 \end{vmatrix} \begin{vmatrix} s + \omega_0/Q & \omega_0 \\ -\omega_0 & s \end{vmatrix}^{-1} \begin{vmatrix} \omega_0 \\ 0 \end{vmatrix} \\ &= \frac{s\omega_0}{s^2 + s\omega_0/Q + \omega_0^2} \end{aligned} \quad (17)$$

Let us now assume that the input u is a voltage denoted by v_{in} . By equating the state variables, x_1 and x_2 , to respective voltages, v_1 and v_2 , and scaling each equation by the same capacitance value C for convenience, one obtains

$$\begin{aligned} \begin{vmatrix} C\dot{v}_1 \\ C\dot{v}_2 \end{vmatrix} &= \begin{vmatrix} -C\omega_0/Q & -C\omega_0 \\ C\omega_0 & 0 \end{vmatrix} \begin{vmatrix} v_1 \\ v_2 \end{vmatrix} + \begin{vmatrix} C\omega_0 \\ 0 \end{vmatrix} v_{in} \\ &= \begin{vmatrix} -C\omega_0/Q & 0 \\ 0 & 0 \end{vmatrix} \begin{vmatrix} v_1 \\ v_2 \end{vmatrix} + \begin{vmatrix} 0 & -C\omega_0 \\ C\omega_0 & 0 \end{vmatrix} \begin{vmatrix} v_1 \\ v_2 \end{vmatrix} + \begin{vmatrix} C\omega_0 \\ 0 \end{vmatrix} v_{in} \\ &= G_{m1}\mathbf{v} + G_{m2}\mathbf{v} + \mathbf{g}_m v_{in} \end{aligned} \quad (18)$$

$$\text{where } \mathbf{v} = \begin{vmatrix} v_1 \\ v_2 \end{vmatrix}$$

Recognizing that $C\omega_0$ has units of conductance, one may easily realize this bandpass filter with only a resistor, implementing G_{m1} , a gyrator, implementing G_{m2} , and a transconductance amplifier realizing the nonzero term in \mathbf{g}_m . This realization is shown in Fig. 17, where $g_{m01} = C\omega_0$ and $R = Q/C\omega_0$. Observe that this realization is essentially the same as that obtained by replacing the grounded inductor in the bandpass filter of Fig. 4 with a gyrator/capacitor combination.

The generalization of this synthesis technique to arbitrary-order systems is straightforward, although cumbersome. In this case, the G_m matrix is again partitioned into symmetric and skew symmetric matrices; however, each related off-diagonal pair of elements in the skew symmetric G_{m2} matrix must be realized with a separate gyrator.

Figure 17. General synthesis realization for a bandpass filter.

This will not be much of a problem if the matrix is sparse, which can often be arranged in setting up the state equations. The N -port gyrator described in, for example, Refs. 9 and 10 can be used to realize the entire G_{m2} matrix at one time.

6. ADVANCED TOPICS

6.1. Energy and Initial Conditions

Gyrators have already been shown to be lossless two-ports. This idea can be extended to show a duality between the energy stored on a capacitor and the energy stored in an inductor. Suppose that a capacitor, of value C , is connected to one port of a gyrator. Further suppose that this capacitor is charged to a voltage V . Then the energy stored in this capacitor is given by $\frac{1}{2}CV^2$. As described earlier, the impedance seen looking into the other port of the gyrator is an equivalent inductor. Given the lossless nature of the gyrator, this equivalent inductor should be expected to have the same apparent stored energy. However, in the case of an inductor the energy stored is $\frac{1}{2}LI^2$, where I is the current flowing in the inductor. A capacitor is in equilibrium with an open circuit across it, and an inductor is in equilibrium with a short circuit across it. Hence, by short-circuiting the port of the gyrator opposite the capacitor, a current flows that will be equal to the equilibrium current in the equivalent inductor. The following analysis shows that the stored energy in the equivalent inductor equals that actually stored on the capacitor:

$$\frac{1}{2}LI^2 = \frac{1}{2} \frac{C}{g^2} (gV)^2 = \frac{1}{2} CV^2 \quad (19)$$

The natural consequence of this energy relationship is that the current at the inductive port cannot change instantaneously, since the voltage at the capacitive port cannot change instantaneously. Hence, initial conditions can be readily translated from one port to another. These facts demonstrate that the gyrator is truly an energy conservative two-port, satisfying any intuition take one might have regarding its operation.

6.2. Nonideal Effects

Gyrators, in practice, cannot be made to be ideal. Therefore, practical gyrators are not lossless. Instead they introduce small losses into the system. This is explained by modifying the y -parameter matrix for the gyrator to include diagonal terms. With these terms the two-port is no longer lossless, as is clear from this analysis:

$$\begin{aligned} \mathbf{I} = \mathbf{YV} &= \begin{vmatrix} g_{11} & -g \\ g & g_{22} \end{vmatrix} \mathbf{V} = \mathbf{GV} \\ \Rightarrow \mathbf{V}^T \mathbf{I} &= \mathbf{V}^T \mathbf{GV} = g_{11} V_1^2 + g_{22} V_2^2 \end{aligned} \quad (20)$$

If the diagonal elements, g_{11} and g_{22} , are both positive, then the two-port described in the equation is lossy, since

the power delivered to this two-port must be positive. In practice, the loss terms arise naturally from the fact that the transconductors comprising the gyrator are nonideal. For example, the input/output impedance of the transconductors will not be infinite in a practical device. In this case, g_{11} and g_{22} are the nonzero input admittance of the transconductors.

Furthermore, the transfer characteristics will not in general be ideal. As an example, consider the case of the gyrator realized using op amps as in Fig. 10. Suppose that the op amps have a finite gain A . Then the y -parameter matrix can be derived, and is found to be

$$Y = \begin{vmatrix} g_0 & -G \\ G - \delta G & g_0 \end{vmatrix}$$

where $G = \frac{1}{R}$; $g_0 = 2(1 - K)G$
 $\delta G = 2(1 - K^2)G$; $K = \frac{1}{1 + 2/A}$

where A is the open-loop voltage gain of the operational amplifiers. Notice that this Y matrix corresponds to an ideal gyrator when A becomes infinite. Also observe that the finite gain of the op amps has caused the y -parameter matrix to no longer be skew symmetric, which in itself adds loss to the system. Hence, in general, practical gyrators exhibit loss and asymmetry—that is, they lack skew symmetry—in their transfer characteristics.

Another possibility, considering Eq. (20), is for the diagonal elements, g_{11} and g_{22} , to be purely imaginary. In this case, the power computed in Eq. (20) is imaginary, which translates to purely reactive power. When dissipated power is purely reactive, no average power is dissipated. Hence, a gyrator with purely imaginary diagonal elements is still lossless. Such a device could be synthesized by adding reactive elements in series or parallel with the ports of the gyrator, since the diagonal elements, g_{11} and g_{22} , amount to the input admittance looking into the respective ports of the gyrator. Furthermore, stray capacitance or inductance associated with the inputs or the active circuitry making up the gyrator does not contribute to loss.

6.3. The Hall Effect Device and Isolators

It has been observed that Hall effect devices implement a lossy gyrator. This is because the physics of these devices is such that the two electric field controlled ports behave as a pair as if they were a gyrator with loss—that is, g_{11} and g_{22} in Eq. (20) are nonzero and not purely imaginary. The physics of such devices is explained in Ref. 11.

Figure 18 shows an interesting usage for a Hall effect gyrator, and in fact any lossy gyrator. In the figure, a gyrator, assumed to have the y -parameter matrix of Eq. (20), has bridging components, R_{p1} and R_{p2} , added around it. Then a pair of sources, V_{S1} and V_{S2} , with respective source resistance, R_{S1} and R_{S2} , are attached as shown. With a little effort the response of this circuit from the sources to

Figure 18. Connection for a lossy gyrator to implement an isolator.

the port voltages of the gyrator can be found to be

$$\begin{vmatrix} V_1 \\ V_2 \end{vmatrix} = \alpha \begin{vmatrix} G_{S1}(g_{22} + G_{S2} + G_P) & -G_{S2}(G_P + g) \\ G_{S1}(G_P - g) & G_{S2}(g_{11} + G_{S1} + G_P) \end{vmatrix} \begin{vmatrix} V_1 \\ V_2 \end{vmatrix}$$

where $\alpha = (g_{11} + G_{S1} + G_P)(g_{22} + G_{S2} + G_P) + G_P^2 - g^2$

$$G_P = G_{P1} + G_{P2}$$

(22)

By choosing the sum of the bridging elements equal to gyration constant g , the response at port 2 can be made totally independent of V_{S1} , as opposed to the response at port 1, which will depend on both sources. This creates a circuit called an *isolator*, which can be found in various applications, especially microwaves and optics.

6.4. Multiport and Gyrators

The concept of a gyrator need not be restricted solely to two-port networks. In fact, an N -port gyrator can be contrived as a natural extension of the two-port gyrator. As one might expect, the N -port gyrator must inherit the key properties of the two-port type. It must be a nonreciprocal lossless network; it must also reflect impedances in a way similar to the two-port gyrator. In general, N -port gyrators have not found use in electrical systems. For a detailed discussion of such networks, refer to Refs. 9 and 10.

There is one special case, however, of an N -port complex gyrator, for $N = 3$, which has found extensive use in microwave systems—namely, the circulator. While practical circulators are quite complex structures, electrically speaking, they can be viewed over a certain range of frequency to be an approximately lossless three-port complex gyrator. Reference 12 describes the three-port y -parameter matrix for a circulator. Specifically

$$Y = \begin{vmatrix} \alpha & \beta & \gamma \\ -\beta^* & \alpha & \beta \\ -\gamma^* & -\beta^* & \alpha \end{vmatrix} \tag{23}$$

where the superscript $*$ denotes complex conjugation. It is referred to as being complex since the lower triangular matrix part of Y is the negative of the conjugate transpose of the upper triangular part. The power P delivered to a

three-port having this y -parameter matrix is given by

$$P = \begin{vmatrix} \alpha & \beta & \gamma \\ -\beta^* & \alpha & \beta \\ -\gamma^* & -\beta^* & \alpha \end{vmatrix} \begin{vmatrix} V_1 \\ V_2 \\ V_3 \end{vmatrix} \quad (24)$$

$$= \alpha(V_1^2 + V_2^2 + V_3^2) + (\beta - \beta^*)(V_1V_2 + V_2V_3) + (\gamma - \gamma^*)V_1V_3$$

As suggested, this power can be made purely reactive if all the coefficients multiplying the voltage products are purely imaginary. This condition is always met if α is imaginary, since the real parts of β and γ cancel in the final result. Hence, the circulator described by this equation is a lossless three-port given purely imaginary values for α . The circulator is interesting in that the transfer characteristics from port to port when driven by sources—for example, V_{S1} , V_{S2} , and V_{S3} —is similar to the isolator previously described. Specifically, V_{S1} does not affect the port 2 voltage, V_{S2} does not affect the port 3 voltage, and V_{S3} does not affect the port 1 voltage. More details of the design and use of circulators is given in Ref. 13.

GYROTRONS

R. LAWRENCE IVES
Calabazas Creek Research, Inc.
Saratoga, California

1. INTRODUCTION

The gyrotron is a vacuum tube capable of delivering high levels of radiofrequency (RF) power at frequencies from several gigahertz (GHz) to more than 200 GHz, which covers most of the microwave and millimeter-wave bands. Because of the structure of the RF fields in the cavity, the magnitude of the electric fields and the RF losses in the cavity walls are much lower in gyrotrons than in most microwave and millimeter-wave vacuum devices. As the RF frequency increases, it is not necessary to reduce the size of the cavity and output waveguide. For these reasons, the gyrotron is the principal RF device for delivering high levels of RF power in this frequency range.

Gyrotrons typically require a very high magnetic field to provide the electron cyclotron motion for power extraction, and most gyrotrons above 30 GHz require a superconducting magnet. Until recently (as of 2003), this significantly increased system cost and complexity, limiting applications for these devices. Recent advances in cryogen-free magnets are eliminating the requirement for liquid cryogenics and allowing additional applications. Gyrotrons also have a narrow RF bandwidth, typically around 0.1%. Historically, narrow bandwidth and the overmoded nature of the gyrotron limited their use as amplifiers, so almost all high-power gyrotrons are oscillators. Research on high-power gyroamplifiers is in progress at several locations around the world, and bandwidths of 7% and higher have been achieved [1], increasing their potential use for high-power, high-resolution radar [2]. Gyrokystrons are also being developed to drive high-power accelerators, which do not require large bandwidths [3,4].

Gyrotrons are used for electron cyclotron resonance heating (ECRH), electron cyclotron current drive (ECCD), and diagnostic measurements in fusion plasma devices. They are also being used for industrial heating applications such as ceramic sintering. Figure 1 shows a photograph of Dr. Howard Jory, one of the pioneers in gyrotron development, holding a 28-GHz, 10-kW continuous-wave (CW) harmonic gyrotron used for industrial heating. Behind him is a 110-GHz gyrotron, rated at approximately 450 kW CW, used for electron cyclotron resonance heating. Communications and Power Industries, Inc. in Palo Alto, CA manufactures both devices.

Research on gyro-type devices began in the 1950s, when the astrophysicist R. Q. Twiss described an amplifying mechanism for monochromatic radiation of angular frequency ω from stimulated emission of an ensemble of electrons [5]. Twiss' formula predicted amplification for Cerenkov radiation and for cyclotron radiation. Working independently, Schneider described the stimulated emission of radiation from electrons in a magnetic field in 1959 using a quantum-mechanical model [6]. Also in 1959,

Figure 1. Dr. Howard Jory holds a 28-GHz, 10-kW CW harmonic gyrotron used for industrial heating. Behind him is a 110-GHz, 450-kW CW, 1-MW pulsed, gyrotron used for electron cyclotron heating of fusion plasmas.

Gapanov described this mechanism using a classical approach [7].

The first experimental results describing a fast-wave cyclotron interaction were reported by R.H. Pantell in 1959 [8]. His device produced radiation between 2.5 and 4.0 GHz from a 1-kV, 3- μ A electron beam. A number of additional experiments were reported during the early 1960s [9–12], but the experiment that confirmed the cyclotron maser interaction was performed by Hirshfield and Wachtel in 1964 [13].

During the mid to late 1960s, major advances were made by scientists in the Soviet Union, although much of this work went unreported in the Western world because of the political climate at the time [14]. Soviet scientists embarked on a major program to develop megawatt gyrotrons and made major advances in electron mode selection, open resonators and waveguides [15], ray tracing to optimize the interaction between the electron beam and the RF wave in the circuit, and high-cross-section cavities utilizing whispering gallery modes [16]. “Whispering gallery modes” are transverse electric modes where the number of azimuthal field variations significantly exceeds the number of radial field variations. Use of these modes was further facilitated by the development by Vlasov et al. of a quasioptical device for converting the whispering gallery waveguide mode into a Gaussian mode that can be propagated in a narrow wave beam without waveguides [17].

An equally important Soviet development was the magnetron injection gun, which generates the required electron beam for efficient gyrotron operation.

For a more complete historical description of gyrotron development, the reader is referred to three publications that cover the subject in more detail [18–20]. The reader is also referred to a listing of journals in the bibliography that contain most of the published work in this area.

2. BASIC THEORY OF OPERATION

Gyrotrons exploit the negative mass instability to achieve azimuthal bunching of a cycloding electron beam. A transverse electric field in the cavity modifies the energy of the electrons such that higher-energy electrons gyrate more slowly around the magnetic flux lines than do lower-energy electrons. A schematic cross section of a gyrotron beam is shown in Fig. 2. The gyrotron beam is a hollow electron beam with individual electrons rotating at the cyclotron frequency around magnetic field lines with orbit diameters equal to twice the Larmour radius. The Larmour radius is given by

$$R_1 = \frac{\gamma m v_{\perp}}{e B_0}$$

where $\gamma = (1 - v_{\perp}^2/c^2 - v_z^2/c^2)^{-1/2}$ is the relativistic factor, m is the rest mass of the electron, v_{\perp} is the velocity of the electron in the plane perpendicular to the gyrotron axis, v_z is the electron velocity in the axial direction, e is the charge of the electron, and B_0 is the applied magnetic field parallel to the gyrotron axis.

Figure 3 more closely examines the effect of the electric field on the individual electrons in a cyclotron orbit when the frequency of the electric field is equal to the cyclotron

Figure 2. The cylindrical electron beam of the gyrotron consists of electrons orbiting around magnetic flux lines.

Figure 3. The cavity electric field interacts with the electrons orbiting around the magnetic flux lines. Each diagram illustrates an integral number of cyclotron periods later in time as the electrons traverse the cavity. The force on the electrons is given by $\vec{F} = -e\vec{E}$.

frequency. The cyclotron frequency is given by

$$\Omega = \frac{eB_0}{\gamma mc}$$

The electric field components have the form

$$E_\theta = E_0 J'_m(k_\perp r) \sin k_z z \cos m\theta$$

$$E_r = \frac{m}{k_\perp r} J_m(k_\perp r) \sin k_z z \sin m\theta$$

where E_θ and E_r are the azimuthal and radial components of the electric field, respectively; J_m and J'_m are the Bessel function and Bessel function derivative, respectively; m is the azimuthal mode number of the electric field; $k_\perp = X'_{mn}/r_0$, where X'_{mn} is the n th root of the corresponding Bessel function derivative and r_0 is the circuit radius; and $k_z = p\pi/L$, where p is the axial mode number of the circuit field (typically = 1) and L is the cavity length.

In Fig. 3, each successive image is an integral number of RF periods later in time as the electrons traverse the cavity. Electrons accelerated by the electric field gain energy and, as a result of the relativistic mass increase, their angular velocity decreases as γ increases. Conversely, electrons decelerated by the electric field lose energy and gain angular velocity. This causes azimuthal bunching of the electrons, sometimes referred to as the *cyclotron resonance maser* (CRM) instability.

If the frequency of the electric field exceeds the cyclotron frequency, the bunch will eventually fall back in phase and more electrons will undergo deceleration than acceleration, as shown in Fig. 4. This will result in transfer of energy from the electrons to the electric field. Optimized performance of gyrotrons requires careful design of the circuit geometry and control of the magnetic field. The circuit geometry affects the strength and profile of the electric field. The magnetic field affects the location of the beam and the amount of transverse energy available for transfer to the electric field. In many cases the magnetic field is tapered, that is, it is modified in strength through the cavity, to optimize the efficiency of power extraction.

Harmonic gyrotrons operate at a multiple of the cyclotron frequency. As the harmonic number increases, beam placement becomes more critical and the theoretical efficiency decreases. The advantage of harmonic gyrotrons is that the magnitude of the magnetic field is $1/n$ times that

required for nonharmonic operation. This can eliminate the need for a superconducting magnet or, at least, significantly reduce the cost.

For a more complete description of gyrotron theory, both linear and nonlinear, the reader is referred to several excellent publications on the subject [20–22].

3. BASIC COMPONENTS

Figure 5 shows a schematic layout of a typical gyrotron oscillator. The basic components are an electron gun, input beam tunnel, circuit, output taper, collector, window, and magnets. There are numerous variations of each of these components, depending on the operating characteristics of the gyrotron. The discussion that follows describes the most common types of components, including their purpose and performance characteristics.

3.1. Electron Gun

The function of the electron gun is to produce the electron beam required for interaction with the desired operating mode in the circuit. The gun must produce an electron beam that will be located at the proper radius for efficient interaction with the cavity electric fields and must contain most of its energy in cyclotron motion. Gyrotrons employ a magnetron injection gun (MIG) that emits electrons into a region of crossed electric and magnetic fields. This geometric configuration causes the individual electrons to spiral around the magnetic field lines as they are accelerated by

Figure 4. When $\omega > \Omega_0$, more electrons will be decelerated than accelerated, resulting in transfer of energy to the electric field.

Figure 5. The basic components of a typical gyrotron are the electron gun, beam tunnel, cavity, output beam tunnel, collector, window, and magnet solenoids.

the electric field toward the circuit. This development was pioneered in the Soviet Union in the 1970s and made rapid development of gyrotrons possible [23].

Gyrotron cathodes typically operate temperature-limited, which means that the amount of current emitted from the cathode is determined primarily by the temperature of the emitting surface. The reader is referred to the excellent treatment of cathode emission mechanisms presented by Gilmour [24]. Typical cathode temperatures range between 950 and 1000°C.

Gyrotron guns come in two basic types, modulated (mod) anode and diode. A mod anode gun contains an electrode near the emitting surface to modulate the electron beam; that is, it uses an applied voltage to modify the characteristics of the beam. This electrode is maintained at a voltage between the cathode and ground and can have a significant effect on the beam characteristics and hence the performance of the gyrotron. By varying the voltage on this electrode, the user can control the output power by varying the amount of transverse energy that is present in the electron beam. Most commercially available gyrotron oscillators using mod anode guns operate at cathode voltages between -60 and -80 kV with mod anode voltages ranging from 15 kV up to about 30 kV above cathode potential.

A diode gun possesses no intermediate electrode, so the cathode voltage or the magnetic field controls gyrotron operation. Because the cathode power supply must also supply the current in the beam, it cannot be modified as easily as a mod anode supply, so diode guns typically operate where RF power is turned on or off by pulsing of the cathode power supply. For applications where it is not necessary to modify the operating characteristics of the tube, this represents a lower cost gyrotron and power supply configuration.

3.2. Magnetic Solenoids

The circuit requires an electron beam where the electrons are orbiting the magnetic field lines at a frequency near that of the RF frequency of the cavity. For gyrotrons operating at frequencies above 30 GHz, this typically requires a superconducting solenoid. An exception can occur

if the circuit is operating at a harmonic of the cyclotron frequency. The requirement of a superconducting solenoid limits applications for gyrotrons to those where the additional weight and complexity do not present a severe burden. Recent development of cryogen-free, superconducting magnets is now allowing mobile or airborne applications [25].

In addition to the solenoids required to produce the cavity magnetic field, other solenoids can be present around the electron gun and collector regions. Solenoids around the electron gun modify the amount of transverse energy in the beam or its size in the circuit. These coils are typically operated at room temperature because the fields in the electron gun are usually a few hundred Gauss. The ratio of the magnetic field magnitude in the circuit to that in the electron gun is referred to as the *beam compression*. This value plays an important role in the design of the electron gun and the combination of electric and magnetic fields required for efficient circuit interaction. Beam compressions of 10–20 are typical.

Solenoids around the collector are used to distribute the power deposited by the electron beam exiting from the circuit. The fringing magnetic fields from superconducting coils impose a magnetic field in the collector that is higher than in other linear beam tubes. This field prevents the electrons from spreading as a result of space charge and results in a relatively thin beam of electrons impacting a small region of the collector. This can result in excessive localized heating of the surface and possible destruction of the gyrotron. The collector coils are used to “buck” the field from the main solenoid and spread the electron impact area over a larger region of the collector. In some more advanced applications, an oscillating power supply drives one or more solenoids to sweep the beam back and forth along the collector surface.

3.3. Beam Tunnel

The beam tunnel must perform two important functions. First, it must prevent RF fields from the circuit from traveling back toward the electron gun. RF fields in the electron gun can severely affect the electron beam and cause excessive current on the body of the tube or the mod anode. It can also result in heating of the cathode emitter,

which will affect the beam current. Either condition will adversely affect tube operation.

The second function of the beam tunnel is to prevent parasitic oscillations between gun and circuit. Parasitic oscillations result in excessive body or mod anode current and can prevent tube operation. In some cases, dielectric material with a high RF loss is used to load out any electromagnetic fields present.

3.4. Circuit

The RF circuit typically consists of a right circular cylinder whose radius a is chosen such that

$$a = \frac{cX'_{mn}}{2\pi f}$$

where X'_{mn} is the n th root of the Bessel function derivative for the TE_{mn} cavity mode, c is the speed of light, and f is the operating frequency. The cavity mode depends primarily on the desired RF frequency and output power level. The application for the tube can also play an important role. The first commercial gyrotrons used TE_{01} , TE_{02} , or TE_{03} modes because they were reasonably close to the fundamental mode, did not couple to nonsymmetric modes that could travel down the beam tunnel toward the electron gun, and had very low RF loss in the circuit walls. More than 100 gyrotrons at frequencies between 28 and 100 GHz and power levels up to 340 kW CW were produced by Varian Associates, Inc. (now Communications and Power Industries, Inc.) from 1978 through 1990. These tubes were used for electron cyclotron resonance heating (ECRH) of plasmas in magnetic confinement fusion research. Gyrotrons of this type were also developed in Germany, China, Japan, France, and Russia [26].

As the demand for higher-power tubes increased, gyrotrons that used whispering gallery modes were developed. Whispering gallery modes allow the electron beam to be larger and minimize mode competition from other circuit modes. These modes also have reasonable RF power dissipation in the circuit.

Designers of high-power gyrotrons must balance a large number of factors to achieve a circuit configuration that will provide the power and frequency required with reasonable efficiency while avoiding parasitic mode competition, instabilities, and excessive RF power densities on the circuit walls. For additional information on the design of high-power gyrotron circuits, the reader is referred to the article by Kreisler et al. [27].

3.5. Output Taper

Most gyrotron circuits are open-ended toward the collector, and the RF power diffracts into the output taper. The output taper is usually a shallow, tapered section of circular waveguide that terminates the circuit interaction and transmits the RF power toward the collector. The waveguide radial dimensions must be increased in such a way that the purity of the output mode is not compromised. For gyrotrons where the RF power is extracted along the axis of the tube, the output taper continues to

increase in the radial dimension until the desired collector radius is achieved. The requirement to maintain mode purity often conflicts with the necessity of achieving the collector radius within a reasonable distance. The size of the collector is driven by the necessity to dissipate the spent electron beam without incurring excessive power densities on the walls, which could lead to melting or loss of vacuum integrity.

For gyrotrons with average RF power levels exceeding 200 kW, particularly those employing whispering gallery circuit modes, it is more expedient to extract the RF power radially to allow more flexibility in the collector design. For these tubes, the output taper transmits the circuit power to an RF launcher/antenna for eventual extraction from the vacuum envelope. This eliminates further requirements on the output taper to maintain mode purity and allows the designer more freedom in transitioning to the collector region.

3.6. Collector

Typical linear beam devices rely on termination of the magnetic field and space charge depression to spread the spent electron beam in the collector. Most of these devices employ an iron polepiece to terminate the magnetic field at the entrance to the collector. While this works well for solid electron beams, it does not apply to gyrotrons. Because of the high magnetic fields required in gyrotrons, this is rarely practical, particularly when superconducting solenoids are used.

Forces imposed by nearby iron on the superconducting coils would dramatically increase the complexity and cost of the magnet. As a result, sufficient magnetic fields exist in the collector to limit spreading of the electron beam from space charge forces. In addition, the beam used in gyrotrons is typically a thin cylindrical beam with high current density. This also exacerbates the problem of beam dissipation in the collector. Power densities up to 500 W/cm² are typical; 1000 W/cm² is considered the upper limit.

For gyrotrons at lower average power levels, these complications may not be a critical issue. For these devices, the output taper conducts the RF power to the collector with high mode purity, and the collector also serves as the output waveguide. In some cases, a downtaper is employed at the end of the collector to reduce the tube diameter before the output window. For these devices, the designer must also be concerned about modes that can be trapped in the collector between the uptaper from the circuit and the downtaper to the window.

For gyrotrons exceeding 500 kW of average power, radial RF power extraction is almost always employed. The size of the collector can be based on the dissipation requirements of the spent beam alone. As a result, collectors for high-power gyrotrons often constitute a major portion of the device. In Fig. 1, the collector of the 500-kW CW gyrotron behind Dr. Jory begins above the output window. The designer must balance low power densities with the increasing size, weight, and cost of large collectors.

Considerable research is now in progress to implement collector voltage depression to improve the total efficiency

of the gyrotron while simultaneously reducing the thermal power dissipation. The efficiency of the RF circuit is typically 30–40%; therefore, most of the incident beam power is dissipated in the collector. For a 1-MW CW gyrotron, approximately 2 MW of thermal power must be dissipated by the collector. To reduce this thermal power and improve the gyrotron efficiency, a voltage can be applied to the collector that is between that of the electron gun and the RF circuit. This slows the electrons and reduces the incident power. Since the total gyrotron input power is proportional to the voltage difference between the electron gun and the collector, this also increases the net efficiency. The amount of voltage depression that can be applied depends on the energy of the electrons following RF power extraction in the circuit. Voltage depression that exceeds the energy of the electrons will lead to reflection of the beam back toward the electron gun or circuit. This will lead to excessive heating, loading of the power supplies, or loss of interaction efficiency. Most gyrotrons in development today implement voltage depression to increase the total efficiency to approximately 50%.

Additional increases in efficiency can be achieved by introducing collectors with multiple electrodes at varying voltages and sorting the energy of the incident electrons using carefully designed magnetic fields. This allows additional increase in depression voltage for the higher-energy electrons while still avoiding reflection of slower ones. A two-stage depressed collector is currently being developed and is predicted to increase the overall efficiency of gyrotrons to more than 55% [28,29].

3.7. RF Launcher System

The RF launcher system converts the circular cavity/waveguide mode to a quasioptical Gaussian mode. This development was pioneered in the Soviet Union and allows transmission of the RF beam with very low loss using a series of metallic mirrors. Modern computer codes and integration with computer numerically controlled (CNC) mills and lathes allow precise control of the RF beam. Modern designs convert the power from the circuit into the desired Gaussian mode with greater than 95% efficiency. More advanced computer codes are in development that could increase the efficiency to more than 98% [30]. The conversion of the waveguide mode to a quasioptical Gaussian mode also results in a more convenient RF mode for most user applications.

Figure 6 shows a typical RF launcher configuration consisting of a waveguide launcher and two mirrors internal to the gyrotron. The exit angle of the RF power from the launcher is at the waveguide bounce angle, and the mirrors concentrate the power into a small circular beam and tailor the distribution of power within the beam as required by the output window.

3.8. Output Window

Until recently, the output power of gyrotrons was limited by the capabilities of the output window. The RF power produced in the high-vacuum region inside the gyrotron is extracted from the device through a dielectric window.

Figure 6. The Gaussian mode launcher converts the waveguide mode to a quasioptical beam, and the internal mirrors shape the RF beam profile.

The window must provide a vacuum interface while transmitting the RF power from the gyrotron into an external waveguide that may, or may not, be under vacuum. Some of the RF power transmitted through the window is absorbed and results in heating of the dielectric material. The window structure must be sufficiently cooled to prevent destruction from thermal stresses.

For gyrotrons producing power levels less than 500 kW continuously, common window materials include alumina and sapphire; however, beryllia oxide, boron nitrite, silicon nitride, and other materials have been used in special devices. At higher average power levels, the thermal characteristics of standard materials is such that the heat deposited in the ceramic cannot be adequately removed by cooling around the edges as in most linear beam devices. Figure 7 shows a schematic diagram of a double disk window that uses a dielectric fluid to convectively face cool the disks.

Development of chemical-vapor-deposited (CVD) diamond windows eliminated thermal stresses as a limiting factor in gyrotrons [31]. CVD diamond is significantly stronger, and has a higher thermal conductivity and much lower RF loss than do other available materials

Figure 7. In the double-disk window, a dielectric fluid flows between the ceramic disks for enhanced cooling.

[32]. Consequently, it has become the window material used in all high-power gyrotrons. Unfortunately, the CVD manufacturing process is time-consuming and expensive. Currently, window ceramics for gyrotrons producing 1 MW or more of continuous power cost in excess of \$100,000. Efforts are underway to develop more efficient and less expensive methods for producing these windows.

4. AMPLIFIERS

While most gyro devices are oscillators, research is in progress to develop gyroamplifiers as drivers for linear accelerators [33,34] and for high-frequency, high-resolution radar [35]. While oscillator design is relatively straightforward, amplifier design presents several challenges. Since the circuits are typically overmoded, it becomes more difficult to prevent RF leakage through the drift regions between cavities. Also, the high cavity Q factors characteristic of gyrotron output cavities limit the bandwidth that can be achieved. While several amplifier configurations have been studied, the gyroklystron and the gyro-TWT (traveling-wave tube) have achieved the most success.

The gyroklystron consists of two or more cavities separated by drift spaces too small to propagate the operating mode. An azimuthal drift is imposed on the electrons by a sinusoidal energy modulation in the first cavity. These drifts are enhanced by intermediate buncher cavities, and the output cavity extracts the power from the azimuthally bunched electron beam. Most gyroklystrons employ cavity modes that are above the fundamental TE_{11} circular waveguide mode. Extreme care must be used to ensure that any RF power converted from the cavity mode to the TE_{11} mode is not allowed to propagate through the drift spaces and cause spurious oscillations. This also limits the circuit modes that can be used to those close to the fundamental (typically TE_{01} or TE_{02}) circuit modes. Gyroklystron bandwidths of 7% have been achieved with saturated gain of 20–40 dB. Operating efficiencies greater than 30% are common. An advanced, high-power, millimeter-wave radar system is currently under development by the U.S. Naval Research Laboratory that uses a 94-GHz gyroklystron with a 700 MHz bandwidth, 10% duty factor, and a saturated gain of 33 dB [1]. The device will be used for tactical radar applications, studies of cloud physics, propagation, and forward and backscatter studies [2].

In the gyro-TWT, an azimuthally bunched helical beam interacts with a traveling wave. If the periodicity and velocity of the electron bunches are such that synchronism occurs between the electrons and the traveling wave, cumulative bunching and energy extraction can occur. These amplifiers have considerably larger bandwidths than do gyroklystrons; however, they operate at lower efficiency (<20%) and generally produce less power.

Research has also been performed on gyro backward-wave oscillators, gyrotwistrons, and gyropeniotrons. The reader is referred to the Further Reading list at the end of this article for information on these devices.

5. CURRENT STATE OF THE ART

Gyrotrons are currently in development in several countries around the world, including Russia, Germany, France, Japan, and the United States. Currently, the highest-power gyrotron is a device jointly developed by Germany, France, and Switzerland to produce 1 MW of RF power in pulses lasting several minutes. The device, shown in Fig. 8, operates at 140 GHz and will be used in the stellerator Wendlestein 7-X currently under construction at IPP Greifswald, Germany. A total of 10 MW of RF power will be required for electron cyclotron heating of the stellerator plasma. Researchers recently reported achieving 850 kW in 3-min pulses, which were partially limited by the available power supply [36]. The gyrotron has also produced 970 kW for 11.8 s. Communications and Power Industries, Inc. in the United States produced several 1-MW, 10-s gyrotrons at 110 GHz. These are used for electron cyclotron heating of the DIII-D tokamak at General Atomics in San Diego, CA.

The current state of the art in gyroklystrons is the 94-GHz device built by Communications and Power Industries, Inc. for the WARLOCK radar system. This device produces a peak power of 100 kW and 10 kW of average power.

Figure 8. A 140-GHz, 1-MW gyrotron under development for the stellerator Wendlestein 7-X currently under construction at IPP Greifswald, Germany.

6. FUTURE DEVELOPMENT

Most gyrotron research is focused on increasing the output power, primarily for ECRH and ECCD of fusion plasmas. It is anticipated that several tens of megawatts of RF power will be required for heating these plasmas. It is desirable to maximize the output power of the individual gyrotrons to reduce the number of gyrotrons required. The current goal is to develop gyrotrons producing 1–2 MW of CW power at frequencies between 100 and 170 GHz.

Researchers in the United States are developing a 1.5-MW, long-pulse gyrotron operating at 110 GHz. This device will be used for electron cyclotron heating of the DIII-D tokamak operated by General Atomics in San Diego, CA. The gyrotron will use a conventional cylindrical cavity, diode electron gun, and a depressed collector.

As the required output power increases, the size of the cavity must increase to maintain and handle the RF currents in the walls. Increasing the cavity size increases the number of RF modes that can be excited, thereby increasing problems with mode competition. Above 1.5 MW, it becomes more attractive to utilize a coaxial cavity to decrease the number of competing modes. Researchers in Germany are developing a 2-MW coaxial gyrotron at 170 GHz for anticipated heating requirements for the next generation of fusion experiments. The device incorporates a depressed collector and quasioptical output [37]. Additional complications are introduced by the center conductor, which must be supported, aligned, and cooled within the vacuum envelope of the gyrotron.

Research is in progress to develop step-tunable gyrotrons for operation over increased frequency ranges. Since the gyrotron frequency is partially determined by the magnetic field, it becomes possible to use this characteristic to excite operating modes at different frequencies. As the magnitude of the magnetic field is varied, different operating modes are excited. The frequency of the gyrotron jumps to the resonant frequency of that particular mode [38,39]. A problem arises, however, with designing a ceramic window capable of operating over the required range of frequencies. Several alternatives are under development, including Brewster angle windows.

Amplifier research is focused on developing gyroamplifiers for high-resolution radar and for high-power linear accelerators. Current research goals for radar applications include bandwidth enhancement, increased efficiency, increased output power, and gains exceeding 30 dB. Accelerator applications do not require large bandwidths, but peak powers exceeding 100 MW at frequencies between 11 and 20 GHz and 10 MW devices at W band will be required. Figure 9 shows a 10-MW gyrokyklystron designed to operate at 91.392 GHz that is currently under development. High efficiency and reasonable gain will be major goals. Advances in gyrotron components, such as windows, electron guns, launcher systems, and depressed collectors, will also be applicable to amplifier development.

Research is in progress to develop gyrotrons for industrial heating applications, particularly for sintering of fine-grain ceramics. Studies indicate that microwave and millimeter sintering can produce extremely high heating rates or selective heating in multiphase systems, leading

Figure 9. A 10-MW, 91-GHz gyrokyklystron under development for high-power accelerator research.

to novel ceramic materials with compositions and microstructures not possible using standard techniques [40]. Several experiments are in progress to develop sources for these applications [41,42]. It is anticipated that other applications will materialize when efficient, cost effective sources are available.

HANKEL TRANSFORMS

M. RAHMAN

The object of this article is to introduce integral transform of a particular type, called the *Hankel transform*, and to illustrate the *use* of this method by means of examples. The treatment is that of a review article and as such is not meant to be exhaustive; its aim is to give a concatenated account of known results rather than present new ones. The emphasis throughout is on those results that are of frequent occurrence in boundary value problems of mathematical physics, but some indication is also given for possible theoretical investigations.

Proofs are either omitted entirely or only the key steps are outlined. Readers interested in rigorous proofs of some of the statements in this article are referred to the books by Sneddon [1,2], Davies [3], Andrews and Shivamoggi [4], and Zayed [5].

The organization of the article is as follows. In the first section, we illustrate the motivation behind introducing the Hankel transform and then give a precise definition of the Hankel transform and its inversion. The next two sections are devoted to the derivation of some basic properties of Hankel transforms. In the following section, we explore the connection between Fourier and Hankel transforms. Parseval's relation for Hankel transforms is then deduced. We next introduce the modified operator of Hankel transforms. An overview of Erdelyi-Kober operators and their generalization by Sneddon and Cooke is given. We then derive Beltrami-type relations and give a brief account of their generalization by Sneddon. An extensive account is given of the applications of Erdelyi-Kober and Cooke operators to dual, triple, and quadruple integral equations involving Hankel transforms. A number of issues that arise in connection with applications of Hankel transforms to many physical problems is then addressed. For the convenience of the readers, a compendium is given in the last section of the basic theorems and formulas of Hankel transforms that are of frequent occurrence in applications.

1. THE HANKEL TRANSFORM

The Hankel transform arises naturally as a result of using the method of separation of variables to boundary value problems of mathematical physics in cylindrical coordinates, for example, boundary value problems for the Laplace and Helmholtz equations involving half-spaces and regions bounded by parallel planes. In general, application of this technique is relevant to problems leading to the integration of equations of the type

$$\frac{\partial^2 \phi}{\partial r^2} + \frac{1}{r} \frac{\partial \phi}{\partial r} - \frac{v^2}{r^2} \phi + L\phi = f(r, \dots)$$

where L is a linear operator that does not contain r , and $f(r, \dots)$ is a prescribed function.

To illustrate this, let us consider the axisymmetric solution $\phi(r, z)$ of Laplace's equation

$$\frac{\partial^2 \phi}{\partial r^2} + \frac{1}{r} \frac{\partial \phi}{\partial r} + \frac{\partial^2 \phi}{\partial z^2} = 0 \tag{1}$$

in the half-space $r > 0, z > 0$, which satisfies the boundary condition

$$\phi(r, 0) = f(r) \tag{2}$$

where $f(r)$ is a prescribed function of r .

In addition, the solution of the problem must satisfy the regularity conditions so that the field decays as $R \rightarrow \infty$, where $R = \sqrt{r^2 + z^2}$.

Assuming that the solution can be represented in the separated-variable form

$$\phi(r, z) = \phi_1(r)\phi_2(z)$$

we find that Eq. (1) reduces to

$$\frac{1}{\phi_1} \frac{d^2 \phi_1}{dr^2} + \frac{1}{\phi_1 r} \frac{d\phi_1}{dr} = -\frac{1}{\phi_2} \frac{d^2 \phi_2}{dz^2} \tag{3}$$

Since the left-hand side of Eq. (3) depends only on r while the right-hand side only on z , we conclude that they must be equal to a constant, say, $\lambda = -s^2$, where s is a real quantity. Thus, we obtain two ordinary differential equations

$$\begin{aligned} \frac{d^2 \phi_1}{dr^2} + \frac{1}{r} \frac{d\phi_1}{dr} + s^2 \phi_1 &= 0 \\ \frac{d\phi_2}{dz^2} - s^2 \phi_2 &= 0 \end{aligned} \tag{4}$$

The first of these equations is that of Bessel [6], whose solution bounded at the origin is

$$\phi_1(r) = A_1(s)J_0(sr)$$

where $A_1(s)$ is an arbitrary function of s and $J_0(sr)$ is the zeroth-order Bessel function of the first kind.

On the other hand, the solution of the second relation of Eq. (4) ensuring a decaying field is given by

$$\phi_2(z) = A_2(s)e^{-sz}$$

Therefore, the solution of Eq. (1) is

$$\phi(r, z) = A(s)J_0(sr)e^{-sz} \tag{5}$$

where $A(s)$ is an arbitrary function of s . Readers can easily verify that the other cases, namely, $\lambda = 0$ and $\lambda = s^2$ (s is a real quantity), must be ignored, since they do not ensure a decaying field as $R \rightarrow \infty$.

The solution of Eq. (5) has the property that, if $s > 0$, $\phi(r, z) \rightarrow 0$ as $R \rightarrow \infty$. By simple superposition, we can therefore construct the solution of the form

$$\phi(r, z) = \int_0^\infty sA(s)J_0(sr)e^{-sz} ds \tag{6}$$

The condition of Eq. (2) will be satisfied if

$$f(r) = \int_0^\infty sA(s)J_0(sr) ds \tag{7}$$

yielding an equation for determining the unknown function $A(s)$. It will be shown later that $A(s)$ is given by the formula

$$A(s) = \int_0^\infty rf(r)J_0(sr) dr \tag{8}$$

which on substitution into Eq. (6) then formally gives the solution of our problem.

The formulas in Eqs. (7) and (8) define a transformation pair called the *Hankel transform of order zero*. We now give a formal definition of the Hankel transform of an arbitrary order of a function.

Given a real function $f(r)$ defined in the interval $(0, \infty)$, suppose that

1. $f(r)$ is piecewise continuous and of bounded variation in every finite subinterval $[a, b]$, where $0 < a < b < \infty$
2. The integral

$$\int_0^\infty \sqrt{r}|f(r)|dr < \infty$$

Then, the *Hankel transform of the v th order* of the function $f(r)$ satisfying the preceding conditions is defined as

$$\tilde{f}_v(s) = \int_0^\infty rf(r)J_v(sr) dr \tag{9}$$

which we shall write as

$$\tilde{f}_v(s) = \mathcal{H}_v[f(r); r \rightarrow s] \tag{10}$$

Sometimes, for the sake of brevity, we shall write this notation as $\mathcal{H}_v[f(r); s]$, $\mathcal{H}_v[f(r)]$, or simply $\mathcal{H}_v f(r)$.

Readers should note that since the kernel of the Hankel transform is the Bessel function, the theory of Hankel transforms relies heavily on the theory of the Bessel functions. Perhaps, for this reason, in some literature, this transform is called Bessel transformation or Fourier-Bessel transformation.

The *Hankel inversion theorem* states that if the function $f(r)$ satisfies the preceding conditions, then

$$\int_0^\infty s\tilde{f}_v(s)J_v(sr) ds = f(r) \tag{11}$$

If the function has a jump discontinuity at a point, then the right-hand side of Eq. (11) should be replaced by the sum

$$\frac{1}{2}[f(r+0) + f(r-0)]$$

We shall not give a proof of the Hankel inversion theorem here. Interested readers are referred to the book by Sneddon [2].

It follows from Eqs. (10) and (11) that

$$f(r) = \int_0^\infty sJ_v(sr) ds \int_0^\infty r_0f(r_0)J_v(sr_0) dr_0 \tag{12}$$

$$0 < r < \infty, \quad v > -\frac{1}{2}$$

Equation (12) is called *Hankel's integral theorem*.

Evidently, Eq. (11) can be written as

$$f(r) = \mathcal{H}_v^{-1}[\tilde{f}_v(s); s \rightarrow r]$$

which, in the notation of Eq. (10), is equivalent to

$$f(r) = \mathcal{H}_v[\tilde{f}_v(s); s \rightarrow r]$$

hence establishing the rule $\mathcal{H}_v = \mathcal{H}_v^{-1}$. Thus, we see that if $v > -\frac{1}{2}$, there is a symmetric relationship between a function and its Hankel transform of order v , in the sense that if $\tilde{f}_v(s)$ is the Hankel transform of order v of a function $f(r)$, then $f(r)$ is the Hankel transform of order v of $\tilde{f}_v(s)$.

Extensive tables have been constructed of the Hankel direct and inverse transforms of functions usually encountered in applications [e.g., 7].

As in the case of other types of integral transforms, the use of Hankel transform has many advantages, for example, it is applicable to both homogeneous and inhomogeneous problems, it simplifies calculations and singles out the purely computational part of the solution, and it allows us to construct an operational calculus for a given kernel by using tables of direct and inverse transforms.

An extensive account of applications of the Hankel transform as well as other integral transforms to problems in mathematical physics was given by Sneddon [1,2,8] and Lebedev et al. [9]. Perhaps it is Sneddon who may quite justifiably be regarded as the most ardent proponent of using the method of integral transforms—in particular, Hankel transform—to various boundary value problems of mathematical physics.

2. SOME ELEMENTARY PROPERTIES OF HANKEL TRANSFORMS

Property 1.

$$\begin{aligned} \mathcal{H}_{-m}[f(r); r \rightarrow s] &= (-1)^m \mathcal{H}_m[f(r); r \rightarrow s] \\ &\times (m = \pm 1, \pm 2, \dots, \pm n, \dots) \end{aligned}$$

Proof of this property follows from the fact that [6]

$$J_{-m}(sr) = (-1)^m J_m(sr)$$

Property 2.

$$\mathcal{H}_v[f(ar); r \rightarrow s] = a^{-2} \mathcal{H}_v\left[f(r); r \rightarrow \frac{s}{a}\right]$$

Proof: By definition, we have

$$\mathcal{H}_v[f(ar); r \rightarrow s] = \int_0^\infty rf(ar) J_v(sr) dr \tag{13}$$

By making a change of variable $ar = \rho$, we reduce the integral in Eq. (13) to the form

$$\begin{aligned} \mathcal{H}_v[f(ar); r \rightarrow s] &= a^{-2} \int_0^\infty \rho f(\rho) J_v(sa^{-1}\rho) d\rho \\ &= a^{-2} \mathcal{H}_v\left[f(r); r \rightarrow \frac{s}{a}\right] \end{aligned}$$

Property 3.

$$\begin{aligned} \mathcal{H}_v[r^{-1}f(r); r \rightarrow s] \\ = \frac{s}{2v} [\tilde{f}_{v-1}(s) + \tilde{f}_{v+1}(s)] \quad (v \neq 0) \end{aligned}$$

Proof: From the recurrence relation for the Bessel functions [6]

$$j_{v-1}(x) - \frac{2v}{x} J_v(x) + J_{v+1}(x) = 0$$

we deduce

$$\begin{aligned} \mathcal{H}_v[r^{-1}f(r); r \rightarrow s] &= \int_0^\infty f(r) J_v(sr) dr \\ &= \frac{s}{2v} \left(\int_0^\infty rf(r) J_{v-1}(sr) dr \right. \\ &\quad \left. + \int_0^\infty rf(r) J_{v+1}(sr) dr \right) \\ &= \frac{s}{2v} [\tilde{f}_{v-1}(s) + \tilde{f}_{v+1}(s)] \end{aligned}$$

Property 4. The shift formula for the Hankel transforms is

$$\mathcal{H}_n[f(r-a)H(r-a); r \rightarrow s] = \sum_{m=-\infty}^\infty \alpha_m \tilde{f}_m(s)$$

where

$$\begin{aligned} \alpha_m &= J_{n-m}(sa) + \frac{1}{2}as[(m+1)^{-1}J_{n-m-1}(sa) \\ &\quad + (m-1)^{-1}J_{n-m+1}(sa)] \end{aligned}$$

Proof of this property is given in the book of Sneddon [2].

It should be mentioned here that it is not possible to obtain a simple shift formula for the Hankel transforms. This is primarily because the addition formula for the Bessel functions, that is, the Neumann–Lommel addition formula [6]

$$J_n(x+y) = \sum_{m=-\infty}^\infty J_m(x)J_{n-m}(y)$$

is much more complicated than the addition formula for the exponential functions e^x and e^{ix} for the Laplace and Fourier transforms.

3. THE HANKEL TRANSFORMS OF DERIVATIVES OF A FUNCTION

In applications of Hankel transforms to physical problems, it is necessary to have expressions for the Hankel transforms of the derivatives of a function or a combination of them, through the Hankel transforms of the function itself. Using the definition of Hankel’s transform and the formula for integrating by parts, we obtain

$$\begin{aligned} \mathcal{H}_v\left[\frac{df}{dr}; s\right] &= \int_0^\infty r \frac{df}{dr} J_v(sr) dr \\ &= [rf(r)J_v(sr)]_0^\infty \\ &\quad - \int_0^\infty \frac{\partial}{\partial r} [rJ_v(sr)] f(r) dr \end{aligned} \tag{14}$$

The first term on the right vanishes provided that the function $f(r)$ is such that

$$\lim_{r \rightarrow 0} r^{v+1}f(r) = 0, \quad \lim_{r \rightarrow \infty} \sqrt{r}f(r) = 0$$

It follows from the arguments leading to the proof of the Hankel inversion theorem [2] that the second of these conditions holds for any $f(r)$ whose Hankel transform exists. Therefore, the first term on the right in Eq. (14) vanishes if

$$f(r) = o(r^{-v-1}), \quad r \rightarrow 0$$

where o is the Landau’s symbol of order.

From the theory of Bessel functions [6,10], we have

$$\begin{aligned} \frac{\partial}{\partial r} [rJ_v(sr)] &= J_v(sr) + rJ'_v(sr) \\ J'_v(sr) &= srJ_{v-1}(sr) - vJ_v(sr) \end{aligned}$$

so that Eq. (14) now takes the following form:

$$\mathcal{H}_v \left[\frac{df}{dr}; r \right] = (v - 1) \int_0^\infty f(r) J_v(sr) dr - s \int_0^\infty rf(r) J_{v-1}(sr) dr \tag{15}$$

However, the integral on the right is the $(v - 1)$ th-order Hankel transform of $f(r)$:

$$\int_0^\infty rf(r) J_{v-1}(sr) dr = \mathcal{H}_{v-1}[f(r); r \rightarrow s]$$

Thus, Eq. (15) takes the form

$$\mathcal{H}_v \left[\frac{df}{dr}; r \rightarrow s \right] = (v - 1) \int_0^\infty f(r) J_v(sr) dr - s \mathcal{H}_{v-1}[f(r); r \rightarrow s] \tag{16}$$

The first term on the right is obviously the v th-order Hankel transform of the function $r^{-1}f(r)$. However, our objective is to express everything in terms of the Hankel transform of the function $f(r)$. This can be achieved by utilizing the following relation [10]:

$$J_v(sr) = \frac{1}{2v} [J_{v-1}(sr) + J_{v+1}(sr)] \tag{17}$$

Inserting Eq. (17) into Eq. (16), after some arrangements, we finally obtain the following important relationship:

$$\begin{aligned} \mathcal{H}_v \left[\frac{df}{dr}; r \rightarrow s \right] &= -s \frac{v+1}{2v} \mathcal{H}_{v-1}[f(r); r \rightarrow s] \\ &+ s \frac{v-1}{2v} \mathcal{H}_{v+1}[f(r); r \rightarrow s] \end{aligned} \tag{18}$$

Expressions for Hankel transforms of the higher derivatives of the function $f(r)$ may be deduced by repeated application of the formula in Eq. (18). For instance, we obtain

$$\begin{aligned} \mathcal{H}_v \left[\frac{d^2f}{dr^2}; r \rightarrow s \right] &= \frac{s^2(v+1)}{4(v-1)} \mathcal{H}_{v-2}[f(r)] \\ &- \frac{s^2(v^2-3)}{2(v^2-1)} \mathcal{H}_v[f(r)] \\ &+ \frac{s^2(v-1)}{4(v+1)} \mathcal{H}_{v+2}[f(r)] \end{aligned} \tag{19}$$

In applications of Hankel transforms to many physical problems, it becomes necessary to have available the

formula for Hankel transform of the differential operator:

$$\mathcal{B}_v = \frac{d^2}{dr^2} + \frac{1}{r} \frac{d}{dr} - \frac{v^2}{r^2}$$

Integrating by parts and assuming that $df/dr = o(r^{-1})$, we find

$$\int_0^\infty r \frac{d^2f}{dr^2} J_v(sr) dr = - \int_0^\infty \frac{df}{dr} \frac{d}{dr} [r J_v(sr)] dr$$

so that

$$\begin{aligned} \int_0^\infty r \left(\frac{d^2f}{dr^2} + \frac{1}{r} \frac{df}{dr} \right) J_v(sr) dr &= -s \int_0^\infty \frac{df}{dr} r J'_v(sr) dr \\ &= s \int_0^\infty f(r) \frac{d}{dr} [r J'_v(sr)] dr \end{aligned} \tag{20}$$

Equation (20) was derived on the assumption that the function $rf(r) \rightarrow 0$ as $r \rightarrow 0$ or ∞ .

We know from the theory of Bessel functions [6,10] that the function $J_v(sr)$ satisfies the differential equation

$$\frac{d}{dr} [r J'_v(sr)] = - \left(s^2 - \frac{v^2}{r^2} \right) r J_v(sr) \tag{21}$$

On substitution of Eq. (21) into Eq. (20), we obtain the following formula:

$$\begin{aligned} \int_0^\infty r \left(\frac{d^2f}{dr^2} + \frac{1}{r} \frac{df}{dr} - \frac{v^2}{r^2} f \right) J_v(sr) dr &= -s^2 \int_0^\infty rf(r) J_v(sr) dr \\ &= -s^2 \mathcal{H}_v[f(r); r \rightarrow s] \end{aligned} \tag{22}$$

An immediate consequence of Eq. (22) is the formula

$$\begin{aligned} \int_0^\infty r \left(\frac{d^2f}{dr^2} + \frac{1}{r} \frac{df}{dr} \right) J_0(sr) dr &= -s^2 \mathcal{H}_0[f(r); r \rightarrow s] \end{aligned} \tag{23}$$

To illustrate the use of the properties of Hankel transforms, let us consider the classic problem of determining the potential at any point in the field induced by an electrified disk of radius a , whose potential is raised to ϕ_0 (ϕ_0 is a constant). The problem is known as *Weber's problem*. A discussion of this problem can be found in the books by Jeans [11] and Smythe [12]. The problem reduces to that of solving Laplace's equation in Eq. (1) with the boundary conditions

$$\begin{aligned} \phi(r, 0) &= \phi_0, \quad 0 \leq r < a \\ \left. \frac{\partial \phi}{\partial z} \right|_{z=0} &= 0, \quad r > a \end{aligned} \tag{24}$$

The second boundary condition in Eq. (24) expresses the symmetry of the field with respect to the plane of the disk, that is, the plane $z = 0$.

To solve the problem, we use the zeroth-order Hankel transform of the function $\phi(r, z)$:

$$\phi(r, z) = \mathcal{H}_0[\tilde{\phi}(s, z); s \rightarrow r] \tag{25}$$

Applying the transformation in Eq. (25) to Eq. (1) and making use of the relation of Eq. (23), we obtain the following ordinary differential equation

$$\frac{d^2 \tilde{\phi}}{dz^2} - s^2 \tilde{\phi} = 0$$

whose solution is

$$\tilde{\phi}(s, z) = A(s)e^{-sz} + B(s)e^{sz} \tag{26}$$

where $A(s)$ and $B(s)$ are some unknown functions of s .

Because of symmetry, it is sufficient to consider the half-space $z \geq 0$ only. Then, since the field must vanish at infinity (regularity conditions), we must set $B = 0$, so that Eq. (26) reduces to

$$\tilde{\phi}(s, z) = A(s)e^{-sz}$$

Therefore, our formal solution of the problem takes the form

$$\phi(r, z) = \mathcal{H}_0[A(s)e^{-sz}; s \rightarrow r] \tag{27}$$

Utilizing the boundary conditions in Eq. (24), we get the following equations to determine the unknown function $A(s)$:

$$\begin{aligned} \mathcal{H}_0[A(s); s \rightarrow r] &= \phi_0, & 0 \leq r < a \\ \mathcal{H}_0[sA(s); s \rightarrow r] &= 0, & r > a \end{aligned}$$

or writing in integral form

$$\begin{aligned} \int_0^\infty sA(s)J_0(sr)ds &= \phi_0, & 0 \leq r < a \\ \int_0^\infty s^2A(s)J_0(sr)ds &= 0, & r > a \end{aligned} \tag{28}$$

Equations of the type in Eq. (28) are called *dual-integral equations*. A systematic treatment of this kind of equations will be discussed later. Here, we give a rather heuristic solution. Gradshteyn and Ryzhik [13] provide the following integrals:

$$\begin{aligned} \int_0^\infty \frac{\sin s}{s} J_0(sr) ds &= \frac{\pi}{2}, & 0 \leq r < a \\ \int_0^\infty (\sin s) J_0(sr) ds &= 0, & r > a \end{aligned} \tag{29}$$

A comparison of Eqs. (28) and with Eqs. (29) shows that the solution for $A(s)$ is

$$A(s) = \frac{2\phi_0}{\pi} \frac{\sin s}{s} \tag{30}$$

Putting Eq. (30) into Eq. (27), we obtain the solution of our problem as

$$\phi(r, z) = \frac{2\phi_0}{\pi} \int_0^\infty \frac{\sin s}{s} J_0(sr) e^{-sz} ds \tag{31}$$

The uniqueness of Eq. (31) follows from the physical contents of the problem.

4. RELATION BETWEEN FOURIER AND HANKEL TRANSFORMS

In this section, the relationship between Hankel and Fourier transforms of a function of two variables is explored. Specifically, we shall see that there exists a close relationship between the double Fourier transform of a function of two variables of a particular type and its Hankel transform.

Consider a function $f(x_1, x_2)$ that is a function of $r = x_1^2 + x_2^2$ only. The double Fourier transform $F(\alpha_1, \alpha_2)$ is

$$\begin{aligned} F(\alpha_1, \alpha_2) &= \frac{1}{2\pi} \int_{-\infty}^\infty \int_{-\infty}^\infty f(\sqrt{x_1^2 + x_2^2}) \\ &\times e^{i(\alpha_1 x_1 + \alpha_2 x_2)} dx_1 dx_2 \end{aligned} \tag{32}$$

If we make the substitutions into Eq. (32)

$$\begin{aligned} x_1 &= r \cos \theta, & x_2 &= r \sin \theta, \\ \alpha_1 &= s \cos \varphi, & \alpha_2 &= s \sin \varphi \end{aligned}$$

then, since

$$dx_1 dx_2 = r dr d\theta, \quad \alpha_1 x_1 + \alpha_2 x_2 = rs \cos(\theta - \varphi)$$

the double integral in Eq. (32) reduces to

$$F(\alpha_1, \alpha_2) = \frac{1}{2\pi} \int_0^\infty r f(r) dr \int_0^{2\pi} e^{irs \cos(\theta - \varphi)} d\theta \tag{33}$$

Since the inner integral on the right is 2π -periodic, it does not depend on φ , that is

$$\int_0^{2\pi} e^{irs \cos(\theta - \varphi)} d\theta = \int_0^{2\pi} e^{irs \cos \theta} d\theta$$

which is equal to $2\pi J_0(rs)$ [6,10], where $s = \sqrt{\alpha_1^2 + \alpha_2^2}$. We therefore see that the function $F(\alpha_1, \alpha_2)$ is a function of s only and may be written as

$$F(s) = \int_0^\infty r f(r) J_0(sr) dr = \mathcal{H}_0[f(r); r \rightarrow s] \tag{34}$$

which, of course, is the zeroth-order Hankel transform of $f(r)$. On the other hand, by the Fourier inversion theorem, we have

$$f(x_1, x_2) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F(\alpha_1, \alpha_2) \times e^{-i(\alpha_1 x_1 + \alpha_2 x_2)} d\alpha_1 d\alpha_2$$

Using the same substitution as before, the preceding expression can be reduced to the following formula:

$$f(r) = \int_0^{\infty} sF(s)J_0(sr) ds = \mathcal{H}_0[F(s); s \rightarrow r] \quad (35)$$

Formulas in Eqs. (34) and (35) obviously express the Hankel inversion theorem in the special case where $v = 0$.

The preceding results can be easily generalized in case of n -dimensional Fourier transforms. If the functions $f(x_1, x_2, \dots, x_n)$ is function only of $r = \sqrt{x_1^2 + x_2^2 + \dots + x_n^2}$, then its Fourier transform $F(\alpha_1, \alpha_2, \dots, \alpha_n)$ is a function of s only where $s = \sqrt{\alpha_1^2 + \alpha_2^2 + \dots + \alpha_n^2}$. More specifically, the following relationship holds:

$$s^{(n-1)/2}F(s) = \int_0^{\infty} r[r^{(n-1)/2}f(r)] \times J_{(n-1)/2}(sr) dr \quad (36)$$

For proof, the readers are referred to the book by Sneddon [1].

It therefore follows from Eq. (36) that $s^{(n-1)/2}F(s)$ is the Hankel transform of order $(n - 1)/2$ of the function $r^{(n-1)/2}f(r)$.

Similarly, by n -dimensional Fourier inversion theorem, it can be shown that

$$r^{(n-1)/2}f(r) = \int_0^{\infty} s[s^{(n-1)/2}F(s)] \times J_{(n-1)/2}(sr) ds \quad (37)$$

If we write

$$\phi(r) = r^{(n-1)/2}f(r), \quad \tilde{\phi}_v(s) = s^{(n-1)/2}F(s),$$

$$v = \frac{n - 1}{2}$$

then Eqs. (36) and (37) take the following form:

$$\tilde{\phi}_v(s) = \int_0^{\infty} r\phi(r)J_v(sr) dr = \mathcal{H}_v[\phi(r); r \rightarrow s]$$

$$\phi(r) = \int_0^{\infty} s\tilde{\phi}_v(s)J_v(sr) ds = \mathcal{H}_v[\tilde{\phi}_v(s); s \rightarrow r]$$

These formulas obviously define the v th-order Hankel transformation pair for the function $\phi(r)$.

5. PARSEVAL'S RELATION FOR HANKEL TRANSFORMS

Suppose that

$$\tilde{f}_v(s) = \mathcal{H}_v[f(r); r \rightarrow s], \quad \tilde{g}_v(s) = \mathcal{H}_v[g(r); r \rightarrow s]$$

Then, putting formally, we obtain the equation

$$\int_0^{\infty} s\tilde{f}_v(s)\tilde{g}_v(s) ds = \int_0^{\infty} s\tilde{f}_v(s) ds \int_0^{\infty} xg(x)J_v(sx) dx \quad (38)$$

$$= \int_0^{\infty} xg(x) dx \int_0^{\infty} s\tilde{f}_v(s)J_v(sx) ds$$

in which the inner integral, by Hankel's inversion theorem, is obviously equal to $f(r)$.

Equation (38) then yields the following formula:

$$\int_0^{\infty} s\tilde{f}_v(s)\tilde{g}_v(s) ds = \int_0^{\infty} xf(x)g(x) dx \quad (39)$$

The expression Eq. (39) is evidently the Parseval relation for the Hankel transform. As in the case of other integral transforms, such a Fourier, Laplace, Mellin, and Kantorovich-Lebedev transforms, Parseval's relation is a very useful tool in many theoretical and practical investigations.

It should be noted here that a general Parseval relation involving Hankel transforms of two functions of different orders does not exist. This is primarily because the Neumann-Rahman formula [6,14] for the product of two first-kind Bessel functions of different orders

$$J_{m+n}(sr)J_n(sr_0)$$

$$= \frac{1}{\pi} \int_0^{\pi} \left\{ \cos(n\varphi)T_m\left(\frac{r-r_0 \cos \varphi}{R}\right) + \frac{r_0 \sin n\varphi \sin \varphi}{R} \right.$$

$$\left. \times U_{m-1}\left(\frac{r-r_0 \cos \varphi}{R}\right) \right\} J_m(R) d\varphi, \quad U_{-1}(\dots) = 0 \quad (40)$$

where $R = \sqrt{r^2 + r_0^2 - 2rr_0 \cos \varphi}$, $T_m(\dots)$ and $U_{m-1}(\dots)$ are the Chebyshev polynomials of the first and second kinds, respectively, is much more complicated than the simplest rule for the product of two exponential functions (kernels of Laplace and Fourier transforms) of different powers.

As an example of application of Parseval's relation in Eq. (39), let us evaluate the integral

$$\mathcal{H}_v[x^{-2}J_v(ax); x \rightarrow s], \quad v > -\frac{1}{2}$$

Taking $f(x) = x^v H(a - x) (a > 0)$ and $g(x) = x^v H(b - x) (b > 0)$, where $\mathcal{H}(\dots)$ is the step function, we have

$$\tilde{f}_v(s) = \int_0^a x^{v+1} J_v(sx) dx;$$

$$\tilde{g}_v(s) = \int_0^b x^{v+1} J_v(sx) dx$$

These integrals are easily evaluated [13] as

$$\begin{aligned} \tilde{f}_v(s) &= \frac{a^{v+1}}{s} J_{v+1}(sa), \\ \tilde{g}_v(s) &= \frac{b^{v+1}}{s} J_{v+1}(sb) \end{aligned}$$

Now, using Parseval's relation in Eq. (39), we obtain

$$\begin{aligned} (ab)^{v+1} \int_0^\infty s^{-1} J_{v+1}(sa) J_{v+1}(sb) ds \\ = \int_0^{\min(a,b)} x^{2v+1} dx \end{aligned}$$

Assuming that $0 < a < b$, we find that (13)

$$\begin{aligned} \int_0^\infty s^{-1} J_{v+1}(sa) J_{v+1}(sb) ds \\ = \frac{1}{2(v+1)} \left(\frac{a}{b}\right)^{v+1} \\ 0 < a < b, v > -\frac{1}{2} \end{aligned}$$

It therefore follows from the preceding equation that

$$\begin{aligned} \mathcal{H}_v [x^{-2} J_{v+1}(ax); x \rightarrow s] \\ = \begin{cases} \frac{1}{2v} \left(\frac{s}{a}\right)^v, & 0 < s < a \\ \frac{1}{2v} \left(\frac{a}{s}\right)^v, & s > a \end{cases} \end{aligned}$$

where, $v > \frac{1}{2}$.

6. THE HANKEL OPERATOR

In many theoretical investigations, it is more convenient to use a modified operator of Hankel transform $S_{\eta,\alpha}$ instead of the operator \mathcal{H}_v . This modified Hankel operator is defined by the formula

$$S_{\eta,\alpha}[f(t); x] = 2^\alpha x^{-\alpha} \mathcal{H}_{2\eta+\alpha}[t^{-\alpha} f(t); t \rightarrow x] \tag{41}$$

so that

$$S_{\eta,\alpha}[f(t); x] = 2^\alpha x^{-\alpha} \int_0^\infty t^{1-\alpha} f(t) J_{2\eta+\alpha}(xt) dt \tag{42}$$

If we write

$$\tilde{f}_{\eta,\alpha}(x) = S_{\eta,\alpha}[f(t); x] \tag{43}$$

then from Eq. (41), we obtain

$$\mathcal{H}_{2\eta+\alpha}[t^{-\alpha} f(t); x] = 2^{-\alpha} x^\alpha \tilde{f}_{\eta,\alpha}(x) \tag{44}$$

Applying Hankel's inversion, we deduce from Eq. (43) that

$$f(t) = 2^{-\alpha} t^\alpha \mathcal{H}_{2\eta+\alpha}[x^\alpha \tilde{f}_{\eta,\alpha}(x); t]$$

or writing out the above expression in full, we obtain

$$f(t) = S_{\eta+\alpha,-\alpha}[\tilde{f}_{\eta,\alpha}(x); t]$$

thus establishing the rule

$$S_{\eta,\alpha}^{-1} = S_{\eta+\alpha,-\alpha} \tag{45}$$

In applications, the following relationship is useful

$$S_{\eta,\alpha} f(x) = 2^{-\lambda} x^\lambda S_{\eta\lambda/2,\alpha+\lambda}[x^\lambda f(x)]$$

the validity of which can be easily proved by writing out both sides of the equation using the definition in Eq. (42).

7. THE ERDELYI-KOBER OPERATORS OF FRACTIONAL INTEGRATION

In this section, we present a brief exposition of the so-called Erdelyi-Kober operators of fractional integrations [15–17] and their generalization due to Sneddon and Erdelyi [8,18] and Cooke [19,20]. We next illustrate applications of these operators to the solution of dual-, triple- and quadruple-integral equations involving Hankel transforms, which arise in many boundary value problems of mathematical physics, especially electrostatics and electromagnetic scattering. The description here closely follows Sneddon [21].

In a series of papers [15–17], Erdelyi and Kober investigated properties of the fractional integral

$$\frac{x^{-\eta-\alpha+1}}{\Gamma(\alpha)} \int_0^x (x-t)^{\alpha-1} t^{\eta-1} f(t) dt \quad (\alpha > 0, \eta > 0)$$

which is a generalization of Riemann's integral

$$\frac{1}{\Gamma(\alpha)} \int_0^x (x-t)^{\alpha-1} f(t) dt$$

and Weyl's integral

$$\frac{x^\alpha}{\Gamma(\alpha)} \int_x^\infty (t-x)^{\alpha-1} t^{-\alpha-\eta} f(t) dt \quad (\alpha > 0, \eta > 0)$$

7.1. Definitions and Basic Results

If $\alpha > 0, \eta > -\frac{1}{2}$, we define the operator $I_{\eta,\alpha}$ by the equation

$$\begin{aligned} I_{\eta,\alpha} f(x) \\ = \frac{2x^{-2\alpha-2\eta}}{\Gamma(\alpha)} \int_0^x (x^2 - u^2)^{\alpha-1} u^{2\eta+1} f(u) du \end{aligned}$$

$I_{\eta,0}$ is the identity operator, and if $\alpha < 0$, we define $I_{\eta,\alpha}$ by the relation

$$I_{\eta,\alpha}f(x) = x^{-2\eta-2\alpha-1}D_x^n x^{2\eta+2\alpha+2n+1}I_{\eta,\alpha+n}f(x)$$

where n is a positive integer such that $0 < \alpha + n < 1$ and D_x is the differential operator

$$D_x = \frac{d}{dx}x^{-1}$$

Similarly, $\alpha > 0, \eta > -\frac{1}{2}$, we define the operator $K_{\eta,\alpha}$ by the equation

$$\begin{aligned} K_{\eta,\alpha}f(x) &= \frac{2x^{2\eta}}{\Gamma(\alpha)} \int_x^\infty (u^2 - x^2)^{\alpha-1} u^{-2\alpha-2\eta+1} f(u) du \end{aligned}$$

$K_{\eta,0}$ is the identity operator, and if $\alpha < 0$, we define $K_{\eta,\alpha}$ by the equation

$$K_{\eta,\alpha}f(x) = (-1)^n x^{2\eta-1} D_x^n x^{2n-2\alpha+1} K_{\eta-n,\alpha+n} f(x)$$

Operators $I_{\eta,\alpha}$ and $K_{\eta,\alpha}$ are called Erdelyi-Kober operators.

We next establish some properties of these operators. If we assume that $\alpha > 0, \beta > 0$, we have

$$\begin{aligned} I_{\eta,\alpha}I_{\eta+\alpha,\beta}f(x) &= \frac{2x^{-2\eta-2\alpha}}{\Gamma(\alpha)} \int_0^x (x^2 - u^2)^{\alpha-1} u^{2\eta+1} du \frac{2u^{-2\eta-2\alpha-2\beta}}{\Gamma(\beta)} \\ &\times \int_0^u (u^2 - t^2)^{\beta-1} t^{2\eta+2\alpha+1} f(t) dt \end{aligned}$$

Interchanging the order of integration and using the result (13)

$$\begin{aligned} &2 \int_t^x (x^2 - u^2)^{\alpha-1} (u^2 - t^2)^{\beta-1} u^{-2\alpha-2\beta+1} du \\ &= \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha+\beta)} t^{-2\alpha} x^{-2\beta} (x^2 - t^2)^{\alpha+\beta-1} \end{aligned}$$

we obtain

$$\begin{aligned} I_{\eta,\alpha}I_{\eta+\alpha,\beta}f(x) &= \frac{2x^{-2\eta-2\alpha-\beta}}{\Gamma(\alpha+\beta)} \int_0^x t^{2\eta+1} (x^2 - t^2)^{\alpha+\beta-1} f(t) dt \end{aligned}$$

The expression on the right is equal to $I_{\eta,\alpha+\beta}$, which follows from its definition, thus establishing the rule

$$I_{\eta,\alpha}I_{\eta+\alpha,\beta} = I_{\eta,\alpha+\beta} \tag{46}$$

Similarly, it can be shown that

$$K_{\eta,\alpha}K_{\eta+\alpha,\beta} = K_{\eta,\alpha+\beta} \tag{47}$$

The preceding relations are valid for $\alpha > 0, \beta > 0$, but it is a simple exercise to show that they are also valid for negative values of α and β . Also, it can be shown from the theory of integral equations of Abel type [8] that the inverse of the Erdelyi-Kober operators are given by the formulas

$$I_{\eta,\alpha}^{-1} = I_{\eta+\alpha,-\alpha}, \quad K_{\eta,\alpha}^{-1} = K_{\eta+\alpha,-\alpha} \tag{48}$$

The following formulas hold, whose validity can be proved very easily:

$$\begin{aligned} I_{\eta,\alpha}\{x^{2\beta}f(x)\} &= x^{2\beta}I_{\eta+\beta,\alpha}f(x) \\ K_{\eta,\alpha}\{x^{2\beta}f(x)\} &= x^{2\beta}K_{\eta+\beta,\alpha}f(x) \end{aligned}$$

The following relationships hold between the Erdelyi-Kober and Hankel operators:

$$\begin{aligned} I_{\eta+\alpha,\beta}S_{\eta,\alpha} &= S_{\eta,\alpha+\beta}, \quad K_{\eta,\alpha}S_{\eta+\alpha,\beta} = S_{\eta,\alpha+\beta} \\ S_{\eta+\alpha,\beta}S_{\eta,\alpha} &= I_{\eta,\alpha+\beta}, \quad S_{\eta,\alpha}S_{\eta+\alpha,\beta} = K_{\eta,\alpha+\beta} \\ S_{\eta+\alpha,\beta}I_{\eta,\alpha} &= S_{\eta,\alpha+\beta}, \quad S_{\eta,\alpha}K_{\eta+\alpha,\beta} = S_{\eta,\alpha+\beta} \end{aligned} \tag{49}$$

The proofs of these identities are based on the properties of Bessel functions and are given in the book by Davies [3].

7.2. The Cooke Operators

Cooke [19,20] has defined the operators

$$\begin{pmatrix} b \\ a \end{pmatrix} I_{\eta,\alpha}$$

and

$$\begin{pmatrix} d \\ c \end{pmatrix} K_{\eta,\alpha}$$

by the formulas

$$\begin{aligned} &\begin{pmatrix} b \\ a \end{pmatrix} I_{\eta,\alpha}f(x) \\ &= \begin{cases} \frac{2x^{-2\alpha-2\eta}}{\Gamma(\alpha)} \int_a^b (x^2 - u^2)^{\alpha-1} u^{2\eta+1} f(u) du, & \alpha > 0 \\ f(x), & \alpha = 0 \\ \frac{x^{-2\alpha-2\eta-1}}{\Gamma(1+\alpha)} \frac{d}{dx} \int_a^b (x^2 - u^2)^\alpha u^{2\eta+1} f(u) du, & -1 < \alpha < 0 \end{cases} \end{aligned} \tag{50}$$

for $0 < a < b < \infty$ and

$$\begin{aligned} & \begin{pmatrix} d \\ c \end{pmatrix} K_{\eta,\alpha} f(x) \\ &= \begin{cases} \frac{2x^{2\eta}}{\Gamma(\alpha)} \int_c^d (u^2 - x^2)^{\alpha-1} u^{-2\alpha-2\eta+1} f(u) du, & \alpha > 0 \\ f(x), & \alpha = 0 \\ \frac{-x^{2\eta-1}}{\Gamma(1+\alpha)} \frac{d}{dx} \int_c^d (u^2 - x^2)^\alpha u^{-2\alpha-2\eta+1} f(u) du, & -1 < \alpha < 0 \end{cases} \end{aligned} \tag{51}$$

for $0 < x < c < d$. It will be observed that these operators are related to the Erdelyi-Kober operators by the relations

$$\begin{pmatrix} x \\ 0 \end{pmatrix} I_{\eta,\alpha} = I_{\eta,\alpha}, \quad \begin{pmatrix} \infty \\ x \end{pmatrix} K_{\eta,\alpha} = I_{\eta,\alpha}$$

Cook [19,20] also defined the operators L and M by the equations

$$\begin{aligned} & \begin{pmatrix} x & b \\ c & a \end{pmatrix} L_{\eta,\alpha} f(x) = \begin{pmatrix} x \\ c \end{pmatrix} I_{\eta,\alpha}^{-1} \begin{pmatrix} b \\ a \end{pmatrix} I_{\eta,\alpha} f(x) \\ & \begin{pmatrix} d & b \\ x & a \end{pmatrix} M_{\eta,\alpha} f(x) = \begin{pmatrix} d \\ x \end{pmatrix} K_{\eta,\alpha}^{-1} \begin{pmatrix} b \\ a \end{pmatrix} K_{\eta,\alpha} f(x) \end{aligned} \tag{52}$$

and showed that if $a < b < c < x$, then

$$\begin{aligned} & \begin{pmatrix} x & b \\ c & a \end{pmatrix} L_{\eta,\alpha} f(x) = \frac{2 \sin(\pi\alpha)}{\pi} x^{-2\eta} (x^2 - c^2)^{-\alpha} \\ & \quad \times \int_a^b \frac{(c^2 - t^2)^\alpha t^{2\eta+1}}{x^2 - t^2} f(t) dt \end{aligned} \tag{53}$$

and that if $x < d < a < b$, then

$$\begin{aligned} & \begin{pmatrix} d & b \\ x & a \end{pmatrix} M_{\eta,\alpha} f(x) = \frac{2 \sin(\pi\alpha)}{\pi} x^{2\eta+2\alpha} (d^2 - x^2)^{-\alpha} \\ & \quad \times \int_a^b \frac{(t^2 - d^2)^\alpha t^{-2\alpha-2\eta+1}}{t^2 - x^2} f(t) dt \end{aligned} \tag{54}$$

8. BELTRAMI-TYPE RELATIONS

A classic problem of electrostatics concerns that of determining the potential of the electrostatic field due to a circular disk whose potential is prescribed. One way to solve this problem is to determine the charge density q on the disk and then to calculate the potential at any field

point \mathbf{r} by evaluating the integral

$$\int_S \frac{q(\mathbf{R}')}{|\mathbf{R} - \mathbf{R}'|} dS'$$

over the surface of the disk. In the case of axisymmetry, that is, when the prescribed potential $\phi(r)$ is a function of r only, Beltrami [22] showed that the density of the surface charge is given by the formula

$$\begin{aligned} q(r) &= \frac{-1}{\pi r} \frac{d}{dr} \int_r^\infty \frac{xdx}{\sqrt{x^2 - r^2}} \frac{d}{dx} \\ & \quad \times \int_0^x \frac{y\phi(y) dy}{\sqrt{x^2 - y^2}}, \quad 0 \leq r \leq a \end{aligned} \tag{55}$$

where a is the radius of the disk.

Sneddon [23] showed that Beltrami's relation in Eq. (55) is a special case of a general relation between Hankel transforms. In particular, he showed that the expression

$$\mathcal{H}_\mu[s^\delta \mathcal{H}_\nu f(s); r]$$

can be expressed as a double integral involving $f(r)$, which is a generalization of the integral occurring on the right-hand side of Beltrami's relation in Eq. (55). By assigning particular values of the parameters μ , δ , and ν , we can deduce relations that are of interest in the investigations into axisymmetric boundary value problems of potential theory.

If we apply the operator $K_{\eta-\gamma,\gamma}$ to both sides of the first equation of Eqs. (49) and make use of the second relation of Eqs. (49), we obtain

$$K_{\eta-\gamma,\gamma} I_{\eta+\alpha,\beta} S_{\eta,\alpha} = S_{\eta-\gamma,\alpha+\beta+\gamma} \tag{56}$$

Equation (56) can be written in terms of Hankel transforms as follows:

$$\begin{aligned} & \mathcal{H}_{2\eta+\alpha+\beta-\gamma}[t^{-\alpha-\beta-\gamma} f(t); r] \\ &= \left(\frac{r}{2}\right)^{\alpha+\beta+\gamma} K_{\eta-\gamma,\gamma} I_{\eta+\alpha,\beta} 2^\alpha \\ & \quad \times x^{-\alpha} \mathcal{H}_{2\eta+\alpha}[t^{-\alpha} f(t); x] \end{aligned} \tag{57}$$

For $\alpha = 0$ $\beta = (\mu - \nu - \delta)/2, \eta = \nu/2$, Eq. (57) simplifies significantly

$$\begin{aligned} & \mathcal{H}_\mu[s^\delta \tilde{f}(s); r] \\ &= 2^\delta r^\delta K_{(\mu+\delta)/2, (\nu-\mu-\delta)/2} I_{\nu/2, (\mu-\nu-\delta)/2} \tilde{f}(r) \end{aligned} \tag{58}$$

Some special cases of formulas in Eq. (58) are of particular interest. If we set $\mu = \nu$, we obtain

$$\mathcal{H}_\mu[s^\delta \tilde{f}(s); r] = 2^\delta r^{-\delta} K_{(\mu+\delta)/2, -\delta/2} I_{\nu/2, -\delta/2} \tilde{f}(r) \tag{59}$$

Special cases of particular interest are given by assigning $\delta = \pm 1$ to Eq. (59); we then obtain

$$\begin{aligned} \mathcal{H}_v [s\tilde{f}_v(s); r] &= \frac{-2}{\pi} r^{v-1} \frac{d}{dr} \int_r^\infty \frac{x^{1-2v}}{\sqrt{x^2 - r^2}} \frac{d}{dx} \\ &\quad \times \int_0^x \frac{y^{v+1} f(y) dy}{\sqrt{x^2 - y^2}} \quad (v \geq 0) \\ \mathcal{H}_v [s^{-1}\tilde{f}(s); r] &= \frac{2}{\pi} r^v \int_r^\infty \frac{x^{-2v}}{\sqrt{x^2 - r^2}} \\ &\quad \times \int_0^x \frac{y^{v+1} f(y) dy}{\sqrt{x^2 - y^2}} \quad (v \geq 0) \end{aligned} \tag{60}$$

On the other hand, if we put $\mu = v + 1$ in Eq. (59), we obtain the relation

$$\begin{aligned} \mathcal{H}_{v+1} [s^\delta \tilde{f}_v(s); r] \\ = 2^\delta r^{-\delta} K_{(v+\delta+1)/2, (-1-\delta)/2} I_{v/2, (1-\delta)/2} f(r) \end{aligned}$$

The special case $\delta = 1$ corresponds to the well-known formula

$$\mathcal{H}_{v+1} [s\tilde{f}_v(s); r] = -r^v \frac{d}{dr} [r^{-v} f(r)] \tag{61}$$

Expressions corresponding to the particular values 0 and -1 of δ are, respectively,

$$\begin{aligned} \mathcal{H}_{v+1} [\tilde{f}_v(s); r] &= \frac{-2}{\pi} r^v \frac{d}{dr} \int_r^\infty \frac{x^{-2v} dx}{\sqrt{x^2 - r^2}} \int_0^x \frac{y^{v+1} f(y) dy}{\sqrt{x^2 - y^2}} \quad (v \geq 0) \\ \mathcal{H}_{v+1} [s^{-1}\tilde{f}_v(s); r] &= r^{-v-1} \int_0^r u^{v+1} f(u) du \quad (v \geq 0) \end{aligned} \tag{62}$$

Finally, if we set $\mu = v - 1$ in Eq. (59), we obtain the relation

$$\mathcal{H}_{v-1} [s^\delta \tilde{f}_v(s); r] = 2^\delta r^{-\delta} K_{(v-1+\delta)/2, (v-1-\delta)/2} f(r) \tag{63}$$

The most frequently occurring special cases of the formula in Eq. (63) are

$$\begin{aligned} \mathcal{H}_{v-1} [s\tilde{f}_v(s); r] &= r^{-v} \frac{d}{dr} [r^v f(r)] \quad (v \geq 1) \\ \mathcal{H}_{v-1} [\tilde{f}_v(s); r] &= \frac{2}{\pi} r^{v-1} \int_r^\infty \frac{x^{1-2v} dx}{\sqrt{x^2 - r^2}} \frac{d}{dx} \int_0^x \frac{y^{v+1} f(y) dy}{\sqrt{x^2 - y^2}} \\ &\quad (v \geq 1) \\ \mathcal{H}_{v-1} [s^{-1}\tilde{f}_v(s); r] &= r^{v-1} \int_r^\infty x^{1-v} f(x) dx \quad (v \geq 1) \end{aligned} \tag{64}$$

8.1. Beltrami's Relation for an Electrified Disk

As an application of Beltrami-type relations just derived, let us consider the problem of an electrified disk of radius a lying in the plane $z = 0$ with its center at the origin of the

coordinate system. Let the surface charge density be $q(r)$. Then in the half-space $z \geq 0$ the potential of the electrostatic field will be $\phi_+(r, z)$ and in the half-space $z \leq 0$, it will be $\phi_-(r, z)$, where

$$\phi_\pm(r, z) = \mathcal{H}_0 [\tilde{\phi}_0(s) e^{\pm sz}; r]$$

where

$$\tilde{\phi}_0(s) = \mathcal{H}_0 [\phi(r, 0); s]$$

The charge density on the plane $z = 0$ is given by the equation

$$q(r) = \frac{-1}{4\pi} \left(\frac{\partial \phi_+}{\partial z} - \frac{\partial \phi_-}{\partial z} \right)_{z=0}$$

and it immediately follows from this equation that

$$q(r) = \frac{1}{2\pi} \mathcal{H}_0 [s\tilde{\phi}_0(s); r] \tag{65}$$

From the first equation of Eqs. (60) then we deduce Beltrami's relation in Eq. (55). On the other hand, we could write Eq. (65) in the form

$$\phi(r, 0) = 2\pi \mathcal{H}_0 [s^{-1}\tilde{q}_0(s); r]$$

and then using the second relation of Eq. (60) deduce the equation

$$\phi(r, 0) = 4 \int_r^\infty \frac{dx}{\sqrt{x^2 - r^2}} \int_0^{\min(a, x)} \frac{yq(y) dy}{\sqrt{x^2 - y^2}}$$

Interchanging the order of integration, the last equation can be written as

$$\phi(r, 0) = \int_0^a \sigma(y) K(r, y) dy$$

where

$$K(r, y) = 4y \int_{\min(r, y)}^\infty \frac{du}{\sqrt{(u^2 - r^2)(u^2 - y^2)}}$$

9. DUAL-INTEGRAL EQUATIONS INVOLVING HANKEL TRANSFORMS

In the applications of the theory of Hankel transforms to the solution of boundary value problems of mathematical physics, it often happens that the problem may be reduced to the solution of a pair of simultaneous equations of the form

$$\begin{aligned} f(x) &= S_{\mu/2-\alpha, 2\alpha} [1 + k(x)]\psi(x); \\ g(x) &= S_{\nu/2-\beta, 2\beta} \psi(x) \end{aligned} \tag{66}$$

in which

$$f(x) = \begin{cases} f_1(x), & x \in I_1 = \{x : 0 < x < 1\} \\ f_2(x), & x \in I_2 = \{x : 1 < x < \infty\} \end{cases}$$

$$g(x) = \begin{cases} g_1(x), & x \in I_1 = \{x : 0 < x < 1\} \\ g_2(x), & x \in I_2 = \{x : 1 < x < \infty\} \end{cases}$$

The problem is as follows. Knowing the functions $k(x)[k(x) \rightarrow 0, x \rightarrow \infty]$, f_1 , and g_2 , is it possible to find the functions ψ , f_2 , and g_1 ? In the following, we consider the special case where $k(x) = 0$, but it is straightforward to generalize the results for $k(x) \neq 0$.

To solve the problem, Sneddon proposed the following trial solution:

$$\psi(x) = S_{\nu/2 + \beta, \mu/2 - \nu/2 - \alpha - \beta} h(x) \tag{67}$$

Putting Eq. (67) into Eqs. (65), we obtain

$$S_{\mu/2 - \alpha, 2\alpha} S_{\nu/2 + \beta, \mu/2 - \nu/2 - \alpha - \beta} h = f$$

$$S_{\nu/2 - \beta, 2\beta} S_{\nu/2 + \beta, \mu/2 - \nu/2 - \alpha - \beta} h = g$$

which can be rewritten, using the third and fourth relations of Eq. (49), as

$$I_{\nu/2 + \beta, \nu/2 - \nu/2 + \alpha - \beta} h = f$$

$$K_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta} h = g$$

when

$$h = I_{\nu/2 + \beta, \mu/2 - \nu/2 + \alpha - \beta}^{-1} f \tag{68}$$

$$h = K_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta}^{-1} g$$

Writing Eqs. (68) on the intervals I_1 and I_2 , we have

$$h_1(x) = \begin{pmatrix} x \\ 0 \end{pmatrix} I_{\nu/2 + \beta, \mu/2 - \nu/2 + \alpha - \beta}^{-1} f_1$$

$$h_2(x) = \begin{pmatrix} 1 \\ 0 \end{pmatrix} I_{\nu/2 + \beta, \mu/2 - \nu/2 + \alpha - \beta}^{-1} f_1$$

$$+ \begin{pmatrix} x \\ 1 \end{pmatrix} I_{\nu/2 + \beta, \mu/2 - \nu/2 + \alpha - \beta}^{-1} f_2$$

$$h_2(x) = \begin{pmatrix} \infty \\ x \end{pmatrix} K_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta}^{-1} g_2$$

$$h_1(x) = \begin{pmatrix} \infty \\ 1 \end{pmatrix} K_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta}^{-1} g_2$$

$$+ \begin{pmatrix} 1 \\ x \end{pmatrix} K_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta}^{-1} g_1 \tag{69}$$

Putting the first and third equations of Eqs. (69) into Eq. (67), we obtain the solution for $\psi(x)$. On the other hand, from the second and third equations of Eqs. (69), we deduce that

$$\begin{pmatrix} x \\ 1 \end{pmatrix} I_{\nu/2 + \beta, \mu/2 - \nu/2 + \alpha - \beta}^{-1} f_2$$

$$= \begin{pmatrix} \infty \\ x \end{pmatrix} K_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta}^{-1} g_2$$

$$- \begin{pmatrix} 1 \\ 0 \end{pmatrix} I_{\nu/2 + \beta, \mu/2 - \nu/2 + \alpha - \beta}^{-1} f_1$$

whence it follows by use of the L operator defined by Eq. (53) that

$$f_2 = \begin{pmatrix} x \\ 1 \end{pmatrix} I_{\nu/2 + \beta, \mu/2 - \nu/2 + \alpha - \beta}$$

$$\times \begin{pmatrix} \infty \\ x \end{pmatrix} K_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta}^{-1} g_2 \tag{70}$$

$$- \begin{pmatrix} x & 1 \\ 1 & 0 \end{pmatrix} L_{\nu/2 + \alpha, \nu/2 - \mu/2 + \beta - \alpha} f_1$$

Thus, f_2 is determined. Similarly, using the first and fourth equations of Eqs. (68), we obtain for g_1 the formula

$$g_1 = \begin{pmatrix} 1 \\ x \end{pmatrix} K_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta} I_{\nu/2 + \beta, \mu/2 - \nu/2 + \alpha - \beta} f_1$$

$$- \begin{pmatrix} 1 & \infty \\ x & 1 \end{pmatrix} M_{\nu/2 - \beta, \mu/2 - \nu/2 - \alpha + \beta} g_2 \tag{71}$$

Thus, the first two equations in Eqs. (69) and Eqs. (70) and (71) give the complete solution to our problem. The same procedure, applied to the case where $k(x) \neq 0$, yields

$$h_1 + E(x) = \begin{pmatrix} x \\ 0 \end{pmatrix} I^{-1} f_1 \quad (x \in I_1)$$

$$h_2 + E(x) = \begin{pmatrix} 1 \\ 0 \end{pmatrix} I^{-1} f_1 + \begin{pmatrix} x \\ 1 \end{pmatrix} I^{-1} f_2 \quad (x \in I_2)$$

$$\begin{aligned}
 h_2 &= \begin{pmatrix} \infty \\ x \end{pmatrix} K^{-1}g_2 \quad (x \in I_2) \\
 h_1 &= \begin{pmatrix} \infty \\ 1 \end{pmatrix} K^{-1}g_2 + \begin{pmatrix} 1 \\ x \end{pmatrix} K^{-1}g_1 \quad (x \in I_1)
 \end{aligned}
 \tag{72}$$

where

$$\begin{aligned}
 E(x) &= S_{\mu/2-\alpha, \nu/2+\beta+\alpha-\mu/2} \\
 &\times k S_{\nu/2+\beta, \mu/2-\nu/2-\alpha-\beta} h(x)
 \end{aligned}
 \tag{73}$$

The subscripts with the I and K in Eqs. (72) are the same as those in Eqs. (69). Further details are carried out for the special case where $\nu = \mu$, $\beta = 0$, $g_2 = 0$, which is the most frequently occurring case in applications. In this case, we find from Eqs. (72) that $h_2(x) = 0$ and $h_1(x)$ solves the integral equation

$$h_1(x) + E(x) = \begin{pmatrix} x \\ 0 \end{pmatrix} I_{\nu/2, \alpha}^{-1} f_1 \quad (x \in I_1)
 \tag{74}$$

where

$$\begin{aligned}
 E(x) &\equiv S_{\nu/2-\alpha, \alpha} k S_{\nu/2, -\alpha} h(x) \\
 &= 2^\alpha x^{-\alpha} \int_0^\infty t^{1-\alpha} k(t) 2^{-\alpha} t^\alpha J_{\nu-\alpha}(xt) dt \\
 &\int_0^1 u^{1+\alpha} h_1(u) J_{\nu-\alpha}(tu) du
 \end{aligned}$$

and inverting the order of intergration, we have

$$E(x) = x^{-\alpha} \int_0^1 u^{1+\alpha} K(x, u) h_1(u) du
 \tag{75}$$

where

$$K(x, u) = \int_0^\infty t k(t) J_{\nu-\alpha}(xt) J_{\nu-\alpha}(ut) dt
 \tag{76}$$

Since the functions h_1 and h_2 have been determined, it is possible to find the functions ψ , f_2 , and g_1 following the procedure for the case $k(x) = 0$. These details can be found in the papers by Sneddon [8] and Cooke [19,20].

9.1. An Example: Two Coaxial Electrified Circular Disks

The problem of two solid disks, each charged to a uniform potential ϕ_0 , was the subject of numerous research starting with Love's paper [24] (for references, see Cooke [19]). If the disks have different potentials the problem may be reduced to two separate problems, in one of which the potentials are equal and in the other they are equal and opposite. Assume that the disks have the same radii, equal to unity, and are situated in the planes $z = 0$ and $z = h$, where r , θ , and z are cylindrical coordinates. Then, the problem reduces to that of solving

Laplace's equation in Eq. (1) subject to the following boundary conditions:

$$\begin{aligned}
 \phi(r, 0) &= \phi_0, \quad 0 < r < 1 \\
 \phi(r, 0_-) &= \phi(r, 0_+), \quad 0 \leq r < \infty \\
 \frac{\partial \phi}{\partial z} \Big|_{z=0_-} &= \frac{\partial \phi}{\partial z} \Big|_{z=0_+}, \quad r > 1 \\
 \phi(r, h) &= \pm \phi_0, \quad 0 < r < 1 \\
 \phi(r, h_-) &= \phi(r, h_+), \quad 0 \leq r < \infty \\
 \frac{\partial \phi}{\partial z} \Big|_{z=h_-} &= \frac{\partial \phi}{\partial z} \Big|_{z=h_+}, \quad r > 1
 \end{aligned}
 \tag{77}$$

The sign in fourth of the preceding conditions is positive or negative according to whether the disks are of like or unlike potentials ϕ_0 .

The solution of the problem must satisfy the regularity conditions at infinity. Besides, in order to guarantee uniqueness of solution, it must satisfy the *edge condition* [25,26] so that the electric energy stored in any neighborhood of the sharp edge $r = 1$ be finite, which imposes the restriction that the surface charge density not grow more rapidly than $\rho^{-1+\tau}$ with $\tau > 0$ as $\rho \rightarrow 0$, where $\rho = 1 - r$.

It can be shown by using zeroth-order Hankel transform to Laplace's equation in Eq. (1) that the electrostatic field can be represented by the potential function

$$\phi(r, z) = H_0[\phi_0 s^{-1}(e^{-|z|s} + e^{-|z-h|s})A(s); s \rightarrow r]
 \tag{78}$$

which satisfies the second and fifth continuity conditions in Eqs. (77), the sign in Eq. (78) being positive or negative depending on whether the disks are of like or unlike potentials ϕ_0 .

We find that the third and sixth conditions in Eqs. (77) will be satisfied if the function $A(s)$ satisfies the equation

$$\mathcal{H}_0[A(s); s \rightarrow r] = 0, \quad r > 1
 \tag{79}$$

Using the second and fourth boundary conditions in Eqs. (77) and Eqs. (79), we obtain the following dual integral equations:

$$\begin{aligned}
 \mathcal{H}_0[s^{-1}(1 \pm e^{-hs})A(s); s \rightarrow r] &= 1, \quad 0 \leq r < 1 \\
 \mathcal{H}_0[A(s); s \rightarrow r] &= 0, \quad r > 1
 \end{aligned}
 \tag{80}$$

Using the modified operator of Hankel transform, we rewrite Eqs. (80) in the form

$$\begin{aligned}
 S_{-1/2, 1}[1 \pm k(r)]A(r) &= 1, \quad 0 \leq r < 1 \\
 S_{0, 0}A(r) &= 0, \quad r > 1
 \end{aligned}
 \tag{81}$$

where $k(s) = e^{-hs}$. Thus, for our problem

$$\alpha = \frac{1}{2}, \quad \mu = 0, \quad \beta = 0, \quad \nu = 0$$

$$f_1(r) = \frac{r}{2\phi_0}, \quad g_2(r) = 0$$

Therefore, following the procedure outlined in the previous section, we find that $h_2(r) = 0$ and $h_1(r)$ solves the following integral equation

$$h_1(r) + r^{-1/2} \int_0^1 u^{3/2} K(r, u) h_1(u) du$$

$$= \begin{pmatrix} r \\ 0 \end{pmatrix} I_{1/2, -1/2} f_1(r) \quad 0 \leq r < 1 \tag{82}$$

where

$$K(r, u) = \pm \int_0^\infty tk(t) J_{-1/2}(rt) J_{-1/2}(ut) dt$$

Writing $rh_1(r) = H(r)$, we reduce Eq. (82) to the following Fredholm integral equation of the second kind

$$H(r) + \int_0^1 H(u) N(r, u) du$$

$$= \begin{pmatrix} r \\ 0 \end{pmatrix} I_{1/2, -1/2} f_1(r) \tag{83}$$

where

$$N(r, u) = \pm \sqrt{ru} \int_0^\infty tk(t) J_{-1/2}(rt) J_{-1/2}(ut) dt \tag{84}$$

The kernel $N(r, u)$ in Eq. (84) can be evaluated in closed form:

$$N(r, u) = \pm \left(\frac{1}{(r+u)^2 + h^2} + \frac{1}{(r-u)^2 + h^2} \right) \tag{85}$$

The integral equation defined by Eqs. (83) and (85) can be solved numerically.

The surface density at any point of a disk in the plane $z = 0$ is equal to

$$\frac{-1}{4\pi} \left(\frac{\partial \phi}{\partial z} \right)_{z=0}$$

When both sides of the disk are taken into account, this gives for the total charge Q

$$Q = \frac{\phi_0}{2\pi} \int_0^1 2\pi r dr \int_0^\infty A(s) J_0(sr) ds$$

$$= \phi_0 \int_0^1 r g_1(r) dr$$

$$= \phi_0 \int_0^1 r \begin{pmatrix} 1 \\ r \end{pmatrix} K_{0, -1/2} h_1(r) dr \tag{86}$$

$$= -\frac{\phi_0}{\sqrt{\pi}} \int_0^1 dr \frac{d}{dr} \int_x^1 \frac{u^2 h_1(u) du}{\sqrt{u^2 - 1}}$$

$$= \frac{2\phi_0}{\pi} \int_0^1 \frac{u H(u) du}{\sqrt{u^2 - 1}}$$

Once the integral equation in Eq. (83) is solved for $H(r)$, the total charge can be found by evaluating the integral in Eq. (86) numerically and hence the capacity $C = Q/\phi_0$ can be found.

10. TRIPLE-INTEGRAL EQUATIONS INVOLVING HANKEL TRANSFORMS

As an example of the use of Cooke operators, we consider the solution of certain triple-integral equations involving Hankel transforms. The problem consists in finding a function $\Phi(\xi)$ satisfying

$$\int_0^\infty \Phi(\xi) J_\nu(\xi x) d\xi = G_1(x), \quad x \in I_1$$

$$\int_0^\infty \xi^{-2\alpha} [1 + k(\xi)] \Phi(\xi) J_\nu(\xi x) d\xi = F_2(x), \quad x \in I_2 \tag{87}$$

$$\int_0^\infty \Phi(\xi) J_\nu(\xi x) d\xi = G_3(x), \quad x \in I_3$$

where I_j ($j = 1, 2, 3$) denote, respectively, the intervals $(0, a)$, (a, b) and (b, ∞) with $0 < a < b$. The functions G_1 , F_2 , and G_3 are assumed to be prescribed. Assuming that

$$\Phi(\xi) = \xi \psi(\xi), \quad f(x) = \left(\frac{2}{x} \right)^{2\alpha} F(x),$$

$$g(x) = G(x)$$

and using the modified operator of the Hankel transform, we rewrite Eqs. (87) in the form

$$S_{\nu/2 - \alpha, 2\alpha} [1 + k(\xi)] \psi(\xi); x = f(x) \tag{88}$$

$$S_{\nu/2, 0} \psi(\xi) = g(x)$$

We first consider the case where $k = 0$, $g_1 = g_3 = 0$, $|\alpha| < 1$. There are two different ways of solving Eqs. (88), one proposed by Sneddon and the other by Borodachev.

10.1. The Sneddon Trial Solution

Sneddon proposed the following solution for the equations in Eq. (88):

$$\psi = S_{\nu/2, -\alpha} h \tag{89}$$

Then, putting Eq. (89) into Eq. (88), we find that

$$S_{\nu/2,0}\psi = K_{\nu/2,\alpha}h = g(x)$$

$$S_{\nu/2-\alpha,2\alpha}\psi = I_{\nu/2,-\alpha}h = f(x)$$

and solving for h , we obtain

$$h = I_{\nu/2,-\alpha}^{-1}f(x)$$

$$h = K_{\nu/2,\alpha}^{-1}g(x) \tag{90}$$

Now, suppose that $f(x) = f_1(x)$, $x \in I_1$, $f(x) = f_3(x)$, $x \in I_3$, and $g(x) = g_2(x)$, $x \in I_2$. We also write $h(x) = h_j(x)$, $x \in I_j$.

If we evaluate Eqs. (90) on I_3 and use $g_3 = 0$, We deduce that $h_3 = 0$. Similarly, if we evaluate Eq. (90) on I_1 , we have

$$f_1(x) = \begin{pmatrix} x \\ 0 \end{pmatrix} I_{\nu/2,\alpha} h_1(x) \tag{91}$$

and if we evaluate Eq. (90) on I_2 we have

$$h_2 = \begin{pmatrix} a \\ 0 \end{pmatrix} I_{\nu/2,\alpha}^{-1} f_1 + \begin{pmatrix} x \\ a \end{pmatrix} I_{\nu/2,\alpha}^{-1} f_2, \quad x \in I_2 \tag{92}$$

Putting Eq. (92) into Eq. (91) and using the L operator defined by Eq. (53), we obtain

$$h_2 = - \begin{pmatrix} x, & a \\ a, & 0 \end{pmatrix} L_{\nu/2,\alpha} h_1 + \begin{pmatrix} x \\ a \end{pmatrix} I_{\nu/2,\alpha}^{-1} f_2, \quad x \in I_2 \tag{93}$$

Now, evaluating Eq. (90) on I_2 and I_1 , respectively, we obtain the equations

$$g_2 = \begin{pmatrix} b \\ x \end{pmatrix} K_{\nu/2,-\alpha} h_2, \quad h_1 = \begin{pmatrix} b \\ a \end{pmatrix} K_{\nu/2,-\alpha}^{-1} g_2 \tag{94}$$

Putting first of the relation in Eq. (94) into the second and using M operator defined by Eq. (54), we obtain

$$h_1 = - \begin{pmatrix} a, & b \\ x, & a \end{pmatrix} M_{\nu/2,-\alpha} h_2 \quad (x \in I_1) \tag{95}$$

Equations (93) and (95) form a pair of simultaneous equations for the unknown functions h_1 and h_2 , but, by eliminating h_1 between them, we can derive a single Fredholm integral equation of the second kind for h_2 . Solving it, we can determine h_1 using Eq. (95).

The same procedure applied formally to the case in which $k(\xi) \neq 0, g_1 = g_3 = 0, |\alpha| < 1$ leads to the set of

simultaneous equations

$$h_1 + E = k_1(x \in I_1)$$

$$h_2 + E = - \begin{pmatrix} x, & a \\ a, & 0 \end{pmatrix} L_{\nu/2,\alpha} k_1 + \begin{pmatrix} x \\ a \end{pmatrix} I_{\nu/2,\alpha}^{-1} f_2 \quad (x \in I_2) \tag{96}$$

$$h_1 = - \begin{pmatrix} a, & b \\ x, & a \end{pmatrix} M_{\nu/2,-\alpha} h_2 \quad (x \in I_1)$$

where

$$E(x) \equiv S_{\nu/2-\alpha,\alpha} k S_{\nu/2-\alpha} h$$

$$= 2^\alpha x^{-\alpha} \int_0^\infty t^{1-\alpha} k(t) 2^{-\alpha} t^\alpha J_{\nu-\alpha}(xt) dt$$

$$\times \left(\int_0^a u^{1+\alpha} h_1(u) J_{\nu-\alpha}(tu) du \right.$$

$$+ \int_a^b u^{1+\alpha} h_2(u) J_{\nu-\alpha}(tu) du$$

$$\left. + \int_b^\infty u^{1+\alpha} h_3(u) J_{\nu-\alpha}(tu) du \right)$$

and inverting the order of integration in each of the three repeated integrals, we have

$$E(x) = x^{-\alpha} \int_0^\infty u^{1+\alpha} K(x, u) h(u) du \tag{97}$$

where

$$K(x, u) = \int_0^\infty tk(t) J_{\nu-\alpha}(xt) J_{\nu-\alpha}(ut) dt \tag{98}$$

Thus, we have three equations with three unknown h_1, h_2, k_1 . As before $h_3 = 0$. Solving for them, the unknown functions f_1 and f_3 can be found by the formulas

$$f_1 = \begin{pmatrix} x \\ 0 \end{pmatrix} I_{\nu,\alpha} k_1 \tag{99}$$

$$f = I_{\nu/2,\alpha} h + S_{\nu/2-\alpha,2\alpha} k S_{\nu/2,-\alpha} h$$

Equations (93) and (95) to (98) allow us to obtain the complete solution of the problem. (For further details, readers are referred to the papers by Cooke [19,20,27,28]).

10.2. The Borodachev Trial Solution

Borodachev [29] developed a different trial solution to solve the triple integral equations (87). He argued as follows. Assume that the solution of the equations has the form

$$\psi(\xi) = S_{\beta,\gamma} h \tag{100}$$

Eqs. (88), for the case $k(\xi)=0$, may be reduced to the following form

$$I_{\mu_1, \lambda_1} h = f, \quad K_{\mu_2, \lambda_2} h = g$$

which occur when

$$S_{v/2-\alpha} S_{\beta, \gamma} = I_{\mu_1, \lambda_1}, \quad S_{v/2, 0} S_{\beta, \gamma} = K_{\mu_2, \lambda_2} \quad (101)$$

Using the third and fourth relations of Eqs. (49), we infer that

$$\beta + \gamma = \frac{v}{2} - \alpha, \quad \mu_1 = \beta, \quad \lambda_1 = 2\alpha + \gamma$$

$$\beta = \frac{v}{2}, \quad \mu_2 = \frac{v}{2}, \quad \lambda_2 = \gamma$$

which yield

$$\beta = \frac{v}{2}, \quad \gamma = -\alpha, \quad \mu_1 = \frac{v}{2}, \quad \mu_2 = \frac{v}{2},$$

$$\lambda_1 = \alpha, \quad \lambda_2 = -\alpha$$

Thus, in this case Eq. (100) takes the form $\psi = S_{v/2, -\alpha} h$, that is, we have Sneddon's trial solution.

On the other hand, readers might note that Eqs. (88) can be reduced to the form

$$K_{\mu_3, \lambda_3} H = f, \quad I_{\mu_4, \lambda_4} H = g \quad (102)$$

Carrying out calculations similar to the ones done, we have

$$\beta = \frac{v}{2} + \alpha, \quad \gamma = -\alpha, \quad \mu_3 = \frac{v}{2} - \alpha, \quad \mu_4 = \frac{v}{2} + \alpha \quad (103)$$

$$\lambda_3 = \alpha, \quad \lambda_4 = -\alpha$$

Accordingly, in this case

$$\psi = S_{v/2+\alpha, -\alpha} H \quad (104)$$

Equation (104) is called Borodachev's trial solution.

We will now use Borodachev's trial solution to reduce the triple integral equations in Eq. (88) to a Fredholm integral equation of the second kind. Substituting Borodachev's trial solution in Eq. (104) into Eqs. (88), we obtain [see Eqs. (102) and (103)]

$$K_{v/2-\alpha, \alpha} H = f, \quad I_{v/2+\alpha, -\alpha} H = g,$$

whence

$$H = K_{v/2-\alpha, \alpha}^{-1} f, \quad H = I_{v/2+\alpha, -\alpha}^{-1} g \quad (105)$$

As before, for the sake of simplicity, we consider the case where $g_1 = g_3 = 0$. Then writing Eq. (105) for each

interval, we obtain

$$H_1 = \begin{pmatrix} x \\ 0 \end{pmatrix} I_{v/2+\alpha, -\alpha}^{-1} g_1 = 0$$

$$H_2 = \begin{pmatrix} a \\ 0 \end{pmatrix} I_{v/2+\alpha, -\alpha}^{-1} g_1 + \begin{pmatrix} x \\ a \end{pmatrix} I_{v/2+\alpha, -\alpha}^{-1} g_2$$

$$= \begin{pmatrix} x \\ a \end{pmatrix} I_{v/2+\alpha, -\alpha}^{-1} g_2$$

$$H_3 = \begin{pmatrix} a \\ 0 \end{pmatrix} I_{v/2+\alpha, -\alpha}^{-1} g_1 + \begin{pmatrix} b \\ a \end{pmatrix} I_{v/2+\alpha, -\alpha}^{-1} g_2$$

(106)

$$+ \begin{pmatrix} x \\ b \end{pmatrix} I_{v/2+\alpha, -\alpha}^{-1} g_3$$

$$= \begin{pmatrix} b \\ a \end{pmatrix} I_{v/2-\alpha, \alpha}^{-1} g_2$$

$$H_3 = \begin{pmatrix} \infty \\ x \end{pmatrix} K_{v/2-\alpha, \alpha}^{-1} f_3$$

$$H_2 = \begin{pmatrix} \infty \\ b \end{pmatrix} K_{v/2-\alpha, \alpha}^{-1} f_3 + \begin{pmatrix} b \\ x \end{pmatrix} K_{v/2-\alpha, \alpha}^{-1} f_2$$

From the second and fourth formulas in Eqs. (106), we deduce that

$$g_2 = \begin{pmatrix} x \\ a \end{pmatrix} I_{v/2+\alpha, -\alpha} H_2,$$

(107)

$$f_3 = \begin{pmatrix} \infty \\ x \end{pmatrix} K_{v/2-\alpha, \alpha} H_3$$

Substituting Eq. (107) into the third and fifth equations in Eqs. (106) and making use of the operators L and M , we obtain the following system of equations:

$$H_2 = \begin{pmatrix} b \\ x \end{pmatrix} K_{v/2-\alpha, \alpha}^{-1} f_2$$

$$- \begin{pmatrix} b, & \infty \\ x, & b \end{pmatrix} M_{v/2-\alpha, \alpha} H_3 \quad (a < x < b)$$

(108)

$$H_3 = - \begin{pmatrix} x, & b \\ b, & a \end{pmatrix} L_{v/2+\alpha, -\alpha} H_2 \quad (b < x < \infty)$$

Using the definitions of L and M operators, we see that the formulas in Eq. (108) constitute a pair of coupled integral equations, upon solving for which we can find the functions and H_2 and H_3 , while $H_1 = 0$.

Putting the second formula of Eq. (108) into the first equation, we obtain a single-integral equation of the second kind involving only H_2 :

$$H_2(x) = \varphi(x) - \left(\frac{2}{\pi}\right)^2 \int_a^b K(x,y)H_2(y) dy \quad (109)$$

where

$$\begin{aligned} \varphi(x) &= \begin{pmatrix} b \\ x \end{pmatrix} K_{\nu/2, -\alpha} f_2 \\ K(x,y) &= \sin^2(\alpha\pi) \frac{x^\nu y^{1+2\alpha+\nu}}{(b^2 - x^2)^\alpha (b^2 - y^2)^\alpha} \\ &\times \int_0^\infty \frac{t^{1-2\nu-2\alpha}(t^2 - b^2)^{2\alpha}}{(t^2 - x^2)(t^2 - y^2)} dt \\ &\times \left(-\frac{1}{2} < \alpha < 1\right) \end{aligned} \quad (110)$$

10.3. An Example: An Electrified Annular Disk

To illustrate the application of Cooke's and Borodachev's solutions to the set of triple integral equations in Eq. (98), we consider the electrostatic field induced by an annular disk with internal and external radii a and b , respectively, the disk being charged to a potential equal to ϕ_0 . The disk is assumed to lie in the plane $z = 0$.

The solution of the problem must satisfy Laplace's equation in Eq. (1) and the following boundary conditions:

$$\begin{aligned} \phi(r, 0) &= \phi_0, \quad a < r < b \\ \frac{\partial \phi}{\partial z} \Big|_{z=0} &= 0, \quad 0 \leq r < a, \quad b < r < \infty \end{aligned} \quad (111)$$

Furthermore, the solution must satisfy the regularity condition and the edge conditions at the edges $r = a$ and $r = b$. As before, applying zeroth-order Hankel transform to the Eq. (1), it can be shown that the electrostatic potential is given by the equation

$$\phi(r, z) = \phi_0 \mathcal{H}_0[s^{-1}A(s)e^{-sz}, s \rightarrow r] \quad (112)$$

Where $A(s)$ is an unknown function of s to be determined. Equation (112) automatically satisfies the radiation conditions.

Making use of the boundary conditions in Eq. (111), we obtain the following triple-integral equations:

$$S_{-1/2,1}A(r) = f(r), \quad S_{0,0}A(r) = g(r)$$

where $f_2(r) = 2r/\phi_0$, $g_1(r) = 0$, $g_3(r) = 0$. Following Sneddon's trial solution in Eq. (89), we obtain the following Fredholm

integral equation of the second kind:

$$\frac{x^2 - \epsilon^2}{x^2} F(x) = 1 - \left(\frac{2}{\pi}\right)^2 \int_\epsilon^1 K(x,y)F(y) dy \quad (113)$$

where

$$\begin{aligned} x &= \frac{r}{a}, \quad \epsilon = \frac{a}{b}, \quad F(x) = h_2^*(xb) \\ K(x,y) &= \frac{1}{2(x^2 - y^2)} \\ &\times \left(\frac{x^2 - \epsilon^2}{x} \log \frac{x + \epsilon}{x - \epsilon} - \frac{y^2 - \epsilon^2}{y} \log \frac{y + \epsilon}{y - \epsilon} \right) \end{aligned}$$

On the other hand, making use of Borodachev's trial solution in Eq. (104), we obtain the following Fredholm integral equation

$$\frac{1 - x^2}{x^2} G(x) = 1 - \left(\frac{2}{\pi}\right)^2 \int_\epsilon^1 M(x,y)G(y) dy \quad (114)$$

where

$$\begin{aligned} G(x) &= h_2^*(bx), \quad h_2^*(r) = \frac{\sqrt{\pi}r^2}{2\phi_0\sqrt{b^2 - r^2}} h_2(r) \\ M(x,y) &= \frac{1}{2(x^2 - y^2)} \\ &\times \left(\frac{1 - y^2}{y} \log \frac{1 + y}{1 - y} - \frac{1 - x^2}{x} \log \frac{1 + x}{1 - x} \right) \end{aligned} \quad (115)$$

The surface charge density at any point of the disk is

$$\begin{aligned} q &= \frac{-1}{4\pi} \left(\frac{\partial \phi}{\partial z} \right)_{z=0} = \frac{\phi_0}{4\pi} g_2(r) \\ &= \begin{cases} \frac{1}{2\pi^2 r} \frac{d}{dr} \int_a^r \sqrt{\frac{b^2 - u^2}{r^2 - u^2}} h_2^*(u) du, & a < r < b \\ \frac{b\phi_0}{2\pi^2 r} \frac{d}{dr} \int_\epsilon^{r/b} \sqrt{\frac{1 - y^2}{r^2/b^2 - y^2}} G(y) dy, & a < r < b. \end{cases} \end{aligned} \quad (116)$$

Thus, the charge density at any point of the disk can be calculated once the integral equation in Eq. (114) is solved.

Considering both sides of the disk, the total charge is

$$\begin{aligned} Q &= 4\pi \int_a^b r q(r, 0) dr = \frac{2\phi_0 b}{\pi\gamma} \\ \gamma^{-1} &= \int_\epsilon^1 G(y) dy \end{aligned}$$

Whence

$$\phi_0 = \frac{\pi Q \gamma}{2b}$$

so that formula in Eq. (116) takes the form

$$q(r, 0) = \frac{\gamma Q}{2\pi r} \frac{d}{dr} \int_{\varepsilon}^{r/b} \sqrt{\frac{1-y^2}{r^2/b^2 - y^2}} \times G(y) d(y), \quad a < r < b \quad (117)$$

Of great interest is to find the asymptotic representation of the charge density $q(r, 0)$ as $r \rightarrow a + 0$ in the sense of Erdelyi, that is, the first term in the asymptotic expansion of $q(r, 0)$ as $r \rightarrow a + 0$. By letting $r \rightarrow a + 0$ in Eq. (117), we obtain

$$q(r, 0) \approx \frac{Q\omega_a(\varepsilon)}{2\sqrt{2}\pi b^2} \left(\frac{r}{b} - \varepsilon\right)^{-1/2}, \quad r \rightarrow a + 0 \quad (118)$$

where

$$\omega_a(\varepsilon) = \frac{\gamma}{\varepsilon} \sqrt{\frac{1-\varepsilon^2}{\varepsilon}} G(\varepsilon) \quad (119)$$

Performing similar analyses on the Sneddon’s trial solution, it can be shown that the surface charge density exhibits the following behavior as the outer contour of the disk is approached

$$q(r, 0) = \frac{Q\omega_b(\varepsilon)}{\sqrt{2}\pi b^2} \left(1 - \frac{r}{b}\right)^{-1/2}, \quad r \rightarrow b - 0 \quad (120)$$

where

$$\omega_b(\varepsilon) = \gamma \sqrt{1 - \varepsilon^2} F(1) \quad (121)$$

Equations (118)–(121) show that the surface charge density exhibits a square-root singularity as the inner and outer edges of the disk are approached. Thus, edge conditions (Meixner’s conditions) are satisfied.

Integral equations in Eqs. (113) and (114) admit closed-form solutions only in the special case where $\varepsilon = 0$, that is, for the case of a circular disk:

$$F(x) = 1, \quad G(x) = \frac{x}{\pi\sqrt{1-x^2}} \log \frac{1+x}{1-x} \quad (122)$$

In the context of mathematically similar elastic contact problems, Borodachev [29] showed that the values of $G(x)$ do not differ practically in the range $0 \leq \varepsilon \leq 0.5$. Therefore for this range, approximate values of the surface charge density can be calculated by using formulas in Eq. (122) while the intergral equation in Eq. (113) can be solved to find the surface charge density for the range $0.5 < \varepsilon < 1.0$.

Many other application of the triple integral equations considered here to problems of electrostatics are given in Sneddon’s book [8]. It should be noted that using the same approach, it is possible to solve a wide variety of problems concerning diffraction of a plane electromagnetic wave by an annular disk and by a system of coaxial annular disks. Many examples of electromagnetic scattering by objects of

different shapes are analyzed in the books by Bowman et al. [30] and by Uslenghi [31].

11. QUADRUPLE-INTEGRAL EQUATIONS INVOLVING HANKEL TRANSFORMS

We now use Cooke operators to reduce certain quadruple integral equations involving Hankel transforms to a Fredholm integral equation of the second kind or a system of those. The problem is to find a function $\psi(x)$ satisfying the equations

$$\begin{aligned} S_{\nu/2-\alpha, 2\alpha} \psi(x) &= f_1(x), \quad x \in I_1 = \{x : 0 < x < a\} \\ S_{\nu/2-\beta, 2\beta} \psi(x) &= 0, \quad x \in I_2 = \{x : a < x < b\} \\ S_{\nu/2-\alpha, 2\alpha} \psi(x) &= f_3(x), \quad x \in I_3 = \{x : b < x < c\} \\ S_{\nu/2-\beta, 2\beta} \psi(x) &= 0, \quad x \in I_4 = \{x : c < x < \infty\} \end{aligned} \quad (123)$$

Taking a trial solution in the form

$$\psi(x) = S_{\nu/2+\beta, -\alpha-\beta} h(x)$$

and then using the third and fourth relations from Eqs. (49), we obtain

$$\begin{aligned} f(x) &\equiv S_{\nu/2-\alpha, 2\alpha} \psi(x) = I_{\nu/2+\beta, \alpha-\beta} h(x) \\ g(x) &\equiv S_{\nu/2-\beta, 2\beta} \psi(x) = K_{\nu/2-\beta, \beta-\alpha} h(x) \end{aligned} \quad (124)$$

whence

$$\begin{aligned} h(x) &= I_{\nu/2+\beta, \alpha-\beta}^{-1} f(x) \\ h(x) &= K_{\nu/2-\beta, \alpha-\beta}^{-1} g(x) \end{aligned} \quad (125)$$

Writing out Eqs. (125) on $I_j (j = 1, \dots, 4)$, we have

$$\begin{aligned} h_1(x) &= \begin{pmatrix} x \\ 0 \end{pmatrix} I_{\nu/2+\beta, \alpha-\beta}^{-1} f_1 \quad (x \in I_1) \\ h_2(x) &= \begin{pmatrix} a \\ 0 \end{pmatrix} I_{\nu/2+\beta, \alpha-\beta} f_1 \\ &+ \begin{pmatrix} x \\ a \end{pmatrix} I_{\nu/2+\beta, \alpha-\beta}^{-1} f_2 \quad (x \in I_2) \\ h_3(x) &= \begin{pmatrix} a \\ 0 \end{pmatrix} I_{\nu/2+\beta, \alpha-\beta}^{-1} f_1 + \begin{pmatrix} b \\ a \end{pmatrix} I_{\nu/2+\beta, \alpha-\beta}^{-1} f_2 \\ &+ \begin{pmatrix} x \\ b \end{pmatrix} I_{\nu/2+\beta, \alpha-\beta}^{-1} f_3 \quad (x \in I_3) \end{aligned}$$

$$\begin{aligned}
 h_4(x) &= \begin{pmatrix} a \\ 0 \end{pmatrix} I_{\nu/2+\beta,\alpha-\beta}^{-1} f_1 \\
 &+ \begin{pmatrix} b \\ a \end{pmatrix} I_{\nu/2+\beta,\alpha-\beta}^{-1} f_2 + \begin{pmatrix} c \\ b \end{pmatrix} I_{\nu/2+\beta,\alpha-\beta}^{-1} f_3 \\
 &+ \begin{pmatrix} \infty \\ c \end{pmatrix} I_{\nu/2+\beta,\alpha-\beta}^{-1} f_4 \quad (x \in I_4) \\
 h_4(x) &= \begin{pmatrix} \infty \\ x \end{pmatrix} K_{\nu/2-\beta,\alpha-\beta}^{-1} g_4 = 0 \quad (x \in I_4) \\
 h_3(x) &= \begin{pmatrix} c \\ x \end{pmatrix} K_{\nu/2-\beta,\alpha-\beta}^{-1} g_3 \quad (x \in I_3) \\
 h_2(x) &= \begin{pmatrix} c \\ b \end{pmatrix} K_{\nu/2-\beta,\alpha-\beta}^{-1} g_3 \quad (x \in I_2) \\
 h_1(x) &= \begin{pmatrix} c \\ b \end{pmatrix} K_{\nu/2-\beta,\alpha-\beta}^{-1} g_3 \\
 &+ \begin{pmatrix} a \\ x \end{pmatrix} K_{\nu/2-\beta,\alpha-\beta}^{-1} g_1 \quad (x \in I_1)
 \end{aligned} \tag{126}$$

From sixth equation of Eqs. (126), we have

$$g_3 = \begin{pmatrix} c \\ b \end{pmatrix} K_{\nu/2-\beta,\beta-\alpha} h_3$$

which upon substitution into the seventh equation of Eq. (126) yields

$$h_2(x) = - \begin{pmatrix} b, & c \\ x, & b \end{pmatrix} M_{\nu/2-\beta,\beta-\alpha} h_3(x) \tag{127}$$

Writing Eq. (124) on I_3 , we obtain

$$\begin{aligned}
 f_3(x) &= \begin{pmatrix} a \\ 0 \end{pmatrix} I_{\nu/2+\beta,\alpha-\beta} h_1 + \begin{pmatrix} b \\ a \end{pmatrix} I_{\nu/2+\beta,\beta-\alpha} h_2 \\
 &+ \begin{pmatrix} x \\ b \end{pmatrix} I_{\nu/2+\beta,\beta-\alpha} h_3
 \end{aligned} \tag{128}$$

Applying the operator

$$\begin{pmatrix} x \\ b \end{pmatrix} I_{\nu/2+\beta,\beta-\alpha}^{-1}$$

to both sides of Eq. (128), we obtain

$$h_3(x) = \Lambda(x) + \begin{pmatrix} x, & b \\ b, & a \end{pmatrix} L_{\nu/2+\beta,\alpha-\beta} h_2(x) \tag{129}$$

where $\Lambda(x)$ is the known function given by

$$\begin{aligned}
 \Lambda(x) &= \begin{pmatrix} x \\ b \end{pmatrix} I_{\nu/2+\beta,\alpha-\beta}^{-1} f_3(x) \\
 &- \begin{pmatrix} x, & a \\ b, & a \end{pmatrix} L_{\nu/2+\beta,\alpha-\beta} h_2(x)
 \end{aligned} \tag{130}$$

Equations (127) and (129) constitute a pair of coupled integral equations for the determination of the unknown functions h_2 and h_3 , but eliminating h_2 , we obtain a single Fredholm equation of the second kind, namely

$$\begin{aligned}
 h_3(x) + \mu \int_b^c K(x, x_0) h_3(x_0) dx_0 \\
 = \Lambda(x) \quad (b < x < c)
 \end{aligned} \tag{131}$$

where $\mu = (4/\pi^2) \sin^2[\pi(\alpha - \beta)]$ and the kernel is given by the equation

$$\begin{aligned}
 K(x, x_0) \\
 = x^{-\nu-2\beta} (x^2 - b^2)^{\beta-\alpha} (x_0^2 - b^2)^{\beta-\alpha} x_0^{2\alpha-\nu+1} \\
 \times \int_a^b \frac{(b^2 - y^2)^{2\alpha-2\beta} y^{2\nu-2\alpha+2\beta+1}}{(x_0^2 - y^2)(x^2 - y^2)} dy \quad (b < x, x_0 < c)
 \end{aligned} \tag{132}$$

Further details can be found in the article by Sneddon [21] and the references cited therein.

Quadruple integral equations of the type in Eq. (123) arise in many boundary value problems of mathematical physics. For instance, the electrostatic problem of three coplanar circular disks charged to a uniform potential can be reduced to this kind of quadruple integral equations.

Finally, it should be noted that a new set of particular solutions can be derived for the quadruple integral equations of the type in Eq. (123) analogous to Borodachev's trial solution for the triple integral equations in Eq. (88), by assuming

$$\psi(x) = S_{\nu/2+\alpha,-\alpha-\beta} H(x) \tag{133}$$

On substituting Eq. (133) into Eqs. (123), we obtain

$$f(x) = K_{\nu/2-\alpha,\alpha-\beta} H(x)$$

$$g(x) = I_{\nu/2+\alpha,-\alpha+\beta} H(x)$$

12. MISCELLANEOUS

1. There is a generalization of the Hankel integral theorem in Eq. (12), known as Weber's integral [32]

$$f(r) = \int_0^\infty \frac{\varphi_s(r)s ds}{J_v^2(sa) + Y_v^2(sa)} \times \int_0^\infty r_0 f(r_0)\varphi_s(r_0) dr_0 \quad a < r < \infty \tag{134}$$

involving the linear combination

$$\varphi_s(r) = J_v(sa)Y_v(sr) - Y_v(sa)J_v(sr) \tag{135}$$

of Bessel functions of the first and second kinds ($v > -\frac{1}{2}$). A sufficient condition for the validity of the Eq. (133) is that $f(r)$ be piecewise continuous and of bounded variation in every finite subinterval $[\alpha, \beta]$, where $a < \alpha < \beta < \infty$, and the integral

$$\int_a^\infty \sqrt{r}|f(r)|dr < \infty$$

It should be noted that Weber's integral reduces to Hankel's integral in the limit as $a \rightarrow 0$. Derivation of equations in Eqs. (134) and (135) is given in the famous book by Titchmarsh [32]. Properties of Weber's transformation are also similar to those derived for Hankel transforms. Weber's transform is suited for solving equations of the form in Eq. (1) for domains with an excluded circular region. We illustrate the use of Weber's integral by one example.

Given: A cylindrical hole of radius a is drilled in an infinite body, and the walls of the hole are maintained at a temperature T_0 starting from the time $t = 0$. It is required to determine the temperature distribution in the body assuming that the initial temperature is zero. The two-dimensional temperature distribution in the body is governed by the heat conduction equation

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial T}{\partial r} \right) = \frac{\partial T}{\partial t}, \quad a < r < \infty \tag{136}$$

satisfying the initial condition $T|_{t=0} = 0$ and the boundary and radiation conditions

$$T|_{r=a} = T_0, \quad T|_{r \rightarrow \infty} \rightarrow 0$$

Multiplying both sides of Eq. (136) by $r \varphi_s(r)$ and integrating the resulting expression from a to ∞ , we obtain

$$\frac{d\tilde{T}}{dt} - s^2 \tilde{T} = \frac{2T_0}{\pi} \tag{137}$$

where

$$\tilde{T}(s, t) = \int_a^\infty r \tilde{T}(r, t) \varphi_s(r) dr$$

may be called the *Weber transform* of zeroth order of the function $T(r, t)$. In deriving Eq. (137), use has been made of the relations

$$\varphi_s(a) = 0, \quad \varphi_s'(a) = \frac{2}{\pi a}$$

The solution of Eq. (137) satisfying the boundary condition $\tilde{T}|_{t=0}$ is

$$\tilde{T}(s, t) = \frac{2T_0}{\pi s^2} (1 - e^{-s^2 t})$$

Now, using Weber's inversion, we finally obtain the following formula for the temperature evolution in the body:

$$T(r, t) = \frac{2T_0}{\pi} \int_0^\infty \frac{(1 - e^{-s^2 t}) \varphi_s(r) ds}{s [J_0^2(sa) + Y_0^2(sa)]} \tag{138}$$

Many other practical applications of Weber's integral are given in the book by Lebedev et al. [9].

2. In applications of Hankel transforms to many physical problems, integrals of the following form are encountered:

$$\int_0^\infty s \tilde{f}_n(s) \tilde{F}_m(s) J_{m+n}(sr) ds \tag{139}$$

The need to evaluate such integrals arises in connection with the desire of transforming the solution for the physical quantities given in the space of Hankel Transform domain into the physical space. Using Parseval's relation in Eq. (39), we reduce the integral in Eq. (139) to the form

$$\int_0^\infty s \tilde{f}_n(s) \tilde{F}_m(s) J_{m+n}(sr) ds = \int_0^\infty r_0 f(r_0) \Phi(r_0) dr_0 \tag{140}$$

where

$$\Phi(r_0) = H_n[\tilde{F}_m(s) J_{m+n}(sr); s \rightarrow r_0] = \int_0^\infty s \tilde{F}_m(s) J_{m+n}(sr) J_n(sr_0) dr_0 \tag{141}$$

For the product of Bessel functions in Eq. (141), we use Neumann's formula generalized by Rahman [14], and then interchanging the order of integration, we get

$$\Phi(r_0) = \frac{1}{\pi} \int_0^\pi \left[\cos(n\phi) T_m \left(\frac{r - r_0 \cos \phi}{R} \right) + \frac{r_0 \sin n\phi \sin \phi}{R} U_{m-1} \left(\frac{r - r_0 \cos \phi}{R} \right) \right] F(R) d\phi \tag{142}$$

In specific physical problems, however, the cases where $m = 0$ and $m = 1, n = 0$ are the most frequently encountered

ones. In these cases, formula in Eq. (142) simplifies significantly. For instance, for $m = 0$, we have

$$\Phi(r_0) = \frac{1}{\pi} \int_0^\pi \cos(n\phi) F(R) d\phi$$

while for $m = 1, n = 0$, we have

$$\Phi(r_0) = \frac{1}{\pi} \int_0^\pi \frac{r - r_0 \cos \phi}{R} F(R) d\phi$$

3. An efficient method of solving the integral equation (74) is based on representing the unknown function $h_1(x)$ in the form [33]

$$h_1(x) = x^{v-2\alpha} \sum_{n=0}^\infty a_n P_n^{v-\alpha,0}(1-2x^2) \tag{143}$$

where $P_n^{v-\alpha,0}(1-2x^2)$ is the Jacobi polynomial and a_n are the unknown expansion coefficients to be determined.

Putting the expansion in Eq. (143) into Eq. (73) and considering the orthogonality relationship for the Jacobi polynomials

$$\begin{aligned} & \int_0^1 \frac{P_n^{\alpha,\beta}(1-2x^2) P_m^{\alpha,\beta}(1-2x^2) dx}{2^{-2-\alpha-\beta} x^{-1-2\alpha} (1-x^2)^{-\beta}} \\ &= \frac{2^{\alpha+\beta+1} \Gamma(\alpha+n+1) \Gamma(\beta+n+1)}{n! \Gamma(n+\alpha+\beta+1) (\alpha+\beta+2n+1)} \delta_{mn} \\ & \times (\delta_{mn} - \text{Kr\"{o}necker's delta}) \end{aligned}$$

we obtain the following infinite system of linear algebraic equations:

$$\begin{aligned} & \frac{a_m}{2(1+v-\alpha+2m)} + \sum_{n=0}^\infty a_n K_{mn} = r_m \\ & (m = 0, 1, 2, \dots, \infty) \end{aligned} \tag{144}$$

where

$$\begin{aligned} K_{mn} &= \int_0^\infty t^{-1} k(t) J_{1+v-\alpha+2m}(t) J_{1+v-\alpha+2n}(t) dt \\ r_m &= \int_0^1 x^{1+\alpha} r(x) P_m^{v-\alpha,0}(1-2x^2) dx \end{aligned} \tag{145}$$

A key result that was used to obtain Eqs. (144) and (145) is the following integral [34]:

$$\begin{aligned} & s_{a,-a} [(1-x^2)^{-b} P_n^{a,-b}(1-2x^2)] \\ &= \frac{\Gamma(1-b+n)}{2^{\alpha+b} n! x^{1-a-b}} J_{1+a-b+2n}(x) \end{aligned}$$

The infinite system in Eq. (144) can be solved by truncation for the unknown expansion coefficients a_n . In boundary value problems, often it is often the case that the quantity $g_1(x)$ is of prime importance. For instance, in the

charged disk problems, the function $g_1(x)$ is directly proportional to the surface charge density $q(r, 0)$ ($0 \leq r < a$), which, in turn, is essential for finding the capacitance. Rahman [33] showed that with the representation in Eq. (143), the function g_1 is given by

$$\begin{aligned} g_1(x) &= x^v \sum_{n=0}^\infty a_n \frac{n!}{\Gamma(1-\alpha+n)} \\ & \times (1-x^2)^{-b} P_n^{v-\alpha}(1-2x^2) \end{aligned}$$

The method of solution is certainly preferable to that based on using the numerical quadrature, because it bypasses the arduous job of evaluating Abel integrals numerically. Furthermore, it was shown [34] that the following relation holds:

$$\begin{aligned} & \begin{pmatrix} 1 \\ x \end{pmatrix} K_{v/2,-\alpha} \left(\frac{x^{v-2\alpha}}{(1-x^2)^b} P_n^{v-\alpha,-b}(1-2x^2) \right) \\ &= \frac{\Gamma(1-b+n)}{\Gamma(1-b-\alpha+n)} x^v (1-x^2)^{-b-\alpha} \\ & \times P_n^{v,-b-\alpha}(1-2x^2) \end{aligned} \tag{146}$$

Formula in Eq. (146) gives a class of *spectral relationship* for the operator $K_{v/2,-\alpha}$. It can be seen by writing out Eq. (146) in full that it gives a closed-form expression for a class of Abel integrals involving Jacobi polynomials. It can be used to a polynomial solution to Abel integral equations, which a number of boundary value problems of electrostatics can be reduced to.

4. The methods described in this article for solving dual integral equations are also applicable to a system of those of the form

$$\begin{aligned} S_{\mu_i/2-\alpha,2\alpha} \sum_{j=1}^n c_{ij} \psi_j(x) &= f_i(x), \quad x \in I_1 \\ S_{\nu_i/2-\beta,2\beta} \psi_i(x) &= g_i(x), \quad x \in I_2 \end{aligned}$$

By a systematic use of the properties of Erdelyi-Kober operators Lowndes was able to show that the problem of solving a system of simultaneous equations of this type can be reduced to that of solving a system of simultaneous integral equations. Details of these results can be found in Sneddon's book [8]. To the best of the writer's knowledge, generalization of these results has not yet been attempted for the case of simultaneous triple- and quadruple-integral equations.

5. The theory of Hankel transforms can also be extended to generalized functions or distributions via embedding theory or adjoint method. Interested readers are referred to consult the books by Zayed [5], Zemanian [34,35], and Brychkov and Prudnikov [36].

13. COMPENDIUM OF BASIC FORMULAS

For the sake of convenience of the readers, below we give a compendium of the basic formulas that are of frequent use in applications.

13.1. Definition of Hankel Transforms

$$\begin{aligned} \tilde{f}_v(s) &= \mathcal{H}_v[f(r), r \rightarrow s] = \int_0^\infty r f(r) J_v(sr) dr \\ f(r) &= \mathcal{H}_v[\tilde{f}_v(s), s \rightarrow r] = \int_0^\infty s \tilde{f}_v(s) J_v(sr) dr \end{aligned}$$

13.2. Some Properties of Hankel Transforms

$$\begin{aligned} \mathcal{H}_{-m}[f(r), r \rightarrow s] &= (-1)^m \mathcal{H}_m[f(r), r \rightarrow s] \\ (m = \pm 1, \pm 2, \dots, \pm n, \dots) \\ \mathcal{H}_v[f(ar), r \rightarrow s] &= a^{-2} \mathcal{H}_v\left[f(r), r \rightarrow \frac{s}{a}\right] \\ \mathcal{H}_v[r^{-1}f(r), r \rightarrow s] &= \frac{s}{2v} [\tilde{f}_{v-1}(s) + \tilde{f}_{v+1}(s)] \quad (v \neq 0) \\ \mathcal{H}_n[f(r-a)H(r-a), r \rightarrow s] &= \sum_{m=-\infty}^\infty \alpha_m \tilde{f}_m(s) \\ \alpha_m &= J_{n-m}(sa) + \frac{1}{2}as[(m+1)^{-1}J_{n-m-1}(sa) \\ &\quad + (m-1)^{-1}J_{n-m+1}(sa)] \\ \mathcal{H}_v[\mathcal{B}_v f(r), r \rightarrow s] &= -s^2 \mathcal{H}_v[f(r), r \rightarrow s] \\ \mathcal{B}_v &= \frac{d^2}{dr^2} + \frac{1}{r} \frac{d}{dr} - \frac{v^2}{r^2} \quad (v = 0, 1, \dots) \\ \mathcal{H}_v\left[r^{v-1} \frac{d}{dr} [r^{1-v} f(r), r \rightarrow s]\right] &= -s \mathcal{H}_{v-1}[f(r), r \rightarrow s] \end{aligned}$$

13.3. Parseval's Relation

$$\int_0^{-\infty} s \tilde{f}_v(s) \tilde{g}_v(s) ds = \int_0^\infty r_0 f(r_0) g(r_0) dr_0$$

13.4. Modified Operator of Hankel Transform and Erdelyi-Kober Operators

$$\begin{aligned} I_{\eta,0} &= K_{\eta,0} = I \\ I_{\eta,\alpha} x^{2\beta} f(x) &= x^{2\beta} I_{\eta+\beta,\alpha} f(x) \\ I_{\eta,\alpha} I_{\eta+\alpha,\beta} &= I_{\eta,\alpha+\beta} \\ K_{\eta,\alpha} x^{2\beta} f(x) &= x^{2\beta} K_{\eta-\beta,\alpha} f(x) \\ K_{\eta,\alpha} K_{\eta+\alpha,\beta} &= K_{\eta,\alpha+\beta} \\ I_{\eta,-n} f(x) &= x^{2n-2\eta-1} D_x^n x^{2\eta+1} f(x) \end{aligned}$$

$$\begin{aligned} I_{\eta,\alpha} f(x) &= x^{-2\eta-2n-1} D_x^n x^{2n+2\eta+2\alpha+1} I_{\eta,\alpha+n} f(x) \\ K_{\eta,-n} f(x) &= (-1)^n x^{2\eta-1} D_x^n x^{2n-2\eta+1} f(x) \\ K_{\eta,\alpha} f(x) &= (-1)^n x^{2\eta-1} D_x^n x^{2n-2\eta+1} f(x) K_{\eta-n,\alpha+n} f(x) \end{aligned}$$

$$\begin{aligned} I_{\eta,\alpha}^{-1} &= I_{\eta+\alpha,-\alpha} \\ K_{\eta,\alpha}^{-1} &= K_{\eta+\alpha,-\alpha} \\ S_{\eta,\alpha} f(x) &= 2^\alpha x^{-\alpha} H_{2\eta+\alpha}[t^{-\alpha} f(t), t \rightarrow x] \\ S_{\eta,\alpha}^{-1} &= S_{\eta+\alpha,-\alpha} \\ S_{\eta,\alpha} f(x) &= 2^{-\lambda} x^\lambda S_{\eta\lambda/2,\alpha+\lambda}[x^\lambda f(x)] \\ I_{\eta+\alpha,\beta} S_{\eta,\alpha} &= S_{\eta,\alpha+\beta} \\ K_{\eta,\alpha} S_{\eta+\alpha,\beta} &= S_{\eta,\alpha+\beta} \\ S_{\eta+\alpha,\beta} S_{\eta,\alpha} &= I_{\eta,\alpha+\beta} \\ S_{\eta,\alpha} S_{\eta+\alpha,\beta} &= K_{\eta,\alpha+\beta} \\ S_{\eta+\alpha,\beta} I_{\eta,\alpha} &= S_{\eta,\alpha+\beta} \\ S_{\eta,\alpha} K_{\eta+\alpha,\beta} &= S_{\eta,\alpha+\beta} \end{aligned}$$

13.5. Some Beltrami-Type Relations of Common Occurrence

$$\begin{aligned} \mathcal{H}_0[s^{-1} \tilde{f}_0(s), s \rightarrow r] &= \frac{2}{\pi} \int_r^\infty \frac{dt}{\sqrt{t^2 - r^2}} \int_0^t \frac{xf(x) dx}{\sqrt{t^2 - x^2}} \\ \mathcal{H}_0[s \tilde{f}_0(s), s \rightarrow r] &= \frac{-2}{\pi r} \frac{d}{dr} \int_r^\infty \frac{tdt}{\sqrt{t^2 - r^2}} \frac{d}{dt} \int_0^t \frac{xf(x) dx}{\sqrt{t^2 - x^2}} \end{aligned}$$

13.6. Some Useful Relations

$$\begin{aligned} &\int_0^\infty s \tilde{f}_n(s) \tilde{F}_m(s) J_{m+n}(sr) ds \\ &= \int_0^\infty r_0 f(r_0) \Phi(r_0) dr_0 \\ \Phi(r_0) &= \frac{1}{\pi} \int_0^\pi \left[\cos(n\phi) T_m\left(\frac{r-r_0 \cos \phi}{R}\right) \right. \\ &\quad \left. + \frac{r_0 \sin n\phi \sin n\phi}{R} U_{m-1}\left(\frac{r-r_0 \cos \phi}{R}\right) \right] F(R) d\phi \end{aligned}$$

$$\begin{aligned}
 & J_{m+n}(sr)J_n(sr_0) \\
 &= \frac{1}{\pi} \int_0^\pi \left[\cos(n\phi) T_m \left(\frac{r-r_0 \cos \phi}{R} \right) \right. \\
 &\quad \left. + \frac{r_0 \sin n\phi \sin n\phi}{R} U_{m-1} \left(\frac{r-r_0 \cos \phi}{R} \right) \right] \\
 &\quad \times J_m(sR) d\phi \\
 S_{\eta, -\eta} [(1-x^2)^{-\alpha} P_n^{\eta, -\alpha} (1-2x^2)] \\
 &= \frac{\Gamma(1-\alpha+n)}{2^{\eta+\alpha} n! x^{1-\eta-\alpha}} J_{1+\eta-\alpha+2n}(x) \\
 &\quad \left(\frac{1}{x} \right) K_{\nu/2, -\alpha} \left(\frac{x^{v-2x}}{(1-x^2)^\beta} P_n^{v-\alpha, -\beta} (1-2x^2) \right) \\
 &= \frac{\Gamma(1-\beta+n)}{\Gamma(1-\beta-\alpha+n)} x^\nu (1-x^2)^{-\alpha-\beta} \\
 &\quad \times P_n^{v-\alpha-\beta} (1-2x^2)
 \end{aligned}$$

14. SUGGESTED LITERATURE

Readers interested in rigorous proofs of various aspects of the theory of Hankel transforms are referred to the books by Sneddon [1,2] Davies [3], Andrews and Shivamoggi [4], and Zayed [5] and the papers by Erdelyi (15) and Erdelyi and Kober (16). Many applications of the theory of Hankel transforms to physical problems are given in the books by Sneddon [8] and Lebedev et al. [9]. Fractional integrals and derivatives and their applications to dual-, triple-, and quadruple-integral equations involving Hankel transforms are discussed at greater length in Sneddon [8,21], Cooke [19,20,27,28], Borodachev [29], and Samko et al. [37]. Extension of the theory of Hankel transforms to generalized functions or distributions is presented in the books by Zayed [5], Zemanian [34,35], and Brychkov and Prudnikov [36].

Acknowledgments

The writer wishes to express his deepest gratitude to Professor Raj Mittra (Department of Electrical Engineering, Pennsylvania State University) for his kind response to queries with respect to some of the materials presented herein. He also gratefully acknowledges encouragement from his friends S. Rajeswaran and P. K. Jindal during the period of writing of the article.

HARMONIC OSCILLATORS, CIRCUITS

BERNABÉ LINARES-BARRANCO
 ÁNGEL RODRÍGUEZ-VÁZQUEZ
 National Microelectronics
 Center (CNM)

In electronics a harmonic oscillator is an electronic circuit that generates a sinusoidal signal. This signal can either be a voltage, a current, or both. Harmonic oscillators are not restricted to electronics. They can be found in many other disciplines. However, they always can be described by similar mathematical equations. A very familiar harmonic oscillator is the harmonic pendulum, which is found in many high-school physics textbooks. It is a mechanical system consisting of a mass suspended by a fixed-length thread. Figure 1 illustrates this. When mass m is slightly separated from its equilibrium point (so that angle θ in Fig. 1 is sufficiently small) and set free, the earth's gravitational force will make it move toward its resting point. When the mass reaches the resting point it has gained some speed that will make it keep running toward the other side of the equilibrium point, until it stops and comes back. And so it will oscillate from one side of the equilibrium point to the other. What happens is that by initially departing the mass from its equilibrium point, an external agent is increasing its potential energy. When it is set free the action of the earth's gravitational force, together with the constraint imposed by the fixed length thread, will gradually change this initial increase of potential energy into kinetic energy. At the equilibrium point all potential energy supplied initially by the external agent is in form of kinetic energy and speed is maximum. At the points of maximum elongation the kinetic energy (and speed) is zero and the original potential energy is recovered. The

Figure 1. The mechanical pendulum behaves as a harmonic oscillator in the limit of very small maximum angle deviations.

pendulum oscillates at constant frequency and, if there is no friction, it keeps on oscillating indefinitely with constant maximum elongation or amplitude. However, in practice friction cannot be completely suppressed. Consequently, in order to have a pendulum oscillating permanently there must be a way of supplying the energy lost by friction.

In the electronic oscillator there is also a mechanism by which energy of one type is changed into another type (energy can also be of the same type but interchanged between different devices). Figure 2 shows a capacitor connected in parallel with an inductor. At equilibrium there is no voltage across the capacitor and no current through the inductor. However, if by some means, an initial voltage (or equivalently, charge) is supplied to the capacitor, its stored energy increases. The inductor provides a path to discharge the capacitor so that a current builds up through the inductor. However, by the time the capacitor has zero charge the current flowing through the inductor is maximum and the inductor stores all the original capacitor energy in the form of magnetic flux energy. The consequence is that the current keeps flowing through the inductor, charging now the capacitor oppositely, until the current is zero. If there are no resistive losses this process will continue indefinitely; capacitor and inductor continue to interchange their stored energies. The voltage across the capacitor will be sinusoidal in time, and so will be the current through the inductor. The amplitude (or maximum elongation) of the voltage oscillations is equal to the initial voltage supplied to the capacitor. In practice both capacitor and inductor have resistive losses, so that in order to keep the system oscillating indefinitely there must be a way of supplying the energy being lost.

Figure 2. An ideal capacitor connected in parallel with an ideal inductor form a harmonic oscillator.

1. IDEAL RESONATOR MATHEMATICAL MODEL

In Fig. 2 the capacitor voltage v_C and its current i_C are related mathematically by the expression

$$i_C = C \frac{dv_C}{dt} \quad (1)$$

where C is the capacitor's capacitance. For the inductor, its voltage v_L and current i_L are related by

$$v_L = L \frac{di_L}{dt} \quad (2)$$

where L is the inductor's inductance. Besides this, the circuit of Fig. 2 imposes the following topological constraints

$$\begin{aligned} v_C &= v_L \\ i_C &= -i_L \end{aligned} \quad (3)$$

Solving Eqs. (1)–(3) yields

$$\frac{d^2 v_C}{dt^2} + \frac{1}{LC} v_C = 0 \quad (4)$$

The solution to this second-order time-domain differential equation is

$$v_C(t) = v_C(0) \cos(\omega t) - i_L(0) \sqrt{L/C} \sin(\omega t) \quad (5)$$

where $v_C(0)$ is the capacitor voltage at time zero, $i_L(0)$ is the inductor current at time zero, and ω is the angular frequency of the resulting oscillation whose value is

$$\omega = \frac{1}{\sqrt{LC}} \quad (6)$$

Using Eqs. (3), (5), and (6) in Eq. (1) results in

$$i_L(t) = i_L(0) \cos(\omega t) + v_C(0) \sqrt{C/L} \sin(\omega t) \quad (7)$$

By means of basic trigonometric manipulation, Eqs. (5) and (7) can be rewritten as

$$\begin{aligned} v_C(t) &= V_{\max} \cos(\omega t + \varphi) \\ i_L(t) &= V_{\max} \sqrt{C/L} \sin(\omega t + \varphi) \end{aligned} \quad (8)$$

where

$$\begin{aligned} V_{\max} &= \sqrt{v_C^2(0) + i_L^2(0)L/C} \\ \varphi &= \arctan\left(\frac{i_L(0)}{v_C(0)} \sqrt{L/C}\right) \end{aligned} \quad (9)$$

Equation (8) reveals that $v_C(t)$ and $i_L(t)$ have a phase shift of $\pi/2$ radians. This is usually referred to as $v_C(t)$ and $i_L(t)$ being in quadrature, and the resonator in Fig. 2 as being a quadrature resonator or oscillator. Note that the maximum oscillation amplitudes (V_{\max} or $V_{\max} \sqrt{C/L}$, respectively) depend on the initial conditions $v_C(0)$ and $i_L(0) = -C\dot{v}_C(0)$.

Usually, differential equations like Eq. (4) are not solved directly in the time domain but in the frequency domain. For this, let us take the Laplace transform of Eq. (4)

$$s^2 V_C(s) - s v_C(0) - \dot{v}_C(0) + \frac{V_C(s)}{LC} = 0 \quad (10)$$

where $V_C(s)$ is the Laplace transform of $v_C(t)$. Since $i_L(0) = -C\dot{v}_C(0)$, Eq. (10) can be rewritten as

$$V_C(s) = \frac{s}{s^2 + 1/LC} v_C(0) - \frac{1}{s^2 + 1/LC} \frac{i_L(0)}{C} \quad (11)$$

Taking the inverse Laplace transform of Eq. (11) results in Eq. (5). Usually in circuits, the initial conditions involved in the Laplace transform are ignored and Eq. (10) is simplified to

$$s^2 + \frac{1}{LC} = 0 \quad (12)$$

which has the following solutions

$$\begin{aligned} s_1 &= j\omega, \quad s_2 = -j\omega \\ \omega &= \frac{1}{\sqrt{LC}} \end{aligned} \quad (13)$$

Solutions s_1 and s_2 are called the *poles* of the system, and in this case the two poles are complex conjugate and are purely imaginary (their real part is zero). In circuits, people don't take the inverse Laplace transform to know the solution. They know that if a system has a pair of purely

imaginary poles the signals have a sinusoidal steady state whose amplitude depends on the initial conditions.

2. REAL RESONATOR MATHEMATICAL MODEL

As mentioned earlier, the circuit of Fig. 2 is ideal. In practice there will always be resistive losses in the capacitor, in the inductor, or in both. Either introducing a small resistance R_L in series with the inductor, a large resistance R_C in parallel with the capacitor, or both can model this. Solving such a circuit yields the following time-domain differential equation

$$\frac{d^2 v_C(t)}{dt^2} + b \frac{dv_C(t)}{dt} + \omega^2 v_C(t) = 0 \quad (14)$$

with

$$b = \frac{1}{R_C C} + \frac{R_L}{L} \quad (15)$$

$$\omega^2 = \frac{1 + R_L/R_C}{LC}$$

The solution to Eq. (14) is

$$v_C(t) = V_{\max} e^{-bt/2} \cos(\omega_0 t + \rho) \quad (16)$$

where $\omega_0^2 = \omega^2 - (b/2)^2$. Parameters V_{\max} and ρ can be found from the initial conditions $v_C(0)$ and $\dot{v}_C(0)$,

$$V_{\max} = \frac{v_C(0)}{\cos \rho} \quad (17)$$

$$\rho = -\arctan\left(\frac{\dot{v}_C(0) + \frac{b}{2}v_C(0)}{\omega_0 v_C(0)}\right)$$

However, circuit people prefer to solve Eq. (14) in the frequency domain by taking its Laplace transform:

$$s^2 + bs + \omega^2 = 0 \quad (18)$$

The solution to this equation provides the following poles

$$s_1 = -\frac{b}{2} + j\omega \sqrt{1 - \left(\frac{b}{2\omega}\right)^2} = -\frac{b}{2} + j\omega_0 \quad (19)$$

$$s_2 = -\frac{b}{2} - j\omega \sqrt{1 - \left(\frac{b}{2\omega}\right)^2} = -\frac{b}{2} - j\omega_0$$

which are two complex conjugate poles with a negative real part. Circuit people know that when a system has a pair of complex conjugate poles with a negative real part, the system oscillates in a sinusoidal fashion with an amplitude that vanishes after some time. This is what Eq. (16) shows. The amplitude of the oscillations $A(t) = V_{\max} e^{-bt/2}$ decreases exponentially with time. After a few time constants $2/b$ the amplitude is negligible and one can

consider that the system has stopped oscillating. Consequently, in practice, the circuit of Fig. 2 is not useful for building an oscillator.

Imagine that somehow we could make R_L or R_C (or both) negative, so that $b < 0$. A negative resistance behaves as an energy source that replaces the energy dissipated by positive resistances. In this case the poles would have a positive real part and the amplitude of the oscillations

$$A(t) = V_{\max} e^{-bt/2} \quad (20)$$

would increase exponentially in time, assuming $V_{\max} \neq 0$ (due to noise V_{\max} cannot be exactly zero all the time). This would yield an oscillator with initial startup but that would be unstable, because its amplitude would be “out of control.” What circuit designers do to build oscillators with stable amplitude is to make the term b in Eq. (18) depend on the instantaneous oscillation amplitude $A(t)$

$$b(t) = b(A(t)) \quad (21)$$

and in such a way that b increases with A , b is negative for $A = 0$ (to ensure initial startup), and b becomes positive above a certain amplitude. This is called amplitude control. For instance, assume that by adding some special circuitry to Fig. 2 we are able to make

$$b(A) = -b_0 + b_1 A \quad (22)$$

where b_0 and b_1 are positive constants (note that A is always positive). Initially, if $A = 0$, $b = -b_0$ is negative and the real part of the poles is positive: amplitude $A(t)$ increases exponentially with time. As $A(t)$ increases b will eventually become positive (poles with negative real part) and this will decrease the amplitude $A(t)$. The consequence of these two tendencies is that a steady state will be reached for which $b = 0$ and the amplitude is constant. Solving Eq. (22) for $b = 0$ yields the value of the steady state oscillation amplitude A_0 ,

$$A_0 = \frac{b_0}{b_1} \quad (23)$$

Note that, as opposed to the ideal resonator, the steady-state amplitude is independent of any initial conditions.

In general, a harmonic oscillator does not have to be a second order system like the case of Eq. (14) or Eq. (18). It can have any order. What is important is that it has a pair of complex conjugate poles whose real part can be controlled by the oscillation amplitude (so that the real part becomes zero in the steady state), and that the rest of the poles (either complex conjugate or not) have negative real parts. The way b depends on A does not have to be as in Eq. (22). Strictly speaking, the conditions are

$$b(A=0) = -b_0 < 0 \quad \text{for initial startup}$$

$$b > 0 \quad \text{for some } A \quad (24)$$

$$\frac{db(A)}{dA} > 0 \quad \text{for stable amplitude control}$$

This will ensure stable oscillator operation. In what follows we will concentrate on second order systems and will provide two different ways of performing amplitude control.

3. AMPLITUDE CONTROL BY LIMITATION

A very widely used method for oscillator amplitude control is by limitation. This method usually is simple to implement, so simple that many times it is implicit in the components used to build the resonator with initial startup. This makes practical circuits easy to build, although many times people don't understand the underlying amplitude control mechanism.

Let us consider the ideal resonator of Fig. 2 with an additional resistor R_p in parallel to make it real. In order to assure initial startup, let us put a negative resistor in parallel also. Figure 3a shows a very simple way to implement one using a real (positive) resistor and a voltage amplifier of gain larger than one (for example, two). Current I_{in} will be

$$I_{in} = -\frac{V_{in}}{R_n} \tag{25}$$

and the structure resistor–amplifier behaves as a grounded negative resistor of value $-R_n$. Figure 3b shows how to build the amplifier using an operational amplifier and resistors. Connecting this negative resistor in parallel with a positive one of value $R_p = R_n + R_e$ (with $R_e \ll R_n$), the equivalent parallel resistance would be

$$R_{eq} = -\frac{R_n^2}{R_e} \tag{26}$$

which is a very high but negative resistance. Connecting this equivalent resistor in parallel with the ideal resonator of Fig. 2 provides an oscillator with initial startup. This is shown in Fig. 3c.

Because the operational amplifier's output voltage cannot go above its positive power supply V_{DD} or below its negative one V_{SS} , the negative resistance emulator circuit just described works as long as the amplifier output is below V_{DD} and above V_{SS} , or equivalently voltage V_{in} is between $V_{DD}/2$ and $V_{SS}/2$. It is easy to compute the current through R_{eq} as a function of V_{in} taking into account this saturation effect. Figure 3d shows the resulting curve. If $V_{SS}/2 \leq V_{in} \leq V_{DD}/2$ resistor R_{eq} behaves as a negative resistance of high value, but if V_{in} is outside this range the slope of I_{in} versus V_{in} is that of a positive resistance with much smaller value. In order to analyze what happens to the circuit of Fig. 3c when the oscillating amplitude increases beyond $V_{DD}/2$ or $V_{SS}/2$ (whichever is smaller) the concept of describing function can be used.

3.1. Describing Function

Figure 4 shows a sinusoidal signal $x(t)$ applied to a non-linear element $f(x)$ that outputs a distorted signal $y(t)$. Signal $y(t)$ is no longer sinusoidal, but it is periodic.

Figure 3. A real harmonic oscillator can be made by adding a negative resistor to a real resonator: (a) a negative resistor can be emulated using a resistor and a voltage amplifier of gain greater than unity; (b) implementation of negative resistor using an operational amplifier and resistors; (c) oscillator composed of capacitor inductor and negative resistor; (d) transfer characteristics of the negative resistor implementation of (b).

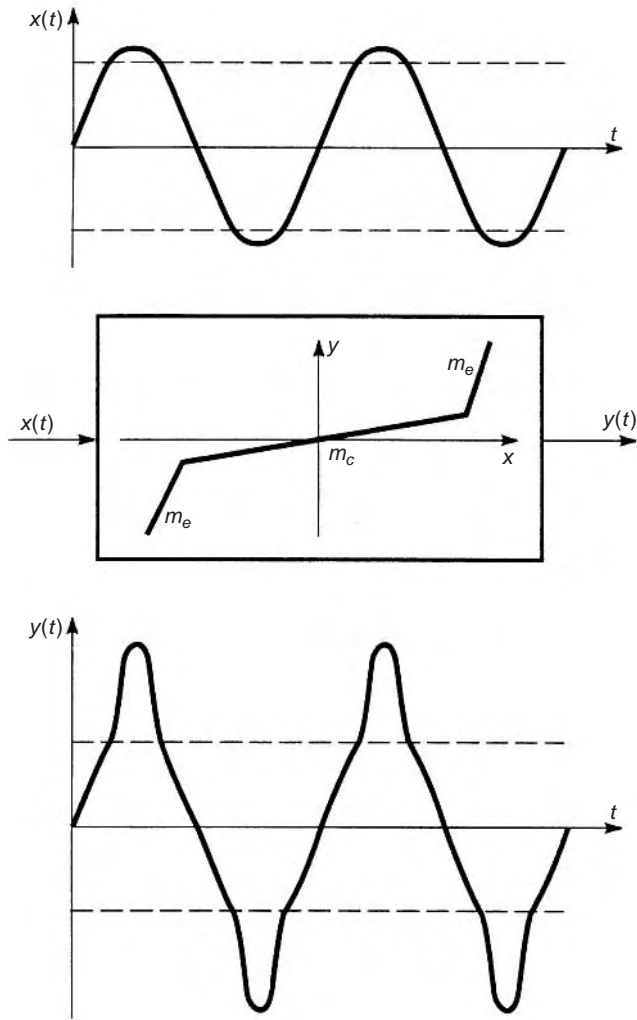

Figure 4. A sinusoidal signal applied to a nonlinear element results, in general, in a distorted output signal.

Consequently, a Fourier series can describe it. The first (or fundamental) harmonic has the same frequency as the input sinusoid, while the others have frequencies which are integer multiples of the first one. If the block of Fig. 4 is used in a system such that the end signals will be approximately sinusoidal (as in a harmonic oscillator) then one can neglect all higher harmonics of the Fourier expansion of $y(t)$ and approximate it using the first or fundamental harmonic only

$$\begin{aligned}
 y(t) &\approx N(A)x(t) \\
 x(t) &= A \sin(\omega t) \\
 N(A) &= \frac{\omega}{\pi A} \int_0^{2\pi/\omega} f(x(t)) \sin(\omega t) dt
 \end{aligned} \tag{27}$$

Note that this approximation makes $y(t)$ to be linear with $x(t)$ so that the nonlinear block in Fig. 4 can be modeled by a linear amplifier of gain $N(A)$. Function $N(A)$ is the “describing” function of the nonlinear element $f(\cdot)$.

This approach is valid for any nonlinear function $f(\cdot)$, but let us consider only piecewise linear functions, as in Figs. 3 and 4, with three pieces: a central linear piece of slope m_c and two external linear pieces of slope m_e . When amplitude A is small enough so that $x(t)$ is always within the central piece then $N(A) = m_c$. When A increases beyond the central piece $N(A)$ will change gradually towards value m_e . In the limit of $A = \infty$ the describing function will be $N(A) = m_e$. Computing the first Fourier term provides the exact expression (let us assume $V_{SS} = -V_{DD}$ for simplicity). If $A \geq V_{DD}/2$

$$N(A) = m_e - 2 \frac{m_e - m_c}{\pi} \left[\sin^{-1} \left(\frac{V_{DD}}{2A} \right) + \frac{V_{DD}}{2A} \sqrt{1 - \left(\frac{V_{DD}}{2A} \right)^2} \right] \tag{28}$$

and if $A \leq V_{DD}/2$

$$N(A) = m_c \tag{29}$$

Applying the describing function method to the nonlinearity of Fig. 3d results in

$$I_{in} = N(A)V_{in} \tag{30}$$

where $N(A) = -R_f/R_n^2$ for $A \leq V_{DD}/2$ and $N(A)$ tends toward $2/R_n$ as it increases beyond $V_{DD}/2$. Since $N(A)$ is continuous and monotonic, there will be a value of A (and only one) for which $N(A) = 0$. Let us call this value A_o . Note that A_o depends only on the shape of the nonlinear function $f(\cdot)$ of Fig. 3d. Equation (29) is the equation of a resistor of value $R_{eq} = 1/N(A)$. For small values of A , $R_{eq} = -R_n^2/R_e$ (high resistance but negative) and the oscillator possesses exponentially increasing amplitude. When A increases beyond $V_{DD}/2$, R_{eq} will become more and more negative until $N(A) = 0$. At this point $A = A_o$, $R_{eq} = \infty$ and we have the ideal resonator. If A increases further, R_{eq} becomes positive and the oscillator presents exponentially decreasing amplitude. This represents a stable amplitude control mechanism such that in the steady state $A = A_o$ and $R_{eq} = \infty$.

3.2. General Formulation

In general, the block diagram of Fig. 5 describes a harmonic oscillator with amplitude control by limitation, where $H(s)$ is a linear block (or filter) and $f(x)$ is the nonlinear element responsible for the amplitude control. Applying the describing function method to the nonlinear block results in

$$y(t) = N(A)x(t) \tag{31}$$

for a time domain description. For a frequency-domain description it would be

$$Y(s) = N(A)X(s) \tag{32}$$

Figure 5. A general block diagram of an oscillator with amplitude control by limitation consists of a linear filter and a nonlinear amplitude controlling element connected in a loop.

On the other hand, input and output of the linear block or filter are related in the frequency domain by

$$X(s) = H(s)Y(s) \tag{33}$$

Equation (32) and (33) result in

$$H(s)N(A) = 1 \tag{34}$$

If $H(s)$ is a second-order block it can be described by

$$H(s) = \frac{a_1s^2 + a_2s + a_3}{s^2 + a_4s + a_5} \tag{35}$$

which together with Eq. (34) yields an equation of the form

$$s^2 + sb + \omega^2 = 0$$

$$b = \frac{a_1 - a_2N(A)}{1 - a_1N(A)} \tag{36}$$

$$\omega^2 = \frac{a_5 - a_3N(A)}{1 - a_1N(A)}$$

For small amplitudes $N(A)$ is equal to some constant (e.g., n_0), and Eq. (36) is called the characteristics equation. It must be assured that $b(A=0) < 0$. This is usually referred to as the *oscillation condition*. For stable amplitude control it should be

$$\frac{db(A)}{dA} > 0 \tag{37}$$

and ω^2 must be kept always positive for all possible values of A . In practice, it is desirable to make in Eq. (35) $a_1 = a_3 = 0$, which will make ω^2 and b not be coupled through a common parameter. This way the oscillation amplitude and frequency can be controlled independently.

3.3. A Practical Example: The Wien Bridge Oscillator

In a practical circuit it is not convenient to rely on inductors because of their limited range of inductance values, high price, and, in VLSI (very large scale integration) design, they are not available unless one operates in the GHz

frequency range. But it is possible to implement the filter function of Fig. 5 without inductors. The Wien bridge oscillator of Fig. 6 is such an example. Figure 6a shows its components: two resistors, two capacitors, and a voltage amplifier of gain k_0 . Figure 6b illustrates an implementation using an op amp and resistors for the voltage amplifier, and Fig. 6c shows its piecewise linear transfer characteristics. Using the describing function, the effective gain of the amplifier $k(A)$ can be expressed as a function of the sinusoidal amplitude A at node v_1

$$k(A) = k_0N(A) \tag{38}$$

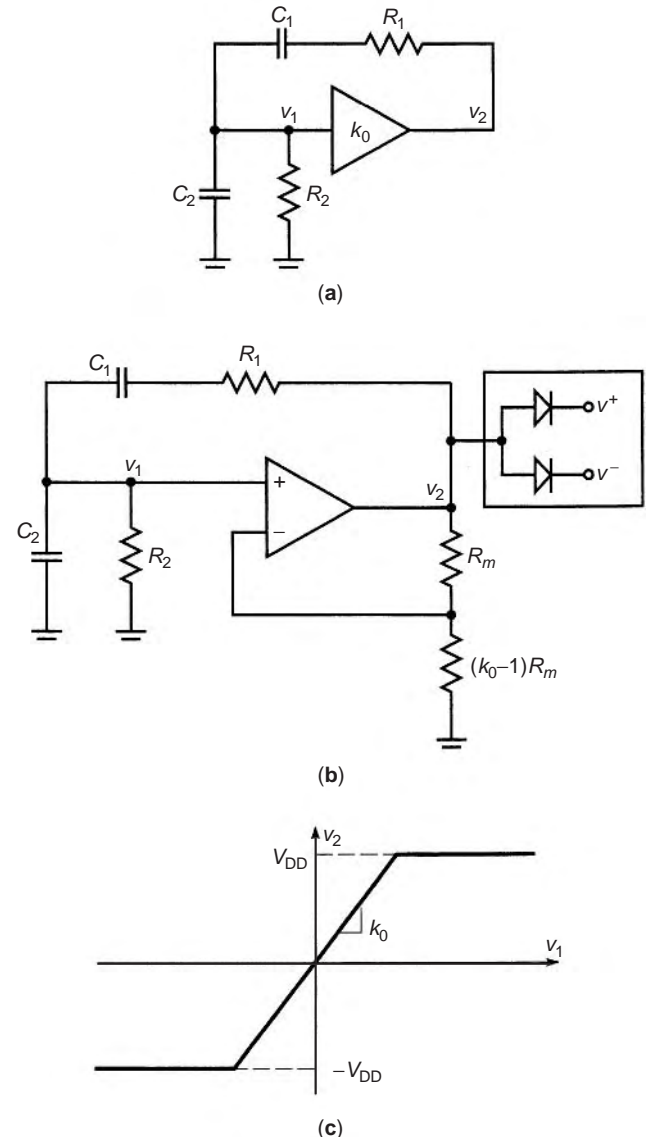

Figure 6. The Wien bridge oscillator is an example of an oscillator that does not require an inductor: (a) it consists of two resistors, two capacitors, and a voltage amplifier circuit; (b) the voltage amplifier can be assembled using an opamp and two resistors; (c) the resulting voltage amplifier has nonlinear transfer characteristics.

where $k_0N(A)$ is the describing function for the function in Fig. 6c and is given by Eq. (28) with $m_c = k_0$, $m_e = 0$, and the breakpoint changes from $V_{DD}/2$ to V_{DD}/k_0 . Consequently, the frequency-domain description of the circuit in Fig. 6a is

$$s^2 + sb + \omega^2 = 0$$

$$b = \frac{1}{R_2C_2} + \frac{1}{R_1C_1} - \frac{k_0N(A) - 1}{R_1C_2} \quad (39)$$

$$\omega^2 = \frac{1}{R_1C_1} \frac{1}{R_2C_2}$$

For initial startup it must be $b < 0$ for $A = 0$. The final amplitude A_0 is obtained by solving $b(A_0) = 0$, and the frequency of the oscillation is ω (in radians per second) or $f = \omega/2\pi$ (in hertz). Optionally, the diodes in Fig. 6b, connected to voltage sources v^+ and v^- , can be added to control the oscillation amplitude. These diodes change the saturation voltage V_{DD} of Fig. 6c, and hence will modify the describing function $N(A)$.

In general, when using amplitude control by limitation, a practical advice is to make $-b_0$ as close as possible to zero but without endangering its sign. This way the nonlinear element will distort very little the final sinusoid, because it needs to use only a small portion of its nonlinear nature to make $b(A)$ become zero. If $-b_0$ is too large the resulting waveform will probably look more like a triangular signal than a sinusoidal one.

4. AMPLITUDE CONTROL BY AUTOMATIC GAIN CONTROL

Let us illustrate the amplitude control by AGC (automatic gain control) using an OTA-C oscillator. An OTA (operational transconductance amplifier) is a device that delivers an output current I_0 proportional to its differential input voltage V_{in} . Figure 7a shows its symbol and Fig. 7b its transfer characteristics. The gain (slope g_m in Fig. 7b) is called the *transconductance*. This gain is electronically tunable through voltage V_{bias} (depending on the technology and the design, the tuning signal can also be a current). Using these devices, the self-starting oscillator of Fig. 7c can be assembled. Note that g_{m1} , g_{m2} , and C_1 emulate an inductance of value $L = C_1/(g_{m1}g_{m2})$, g_{m3} emulates a negative resistance of value $R_3 = -1/g_{m3}$, and g_{m4} emulates a positive one of value $R_4 = 1/g_{m4}$. The characteristics equation of the OTA-C oscillator is

$$s^2 + bs + \omega^2 = 0$$

$$b = \frac{g_{m4} - g_{m3}}{C_2} \quad (40)$$

$$\omega^2 = \frac{g_{m1} g_{m2}}{C_1 C_2}$$

To assure initial startup V_{b3} and V_{b4} must be such that $g_{m3} > g_{m4}$. By making g_{m3} (or g_{m4}) depend on the oscillation amplitude A , an AGC for amplitude control can be

Figure 7. An oscillator with amplitude control by AGC can be made easily with OTAs and capacitors (OTA-C): (a) an OTA delivers an output current proportional to its differential input voltage; (b) it has nonlinear transfer characteristics; (c) a self-starting OTA-C oscillator can be made with four OTAs and two capacitors; (d) the amplitude control by AGC requires an additional peak detector and integrator.

realized. This is illustrated in Fig. 7d, where the box labeled “Oscillator” is the circuit in Fig. 7c, the box labeled “PD” is a peak detector, the large triangle represents a differential input integrator of time constant τ_{AGC} , the small triangle is an amplifier of gain m necessary for stability of the AGC loop, and the circle is a summing circuit. The output of the peak detector $A_{pd}(t)$ follows (with a little delay) $A(t)$, the amplitude of the sinusoid at V_0 . The error signal resulting from subtracting A_{pd} and V_{ref} is integrated and used to control g_{m4} . If $A_{pd} > V_{ref}$ gain g_{m4} will

increase (making b positive, thus decreasing A), and if $A_{pd} < V_{ref}$ gain g_{m4} will decrease (making b negative, thus increasing A). In the steady state $A = A_{pd} = V_{ref}$ and g_{m4} will automatically be adjusted to make $b = 0$. Note that V_{ref} must be such that the node voltages are kept within the linear range of all OTAs, otherwise amplitude control by limitation may be taking place.

OTA-C oscillators are convenient for AGC because their gain can be adjusted electronically. In order to do this for the Wien bridge oscillator of Fig. 6, either a capacitor or a resistor must be made electronically tunable (using a varicap or a JFET). Also, OTA-C oscillators are interesting because they do not need resistors, and this is very attractive for VLSI in CMOS technology where resistors have very poor electrical characteristics and a limited range of values.

4.1. Stability of Automatic Gain Control Loop

An AGC loop for amplitude control, like the one in Fig. 7d, presents a certain dynamic behavior that can be analyzed in order to (1) make sure it is a stable control loop and (2) optimize its time response.

In Fig. 7d the peak detector output $A_{pd}(s)$ can be modeled as a delayed version of $A(s)$

$$A_{pd}(s) = A(s)(1 - s\tau_{pd}) \quad (41)$$

where $A_{pd}(s)$ and $A(s)$ are the Laplace transforms of the small-signal components of $A_{pd}(t)$ and $A(t)$, respectively. Signal $V_{b4}(s)$ [the Laplace transform of the small-signal component of $V_{b4}(t)$], according to Fig. 7d satisfies

$$V_{b4}(s) = \frac{1}{s\tau_{AGC}} [(1 + sm\tau_{AGC})A_{pd}(s) - V_{ref}(s)] \quad (42)$$

and controls parameter b in Eq. (40). Let us assume that $b(t)$ follows instantaneously $V_{b4}(t)$ so that

$$b(s) = \alpha V_{b4}(s) \quad (43)$$

Now what is left in order to close the control loop is to know how the amplitude $A(t)$ (or $A(s)$ in the frequency domain) at node V_0 depends on b .

This dependence can easily be obtained from the time-domain differential equation [like Eq. (14)] in the following way. Assume that $b(t)$ is a time dependent signal that has small changes around $b = 0$ and keeps $A(t)$ approximately constant around A_0 . Then the solution to $V_0(t)$ [or $v_C(t)$ in Eq. (14)] can be written as

$$V_0(t) = A(t) \cos(\omega_0 t + \varphi) \quad (44)$$

where $A(t) = A_0 + a(t)$ and $|a(t)| \ll A_0$. Substituting Eq. (44) into $v_C(t)$ of Eq. (14) yields the following coefficients for the $\cos(\cdot)$ and $\sin(\cdot)$ terms, respectively, which must be iden-

tically zero [if Eq. (44) is indeed a solution for Eq. (14)]:

$$\begin{aligned} \frac{d^2 A(t)}{dt^2} + b(t) \frac{dA(t)}{dt} + b^2(t) \frac{A(t)}{4} &= 0 \\ 2 \frac{dA(t)}{dt} + A(t)b(t) &= 0 \end{aligned} \quad (45)$$

The first equation is not of much use, but from the second it follows that

$$A(t) = A(t_0) e^{-(1/2) \int_{t_0}^t b(t) dt} \quad (46)$$

When the AGC loop is in its steady state $A(t) = A_0 + a(t)$ and the integral is a function that moves above and below zero but is always close to zero. Consequently, the exponential can be approximated by its first-order Taylor expansion resulting in

$$\begin{aligned} A(t) &\approx A(t_0) \left[1 - \frac{1}{2} \int_{t_0}^t b(t) dt \right] \\ \Rightarrow a(t) &\approx -\frac{A(t_0)}{2} \int_{t_0}^t b(t) dt \approx -\frac{A_0}{2} \int_{t_0}^t b(t) dt \end{aligned} \quad (47)$$

In the frequency domain this is

$$A(s) \approx -\frac{A_0}{2s} b(s) \quad (48)$$

From Eqs. (41)–(43) and (48) a loop equation for the AGC control can be written

$$\begin{aligned} A(s) &= \frac{V_{ref}(s)}{s^2 k_1 + s k_2 + 1} \\ k_1 &= \frac{2\tau_{AGC}}{\alpha A_0} - m\tau_{AGC}\tau_{pd} \\ k_2 &= m\tau_{AGC} - \tau_{pd} \end{aligned} \quad (49)$$

This equation represents a stable control system if the poles have negative real part. This is achieved if $k_1 \geq 0$ and $k_2 > 0$. Parameters k_1 and k_2 can also be optimized for optimum amplitude transient response [e.g., after a step response in $V_{ref}(t)$].

5. VOLTAGE-CONTROLLED HARMONIC OSCILLATORS

An oscillator whose frequency can be electronically controlled is required in many applications. Such an oscillator is called a *voltage-controlled oscillator* (VCO), although sometimes the control parameter can also be current.

In the case of the Wien bridge oscillator of Fig. 6 the frequency of oscillation ω is controlled by R_1 , R_2 , C_1 , and C_2 . Changing one or more of these parameters would enable external control of the frequency. In order to have an electronic control there are two options: (1) continuous or analog control and (2) discrete or digital control.

Figure 8. The frequency of the Wien bridge oscillator can be digitally controlled by replacing one of the resistors by a binary-weighted resistor array controlled through a digital databus.

For analog control of the Wien bridge oscillator of Fig. 6 either a voltage-controlled resistor (JFET) or a voltage-controlled capacitor (varicap) is needed. Digital control can easily be implemented by using a binary-weighted array of resistors or capacitors that are switched in and out of the circuit by means of a digital bus. This is exemplified in Fig. 8 for resistor R_2 . Signals s_i are either 0 when the switch is open or 1 when it is closed. This yields

$$\frac{1}{R_2} = \frac{1}{r} \left[\frac{1}{2^n} + \sum_{i=1}^n \frac{s_i}{2^i} \right] = \frac{1}{r} d_n \quad (50)$$

where d_n is a number that ranges from $1/2^n$ to 1 in steps of $1/2^n$. Number d_n is represented in binary format by the bits $\{S_n S_{n-1} \dots S_2 S_1\}$.

The OTA-C oscillator of Fig. 7 is much better suited for analog or continuous control of frequency. If $g_{m1} = g_{m2}$ and $C_1 = C_2$, the frequency is equal to $\omega = 2\pi f = g_{m1}/C_1$. Since voltage V_{bf} in Fig. 7d controls simultaneously g_{m1} and g_{m2} (making them equal), this voltage can be used directly to control the frequency of the VCO.

Whether a VCO is made with OTAs and capacitors, or with resistors, capacitors, and op amps, or uses some other technique, in general it turns out that the frequency does not have a linear dependence on the control voltage. In practical circuits it also happens that if the control voltage is maintained constant, the frequency may change over long periods of time due to temperature changes which cause device and circuit parameters (such as transconductance and resistance) to drift. Both problems can be overcome by introducing a frequency control loop.

6. FREQUENCY-CONTROLLED LOOP

Figure 9a shows the basic concept of frequency-controlled loop for VCOs. It consists of a VCO (e.g., the one in Fig. 7d), a differential input voltage integrator, and a frequency to voltage converter (FVC) circuit. Voltage V_{CO} is now the external control of the VCO frequency. The FVC circuit delivers an output voltage V_{FVC} that depends linearly on the frequency f of its input signal V_{OSC} :

$$V_{FVC} = \rho f + V_{F0} \quad (51)$$

Parameters ρ and V_{F0} must be constants and should not depend on temperature or technological parameters that

change from one prototype to another. If such an FVC is available, the circuit in Fig. 9a would stabilize at $V_{FVC} = V_{CO}$. According to Eq. (51), this means that the resulting oscillation frequency f_0 depends on V_{CO} as

$$f_0 = \frac{V_{CO} - V_{F0}}{\rho} \quad (52)$$

which is linear and temperature-independent.

A possible implementation with OTAs of the FVC is shown in Fig. 9b. It uses two OTAs of transconductance g_o , a capacitor C , a peak detector, a switch, a temperature-independent voltage reference V_{ref} , and a monostable triggered by the oscillating signal V_{OSC} . During each period $T = 1/f$ of signal V_{OSC} the monostable delivers a pulse of constant width t_0 , which must be temperature-independent and well calibrated. Many times it is convenient to add a sine-to-square-wave converter (and even a frequency divider) between V_{OSC} and the monostable. The circuit of Fig. 9b uses three components that are not temperature-independent and may vary over time and from one prototype to another: the two OTAs and the capacitor. However, provided both OTAs have the same transconductance (which is a reasonable assumption for VLSI implementations), the resulting parameters ρ and V_{F0} do not depend on C nor g_o . An example of the time waveforms of $u(t)$ and $v(t)$ of Fig. 9b is shown in Fig 9c. During each

Figure 9. A frequency-controlled loop can provide a linear dependence between tuning voltage and VCO frequency, and can also make this dependence temperature and prototype independent: (a) it can be made by adding a FVC and an integrator to a VCO; (b) the FVC can be made with a calibrated monostable, a reference voltage, a peak detector, two OTAs, a capacitor, and a switch; (c) after a transient the FVC output stabilizes to a steady-state voltage that depends linearly on the input signal frequency.

period T of V_{OSC} the monostable is triggered once, turning the switch ON during a time t_0 . While the switch is in ON state capacitor C is charged by a constant current $g_0(V_{ref}-v(t))$, and when the switch is OFF a constant current of value $-g_0v(t)$ discharges it. The output of the FVC $v(t)$ changes from cycle to cycle but is constant during each cycle. If v_m is its value during one cycle and v_{m+1} for the next one, it follows that

$$u(t+T) = u(t) + \frac{g_0(V_{ref} - v_m)}{C} t_0 - \frac{g_0 v_{m+1}}{C} (T - t_0) \tag{53}$$

where $u(t)$ is taken at one of peaks: $u(t) = v_m$ and $u(t+T) = v_{m+1}$. Consequently, we obtain

$$v_{m+1} = \frac{v_m(C - g_0 t_0) + V_{ref} g_0 t_0}{C + g_0(T - t_0)} \tag{54}$$

In the steady of the FVC $v_{m+1} = v_m$. Applying this condition to Eq. (54) and calling V_{FVC} the stabilized value of v_m yields

$$V_{FVC} = \frac{V_{ref} t_0}{T} = V_{ref} t_0 f \tag{55}$$

Consequently, the circuit of Fig. 9b implements a FVC with $\rho = V_{ref} t_0$ and $V_{F0} = 0$, which both are temperature- and prototype-independent.

7. FURTHER CONSIDERATIONS

The different concepts and considerations mentioned so far have been illustrated with practical circuits using either resistors, capacitors, and op amps, or using OTAs and capacitors. There are many other circuit techniques available that can be used to implement the different blocks and equations needed for stable harmonic oscillator circuits. Some of these techniques could be continuous current mode, switched capacitor, switched current, digital circuit techniques, or even any combination of these techniques.

Depending on the frequency range of the oscillator it may be necessary to consider circuit parasitics that have not been mentioned so far. For example, op amps and OTAs both have nonideal input and output impedances, leakage currents, and most importantly gains that are frequency-dependent. All these parasitics result in modified characteristics equations. A very sensitive parameter to parasitics is the oscillation condition $-b_0$ required for initial startup. Since in practice it is desirable to have $-b_0$ very close to zero but still guarantee its negative sign, it is apparent that parasitics can result in either very negative (resulting in very distorted sinusoids) or positive (resulting in no oscillation) values. Each circuit technique has its own parasitics, and depending on the intended frequency range, they will have a different impact on the final oscillator performance. Consequently, for good oscillator

design the dominant parasitics need to be well known and taken into account.

Another interesting and advanced issue when designing oscillators in distortion. Both amplitude control mechanisms, limitation and AGC, are nonlinear and will introduce some degree of distortion. Is there a way to predict how much distortion will render an oscillator?

7.1. Distortion for Amplitude Control by Automatic Gain Control

In an oscillator with AGC for amplitude control, as in Fig. 7d, the element that introduces most of the distortion is the peak detector. Figure 10 shows examples of peak detectors based on one-phase or half-wave (Fig. 10a), two-phase or full-wave (Fig. 10b), and four-phase (Fig. 10c) rectifying principles. For the four-phase case, either the oscillator should provide two phases with $\pi/2$ shift, or an additional integrator is needed. Peak detectors with more phases can be implemented by linearly combining previous phases. Increasing the number of phases in the peak detector results in faster response [delay τ_{pd} in Eq. (41) is smaller for more phases] and less distortion. However, all phases have to present the same amplitude; otherwise distortion will increase. In practice, as the number of phases increases, it becomes more difficult (due to offsets

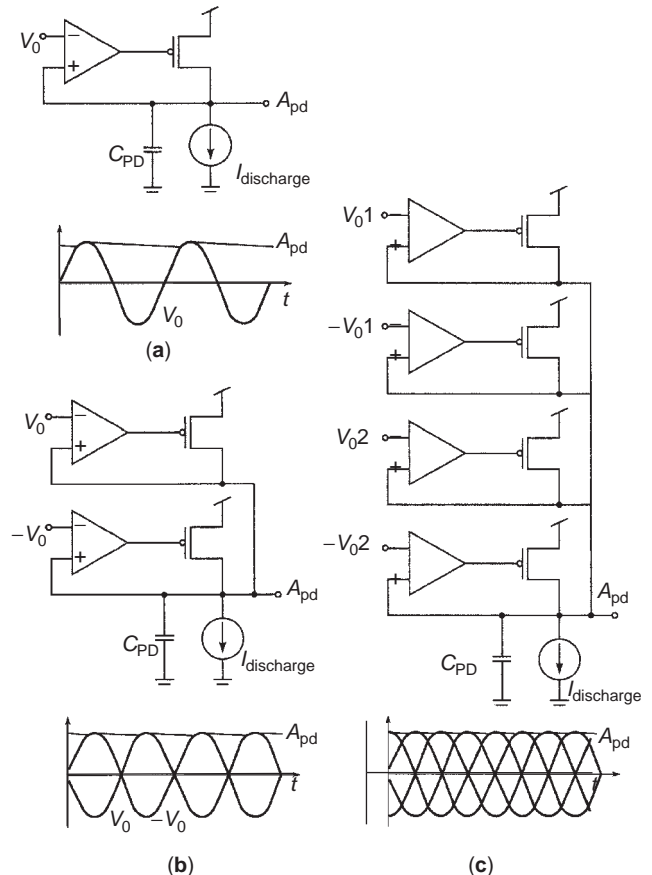

Figure 10. Possible implementations for a peak detector: (a) one phase-based (or half-wave-rectifier based) (b) two phase-based (or full-wave-rectifier-based), and (c) four-phase-based peak detector.

and component mismatch) to keep the amplitude of the phases sufficiently equal.

In the peak detectors of Fig. 10, whenever one of the phases becomes larger than A_{pd} it slightly turns ON its corresponding P transistor injecting a current into C_{PD} until A_{pd} increases sufficiently to turn OFF the P transistor. The discharge current ensures that A_{pd} will follow the amplitude of the oscillations if it decreases. Increasing $I_{discharge}$ results in faster response but higher distortion. Whatever peak detector is used, waveform $A_{pd}(t)$ is not constant nor sinusoidal. It has a shape similar to those shown in Fig. 10. Since $A_{pd}(t)$ is periodic its Fourier series expansion can be computed:

$$A_{pd}(t) = A_0 + \sum_{n=1}^{\infty} a_n \cos(n\omega_0 t + \varphi_n) \quad (56)$$

The high-order harmonic components $\{a_2, a_3, \dots\}$ are those which contribute to distortion at node V_0 (in Fig. 7d). Applying the filtering functions that go from node A_{pd} , through V_{b4} , to V_0 [Eqs. (41)–(43) and (48)] to these higher-order harmonics provides their amplitudes at node V_0 :

$$|A_{on}| = \frac{\alpha A_0}{2\tau_{AGC} n^2 \omega_0^2} |1 + jn\omega_0 m\tau_{AGC}| |1 - jn\omega_0 \tau_{pd}| |a_n| \quad (57)$$

The total harmonic distortion at the output of the oscillator is then defined as

$$\text{THD}(V_0) = \sqrt{\sum_{n=2}^{\infty} \left(\frac{A_{on}}{A_0}\right)^2} \quad (58)$$

7.2. Distortion for Amplitude Control by Limitation

This problem is computationally complicated but can be solved by harmonic balance. Consider the general block diagram of Fig. 5. In the steady state, periodic waveforms $x(t)$ and $y(t)$ can be expressed by their respective Fourier series expansions

$$\begin{aligned} x(t) &= x_1 \cos(\omega_0 t) + \sum_{n=2}^{\infty} x_n \cos(n\omega_0 t + \varphi_n) \\ y(t) &= \sum_{n=1}^{\infty} y_n \cos(n\omega_0 t + \phi_n) \end{aligned} \quad (59)$$

where

$$\begin{aligned} |x_n| &\ll |x_1| \\ |y_n| &\ll |y_1| \end{aligned} \quad (60)$$

In general, this problem is solved numerically for a finite set of harmonics. Let N be the highest harmonic to be computed. Since $f(x(t))$ is also periodic, computing its Fourier series expansion yields that of $y(t)$. Therefore, given a set of parameters for $x(t)$ $\{x_1, \dots, x_N, \varphi_2, \dots, \varphi_N\}$ the set of

parameters $\{y_1, \dots, y_N, \phi_1, \dots, \phi_N\}$ for $y(t)$ can be obtained this way. By applying each component of $y(t)$ (characterized by y_n and ϕ_n) to filter $H(s)$ yields the corresponding component for $x(t)$:

$$\begin{aligned} x_n &= y_n |H(jn\omega_0)| \\ \varphi_n &= \phi_n + \text{phase}(H(jn\omega_0)) \end{aligned} \quad (61)$$

By iterating this procedure until all values x_n, y_n, φ_n , and ϕ_n converge, the distortion of $x(t)$

$$\text{THD}(x) = \sqrt{\sum_{n=2}^N \left(\frac{x_n}{x_1}\right)^2} \quad (62)$$

or $y(t)$

$$\text{THD}(y) = \sqrt{\sum_{n=2}^N \left(\frac{y_n}{y_1}\right)^2} \quad (63)$$

can be predicted.

HELICAL ANTENNAS

ARLON T. ADAMS
JAY K. LEE
Syracuse University
Syracuse, New York

1. INTRODUCTION

The helix antenna has a long and fascinating history. It was discovered in 1946 by John Kraus. Since then, new variations have continued to arise even up to the present day. The discovery itself is a very interesting story, which is told in John Kraus' book *Antennas* [1]. It all started with an afternoon lecture at Ohio State University. John Kraus listened as the speaker described the wave-guiding helix used in traveling-wave tubes; he wondered if this interesting helix could be used as an antenna and, after the

talk, he asked the well-known lecturer. The speaker replied emphatically, "No, I've tried it, and it doesn't work." That very evening, John Kraus went down to his basement, wound a seven-turn helical coil one wavelength in circumference and fed it by means of a coaxial line and ground plane (Fig. 1a). He found that it produced a sharp beam of circularly polarized radiation off the open end of the helix. So the helix antenna was born, despite the advice of experts.

1.1. Helical Curves

The helix was well-known in ancient Greece. Geminus described it in the first century B.C. and there are references to earlier work on the helix. The *cylindrical helix* may be defined by considering a right circular cylinder of radius a , whose axis is the z axis. Using a right-handed cylindrical coordinate system (r, ϕ, z) the equations of the helix are

$$x = a \cos \phi; \quad y = a \sin \phi; \quad z = a\phi \tan \alpha \quad (1)$$

where α is the pitch angle of the helix and $2a$ is the diameter. The lines of the cylinder parallel to the z axis, that is, the lines $(r = a, \phi = \phi_0)$ are considered to be the generators of the cylinder. The cylinder is generated by rotating any generator about the z axis. The helix cuts the generators at a constant angle $\pi/2 - \alpha$. It also projects as a sine curve on any plane parallel to the axis, for example, any plane that includes the axis.

Figure 1a shows the wire helix antenna. Parameters are defined as follows:

D is the diameter of helix, which is equal to $2a$.

C is the circumference.

S is the spacing between turns.

α is the pitch angle.

Figure 1. The helical antenna: (a) a helix fed by a coaxial line and a ground plane; (b) one turn of the helix unrolled on a flat plane.

L is the length of one turn.

N is the number of turns.

C_λ , S_λ , and L_λ represent the respective distances in wavelengths such that $C_\lambda = C/\lambda$, and so on. When one turn of the helix is unrolled on a flat plane, the relationships between the spacing S , circumference C , turn length L , and pitch angle α can be obtained from the triangle shown in Fig. 1b as follows:

$$S = C \tan \alpha, \quad \alpha = \tan^{-1} \frac{S}{C}, \quad L = \sqrt{C^2 + S^2} \quad (2)$$

Thus we need only *three* independent parameters, C , α , N , to describe a helix. Note that when $\alpha = 0^\circ$, $S = 0$, and the helix reduces to a planar loop. When $\alpha = 90^\circ$, $C = 0$, and the helix becomes a straight line.

The round-wire helix such as Kraus first built consists of a round wire whose centerline is the helix curve of Eq. (1). The tape helix is a conducting tape of width w , which is wound around a cylinder or a thin cylindrical tube. Its centerline is the helix of Eq. (1). A single-wire helix is called the *monofilar helix*. The double, or *bifilar*, helix is constructed by adding an additional member, which is formed by replacing ϕ with $\phi - \pi$ everywhere in Eq. (1). The *quadrifilar* helix antenna is formed by adding three members; ϕ in Eq. (1) is replaced with $\phi - (\pi/2)$, π , $(3\pi/2)$. A left-handed helix can be formed by using a left-handed coordinate system, or by replacing ϕ in Eq. (1) with $2\pi - \phi$. Figure 1a shows a right-handed helix. There are other helical curves. The *conical helix* lies on the surface of a cone and cuts the radial lines of the cone, the generators, at a constant angle. The *spherical helix* lies on the surface of the sphere and cuts the generators, for example, the longitude lines, at a constant angle.

There are many striking examples of the helix in nature, from some of the smallest to some of the largest objects. Most important of all is the DNA molecule, which is a double helix. The marks on a snail of the family Helicidae resemble a spherical helix. The human ear has a prominent helical ridge. The *Heliconia* is a family of herbs with a helical shape. The helictite is similar to a stalagmite. Some trees have helical bark. Finally, we have the largest of the nebulae, the Helix Nebula. In addition, we see many manmade forms of the helix around us, including automobile springs, spiral staircases, inductance coils, transformer coils, parking lot ramps, automobile antenna coils, and finally, the lowly screw, which is a combination of conical and cylindrical helices.

2. MONOFILAR HELICAL ANTENNA

We first consider the characteristics of a monofilar, or unifilar, helical antenna. In this section we simply call it a helical antenna, implying that it is a *monofilar* helix. The helix commonly operates in two different modes, the normal mode and the axial mode, depending on the electrical size of the helix. When the dimensions of the helix are small compared with a wavelength ($D \ll \lambda$, $NS \ll \lambda$), the maximum radiation is normal (or perpendicular) to the

helix axis. This condition is called the *normal mode*. When the helix circumference is on the order of one wavelength, the maximum radiation is along the helix axis. Thus, this type of operation is called the *axial mode*. The axial mode helix is a broadband antenna. The radiation from this axial-mode helix is close to circular polarization along the axis. There is also a *backfire mode*, which is discussed in a later section.

2.1. Normal-Mode Helix

Let's consider a helix with its axis along the z axis, centered at the origin (Fig. 2a). The geometry of the helix reduces to a loop when the pitch angle α approaches zero and to a straight wire when it approaches 90° . Since the limiting geometries of the helix are a loop and a dipole, the far field radiated by a small helix can be described by the radiation fields of a small loop and a short dipole when dimensions are small compared to a wavelength. The analysis of a small short helix is facilitated by assuming that the helix consists of a number of small loops and short dipoles connected in series as in Fig. 2b. The diameter of the loops is the same as the helix diameter (D) and the length of the dipoles is approximately the same as the spacing (S) between turns of the helix. Because the helix is small and short, the current distribution is assumed to be *uniform* in magnitude and phase over the entire length of the helix. For the same reason, the far-field (Fraunhofer) pattern will be indepen-

dent of the number of turns and thus can be obtained by considering the pattern of a single-turn helix that consists of a single small loop of diameter D and one short dipole of length S .

Assume that the complex amplitude of current is I and the angular frequency is ω . The radiation electric field of the small loop of diameter D has only an E_ϕ component, given by

$$E_\phi = \eta k^2 I A \frac{e^{-jkr}}{4\pi r} \sin \theta \quad (3)$$

where $A = \pi D^2/4$ is the area of the loop, $k = \omega\sqrt{\mu\epsilon}$ is the propagation constant, and $\eta = \sqrt{\mu/\epsilon}$ is the intrinsic impedance. The far field of the short dipole, or the Hertzian dipole of length S , has only an E_θ component, given by

$$E_\theta = j\omega\mu I S \frac{e^{-jkr}}{4\pi r} \sin \theta \quad (4)$$

The total radiation field for one turn is then given by

$$\mathbf{E} = \hat{\mathbf{a}}_\theta E_\theta + \hat{\mathbf{a}}_\phi E_\phi = \{\hat{\mathbf{a}}_j \omega \mu I S + \hat{\mathbf{a}}_\phi \eta k^2 A\} I \frac{e^{-jkr}}{4\pi r} \sin \theta \quad (5)$$

The normalized radiation field pattern $f(\theta)$ of the normal-mode helix is

$$f(\theta) = \sin \theta \quad (6)$$

which is the same as that of the Hertzian dipole and the small loop and is shown in Fig. 2c. The field is zero along the axis (in the endfire direction) and is maximum in the xy plane ($\theta = 90^\circ$), which is normal to the helix axis.

Because E_θ and E_ϕ are 90° out of phase as shown in Eqs. (3) and (4), the radiated wave is elliptically polarized. The axial ratio (AR) of the polarization ellipse of the far field is obtained by dividing the magnitude of Eq. (4) by that of Eq. (3)

$$\text{AR} = \frac{|E_\theta|}{|E_\phi|} = \frac{\omega\mu S}{\eta k^2 \frac{2\pi}{\lambda} A} = \frac{S\lambda}{2\pi A} = \frac{2S\lambda}{(\pi D)^2} \quad (7)$$

where we have used $k = 2\pi/\lambda$, $nk = \omega\mu$. Because E_θ and E_ϕ are 90° out of phase, the polarization ellipse becomes a circle when $|E_\theta| = |E_\phi|$, indicating circular polarization. Setting $\text{AR} = 1$ yields

$$C = \pi D = \sqrt{2S\lambda} \quad \text{or} \quad C_\lambda = \sqrt{2S} \quad (8)$$

Under this condition the radiation field is circularly polarized in *all* directions except of course along the axis where the radiation is zero. The polarization ellipse of the radiation from a helix of constant turn length (L) changes progressively as the pitch angle α is varied. When $\alpha = \tan^{-1}(S/C) = 0$ (the helix reduces to a loop), $\text{AR} = 0$, $E_\theta = 0$, $\mathbf{E} = \hat{\mathbf{a}}_\phi E_\phi$; thus the wave is linearly polarized with horizontal (or perpendicular) polarization. As α increases, the polarization becomes elliptical, with the major axis of the

Figure 2. The normal-mode helix: (a) coordinate system; (b) loop-dipole model; (c) beam pattern.

ellipse horizontal. When α reaches a value such that condition (8) is satisfied, $AR=1$, and the polarization is circular. With the help of Eq. (2), the condition (8) leads to the following value of α :

$$\alpha_{CP} = \sin^{-1} \left[\frac{-1 + \sqrt{1 + L_\lambda^2}}{L_\lambda} \right] \quad (9)$$

As α increases further, the polarization again becomes elliptical and the major axis is vertical. Finally, when $\alpha=90^\circ$ (the helix reduces to a dipole), $E_\phi=0$, $\mathbf{E}=\hat{\mathbf{a}}_\theta E_\theta$; thus the polarization is linear with vertical (or parallel) polarization. For small pitch angles ($\alpha \ll 1$), Eq. (9) is simplified to

$$\alpha_{CP} = \frac{C_\lambda}{2} \quad (10)$$

where α_{CP} is expressed in radians. For small pitch angles, circular polarization can occur at frequencies such that the circumference is very small compared to a wavelength ($C_\lambda \ll 1$).

From Eqs. (3) and (4), we note that the loop field E_ϕ and the dipole field E_θ , respectively, are proportional to the second and first powers of frequency. Correspondingly, radiation resistance of loop and dipole are proportional to the fourth and second powers, respectively. Thus, as frequency decreases, the dipole radiation predominates and the beam pattern is linearly polarized. In this linearly polarized frequency range, the normal-mode helix has some interesting properties. Its beam pattern is essentially that associated with the dipoles, that is, a monopole of length NS above a ground plane. Its impedance, however, is significantly affected by the loops.

The normal-mode helix is limited by its size. It has the same restrictions and limitations that apply to any electrically small antenna. But within those restrictions, it has certain advantages over a dipole antenna of the same height. These include a lower frequency for resonance and a larger radiation resistance, because of both the longer path of the helical structure. While the dipole may require additional impedance-matching circuits to achieve resonance, the helix is resonant without supplementary matching elements. Another advantage over the dipole is

Figure 4. Measured performance of the monofilar axial mode helix: (a) beamwidth; (b) axial ratio; (c) VSWR. (From Kraus [1], © 1988 by McGraw-Hill, Inc. Reprinted with permission of the McGraw-Hill Companies.)

that the helix is flexible and more resilient. The higher radiation resistance, resonant characteristic, and flexibility make the normal-mode helix suitable for small antennas used in mobile communications.

Figure 3. Measured beam patterns of the monofilar axial mode helix. (From Kraus [1], © 1988 by McGraw-Hill, Inc. Reprinted with permission of the McGraw-Hill Companies.)

2.2. Axial-Mode Helix

A very useful mode of operation for the helical antenna is the axial or endfire mode. In this mode the radiation pattern has a single mainbeam along the axis of the helix (+z direction); that is, it is an endfire antenna. Experiments have shown that the axial mode occurs when the circumference of the helix is approximately one wavelength and when the helix has several turns. A primary component of current on the helix is a wave traveling outward from the feed along the wire at approximately the speed of light and the radiation is a beam off the end of the helix. Because the electric field vector rotates around in a circular fashion as does the current on the helix, we expect that the radiation field is circularly polarized along the helix axis. One very important feature of the axial-mode helical antenna is its *broadband* character. As a rule of thumb, the approximate bandwidth for the axial mode is given as follows [2]:

$$\frac{3}{4} < C_\lambda < \frac{4}{3} \quad (11)$$

The bandwidth ratio, the ratio of the upper and lower frequencies, is $\frac{4}{3} \div \frac{3}{4}$ or 1.78, which is close to a 2-1 bandwidth. The helix is usually fed axially or peripherally with the inner conductor of the coaxial line connected to the helix and the outer conductor attached to the ground plane. The ground plane can be made from either solid metal or wire mesh.

2.2.1. Analysis of Radiation Pattern. The axial-mode helix has a circumference of approximately one wavelength, so the current distribution would not be uniform, and we assume that there is an outgoing current wave, traveling along the helical conductor at phase velocity $v = pc$ (where p is the phase velocity relative to the speed of light c in free space). Then

$$I(l) = I_0 e^{-j\beta l} \quad (12)$$

where l is the distance measured along the helix from the beginning of the turn closest to the ground plane, I_0 the input current, $\beta = k/p$ the phase constant of the current wave. When the total length of one turn is approximately a wavelength, the current distribution in Eq. (12) has opposite phase (180° out of phase) on opposite sides of a turn because they are separated by about a half-wavelength. Also the helical coil physically reverses current direction for opposite points. Thus the currents at opposite points of a turn are essentially in phase, giving rise to reinforcement in the far field along the helix axis. We can find the radiation pattern by using the principle of pattern multiplication because a helix with uniform cross section can be considered as an array of N identical elements (or turns). We have a uniformly excited, equally spaced array with spacing S , so the total pattern is the product of the pattern for one turn (the element pattern) and the pattern for an array of N isotropic point sources (an array factor). When the helix is long (say, $NS > \lambda$), the array factor is much sharper than the element pattern and hence determines the shape of the total far-field pattern.

2.2.1.1. Array Factor. The array factor (AF) of a uniformly excited, equally spaced, linear array of N elements is given by

$$\text{AF} = \frac{\sin \frac{N}{2} \psi}{N \sin \frac{\psi}{2}} \quad (13)$$

$$\psi = kS \cos \theta + \delta \quad (14)$$

where θ is an angle measured from the array axis (z axis) and δ is the phase shift between adjacent elements. Explaining the phase relationships of the axial-mode helix is difficult. Begin by finding the phase shift δ required for endfire operation, because we know that the radiation is endfire. For *ordinary endfire*, we find the conditions such that ψ is zero at $\theta = 0^\circ$.

$$\delta = -kS - 2m\pi \quad (m \text{ is an integer}) \quad (15)$$

where the term $(-2m\pi)$ reflects the basic ambiguity of phase. Next we find conditions for *increased directivity Hansen-Woodyard (HW) endfire* [3], since this is an optimum form of endfire:

$$\begin{aligned} \delta &= -kS - 2m\pi - \frac{\pi}{N} \\ &= -2\pi - \left(kS + \frac{\pi}{N}\right) \quad (m = 1) \end{aligned} \quad (16)$$

To be more accurate, the term π/N should be replaced by $2.94/N$ [3]. However, the choice of π/N hardly changes the radiation field [4] and is convenient for expressing other quantities. We have tried the arbitrary choice ($m = 1$) because this term -2π corresponds roughly to one turn of the circumference at midband ($C_\lambda = 1$). Later it will be clear that other choices are not possible solutions. Experiments show [1,5] that the phase shift δ obtained is close to that of Eq. (16) at midband ($C_\lambda = 1$). How does this happen? We have already pointed out that the term (-2π) corresponds roughly to one turn of the circumference. In addition, the length around one turn of the helix is greater than a wavelength ($L_\lambda > 1$) at midband. More importantly, the velocity of travel is less than that of light ($p \approx 0.9$) at midband [5]. These two additional contributions account for the minor term $-(kS + \pi/N)$. Thus the phase at midband is explained. However, the experimental data for δ track Eq. (16) fairly well over the entire bandwidth of the axial mode. How is this possible? We cannot alter our choice of m ; one choice must work for the entire frequency range; and if p remained constant, Eq. (16) could not be satisfied over the entire band. Fortunately, p does vary quite a bit (from 0.73 to 0.97) over the axial-mode frequency range; the result is that HW endfire described by Eq. (16) is tracked quite well over most of the band, falling off a little toward the high end. All in all, this is quite a remarkable story. The phase, so to speak, *locks in* to HW endfire over the bandwidth of almost 2-1. When first reported by Kraus, this was called an *anomalous* phase progression. It still continues to mystify succeeding generations.

To summarize, the phase progression along the helix wire is relatively simple; it corresponds roughly to that of speed of light along the wire. The phase progression in z , which determines the phase difference δ between turns, follows the phase progression of the wire. Taking into account the phase ambiguity (2π), we see that HW endfire is obtained at midband. The relative phase velocity p then changes with frequency just enough to maintain the HW endfire. Another point worth noting is that we have not discussed backfire ($\theta = 180^\circ$) radiation. It does, in fact, occur along with the axial mode but is usually suppressed by the ground plane. It will return, to our advantage, with the multifilar helix:

$$\beta = -\frac{\delta}{L} = \frac{1}{L} \left[kS + 2\pi \left(1 + \frac{1}{2N} \right) \right] = \frac{2\pi}{L} \left(\frac{S}{\lambda} + \frac{2N+1}{2N} \right) \quad (17)$$

$$p = \frac{k}{\beta} = \frac{L_\lambda}{S_\lambda + (2N+1)/2N} \quad (18)$$

Using p as obtained from Eq. (18) to calculate the array factor yields patterns in good agreement with measured patterns. The p value calculated from Eq. (18) is in close agreement with measured values of p [1]. Therefore, it appears that the Hansen–Woodyard increased directivity condition is a good approximation for helices radiating in the axial mode. For a typical case where $C = \lambda$, $\alpha = 14^\circ$, $N = 10$, we find from Eqs. (2) and (18) that $S = C \tan \alpha = 0.249\lambda$, $L = 1.031\lambda$, and $p = 0.79$. Thus the traveling current wave has a phase velocity less than that of free space. Finally, substituting Eq. (16) into Eq. (14) yields

$$\psi = kS(\cos \theta - 1) - \left(2\pi + \frac{\pi}{N} \right) \quad (19)$$

Equations (13) and (19) provide the complete normalized array pattern of the axial-mode helical antenna. For the element pattern we will need an analysis of the radiation from a circular loop, which is covered in the next section.

2.2.2. Circular Loop Radiation. In this section we consider the radiation from a circular loop carrying a current $I(\phi)$. The result is useful in understanding the operation of the helix in both the mono- and multifilar forms. In addition, it will yield an approximate element factor for a single turn of the helix. The loop of radius a is centered at the origin and lies in the xy plane. The current distribution $I(\phi)$ may be represented in terms of a complex Fourier series representation:

$$I(\phi) = \sum_{n=-\infty}^{\infty} I_n e^{jn\phi} \quad (20)$$

Consider the typical term $I_n e^{jn\phi}$ of the current distribution $I(\phi)$. First we evaluate components $A_{\phi n}$, $A_{\theta n}$ of the far-field magnetic vector potential as follows. Directions ϕ, θ are associated with the field point rather than

the source point:

$$A_{\phi n} = \frac{e^{-jkr}}{4\pi r} \int_0^{2\pi} I_n e^{jn\phi'} \cos(\phi - \phi') e^{jka \sin \theta \cos(\phi - \phi')} a d\phi' \quad (21)$$

$$A_{\theta n} = \frac{e^{-jkr}}{4\pi r} \int_0^{2\pi} I_n e^{jn\phi'} [-\sin(\phi' - \phi)] \times \cos \theta e^{jka \sin \theta \cos(\phi - \phi')} a d\phi' \quad (22)$$

To evaluate A_ϕ , we introduce the change of variables $\psi = \phi' - \phi$ and change limits to obtain

$$A_{\phi n} = \frac{e^{jn\phi} e^{-jkr} I_n a}{4\pi r} \int_0^{2\pi} e^{jn\psi} \left(\frac{e^{j\psi} + e^{-j\psi}}{2} \right) e^{j(ka \sin \theta) \cos \psi} d\psi$$

Next, we use the following integral expression for the Bessel function of the first kind $J_m(x)$:

$$\int_0^{2\pi} e^{jx \cos \theta} e^{jm\theta} d\theta = 2\pi j^m J_m(x)$$

A_ϕ is then evaluated directly to obtain

$$A_{\phi n} = \frac{e^{jn\phi} (I_n a) e^{-jkr} j^{n+1}}{4r} [J_{n+1}(ka \sin \theta) - J_{n-1}(ka \sin \theta)] \quad (23)$$

$$E_{\phi n} = -j\omega\mu A_{\phi n} \quad (24)$$

Using similar methods, we obtain the following evaluation of A_θ :

$$A_{\theta n} = \frac{e^{jn\phi} (I_n a) e^{-jkr} j^{n+1} (j \cos \theta)}{4r} [J_{n+1}(ka \sin \theta) \quad (25)$$

$$+ J_{n-1}(ka \sin \theta)]$$

$$E_{\theta n} = -j\omega\mu A_{\theta n} \quad (26)$$

The total fields may, of course, be obtained by adding contributions of all Fourier modes.

Now let's evaluate the far fields along the z axis ($\theta = 0^\circ$, 180°) for each of the separate Fourier modes. We note that $J_n(0) = 0$ ($n \neq 0$) and $J_0(0) = 1$. Evaluating the cases $n = \pm 1$, we find that, along the z axis

$$\frac{E_\phi}{E_\theta} = \pm j \quad (27)$$

In other words, the modes $n = \pm 1$ representing traveling waves yield circular polarization along the z axis. Note that all other traveling-wave modes yield a null on axis. *Of all the Fourier modes, only $n = \pm 1$ radiate in the forward endfire or backfire direction.* For the helix, we define forward or backward radiation as radiation away from or toward the feedpoint, respectively.

This result can also be seen by considering currents around the loop for various modes. For $n = \pm 1$, each current element is matched by its opposite across the loop,

which is in the same direction such as to add along the z axis and to rotate polarization as time progresses. All the other modes cancel along the axis. For even modes, each element is canceled by its opposite across the loop. For odd modes, a group of elements will cancel. For the general odd case n , any group of n elements, each separated by $180^\circ/n$, yields zero contribution. For $n=5$, for example, any group of five elements, each separated by 36° , yields zero contribution.

Any currents on the cylindrical surface may be resolved into ϕ - and z -directed currents. The z -directed currents do not radiate along the axis. Thus, for currents of any direction, *only the $n = \pm 1$ Fourier modes can contribute to endfire or backfire*. These results will be useful when considering multifilar helices.

This discussion makes it easier to understand the operation of the helical antenna. At low frequencies the zeroth mode ($n=0$) is strongly excited because there is little variation of phase around the cylinder on one turn. In addition, the impedance of the higher modes is highly reactive. As frequency increases and C_λ approaches unity, we have one complete cycle around the cylinder on one turn, and we expect the $e^{-j\phi}$ mode to be excited for a right-hand helix. The phase velocity of the helix is lower than that associated with the speed of light, and the impedance of the mode $n = -1$ is reasonable and so the axial mode begins at about $C_\lambda = 0.75$. Similarly, as frequency increases, we expect the mode $n = -2$ to appear; this mode would produce beam pattern deterioration. The axial mode continues until about $C_\lambda = 1.33$.

2.2.2.1. Element Pattern of the Axial-Mode Helix. For the element pattern of one turn of the helix, the current distribution is assumed to be

$$I(\phi') = I_0 e^{-j\beta l} = I_0 e^{-j\beta a \phi'} \quad (28)$$

where $\beta = k/p$, $a = D/2$, and ϕ' is the angle measured from the x axis. For accurate analysis of the element pattern, Eq. (28) should be used to calculate the radiation integral. However, when the helix with several turns operates in the axial mode ($C_\lambda \approx 1$), the array factor dominates the endfire beam pattern and the element pattern provides minor corrections. Thus it suffices to consider the radiation field of a planar loop with $C_\lambda = 1$, instead of a three-dimensional one-turn helix. If we also assume that $p \approx 1$, then

$$I(\phi') \approx I_0 e^{-jka\phi'} = I_0 e^{-j(2\pi/\lambda)\alpha\phi'} \approx I_0 e^{-j\phi'} \quad (29)$$

Using the simple form of the current distribution in Eq. (29), we can easily calculate the radiation fields for the element pattern from Eqs. (23)–(26) for $C_\lambda = 1$ ($n = -1$):

$$E_\phi(\theta, \phi) = C(r)[J_0(\sin \theta) + J_2(\sin \theta)]e^{-j\phi} \quad (30)$$

$$E_\theta(\theta, \phi) = C(r)[J_0(\sin \theta) - J_2(\sin \theta)](j \cos \theta)e^{-j\phi} \quad (31)$$

where $C(r)$ gives the r dependence of the fields. Note that $ka = 1$ when $C_\lambda = 1$. If we plot the radiation patterns of

$|E_\theta|$ and $|E_\phi|$ using Eqs. (30) and (31), we obtain a figure-eight pattern for E_θ with a null at 90° , and a nearly omnidirectional pattern for E_ϕ [6]. From the plot, it is interesting to note that the normalized E_θ can be approximated by $\cos \theta$. We also observe that E_θ and E_ϕ are 90° out of phase. In particular, when $\theta = 0^\circ$, then $|E_\theta| = |E_\phi|$; thus the radiation field is *circularly polarized* in the endfire direction. As one departs from $\theta = 0^\circ$, E_θ decreases more rapidly than does E_ϕ , so the polarization becomes *elliptical*. Finally, it should be noted that Kraus [1] has analyzed the element pattern, by using a single turn of a three-dimensional helix with uniform traveling-wave current.

2.2.3. Beam Patterns. The complete total far-field pattern is given by the product of the array factor shown by Eq. (13) and the element pattern in Eq. (30) or (31). However, the array pattern is much sharper than the element patterns. Thus the total E_θ and E_ϕ patterns are nearly the same, in spite of the difference in the single-turn patterns. The mainlobes of the E_θ and E_ϕ patterns are very similar to those of the array pattern. Therefore, for long helices ($NS > \lambda$), a calculation of only the array factor is sufficient for an approximate pattern of any field component of the helix.

The measured patterns of a six-turn helix with $\alpha = 14^\circ$ as a function of frequency are presented in Fig. 3. Patterns are shown over a range of circumferences from approximately 0.66λ to 1.35λ . The solid patterns are for the horizontally polarized component (E_ϕ) and the dashed for the vertically polarized (E_θ). Both are adjusted to the same maximum. We observe that the endfire beam patterns are preserved over the range of $0.73 < C_\lambda < 1.22$, indicating that the axial-mode helix is a broadband antenna.

2.2.4. Important Parameters. Four important parameters for practical design of an axial-mode helical antenna are (1) beamwidth (BW), (2) gain or directivity, input impedance and axial ratio (AR). They are all functions of the number of turns, the turn spacing (or pitch angle), and the frequency. For a given number of turns, the behavior of the BW, gain, impedance and AR determines the useful *bandwidth*. The nominal center frequency of this bandwidth corresponds to a helix circumference of about 1λ .

2.2.4.1. Beamwidth. On the basis of a large number of measurements, King and Wong [7] give the following quasiempirical formula for the beamwidths:

$$\text{HPBW (half-power beamwidth)} = \frac{K_B}{C_\lambda \sqrt{NS_\lambda}} \text{ (degrees)} \quad (32)$$

where K_B varies from 61 to 70, for $\frac{3}{4} < C_\lambda < \frac{4}{3}$, $12^\circ < \alpha < 15^\circ$, and $8.6 < N < 10$. Note that as N increases, the beamwidth decreases. Figure 4a shows measured HPBW of a six-turn, 14° axial-mode helix as a function of the normalized circumference (C_λ). E_θ is shown dotted as before. We observe that HPBW changes slowly over the range of approximately $0.7 < C_\lambda < 1.25$.

2.2.4.2. Gain. The gain of the axial mode helix can be approximately obtained [8] by

$$G = K_G C_\lambda^2 N S_\lambda \quad (33)$$

where K_G is the gain factor, which depends on the design parameters. King and Wong [7] report that K_G varies from 4.2 to 7.7. Experiments show that the gain is peak when C is slightly larger than 1λ .

2.2.4.3. Axial Ratio. We have shown from the approximate analysis described in a previous section that the radiation field is circularly polarized in the mainbeam direction ($\theta = 0^\circ$), implying $AR = 1$. With a more accurate analysis, including the effect of relative phase velocity for increased directivity, Kraus [1] obtains the axial ratio along the helix axis as follows:

$$AR = \frac{2N + 1}{2N} (\theta = 0^\circ) \quad (34)$$

If N is large, the axial ratio approaches unity and the polarization is nearly circular. For example, for a six-turn helix, $AR = \frac{13}{12} = 1.08$ according to Eq. (34). This axial ratio is independent of frequency or circumference. In Fig. 4b, the measured values of the axial ratio for the six-turn, 14° axial-mode helix are plotted as a function of the circumference (C_λ). We observe that AR is nearly 1 over the range of about $0.73 < C_\lambda < 1.4$. The sense of circular polarization is determined by the sense of the helix windings.

2.2.4.4. Input Impedance. The input impedance of the axial-mode helical antenna is nearly purely resistive. The empirical formulas for the input resistance are given [1] by

$$R_{in} = 140C_\lambda \quad (35)$$

within 20% for the case of axial feed, and

$$R_{in} = \frac{150}{\sqrt{C_\lambda}} \quad (36)$$

within 10% for the case of peripheral feed. Both relations are valid when $0.8 \leq C_\lambda \leq 1.2$, $12^\circ \leq \alpha \leq 14^\circ$ and $N \geq 4$. With a suitable matching section, R_{in} can be made any desired value from 50 to 150 Ω . In the inset of Fig 4c, trends of input resistance R and reactance X are shown as a function of the relative frequency or circumference. Note that R is relatively constant and X is very small for $0.7 < C_\lambda < 1.5$. Figure 4c also shows the voltage standing-wave ratio (VSWR) measured on a 53 Ω coaxial line. We observe that the VSWR nearly remains constant (approximately 1), and equivalently the input impedance of the helix remains unchanged, over the range of about $0.7 < C_\lambda < 1.6$.

2.2.5. Broadband Characteristics. Considering all the characteristics of beam pattern, input impedance, and polarization as a function of circumference, we find that the

performance of the axial-mode helix is satisfactory over the range of about $0.75 < C_\lambda < 1.25$ within the restrictions given on α and N .

Thus the bandwidth, defined by the ratio of upper and lower frequencies, is almost an octave. The broadband characteristics of the helix can be explained by the natural adjustment of the phase velocity. As the helix size C_λ , or equivalently the frequency, varies over a rather wide range, the phase velocity adjusts itself automatically such that the fields from each turn add nearly in phase in the axial direction.

2.3. Variations and Applications of the Helical Antenna

A slight taper on the end of the helix [9,10] reduces the axial ratio at the expense of a slight reduction in gain. Axial ratio is improved both on and off axis. A taper is also used at the input to improve impedance characteristics. A circular cavity backing is sometimes used to reduce the backradiation and increase the forward gain. Dielectric-tube support has been used with the helix antenna. This lowers the frequency for the onset of axial-mode operation and has an effect on the terminal impedance. A solid dielectric core has also been used with the helix (the polyrod helix). A helix with an inner concentric metal core has been used as a TV transmitter [11]. The antenna utilizes higher-order Fourier modes such as $e^{\pm j2\phi}$, $e^{\pm j5\phi}$, which radiate sidefire rather than endfire. This is particularly useful with towers and masts whose circumference is much larger than a wavelength. An array of helices is stacked along the mast to produce the required beam pattern. The helical antenna has often been used as an element in various types of arrays. Large planar arrays of helices have been used in radio astronomy [12]. An array of axial-mode helices has been used for Global Positioning System (GPS) satellite transmitters [1]. Helices are also used as feeds for parabolic dishes. Applications of the helix are legion.

3. MULTIFILAR HELIX ANTENNAS

The helical antenna described in the preceding section may be termed the *monofilar helical antenna*. It is constructed from a single wire, or tape, and fed from a single source. In this section we consider the multifilar helix antenna, which consists of a number of wires or tapes, each of which may be fed from a separate source. The wires may be interleaved as shown in Fig. 5a for the quadrifilar helix. The excitations in all cases discussed is of the form $e^{\pm j\phi}$. Other excitations are certainly possible but have not been thoroughly studied. Many different forms of the multifilar helix have been used, including bifilar, quadrifilar, and octofilar helices. Two distinct classes of multifilar helices have been used: the broadband forward-fire axial mode multifilar helix and the narrowband backfire multifilar helix. For both, the quadrifilar helix has been widely studied and used.

We have already discussed the *Fourier* modes due to a loop of circumferential current. The rigorous consideration of the entire geometry of the helix yields modes with the same ϕ dependence but yields the phase progres-

Figure 5. Quadrifilar helical antenna: (a) endfire; (b) backfire.

sion in z as well. Samuel Sensiper [13] carried out this rigorous analysis to determine the real propagation constants of the normal and axial modes. He also determined some of the characteristics of the multifilar helix. Later, Paul Klock [14] found an additional mode with a complex propagation constant. This mode starts with backfire and then splits and scans forward as a conical beam as frequency increases. It operates simultaneously with the axial mode but is usually suppressed by the ground plane. Early experimenters of the multifilar helix showed some improvements over the monofilar helix but did not always recognize that greater bandwidth could be obtained nor how to obtain it, as explained in the following section.

3.1. The Axial-Mode Quadrifilar Helix

Gerst and Worden [15] first described the broadband axial-mode multifilar helix. They pointed out that the frequency range of the axial mode could be extended by (1) adding more wires, (2) using $e^{-j\phi}$ excitation to maintain that mode and suppress others, and (3) increasing the pitch angle α . The technique is readily understood by considering the bifilar helix. First, the two wires are fed 180° out of phase. Consider a cross section perpendicular to the helix axis. We find, in any cross section, two wires 180° apart in space and phase. Only the odd Fourier modes ($e^{jn\phi}$, n odd) are excited. The mode $e^{-j2\phi}$, which may be a culprit in the pattern breakup of the monofilar helix, is suppressed. The mode $e^{-j3\phi}$ is not suppressed, and the bandwidth for the axial mode approaches 3–1. A pitch angle of about 25° – 30° is required. Now consider the quadrifilar helix. A cross section through the right-hand helix

of Fig. 5a displays four wires symmetrically arranged around the periphery, with phases 0° , -90° , -180° , -270° . This $e^{-j\phi}$ excitation suppresses all the even modes, as in the bifilar helix, and mode $e^{-j3\phi}$ as well. Mode $e^{-j5\phi}$ is not suppressed. The bandwidth approaches 5–1. A pitch angle of about 40° is required. In general, with the M -filar helix, mode $e^{-j\phi}$ is excited around the periphery. All other modes up to $e^{-jM\phi}$ are suppressed. The bandwidth lies between M and $M+1$.

Gerst and Worden determined that the frequency range of the multifilar axial mode helix may be approximated as follows [15]:

$$C_{\lambda \min} < C_{\lambda} < C_{\lambda \max} \quad (37a)$$

$$C_{\lambda \min} = \frac{\cos \alpha}{1 + \sin \alpha} \quad (37b)$$

$C_{\lambda \max}$ is the lesser of $C_{\lambda \max 1}$ and $C_{\lambda \max 2}$:

$$C_{\lambda \max 1} = \frac{\cos \alpha}{1 - \sin \alpha} \quad (37c)$$

$$C_{\lambda \max 2} = \frac{M}{2} \cot \alpha \quad (37d)$$

where M is the number of wires. Equation (37) can be used to predict the bandwidth of the axial-mode unifilar or multifilar helix. For example, consider the monofilar helix with $\alpha = 14^\circ$, whose beam patterns and other characteristics are given in Figs. 3 and 4. The figures indicate that the bandwidth is approximately $0.75 < C_{\lambda} < 1.25$ as noted previously. In comparison, Eq. (37) predicts that $C_{\lambda \min} = 0.78$ and $C_{\lambda \max} = 1.25$ for an approximate bandwidth of $0.78 < C_{\lambda} < 1.28$. The two bandwidth ratios are very close. Equation (37) has been applied to bifilar, quadrifilar, and octofilar axial-beam helices, and the results agree well with experiment as shown in Refs. 15–17.

Figure 6 shows the beam patterns of a quadrifilar helix antenna with a ground plane (see Fig. 5a). Pitch angle α is 35° , diameter D is 3 in., antenna length is 24 in., ground-plane diameter D_G is 10 in., and tape width is $\frac{1}{2}$ in. The feed system [16] provides four outputs phased 0° , 90° , 180° , 270° , with each output connected to one of the four wires of the quadrifilar helix antenna. Equations (37b) and (37c) yield $C_{\lambda \min} = 0.52$ and $C_{\lambda \max} = 1.92$ for α is 35° and $M = 4$. Thus the bandwidth of the antenna is given by $0.52 < C_{\lambda} < 1.92$ for a bandwidth ratio of 3.7–1. The progression of the beam patterns may be described as follows. At a frequency somewhat below the lower limit, backfire operation begins, as evidenced by the strong backlobe at $C_{\lambda} = 0.44$. The backlobe decreases rapidly as we approach the lower limit. The axial ratio also decreases rapidly and is less than 2–1 at the lower limit. Other antenna characteristics such as VSWR are also acceptable [17]. The axial mode then predominates over the 3.5–1 bandwidth. The beam pattern narrows steadily, and the directivity increases with frequency. The upper limit occurs at $C_{\lambda} = 1.92$, at a frequency just above that of Fig. 6f. Above the upper limit, beamsplitting occurs at $C_{\lambda} = 2.10$, with a complete pattern breakup at $C_{\lambda} = 2.70$. Thus, with the multifilar

Figure 6. Beam patterns of the axial mode quadrifilar helix antenna: $C_\lambda = 0.44, 0.52, 0.72, 1.1, 1.6, 1.8, 2.1, 2.7$ in (a)–(h), respectively. (From Adams and Lumjiak [17], © 1971 IEEE. Reprinted with permission of IEEE.)

helix, the bandwidth of the axial mode is extended to both lower and higher frequencies as predicted in Eq. (37).

The beam pattern at $C_\lambda = 1.80$ exhibits the undesirable characteristic of high sidelobes. This is caused by the backfire operation, which changes from backfire through sidefire toward endfire as frequency increases. It is sometimes called a “scanning” mode. The quadrifilar helix may also be used in a counterwound version with both right- and left-hand windings. The on-axis polarization is linear rather than circular. The backfire mode is much more effectively suppressed in this version, and the sidelobe levels are much lower. Bandwidths are between 4–1 and 5–1 as shown in Eq. (16). Gerst and Worden [15] describe a 53° pitch angle counterwound octofilar helix with 9–1 bandwidth. The multifilar helix antenna does not radiate in a normal mode at low frequencies because of the phase excitation $0^\circ, 90^\circ, 180^\circ, 270^\circ$ of the windings. The excitation $e^{-j\phi}$ is a supergain excitation at low frequencies ($C_\lambda \ll 1$). Details on the axial multifilar antenna are given in Refs. 15–17 and related references.

3.2. The Backfire Quadrifilar Helix

In the analysis of the circular loops, we noted that, with $e^{\pm j\phi}$, circularly polarized radiation occurs at both $\theta = 0^\circ$ and $\theta = 180^\circ$. To distinguish between these two directions, we need additional information about the helix. A rigorous analysis of the infinite monofilar helix by Paul Klock [14] shows that there are two modes operating simultaneously in the axial-mode region. Both involve $e^{-j\phi}$ excitation for right-hand helices and are circularly polarized on axis. One is the axial mode, and the other is a *backfire* mode, which starts at backfire and scans forward as a conical beam as frequency increases. We may, for purposes of discussion, combine the backfire and forward-scanned operations into a single backfire designation. In the mono- and quadrifilar helices the backfire mode shows up just before the onset of the axial mode. The backfire mode exists along with the axial mode, but is suppressed by the presence of the ground plane. The backfire mode is *favored* over the forward endfire as pitch angle increases. Pitch angles in the $40\text{--}50^\circ$ range with no ground plane show both forward and backward radiation. With no ground plane, the radiation is primarily backfire. For the right-hand helices of Figs. 1 and 5, the endfire radiation is right-handed circularly polarized and the backfire radiation is left-handed circularly polarized.

The backfire bifilar helix was first studied by Patton [18], who carried out extensive theoretical and experimental work. He showed the range of backfire beam patterns obtained with the monofilar and bifilar helices. Later, Charles Kilgus [19] showed that beam pattern improvements could be obtained with the quadrifilar helix. He investigated in detail the shaped conical and cardioid patterns that are obtainable with the backfire quadrifilar helix.

Figure 5b shows the backfire quadrifilar helix. It consists of two bifilar antennas fed 90° out of phase to produce the $e^{-j\phi}$ excitation. No ground plane is required, and the ends of the helices may be shorted (short-circuited) together. The backfire helix is used with pitch angles as high as 60° and 70° . With these high pitch angles, the backfire mode can operate at low frequencies, yielding a small cross section for the antenna.

A typically shaped conical beam is shown in Fig. 7. The beam is very wide for broad sector coverage with a dip or a local maximum (not shown) at the center ($\theta = 180^\circ$). The dip is appropriate for satellite coverage because it can be chosen to yield uniform signal strength at the receiver as the satellite passes. Kilgus [19] shows numerous beam patterns for different designs. The beamwidths vary from 100° to 180° . Directivities of up to 7 dB are observed.

The backfire quadrifilar helix has characteristics that make it especially suitable for many satellite, spacecraft, and navigational applications. It has been used as a transmitter and receiver in satellite communication systems and as a receiver for GPS applications [20]. It has also been considered for cellular phones and new GPS applications [21].

3.3. Smart Antennas

The quadrifilar helix antenna can be used as a “smart” or adaptive antenna. Complex weights are added to its four separate channels. The weights are then adjusted to im-

Figure 7. Beam pattern of the backfire quadrifilar helix.

prove selected antenna characteristics [22,23]. The effects of shadowing and multipath, for example, may in some cases be mitigated.

4. HUMAN PROXIMITY EFFECTS

The presence of a human body in close proximity to an antenna may, of course, have significant effects. The human body may absorb radiation. The antenna characteristics may be modified. In particular, handheld antennas with the head and hand very close to the antenna may require a very careful analysis of the situation.

The normal-mode helix antenna has been used for cellular telephone handsets. The antenna is usually electrically small and is *linearly* polarized or nearly so. The head can pick up some radiation but significantly degrades the reception [24]. The axial-mode helix antenna has been proposed for personal satellite communication. This antenna is *circularly* polarized. The head can pick up some radiation and significantly degrades the reception [25].

5. SUMMARY

The helical antenna, first discovered in 1946 by John Kraus, has evolved into many different forms with many different applications. The normal-mode helix has some advantages for low-frequency applications. The broadband, circularly polarized, axial-mode helix radiates forward endfire along its axis. It has been the most widely used of all forms of the helix. The quadrifilar axial-mode helix extends the bandwidth further and can be used as a smart antenna. The backfire quadrifilar helix radiates a broad sector coverage suitable for satellite applications. The presence of a human body in close proximity to handheld antennas may have significant effects on reception.

1. INTRODUCTION

The Helmholtz equation¹ is one of the most fundamental equations of mathematical physics widely used in many areas [4,5,16,17], including classical mechanics (waves and vibrations), thermodynamics [28] (diffusion and heat transport), quantum mechanics [24] (for special forms of potential and scattering theory), and finally electricity and magnetism—especially electromagnetic waves—in problems such as radiation, scattering, and guided and unguided waves as well as oscillations in cavities and resonators. The electromagnetic Helmholtz equation is derived from the Maxwell equations under either static or time-harmonic conditions. It allows one to determine how the geometry of a given physical structure interacts with a time-harmonic (or static) electromagnetic field. The solution of the Helmholtz equation provides information such as the resonant frequencies of an electromagnetic cavity, wavelength of waves guided along transmission lines or waveguides, attenuation of an electromagnetic wave due to finite conductivity of a metal or lossy medium, spatial distribution of fields inside electromagnetic structures, radiation loss in open circuits, and field configuration produced by antennas of different shapes or scattered by objects made of various media. This information is essential for design of RF and microwave circuits and systems. The Helmholtz equation has the form of a partial-differential equation involving spatial derivatives, and its solution is influenced by the shape of the structure under investigation (boundary conditions), media properties, and parameters such as frequency. Depending on the problem, the Helmholtz equation is defined in one, two, or three spatial dimensions.

2. SCALAR AND VECTOR HELMHOLTZ EQUATIONS

The Helmholtz equation results from the separation of space and time variables in partial-differential equations such as wave and diffusion equations. In general, it involves vector fields (or functions) and has the following form

$$\nabla^2 \mathbf{M}(\mathbf{r}) + k^2 \mathbf{M}(\mathbf{r}) = 0 \quad (1)$$

¹Hermann Ludwig Ferdinand Helmholtz [born Aug. 31, 1821, Potsdam, Prussia (Germany); died Sept. 8, 1894, Charlottenburg, Berlin, Germany]; German scientist and philosopher who first expressed the relationship between mechanics, heat, light, electricity, and magnetism in the form of the law of conservation of energy [9].

where \mathbf{M} and \mathbf{r} can be vectors² in any multidimensional space and ∇^2 is the vector Laplacian [2,16]. Examples of the physical quantity represented by \mathbf{M} include electric field, magnetic field, or vector potentials. Whenever possible, the problem is reduced to the scalar form

$$\nabla^2 \Phi(\mathbf{r}) + k^2 \Phi(\mathbf{r}) = 0 \quad (2)$$

which is more amenable for analytical and numerical treatment. Here ∇^2 is the scalar Laplacian operator, and the examples of a physical quantity involved are the electric potential, temperature, or acoustic pressure or a wavefunction (in quantum mechanics). The formula for evaluating the scalar Laplacian depends on coordinate system; for instance, in Cartesian coordinates it reads

$$\nabla^2 f(x, y, z) \equiv \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2} \quad (3)$$

and in spherical coordinates, an analogous formula takes the following form:

$$\begin{aligned} \nabla^2 g(r, \Theta, \phi) \equiv & \frac{\partial^2 g}{\partial r^2} + \frac{2}{r} \frac{\partial g}{\partial r} + \frac{1}{r^2 \sin^2 \phi} \frac{\partial^2 g}{\partial \Theta^2} \\ & + \frac{\cos \phi}{r^2 \sin \phi} \frac{\partial g}{\partial \phi} + \frac{1}{r^2} \frac{\partial^2 g}{\partial \phi^2} \end{aligned} \quad (4)$$

Homogeneous equations (1) and (2) with the right-hand side equal to zero describe the physics of processes that take place when no external excitation is present, such as unforced vibrations.³ If some external force drives the system, this is represented by a source term that appears at the right-hand side of the equation—this is characteristic of nonhomogeneous equations. The nonhomogeneous vector and scalar Helmholtz equation are hence given by

$$\nabla^2 \mathbf{M}(\mathbf{r}) + k^2 \mathbf{M}(\mathbf{r}) = \mathbf{J}(\mathbf{r}) \quad (5)$$

$$\nabla^2 \Phi(\mathbf{r}) + k^2 \Phi(\mathbf{r}) = \rho(\mathbf{r}) \quad (6)$$

These forms of the equation are very general and can represent many physical problems, for instance

- $k = 0$ static problems
- $k^2 > 0$ wave motion and oscillations
- $k^2 < 0$ diffusion and heat transport

In general, the solution to the Helmholtz equation depends on the boundary condition and the value of parameter k . It has to be noted that the solution to the homogeneous or nonhomogeneous equation may not exist for all values of parameter k . In general, the nonhomogeneous equation cannot be solved for values of parameter k

²In this article vector quantities are denoted by bold face.

³An example of unforced vibration is a string that is deflected and then left free to oscillate. The vibrations of the string are not due to a driving force which sustains them but to the initial state of the system.

for which the homogeneous equation is soluble. The Helmholtz equation may be expressed in different coordinate systems, and one usually selects the system that leads to the separation of variables. Separation is particularly important for the analytical treatment of partial-differential equations. The scalar Helmholtz equation is separable in all basic orthogonal coordinate systems [16]. For the vector equation there are fewer coordinate systems where the separation is possible [17].

2.1. Helmholtz Equation from the Wave Motion Perspective

To see the relevance of the Helmholtz equation in investigating wave motion, it is instructive to consider the result of the separation of variables in a one-dimensional wave equation

$$\frac{\partial^2 u}{\partial x^2} - \frac{1}{v^2} \frac{\partial^2 u}{\partial t^2} = 0 \tag{7}$$

where $v^2 > 0$ is the wave velocity squared, t is time, and x is the space variable.

Assuming that $u(x, t)$ can be expressed as $u(x, t) = S(x)T(t)$, we get

$$\frac{d^2 S}{dx^2} - \lambda^2 S(x) = 0 \tag{8}$$

and

$$\frac{d^2 T}{dt^2} - \lambda^2 v^2 T(t) = 0 \tag{9}$$

where λ^2 is the separation constant. In both equations one readily recognizes the form of Eq. (2), namely, of the scalar Helmholtz equation in one dimension. General solutions to these equations for a given $\lambda^2 > 0$ are

$$S(x) = A \cos(\lambda x + \varphi_S) \tag{10}$$

and

$$T(t) = B \cos(\lambda vt + \varphi_T) \tag{11}$$

where A, B and φ_S, φ_T are arbitrary constants.⁴ Function $u(x, t)$ is a product of $S(x)$ and $T(t)$, so, in general, one has to consider products for all λ . In other words, $u(x, t)$ has the form

$$\begin{aligned} u(x, t) &= \int d\lambda AB \cos(\lambda x + \varphi_S) \cos(\lambda vt + \varphi_T) \\ &= \int d\lambda \frac{AB}{2} [\cos(\lambda(x - vt) + \varphi_S - \varphi_T) \\ &\quad + \cos(\lambda(x + vt) + \varphi_S + \varphi_T)] \\ &= E(x - vt) + F(x + vt) \end{aligned} \tag{12}$$

Each term represents a wave, one traveling in the positive and the other in the negative x direction (Fig. 1). This

⁴ $A = A(\lambda), B = B(\lambda), \varphi_S = \varphi_S(\lambda), \varphi_T = \varphi_T(\lambda)$.

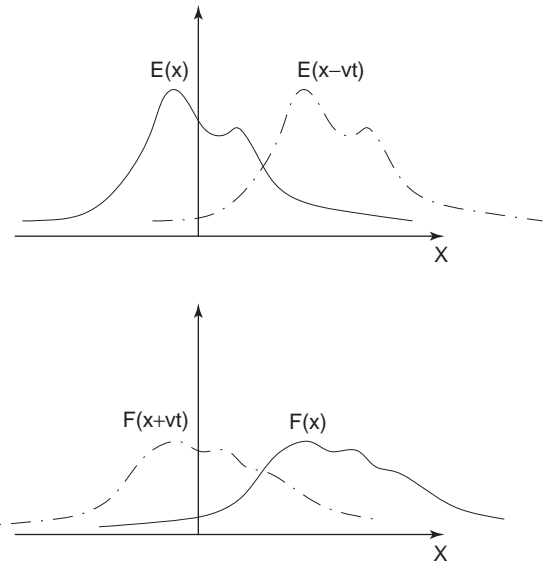

Figure 1. Two waves traveling in opposite directions.

observation is true for higher dimensions and other coordinate systems.

3. HELMHOLTZ EQUATION IN ELECTROMAGNETICS

3.1. Static Problems

Static problems come into play when $k = 0$. In this case the Helmholtz equation transforms into the Laplace or Poisson equation and function $\Phi(\mathbf{r})$ has usually a physical interpretation of the electrostatic or magnetostatic potential. For instance, in electrostatics we have $\nabla \times \mathbf{E}(\mathbf{r}) = 0$ so $\mathbf{E} = -\nabla\phi(\mathbf{r})$. Substituting this relationship into the Gauss law in a homogeneous medium, we get the Poisson equation for the electric charge density $\rho(\mathbf{r})$

$$\nabla^2 \phi(\mathbf{r}) = -\frac{\rho(\mathbf{r})}{\epsilon} \tag{13}$$

which, for $\rho(\mathbf{r}) = 0$, becomes the Laplace equation

$$\nabla^2 \phi(\mathbf{r}) = 0 \tag{14}$$

It is seen that both equations are a particular case ($k = 0$) of the scalar Helmholtz equation.

For $k^2 > 0$ the Helmholtz equation describes wave motion, and hence it is instrumental in investigating radiation and scattering problems, guided and unguided electromagnetic waves, as well as oscillations in cavities.

3.2. One-Dimensional Helmholtz Equation: Transmission Line

One of the most elemental problems whose mathematical model is given by the one-dimensional scalar Helmholtz equation is a transmission line. In the frequency domain, the voltage distribution in an infinitely long transmission line is given by the telegraphist's equation

Figure 2. Lumped-element model of a small segment of a transmission line.

[10,20], which reads

$$\frac{\partial^2 U(x)}{\partial x^2} + (\omega^2 LC - j\omega(RC + GL) - RG)U(x) = 0 \tag{15}$$

where ω is the angular frequency, $j = \sqrt{-1}$ is the imaginary unit, and L, R, C, G denote, respectively, the per unit length series inductance, series resistance, shunt capacitance, and the shunt conductance (Fig. 2).

If one denotes $k^2 = \omega^2 LC - j\omega(RC + GL) - RG$, the telegraphist's equation assumes the form of (2), specifically, of the homogeneous Helmholtz equation. For a lossy line k is complex $k = \alpha + j\beta$. The general solution is

$$U(x) = U_0^+ e^{-\alpha x} e^{-j\beta x} + U_0^- e^{\alpha x} e^{j\beta x} \tag{16}$$

In the term $U_0^+ e^{-\alpha x} e^{-j\beta x}$ we recognize a voltage wave traveling in the positive x direction, whereas $U_0^- e^{\alpha x} e^{j\beta x}$ corresponds to a voltage wave going in the opposite sense.

3.3. Electromagnetic Waves: Auxiliary Potentials

Using time-harmonic Maxwell's equations for the isotropic homogeneous media with the source in the form of electric and magnetic currents and charges [2,12]

$$\begin{cases} \nabla \times \mathbf{E}(\mathbf{r}) = -j\omega \mathbf{B}(\mathbf{r}) - \mathbf{J}_m(\mathbf{r}) \\ \nabla \times \mathbf{H}(\mathbf{r}) = j\omega \mathbf{D}(\mathbf{r}) + \mathbf{J}_e(\mathbf{r}) \\ \nabla \cdot \mathbf{D}(\mathbf{r}) = \rho_e(\mathbf{r}) \\ \nabla \cdot \mathbf{B}(\mathbf{r}) = \rho_m(\mathbf{r}) \end{cases} \tag{17}$$

and eliminating the magnetic field $\mathbf{H}(\mathbf{r})$ vector we get a wave equation for the electric field $\mathbf{E}(\mathbf{r})$

$$\nabla^2 \mathbf{E}(\mathbf{r}) + k^2 \mathbf{E}(\mathbf{r}) = j\omega \mu \mathbf{J}_e(\mathbf{r}) + \nabla \times \mathbf{J}_m(\mathbf{r}) + \frac{\nabla \rho_e(\mathbf{r})}{\epsilon} \tag{18}$$

In a similar vein, elimination of the electric field yields

$$\begin{aligned} \nabla^2 \mathbf{H}(\mathbf{r}) + k^2 \mathbf{H}(\mathbf{r}) \\ = j\omega \epsilon \mathbf{J}_m(\mathbf{r}) - \nabla \times \mathbf{J}_e(\mathbf{r}) + \frac{\nabla \rho_m(\mathbf{r})}{\mu} \end{aligned} \tag{19}$$

Equations (18) and (19) both can be regarded as a nonhomogeneous vector Helmholtz equation with $k^2 = \mu \epsilon \omega^2$. In these equations $\nabla \times$ is the curl, $\nabla \cdot$ is the divergence, ∇^2 is the vector Laplacian, $\mathbf{D}(\mathbf{r})$ is the electric flux density, $\mathbf{B}(\mathbf{r})$ is the magnetic flux density, $\rho_e(\mathbf{r})$ and $\rho_m(\mathbf{r})$ are the electric and magnetic charge density, $\mathbf{J}_e(\mathbf{r})$ and $\mathbf{J}_m(\mathbf{r})$ are the electric and magnetic current density, while ϵ and μ stand for the permittivity and permeability of the medium, respectively. It is seen that the right-hand side of these nonhomogeneous Helmholtz equations involves all types of sources. When only electric sources are present, the result is

$$\nabla^2 \mathbf{E}(\mathbf{r}) + \mu \epsilon \omega^2 \mathbf{E}(\mathbf{r}) = j\omega \mu \mathbf{J}_e(\mathbf{r}) + \frac{\nabla \rho_e(\mathbf{r})}{\epsilon} \tag{20}$$

$$\nabla^2 \mathbf{H}(\mathbf{r}) + \mu \epsilon \omega^2 \mathbf{H}(\mathbf{r}) = -\nabla \times \mathbf{J}_e(\mathbf{r}) \tag{21}$$

3.3.1. Vector and Scalar Potentials. Because electric and magnetic fields are, in general, generated by sources consisting of electric and magnetic currents as well as electric and magnetic charges, it is often convenient to operate with auxiliary functions that are related to one type of source. This simplifies the right-hand side of the resulting nonhomogeneous Helmholtz equations. One popular choice [1,14,29] is the generalized electrostatic potential $\varphi_e(\mathbf{r})$ and the vector magnetic potential $\mathbf{A}(\mathbf{r})$. Potential $\mathbf{A}(\mathbf{r})$ is defined as

$$\mathbf{B}(\mathbf{r}) = \nabla \times \mathbf{A}(\mathbf{r}) \tag{22}$$

With these definitions, one gets from Maxwell's equations

$$\nabla \times (\mathbf{E}(\mathbf{r}) + j\omega \mathbf{A}(\mathbf{r})) = 0 \tag{23}$$

This implies

$$\mathbf{E}(\mathbf{r}) = -j\omega \mathbf{A}(\mathbf{r}) - \nabla \varphi_e(\mathbf{r}) \tag{24}$$

where $\varphi_e(\mathbf{r})$ is an arbitrary function.

Imposing the Lorentz gauge

$$\nabla \cdot \mathbf{A}(\mathbf{r}) = -j\omega \varphi_e(\mathbf{r}) \tag{25}$$

we get the following relationships, which have to be satisfied by potentials $\varphi_e(\mathbf{r})$ and $\mathbf{A}(\mathbf{r})$:

$$\nabla^2 \mathbf{A}(\mathbf{r}) + k^2 \mathbf{A}(\mathbf{r}) = -\mu \mathbf{J}_e(\mathbf{r}) \tag{26}$$

$$\nabla^2 \varphi_e(\mathbf{r}) + k^2 \varphi_e(\mathbf{r}) = -\frac{\rho_e(\mathbf{r})}{\epsilon} \tag{27}$$

From these equations it is seen that the electric scalar potential is due to electric charges, whereas the vector magnetic potential is generated by electric currents. In a similar manner one can introduce the magnetic scalar potential $\varphi_m(\mathbf{r})$ and the electric vector potential $\mathbf{F}(\mathbf{r})$, which are due to magnetic charges and currents. Electric vector potential $\mathbf{F}(\mathbf{r})$ is defined as

$$\mathbf{E}(\mathbf{r}) = -\nabla \times \mathbf{F}(\mathbf{r}) \quad (28)$$

which implies that

$$\mathbf{H}(\mathbf{r}) = -j\omega\mathbf{F}(\mathbf{r}) - \nabla\varphi_m(\mathbf{r}) \quad (29)$$

The Lorentz gauge is

$$\nabla \cdot \mathbf{F}(\mathbf{r}) = -j\omega\varphi_m(\mathbf{r}) \quad (30)$$

Considering Faraday's and Gauss' laws with magnetic currents $\mathbf{J}_m(\mathbf{r})$ and charges $\rho_m(\mathbf{r})$, one gets two nonhomogeneous Helmholtz equations that are satisfied by magnetic scalar potential $\varphi_m(\mathbf{r})$ and electric vector potential $\mathbf{F}(\mathbf{r})$ [12]:

$$\nabla^2\mathbf{F}(\mathbf{r}) + k^2\mathbf{F}(\mathbf{r}) = -\mathbf{J}_m(\mathbf{r}) \quad (31)$$

$$\nabla^2\varphi_m(\mathbf{r}) + k^2\varphi_m(\mathbf{r}) = -\frac{\rho_m(\mathbf{r})}{\mu} \quad (32)$$

To sum up, by introducing the auxiliary vector and scalar potential, one gets the Helmholtz equations in a canonical form with each potential associated with one type of the source. Once the potentials have been found the electric and magnetic field can be obtained from [2,12]

$$\mathbf{B}(\mathbf{r}) = \nabla \times \mathbf{A}(\mathbf{r}) - j\omega\mu\mathbf{E}(\mathbf{r}) + \frac{1}{j\omega} \nabla\nabla \cdot \mathbf{F}(\mathbf{r}) \quad (33)$$

$$\mathbf{E}(\mathbf{r}) = -j\omega\mathbf{A}(\mathbf{r}) + \frac{1}{j\omega\mu\epsilon} \nabla\nabla \cdot \mathbf{A}(\mathbf{r}) - \nabla \times \mathbf{F}(\mathbf{r}) \quad (34)$$

3.3.2. Hertz Potentials. There are also other ways to define potential. For instance, one may define the electric potential as [8]

$$\mathbf{H}(\mathbf{r}) = j\omega\epsilon\nabla \times \mathbf{\Pi}_E(\mathbf{r}) \quad (35)$$

For time-harmonic fields there is no significant mathematical difference between this potential and the vector potential introduced previously. However, this choice is popular for investigating, for instance, guided waves, so before proceeding we assume there are no sources in the region of interest. Under this assumption we get from Faraday's law

$$\nabla \times \mathbf{E}(\mathbf{r}) = \mu\epsilon\omega^2\nabla \times \mathbf{\Pi}_E(\mathbf{r}) \quad (36)$$

and hence

$$\mathbf{E}(\mathbf{r}) = \mu\epsilon\omega^2\mathbf{\Pi}_E(\mathbf{r}) + \nabla\psi(\mathbf{r}) \quad (37)$$

where $\psi(\mathbf{r})$ is an arbitrary function.

Assuming

$$\nabla \cdot \mathbf{\Pi}_E(\mathbf{r}) = \psi(\mathbf{r}) \quad (38)$$

and substituting into the Maxwell's equation (Ampère's law), we have

$$\nabla^2\mathbf{\Pi}_E(\mathbf{r}) + \mu\epsilon\omega^2\mathbf{\Pi}_E(\mathbf{r}) = 0 \quad (39)$$

Note that this expression has the form of the homogeneous vector Helmholtz equation. Substituting (38) into (37), one gets the expression for electric field involving only $\mathbf{\Pi}_E(\mathbf{r})$:

$$\begin{aligned} \mathbf{E}(\mathbf{r}) &= \mu\epsilon\omega^2\mathbf{\Pi}_E(\mathbf{r}) + \nabla\nabla \cdot \mathbf{\Pi}_E(\mathbf{r}) \\ &= \nabla \times \nabla \times \mathbf{\Pi}_E(\mathbf{r}) \end{aligned} \quad (40)$$

The magnetic vector potential can be introduced in a similar manner by assuming that

$$\mathbf{E}(\mathbf{r}) = -j\omega\mu\nabla \times \mathbf{\Pi}_H(\mathbf{r}) \quad (41)$$

The potential thus introduced has to fulfill the vector Helmholtz equation

$$\nabla^2\mathbf{\Pi}_H(\mathbf{r}) + \mu\epsilon\omega^2\mathbf{\Pi}_H(\mathbf{r}) = 0 \quad (42)$$

and the magnetic field can be retrieved from

$$\begin{aligned} \mathbf{H}(\mathbf{r}) &= \mu\epsilon\omega^2\mathbf{\Pi}_H(\mathbf{r}) + \nabla\nabla \cdot \mathbf{\Pi}_H(\mathbf{r}) \\ &= \nabla \times \nabla \times \mathbf{\Pi}_H(\mathbf{r}) \end{aligned} \quad (43)$$

3.4. Homogeneous Helmholtz Equation in Electromagnetic Problems

Two of the most important categories of electromagnetic problems involving homogeneous Helmholtz equation are electromagnetic cavities (resonators) and waveguides. For simple cases (structures filled with homogeneous or layered isotropic media), the most elegant approach to the solution, which yields modal field patterns, involves vector potentials. This is because the complete vector field can be found from a single component of vector potential. To illustrate this solution technique, we shall briefly discuss the mathematics related to guided waves based on Hertz potentials.

3.4.1. Cylindrical Waveguides. The problem is expressed by a 2D homogeneous Helmholtz equation. Assume that the wave propagates in the z direction inside a homogeneous and uniform cylinder of arbitrary but homogeneous cross section [8,10]. This type of a hollow-pipe problem can often be solved analytically in a 2D cur-

Figure 3. Cross section S of a cylindrical waveguide with the curvilinear system coordinates u_1, u_2 .

vilinear system. It is convenient to choose the coordinate system in such a manner that the waveguide boundary L (Fig. 3) coincides with the constant value surfaces of the system.

We shall consider the Helmholtz equation for electric and magnetic Hertz potential. Because of the uniformity of the structure along the z direction, the potentials have only one component, which, for a perfectly conducting cylinder, has to fulfill either the homogeneous Dirichlet or Neumann boundary conditions on the boundary L . The procedure is identical for electric and magnetic potentials, so we can omit the subscript H or E . When the Hertz potential has only the z component [i.e., $\mathbf{\Pi}(\mathbf{r}) = \Pi(\mathbf{r})\mathbf{a}_z$, where \mathbf{a}_z denotes the unit length vector in the z direction], then the vector Helmholtz equation reduces to the scalar one:

$$\nabla^2 \Pi(\mathbf{r}) + \mu\epsilon\omega^2 \Pi(\mathbf{r}) = 0 \tag{44}$$

Decomposing operator ∇^2 into two terms, ∇_z^2 along the z direction and ∇_t^2 acting on u_1 and u_2 , assuming that $\mathbf{\Pi}(\mathbf{r}) = f(u_1, u_2)g(z)$, and applying the separation of variables technique, one gets

$$\frac{\partial^2 g(z)}{\partial z^2} - \gamma^2 g(z) = 0 \tag{45}$$

and

$$\nabla_t^2 f(u_1, u_2) + \beta^2 f(u_1, u_2) = 0 \tag{46}$$

where $\beta^2 = \gamma^2 + \mu\epsilon\omega^2$, from which it follows that

$$g(z) = G_+ e^{\gamma z} + G_- e^{-\gamma z} \tag{47}$$

where subscript $+/-$ refers to waves propagating in opposite senses. Function $f(u_1, u_2)$ depends on the boundary condition imposed on L . For a complete solution, one has to consider two cases: one with the Dirichlet boundary condition and the other with the Neumann boundary condition. For perfectly conducting cylinders the Dirichlet condition has to be imposed on the electric vector Hertz potential. This leads to the TM modes. The TE modes are obtained by considering the Helmholtz equation for mag-

netic Hertz potential $\mathbf{\Pi}_H(\mathbf{r}) = \Pi_H(\mathbf{r})\mathbf{a}_z$, with the boundary condition $(\partial \mathbf{\Pi}_H(\mathbf{r})/\partial \mathbf{n}) = 0$ on L .

To explain the solution procedure based on the Hertz potential in more detail, it suffices to consider a simple geometry with a rectangular cross section. In this case one assumes the rectangular coordinate system $(u_1, u_2) \rightarrow (x, y)$. If the width and the height of the waveguide are denoted by a and b , respectively, then (using the separation of variables technique for the scalar Helmholtz equation), we get

$$f_{nm}(x, y) = A \cos \frac{\pi n x}{a} \cos \frac{\pi m y}{b} \tag{48}$$

for the Neumann boundary conditions, whereas for the Dirichlet boundary conditions we obtain

$$f_{nm}(x, y) = A \sin \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \tag{49}$$

where

$$\beta_{nm}^2 = \left(\frac{\pi n}{a}\right)^2 + \left(\frac{\pi m}{b}\right)^2 \tag{50}$$

To get the TE modes, we set

$$\mathbf{\Pi}_{H, nm}(\mathbf{r}) = B_{\pm} e^{\pm \gamma_{nm} z} \cos \frac{\pi n x}{a} \cos \frac{\pi m y}{b} \mathbf{a}_z \tag{51}$$

where $\gamma_{nm}^2 = (\pi n/a)^2 + (\pi m/b)^2 - \mu\epsilon\omega^2$. The electric and magnetic fields are then obtained directly from (35) and (40):

$$\begin{aligned} \mathbf{E}_{nm}(\mathbf{r}) = & E_0 \frac{\pi m}{b} e^{\pm \gamma_{nm} z} \cos \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \mathbf{a}_x \\ & - E_0 \frac{\pi n}{a} e^{\pm \gamma_{nm} z} \sin \frac{\pi n x}{a} \cos \frac{\pi m y}{b} \mathbf{a}_y \end{aligned} \tag{52}$$

$$\begin{aligned} \mathbf{H}_{nm}(\mathbf{r}) = & \pm E_0 \frac{\pi n}{a} \frac{j \gamma_{nm}}{\mu \omega} e^{\pm \gamma_{nm} z} \sin \frac{\pi n x}{a} \cos \frac{\pi m y}{b} \mathbf{a}_x \\ & \pm E_0 \frac{j \gamma_{nm}}{\mu \omega} \frac{\pi m}{b} e^{\pm \gamma_{nm} z} \cos \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \mathbf{a}_y \\ & - E_0 \frac{j \beta_{nm}^2}{\mu \omega} e^{\pm \gamma_{nm} z} \cos \frac{\pi n x}{a} \cos \frac{\pi m y}{b} \mathbf{a}_z \end{aligned} \tag{53}$$

Likewise, setting

$$\mathbf{\Pi}_{E, nm}(\mathbf{r}) = B_{\pm} e^{\pm \gamma_{nm} z} \sin \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \mathbf{a}_z \tag{54}$$

and applying relationships (41) and (43), one immediately gets the fields for the TM modes:

$$\begin{aligned} \mathbf{H}_{nm}(\mathbf{r}) = & H_0 \frac{\pi m}{b} e^{\pm\gamma_{nm}z} \sin \frac{\pi n x}{a} \cos \frac{\pi m y}{b} \mathbf{a}_x \\ & - H_0 \frac{\pi n}{a} e^{\pm\gamma_{nm}z} \cos \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \mathbf{a}_y \end{aligned} \quad (55)$$

$$\begin{aligned} \mathbf{E}_{nm}(\mathbf{r}) = & \pm H_0 \frac{\pi n}{a} \frac{j\gamma_{nm}}{\varepsilon\omega} e^{\pm\gamma_{nm}z} \cos \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \mathbf{a}_x \\ & \pm H_0 \frac{j\gamma_{nm}}{\varepsilon\omega} \frac{\pi m}{b} e^{\pm\gamma_{nm}z} \sin \frac{\pi n x}{a} \cos \frac{\pi m y}{b} \mathbf{a}_y \\ & - H_0 \frac{j\beta_{nm}^2}{\varepsilon\omega} e^{\pm\gamma_{nm}z} \sin \frac{\pi n x}{a} \sin \frac{\pi m y}{b} \mathbf{a}_z \end{aligned} \quad (56)$$

For other cross-sections the procedure is analogous. There are other wave guidance problems where the Hertz potentials are instrumental. They include parallel plate or rectangular waveguides loaded with transversely inhomogeneous media including stratified isotropic (Figs. 4a,b) [8,18] or gyrotropic (Fig. 4c) media [18]. For these problems the solution can be obtained by considering the Hertz magnetic or electric potential with a single component that is parallel to the inhomogeneity direction (e.g., normal to the strata). For isotropic media or media with diagonal anisotropy, this leads to the classical Sturm–Liouville equation [16] (in general, a different equation is obtained for magnetic and electric potential) with the Hertz potential as its eigenfunctions. The Sturm–Liouville equation can be regarded as a generalized version of one dimensional Helmholtz equations with variable coefficients. From the two sets of eigenfunctions two families of modes (LSE—the longitudinal section electric modes and LSM—the longitudinal section magnetic modes [8]) are derived from the relationships (41) and (43). Hertz potentials can also be defined for the gyrotropic media. Such generalized Hertz potentials can be used to derive a vector analog of the Sturm–Liouville equation for, for example, a stratified gyromagnetic parallel plate waveguide magnetized perpendicularly to the strata (Fig. 4c) [18].

More complex waveguide geometries, such as cylindrical waveguides loaded with inhomogeneous media (other than the categories described above), in general do not support the TE, TM or LSE, LSM modes. For these problems one has to deal with a much more complex two-dimensional partial-differential equation with coefficients depending on the transverse space coordinates [18]. These equations may be regarded as a generalization of a two-dimensional vector Helmholtz equation.

3.4.2. Cavities (Resonators). Most microwave resonators used in practice are in the form of either empty cavities or cavities loaded with isotropic media. For the latter case the relationships for finding natural fields (modes) and resonance frequencies are obtained by taking the curl of one of the equations Maxwell equations and using the other to eliminate either the electric or magnetic field.

Figure 4. Examples of the stratified waveguiding structures that can be conveniently analyzed using the Hertz potential.

This yields

$$\nabla \times \frac{1}{\mu(\mathbf{r})} \nabla \times \mathbf{E}(\mathbf{r}) - \omega^2 \varepsilon(\mathbf{r}) \mathbf{E}(\mathbf{r}) = 0 \quad (57)$$

and

$$\nabla \times \frac{1}{\varepsilon(\mathbf{r})} \nabla \times \mathbf{H}(\mathbf{r}) - \omega^2 \mu(\mathbf{r}) \mathbf{H}(\mathbf{r}) = 0 \quad (58)$$

In the simplest case of cavities filled with a homogeneous medium and no sources inside the cavity volume, one may use the vector identity $\nabla \times \nabla \times \mathbf{M} = \nabla \nabla \cdot \mathbf{M} - \nabla^2 \mathbf{M}$ and the Gauss law to transform the relations given above to the Helmholtz equations.

$$\nabla^2 \mathbf{E}(\mathbf{r}) + k^2 \mathbf{E}(\mathbf{r}) = 0 \quad (59)$$

$$\nabla^2 \mathbf{H}(\mathbf{r}) + k^2 \mathbf{H}(\mathbf{r}) = 0 \quad (60)$$

These equations can be solved by techniques similar to those used for cylindrical waveguides. The simplest formulation is to use vector potentials instead of fields \mathbf{E} and \mathbf{H} . For homogeneously filled structures the complete field can be derived for a single component of the potential. Since only one component is involved, the technique

involving potentials effectively converts a vector problem to a scalar one. If the volume considered is bounded by a perfectly conducting simply connected boundary, then two scalar Helmholtz equations have to be solved—one for the Neumann condition and the other for homogeneous Dirichlet conditions. One family of solutions gives the TE modes, while the other results in the TM modes.

The scalar Helmholtz equation is also used to find a complete set of vector wavefunctions that are required to represent the field in the cavity with sources. The field in such a cavity consists of two parts [6,12,17]. The first part is irrotational (lamellar), which means that the curl vanishes and the divergence is nonzero; the other part is rotational (solenoidal), and for this part the curl is nonzero and the divergence vanishes. To determine the vector wavefunctions that span both parts, one first solves the scalar Helmholtz equation for both Neumann and homogeneous Dirichlet conditions:

$$\nabla^2\psi(\mathbf{r}) + k^2\psi(\mathbf{r}) = 0 \tag{61}$$

The solution of this equation gives a set of generating functions $\psi = \psi(\mathbf{r})$. The rotational part (consisting of divergence-free wavefunctions) is then obtained by substituting generating functions to the formulas [6]

$$\nabla \times (\psi \mathbf{c}) \tag{62}$$

and

$$\frac{1}{k} \nabla \times \nabla \times (\psi \mathbf{c}) \tag{63}$$

where (c) is called the “piloting vector”. This vector can be chosen in such a way that the vector wavefunctions thus obtained have the field distribution corresponding to the electric or magnetic field associated with relevant TE and TM modes. The lamellar wavefunctions are generated also from ψ by the taking the gradient

$$\nabla\psi(\mathbf{r}) \tag{64}$$

If one uses the generating functions calculated from the scalar Helmholtz equation with the Neumann conditions, then Eq. (64) gives the lamellar vector wavefunctions corresponding to the electric field. Likewise, substituting into (64) generating functions calculated from the scalar Helmholtz equation with the homogeneous Dirichlet conditions, one gets the wavefunctions corresponding to the magnetic field.

4. SOLUTION OF A NONHOMOGENEOUS HELMHOLTZ EQUATION: GREEN’S FUNCTION

4.1. Green’s Function for Scalar Helmholtz Equation

A nonhomogeneous Helmholtz equation can readily be solved if one knows the Green function for the problem at

hand. Let us consider a scalar problem [3,25–27]

$$(\nabla^2 + k^2)\Psi(\mathbf{r}) = f(\mathbf{r}) \tag{65}$$

where $f(\mathbf{r})$ is an excitation. If k^2 belongs to the resolvent set [12], then the solution to this equation can be written in as a sum of two terms

$$\Psi(\mathbf{r}) = \phi(\mathbf{r}) + \psi(\mathbf{r}) \tag{66}$$

where $\psi(\mathbf{r})$ is any particular solution of (65) and $\phi(\mathbf{r})$ is a solution of the homogeneous problem

$$(\nabla^2 + k^2)\phi(\mathbf{r}) = 0 \tag{67}$$

Green’s function $G(\mathbf{r}, \mathbf{r}')$ for the scalar Helmholtz equation satisfies the following relationship

$$(\nabla^2 + k^2)G(\mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}') \tag{68}$$

where $\delta(\mathbf{r} - \mathbf{r}')$ is the Dirac function. If $G(\mathbf{r}, \mathbf{r}')$ is known, then $\psi(\mathbf{r})$ can be found as

$$\psi(\mathbf{r}) = \int_V dV' G(\mathbf{r}, \mathbf{r}') f(\mathbf{r}') \tag{69}$$

In general, finding the Green function for various problems of practical significance is a topic of intensive research [12,13,15], but for open-space configuration, Green’s function for the scalar Helmholtz equation has a simple representation collected [3,21] in Table 1.

For bounded regions, the free-space Green function has to be supplemented with a term $F(\mathbf{r}, \mathbf{r}')$ that fulfills the homogeneous equation

$$(\nabla^2 + k^2)F(\mathbf{r}, \mathbf{r}') = 0 \tag{70}$$

Green’s function for bounded region $G_B(\mathbf{r}, \mathbf{r}')$ becomes

$$G_B(\mathbf{r}, \mathbf{r}') = G_0(\mathbf{r}, \mathbf{r}') + F(\mathbf{r}, \mathbf{r}') \tag{71}$$

The techniques for constructing $F(\mathbf{r}, \mathbf{r}')$ are described in several other sources [2,3,5,21].

4.2. Solution of a Nonhomogeneous Vector Helmholtz Equation: Dyadic Green’s Function

The vector Helmholtz equation is by far more difficult to solve as both the solution and the source have many components. It has to be noted that a particular component of the solution vector may be due to source vector components that are oriented in other directions. In this case the

Table 1. Free-Space Green Functions for the Helmholtz Equation

1D ($x \in \mathbb{R}$)	2D ($\rho \in \mathbb{R}^2$)	3D ($\mathbf{r} \in \mathbb{R}^3$)
$\frac{j}{2k} \exp(-jk x - x')$	$\frac{j}{4k} H_0^{(2)}(k \rho - \rho')^a$	$-\frac{j}{4k} \mathbf{r} - \mathbf{r}' ^{-1} \exp(-jk \mathbf{r} - \mathbf{r}')$

^a $H_0^{(2)}(\cdot)$ is the Hankel function of the second kind.

Green function has to describe this complex excitation–response relationship. A convenient way to do this is by using the dyadic representation. Each component in the dyadic Green function corresponds to the response to a single component of a delta-type vector source. The construction and application of the dyadic Green's function are discussed extensively in the literature [6,29] and often constitute an open research problem. For current planar technologies used in the RF and microwave circuits and antennas, of particular interest are dyadic Green functions involving multilayer and possibly anisotropic substrates [15].

4.3. Application of the Scalar Green Function Technique to a Radiation Problem for a Finite-Length Dipole

An example of a nonhomogeneous problem that can be solved in an elegant way by means of a vector potential formulation of Helmholtz equation and Green's function technique is the derivation of the far-field radiated in open space by a dipole of finite length l [1]. Let us assume an infinitesimally thin dipole is oriented along the z direction and the current distribution is given by

$$\mathbf{I}(z') = I_0 \mathbf{a}_z \begin{cases} \sin\left(k\left(\frac{l}{2} + z'\right)\right), & -\frac{l}{2} < z' < 0 \\ \sin\left(k\left(\frac{l}{2} - z'\right)\right), & 0 < z' < \frac{l}{2} \end{cases} \quad (72)$$

The simplest formulation of the problem is obtained by considering the nonhomogeneous Helmholtz equation for vector potential $\mathbf{A}(\mathbf{r})$. With the source current having only one component, one gets $\mathbf{A}(\mathbf{r}) = A(\mathbf{r})\mathbf{a}_z$, and the vector Helmholtz equation reduces to the scalar one

$$\nabla^2 A(\mathbf{r}) + k^2 A(\mathbf{r}) = -\mu I(z') \nabla(x, y) \quad (73)$$

where $k^2 = \mu\epsilon\omega^2$. To find the solution, one uses the 3D free-space Green function

$$A(\mathbf{r}) = \int_{-l/2}^{+l/2} dz' \mu I(z') \frac{e^{-jkR}}{4\pi R} \quad (74)$$

where $R = \sqrt{(x-x')^2 + (y-y')^2 + (z-z')^2}$. Far from the origin $R \approx r - z' \cos \Theta$ and hence

$$\begin{aligned} A(\mathbf{r}) &= \int_{-l/2}^{+l/2} dz' \mu I(z') \frac{e^{-jkr} e^{jkz' \cos \Theta}}{4\pi r} \\ &= \frac{\mu I_0}{4\pi r} e^{-jkr} \left[\int_{-l/2}^0 dz' e^{jkz' \cos \Theta} \sin\left(\frac{kl}{2} + kz'\right) \right. \\ &\quad \left. + \int_0^{+l/2} dz' e^{jkz' \cos \Theta} \sin\left(\frac{kl}{2} - kz'\right) \right] \end{aligned} \quad (75)$$

Both of these integrals can be integrated using

$$\int dx e^{\alpha x} \sin(\beta x + \gamma) = \frac{e^{\alpha x}}{\alpha^2 + \beta^2} [\alpha \sin(\beta x + \gamma) - \beta \cos(\beta x + \gamma)] \quad (76)$$

After some mathematical manipulations, potential $\mathbf{A}(\mathbf{r})$ takes the form of

$$\mathbf{A}(\mathbf{r}) = \frac{\mu I_0}{2\pi r} \frac{\cos\left(\frac{kl}{2} \cos \Theta\right) - \cos\left(\frac{kl}{2}\right)}{k \sin^2 \Theta} e^{-jkr} \mathbf{a}_z \quad (77)$$

or, in spherical coordinates

$$\begin{aligned} \mathbf{A}(\mathbf{r}) &= \frac{\mu I_0}{2\pi r} \frac{\cos\left(\frac{kl}{2} \cos \Theta\right) - \cos\left(\frac{kl}{2}\right)}{k \sin^2 \Theta} \\ &\quad \times e^{-jkr} (\cos \Theta \mathbf{a}_r - \sin \Theta \mathbf{a}_\Theta) \end{aligned} \quad (78)$$

Using relation (22) and neglecting terms inversely proportional to r^2 (far-field region), the magnetic field takes the following form

$$\mathbf{H}(\mathbf{r}) = \frac{jI_0}{2\pi r} \frac{\cos\left(\frac{kl}{2} \cos \Theta\right) - \cos\left(\frac{kl}{2}\right)}{\sin \Theta} e^{-jkr} \mathbf{a}_\phi \quad (79)$$

Then, the electric field can be obtained from Ampère's law

$$\mathbf{E}(\mathbf{r}) = \frac{j\eta I_0}{2\pi r} \frac{\cos\left(\frac{kl}{2} \cos \Theta\right) - \cos\left(\frac{kl}{2}\right)}{\sin \Theta} e^{-jkr} \mathbf{a}_\Theta \quad (80)$$

where $\eta = \sqrt{\mu/\epsilon}$.

There is also a different way to determine fields generated by a finite-length dipole [1]. As a first step one solves the radiation problem for infinitesimally short dipole of length dl that is placed at the origin. Assuming that the current is constant $\mathbf{I}(z') = I_0 \mathbf{a}_z$, one gets

$$\nabla^2 A(\mathbf{r}) + k^2 A(\mathbf{r}) = -\mu I_0 \quad (81)$$

Using the 3D free-space Green function

$$A(\mathbf{r}) = \int_{-dl/2}^{+dl/2} dz' \mu I_0 \frac{e^{-jkR}}{4\pi R} \quad (82)$$

where $R = \sqrt{(x-x')^2 + (y-y')^2 + (z-z')^2}$. Far from the origin $R \approx r$ and hence

$$A(\mathbf{r}) = \mu I_0 \frac{e^{-jkr}}{4\pi r} dl \quad (83)$$

which, expressed in the spherical coordinates, becomes

$$\mathbf{A}(\mathbf{r}) = \mu I_0 \frac{e^{-jkr}}{4\pi r} dl (\cos \theta \mathbf{a}_r - \sin \theta \mathbf{a}_\theta) \tag{84}$$

The magnetic field is obtained directly from (22) as

$$\mathbf{H}(\mathbf{r}) = \frac{jkI_0 dl \sin \theta}{4\pi r} e^{-jkr} \mathbf{a}_\phi \tag{85}$$

and then

$$\begin{aligned} \mathbf{E}(\mathbf{r}) &= \frac{1}{j\omega\epsilon} \nabla \times \mathbf{H}(\mathbf{r}) \\ &= \frac{jk\eta I_0 dl \sin \theta}{4\pi r} e^{-jkr} \mathbf{a}_\theta \end{aligned} \tag{86}$$

Having obtained the fields for a small dipole one can easily get the solution for a finite-length structure with sinusoidal current distribution. To this end one has to divide the structure into short segments and integrate the contributions from each segment. One finds that for a segment dz located at point z' along z the fields can be expressed as

$$d\mathbf{H}(\mathbf{r}) = \frac{jkI(z')dz' \sin \theta}{4\pi r} e^{-jkr} \mathbf{a}_\theta \tag{87}$$

and

$$d\mathbf{E}(\mathbf{r}) = \frac{jk\eta I(z')dz' \sin \theta}{4\pi r} e^{-jkr} \mathbf{a}_\theta \tag{88}$$

where relationship $R = \sqrt{x^2 + y^2 + (z - z')^2} \approx r - z' \cos \theta$ has been used to derive the formula presented above (Fig. 5).

Assuming the current in the form given by (72) and integrating (87) and (88) over z' , ($z' \in [-l/2, +l/2]$), one finally gets expressions for the magnetic and electric fields, identical to (79) and (80).

Figure 5. Dipole of finite length l divided into segments dz .

5. NUMERICAL TECHNIQUES FOR SOLVING THE HELMHOLTZ EQUATION

The class of the problems described by the Helmholtz equation that can be solved analytically is very limited so in most cases the only practical approach is to apply numerical methods. Many methods can be used to this end [13,21]; however, two of them have gained the widest acceptance due to generality. For problems where the Green or the dyadic Green function is known, the method of moments is the most popular choice [11,13,30]. More general problems can be handled with the finite-element method [19,22]. The method of moments⁵ transforms an integral equation into a system of linear equations with a dense coefficient matrix (often called the *impedance* or *admittance matrix*). The technique is very powerful as it often allows one to reduce a three-dimensional problem to two dimensions. For this reason the method of moments is very popular for problems such as scattering from perfectly conducting bodies, radiation from wire antennas, slots and patches on multilayered substrates, or planar microwave circuits. On the other hand, because the coefficient matrix is dense, the numerical costs associated with the method of moments increase rapidly with the number of unknowns. The finite-element method solves the Helmholtz equation by discretizing the whole computational space into small volumes and representing the field over each such element by a superposition of functions with local support (typically simple polynomials). By using the variational principle the Helmholtz equation is transformed into, again, the system of linear equation, but this time, due to the local character of the differential operators and local support of functions, the coefficient matrix is highly sparse. This system is then solved by means of iterative methods of numerical linear algebra. The finite-element method is generally used for problems that cannot be easily handled by the method of moments, such as three-dimensional structures of complicated shape involving inhomogeneous media. The current trend is to develop techniques that combine the advantages of both methods or lead to matrix systems having the coefficient matrices that allows one to use faster computational algorithms [7,23]. These new schemes are aimed at handling larger structures or treating objects that contain geometric features that differ significantly in size.

6. OPERATOR FORMULATION

The Helmholtz equation can be put in the framework of the theory of linear operator equations [12,18]. For instance, the homogeneous Helmholtz equation can be

⁵The method of moments is one of the approximate techniques of the functional analysis that can be applied to solve any equation with a linear operator. Variational techniques—such as the finite-element method—can also be formulated in the framework of the method of moments. However, in the computational electromagnetics community, the term “method of moments” is usually associated with a technique for solving the integral equation involving the Green function. This term is used in this article in this (narrower) sense.

recast in the form

$$-\nabla^2\Phi(\mathbf{r}) = \lambda\Phi(\mathbf{r}) \quad (89)$$

Written like that, it can be seen as a spectral (eigenvalue) problem for a linear operator $-\nabla^2$. From this perspective it is seen that the homogeneous Helmholtz equation has the solution only for λ belonging to the spectrum [4,12] of $-\nabla^2$, while for the nonhomogeneous case λ has to be chosen from the resolvent set [12] of this operator. When the problem is defined in the appropriate functional space setting, defined by the inner product and the boundary condition, it can easily be shown that operator $-\nabla^2$ has many useful properties. For instance, for bounded regions with homogeneous Dirichlet conditions, which in electromagnetics corresponds to oscillations in an perfectly conduction cavity, the following is true for problem (89):

1. Operator $-\nabla^2$ is Hermitian and positive definite.
2. Eigenvalues of $-\nabla^2$ are positive.
3. Eigenfunctions are orthogonal and form a complete set.
4. Operator ∇^2 is invariant under certain symmetries.

The operator approach is a very powerful tool of analysis. It allows one to predict the properties of the solution and often provides a uniform way to treat problems formulated in a different manner. For instance, properties 1 and 2 lead to the conclusion that the resonances in a perfectly conducting homogeneous electromagnetic cavity occur only for positive real frequencies. Furthermore, property 3 implies that all modes oscillate independent of one another and that an arbitrary field inside an empty cavity can be decomposed into modes. Finally, property 4 explains why in certain geometries, such as spheres, several modes may oscillate with the same resonant frequency. The operator approach can also be applied to the Helmholtz equation with a source term providing means to construct Green's function and is very instrumental in investigating complex problems [3,12,18].

For instance, Green's function for any Hermitian operator L can be found [3] by first solving the eigenvalue problem:

$$L\Psi(\mathbf{r}) = \Theta\Psi(\mathbf{r}) \quad (90)$$

Once the eigenvalues Θ_n and eigenfunctions $\Psi_n(\mathbf{r})$ have been found, the Green function can be constructed in the form of a series

$$G(\mathbf{r}, \mathbf{r}') = \sum_n \frac{\Psi_n^*(\mathbf{r}')\Psi_n(\mathbf{r})}{\Theta_n} \quad (91)$$

For the scalar Helmholtz equation, $L \equiv \nabla^2 + k^2$, so if the boundary conditions are such that ∇^2 is Hermitian, one can use the eigenvalues and eigenfunctions of Eq. (89), namely, the negative scalar Laplacian: $\Psi(\mathbf{r}) \equiv \Phi(\mathbf{r})$ and

$\Theta_n \equiv k^2 - \lambda_n$. Green's function is then

$$G(\mathbf{r}, \mathbf{r}') = \sum_n \frac{\Phi_n^*(\mathbf{r}')\Phi_n(\mathbf{r})}{k^2 - \lambda_n} \quad (92)$$

HETEROJUNCTION BIPOLAR TRANSISTOR

JAYASIMHA PRASAD
Maxim
San Jose, California

1. INTRODUCTION

Heterojunction bipolar transistor (HBT) technology has advanced very rapidly since the mid-1980s and has replaced the traditional bipolar transistor in many high-speed applications. An increasing number of commercial HBT products are being introduced into the market almost daily. Foundry services are even available for anyone who wants to design HBT circuits to take advantage of its speed.

The theory behind the HBT is well known and dates back to the time when Shockley invented the transistor [1]. The heterojunction bipolar transistor differs from conventional silicon bipolar junction transistor (BJT) in that at least one of the junctions is formed between dissimilar semiconductor materials and has been widely studied [2–8]. HBTs have been fabricated in III–V semiconductors and silicon. The main advantage of HBTs is an improvement in DC and AC performance. HBT device physics is covered in Section 2.1. The complexities in fabrication of HBTs and reliability issues are discussed in Section 3. The performance of both Si and III–V HBTs are covered in Section 3.6. Some issues in modeling are covered in Section 4. A wide variety of applications are covered in Section 5. Finally, the future of HBT technology is discussed in Section 6.

2. ADVANTAGES OF THE HBT OVER THE BJT

2.1. Wide-Bandgap Emitter

A simple HBT is formed by using a wide-bandgap material for the emitter and a narrow-bandgap material for the base and collector. This is called a *single heterojunction bipolar transistor* (SHBT). If the collector is also made of a wide-bandgap material, then it is called a *double heterojunction bipolar transistor* (DHBT). The difference in bandgap ΔE_g between the two materials is accommodated at the junction by discontinuities in the conduction and valence bands. With abrupt emitter–base junctions, the

band offsets between the wide-bandgap emitter and the narrow-bandgap base lead to a spike ΔE_c in the conduction band and a step ΔE_v in the valence band, as shown in Fig. 1 with the constraint $\Delta E_g = \Delta E_c + \Delta E_v$. The valence band offset prevents the back injection of holes from base to emitter and improves the emitter injection efficiency. On the other hand, the conduction band spike reduces emitter efficiency as the electrons have to surmount that energy to be injected into the base to eventually reach the collector. This also produces a lateral shift of the I_C – V_{CE} curves on the V_{CE} axis by an amount V_{offset} from the origin. In other words, $I_C > 0$ only for $V_{CE} > V_{\text{offset}}$, which is undesirable.

There are two ways to reduce V_{offset} . One is to reduce the conduction band spike, and this can be achieved by smoothly by varying the bandgap of the emitter by varying the composition of the material, in which case ΔE_c almost disappears and the valence band offset ΔE_v approaches ΔE_g as shown in Fig. 2a (dotted lines). The other option is to use a widegap material for the collector (resulting in a symmetric DHBT) and create a conduction band spike at the collector to compensate for the ΔE_c at the emitter. This is illustrated in Fig. 2c (dotted lines).

Thus, under the application of a forward bias, the backward injection of holes into the emitter is reduced by a greater extent than the forward injection of electrons into the base; this leads to two beneficial effects: (1) a reduction in the minority-carrier charge stored in the emitter under forward bias, and hence a reduction in the emitter–base storage capacitance and, consequently, an improvement in high-speed and high-frequency performance; and (2) an improvement in the electron injection efficiency, which impacts directly and favorably on β , the forward common-emitter current gain of the device.

A simple numerical example will illustrate the point. Equations (1) and (2) compare the current gain of a Si BJT with the current gain of an AlGaAs/GaAs HBT. In these equations, we assume that the device has “thin” base and “thin” emitter. We also assume that the base

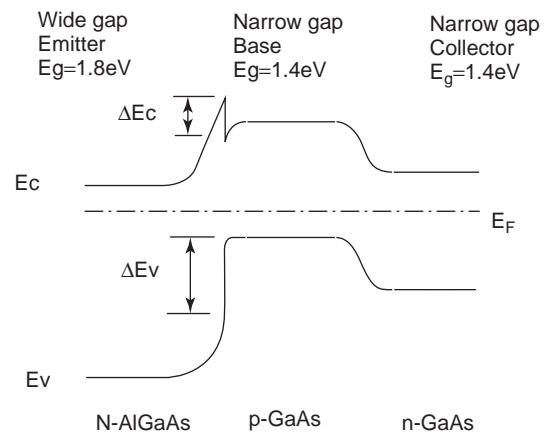

Figure 1. Energy band diagram for a single-heterojunction N-p-n transistor with an emitter having a bandgap wider than that of the base. Let us assume the emitter is doped to 10^{17} cm^{-3} , and the base is doped to 10^{19} cm^{-3} . The hole flow from base to emitter is exponentially reduced by ΔE_v , improving the emitter efficiency.

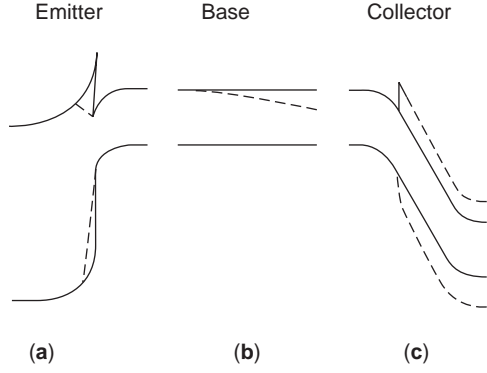

Figure 2. Examples of bandgap engineering in HBT: (a) emitter grading to reduce conduction band spike; (b) base grading to introduce a field to accelerate the electrons; (c) composite collector—a narrow-bandgap collector is used close to the base and a wide-bandgap material is used for the remainder of the collector to improve the breakdown voltage; (d) if all of the collector is made of the same wide-bandgap material as that of the emitter, it is a DHBT. In this case, the conduction band spike occurs exactly at the base–collector junction (not shown) and compensates the ΔE_c at the emitter, reducing the offset voltage V_{offset} . In these figures, the solid lines represent the normal conditions and the dotted lines represent the modifications to the band diagram.

thickness W_B is approximately equal to emitter thickness W_E . D_n and D_p refer to the diffusion constants for electrons and holes, respectively. It is seen that the gain of the HBT is enhanced by the difference in bandgaps between emitter and base:

$$\begin{aligned} \beta(\text{BJT}) &= (N_E W_E D_n / N_B W_B D_p) \\ &= 10^{20}(6.5) / 10^{18}(1.3) = 500 \end{aligned} \quad (1)$$

$$\begin{aligned} \beta(\text{HBT}) &= (N_E W_E D_n / N_B W_B D_p) \exp(\Delta E_g / kT) \\ &= [10^{17}(25) / 10^{19}(5)] 10^5 = 5000 \end{aligned} \quad (2)$$

Additionally, the current gain cutoff frequency f_T is related to transit time of electrons from emitter to collector τ_{EC} by the following relation [6]

$$1/2\pi f_T = \tau_{\text{EC}} = \tau_E + \tau_B + \tau_{\text{CSCR}} + \tau_C \quad (3)$$

where τ_E is the emitter charging time, τ_B is the base transit time, τ_{CSCR} is the transit time in the collector depletion region, and τ_C is the collector charging time. The emitter charging time τ_E has two components; the first is associated with the charge stored in the emitter–base depletion region and the second is due to the holes stored in the emitter as a result of backward-injected holes from the base. In HBTs, the second component is very small, and τ_E can be approximated by the charging time for the emitter–base depletion capacitance C_{BE}

$$\tau_E = C_{\text{BE}}(kT/qI_C) \quad (4)$$

The base transit time in the absence of any electric field in the base is given by

$$\tau_B = (W_B^2/2D_n) + (W_B/v_m) \quad (5)$$

where v_m is the velocity at which the electrons leave the base and $v_m = (kT/2\pi m^*)^{1/2}$.

Typical values for v_m are 5×10^6 cm/s for Si and 1×10^7 for GaAs. If the base has an electric field due to a doping gradient or a bandgap variation, then the carriers move by drift and

$$\tau_B = (W_B^2/\gamma D_n) \quad (6)$$

where γ depends on the electric field present. For a uniform electric field E_0

$$\gamma = 2[1 + (qE_0 W_B/2kT)^{3/2}] \quad (7)$$

Therefore, by creating an electric field, τ_B can be substantially reduced.

The transit time in the collector space charge region is given by

$$\tau_{\text{CSCR}} = W_C/2v_{\text{sat}} \quad (8)$$

where W_C is the collector depletion layer width for a given V_{CB} and v_{sat} is the saturation velocity for electrons. In Si, v_{sat} is 10^7 cm/s. The collector charging time τ_C is the RC time constant of the collector junction capacitance and all the series resistances R_E , R_C and dynamic junction resistance r_e (kT/qI_C).

$$\tau_C = C_{\text{BC}}(R_E + R_C + kT/qI_C) \quad (9)$$

The frequency f_{max} at which the power gain becomes unity is given by

$$f_{\text{max}} = [f_T / (8\pi R_B C_{\text{BC}})]^{1/2} \quad (10)$$

where R_B is the base resistance [9].

Since the reduction in hole flow is large, the emitter doping density N_E can be decreased, and the base doping density N_B can be increased (contrary to that of a BJT), while still maintaining β at an acceptably high value as shown in (2). A lightly doped emitter leads to a reduction in C_{BE} and emitter charging time τ_E , improving f_T , as seen from Eqs. (4) and (3). More importantly, the ability to employ a highly doped base opens up a large number of advantageous possibilities:

1. A reduction in the lateral base resistance R_B , thus improving the power gain at high frequencies, as seen by the expression for f_{max} in Eq. (10)
2. Reduction in emitter–current crowding and also improvement in the noise figure by reducing the thermal noise due to R_B in the base
3. A thinner base in meeting a particular R_B goal, resulting in a shorter base transit time τ_B and, therefore, an improved f_T as seen from Eqs. (6) and (3)

4. A reduction in the collector depletion region encroachments into the base due to heavy doping, leading to higher output conductance and Early voltage, which is often beneficial in analog circuitry, and a reduced susceptibility to device breakdown via punchthrough

It is clear from the discussions above that a HBT gives freedom to independently optimize DC and AC performance. In a BJT, DC and AC parameters are closely coupled and some compromises have to be made in DC performance to meet a given AC performance.

For high-speed digital circuits, bipolar devices are commonly used in two logic families. The current-mode logic (CML) is a simple differential pair with a current source in the emitter leg. The emitter-coupled logic (ECL) is essentially a CML with emitter followers at the outputs. Generally, ECL is faster than CML because of the buffering action of the emitter followers at the expense of additional power dissipation in the emitter followers. The accurate prediction of gate delays of CML and ECL gates is fairly complex and involves several time constants [10]. However, for the purposes of understanding the major factors that contribute to the propagation delay, we can use the approximate expressions given in [11]

$$t_{pd(\text{CML})} = [\tau_{\text{EC}}(R_L + 2R_B)(2C_{\text{BC}} + C_L)]^{0.5} \quad (11)$$

and

$$t_{pd(\text{ECL})} = 1.7 \times [\tau_{\text{EC}}(R_L + 1.4R_B)(3C_{\text{BC}} + C_L)]^{0.5} \quad (12)$$

where R_L is the load resistance and C_L is the parasitic capacitance connected to the output node.

Table 1 shows commonly used material systems, and Table 2 shows the bandgaps and band discontinuities. It is interesting to note from Table 2 that for Si/SiGe system, ΔE_c is almost zero and emitter grading is not necessary.

2.2. Regional Bandgap Engineering

In nearly all the HBTs listed in Table 1, alloy materials are used in some region of the device. By varying the composition of the alloys, it is possible to introduce features that enhance performance of the abrupt-junction HBT.

Table 2. Properties of most Commonly Used Material Systems for HBTs

Material System	E_g (eV)	ΔE_c (eV)	ΔE_v (eV)
$\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}/\text{GaAs}$	1.8/1.42	0.243	0.131
$\text{In}_{0.49}\text{Ga}_{0.51}\text{P}/\text{GaAs}$	1.88/1.42	0.160	0.290
$\text{InP}/\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$	1.35/0.75	0.234	0.366
$\text{Al}_{0.48}\text{In}_{0.52}\text{As}/\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$	1.49/0.75	0.525	0.215
$\text{Si}/\text{Si}_{0.88}\text{Ge}_{0.12}$	1.12/0.99	0.020	0.110

Figure 2 shows some possibilities, which are discussed in the following subsections.

2.2.1. Emitter Grading. Figure 2a illustrates a situation where the wide-bandgap material of the bulk emitter is compositionally graded close to the junction with the base. An example would be an $\text{Al}_x\text{Ga}_{1-x}\text{As}$ emitter with the mole fraction x varied from 0.3 to 0 over a distance of ~ 30 nm from a GaAs base. The diagram depicts a linear grading, as would follow from a linear variation in Al mole fraction. Parabolic grading is also often used. In either case, the objective of the emitter grading is to reduce, or eliminate, the conduction band spike present at abrupt junctions. There are at least two favorable consequences of this. First, because the electron flow across the junction is increased, the collector current and the current gain are enhanced. One advantage of this is a lower turnon voltage—that is, a lower base-emitter bias for a given collector current. This is advantageous for the implementation of HBTs in low-power-consumption circuitry. Second, the ideality factor of the emitter current reduces to unity as thermionic emission takes over from tunneling as the dominant barrier transport mechanism. This fact, when coupled with the increase in emitter current, leads to a lower dynamic emitter resistance and, when coupled with the increase in collector current, leads to an improvement in transconductance. A possible third benefit of a graded emitter is that electrons are injected into the base at near-equilibrium energies, rather than at the elevated kinetic energies possessed by electrons that have tunneled through a high potential barrier, or have been thermionically emitted over it. While these latter “hot” electrons may make a faster transit of the base, they are more likely in GaAs and InP HBTs to be scattered into the lower-mobility, upper-conduction-band valleys on entering the

Table 1. Examples of Material Combinations Frequently Used to Form HBTs with Either a Single Heterojunction (SHBT) or Two Heterojunctions (DHBT)^a

Type	Emitter	Base	Collector	Substrate
SHBT	AlGaAs	GaAs	GaAs	GaAs
SHBT	GaInP	GaAs	GaAs	GaAs
DHBT	AlGaAs	GaAs	AlGaAs	GaAs
SHBT	InP	GaInAs	GaInAs	InP
SHBT	AlInAs	GaInAs	GaInAs	InP
DHBT	AlInAs	GaInAs	InP	InP
SHBT	α -Si	Si	Si	Si
SHBT	SiC	Si	Si	Si
DHBT	Si	SiGe	Si	Si

^aGenerically, the devices are grouped according to the substrate material.

high-field, collector space charge region. Thus, the overall emitter–collector delay time τ_{EC} may in some instances be lower in a graded-junction device.

2.2.2. Base Grading. In base-graded n-p-n HBTs the bandgap is progressively reduced from the emitter to the collector by an appropriate variation in the composition of the base material. As shown in Fig. 2b, the bandgap change is taken up by the conduction band alone. This is because the high hole conductivity precludes any significant variation in the valence band [6].

Thus, the grading has the effect of producing an electric field to aid the passage of electrons across the base. The obvious benefit of this is an improvement in the base transit time τ_B . If, because of the very narrow base that is allowed by having a high base doping density, τ_B is not a major contributor to the overall delay time τ_{EC} , then base grading can be used to achieve an acceptably low value of τ_B in a wider base. The resulting smaller lateral base resistance enables an improvement in f_{max} .

Base grading can also have a beneficial effect on the current gain β ; the reasons for this are twofold:

1. Recombination in the bulk quasineutral base, which can be one of the most significant contributors to the base current, is diminished, with respect to that in a uniform, narrow-bandgap base, because the alloy field increases the electron velocity and, for a given collector current, this means a reduction in the base charge. Of course, this will reduce the base recombination current only if the minority-carrier lifetime is not overly shortened by using an alloy material for the base.
2. Recombination at surface regions of the base is reduced by the tendency of the base alloy field to sweep electrons to the collector—that is, in a direction perpendicular to the base surface. This effect can be particularly beneficial in HBTs with small-dimension emitters, because these devices necessarily have a large emitter perimeter/area ratio.

However, there is a limit to the base grading, beyond which β starts to decrease. Increasing the bandgap of the base material at the emitter–base junction serves to reduce the band offsets, and to make the junction become more and more like a homojunction made from wide-bandgap material. The advantages of a wide-bandgap emitter is lost and current gain degrades to that of a homojunction emitter.

In a wide-bandgap collector DHBT, a further limitation to the permissible amount of base grading is imposed by the need to trade off some of the base grading against the height of the barrier to electron flow into the collector as shown in Fig. 2c. For a given bandgap in the base at the emitter end of the device, decreasing the base bandgap at the collector end increases the amount of base grading, but also increases the barrier to electron flow into the collector. Both β and τ_B are affected by this tradeoff [12].

2.3. Collector Engineering

There are four main motivations for modifying the collector region of a SHBT: (1) to reduce the transit time τ_{CSCR} of electrons in the collector space charge region, (2) to design for a given breakdown voltage BV_{CBO} , (3) to reduce Kirk effect or base pushout effect, and (4) to reduce the collector resistance R_C .

2.3.1. Reduction of τ_{CSCR} . Historically, in bipolar transistors the major transit-time component of τ_{EC} has been τ_B . In modern HBTs, the ability to realize very narrow bases and, to a lesser extent, to implement compositionally graded bases, has led to significant reductions in τ_B , with the result that the dominant transit-related time is τ_{CSCR} . Clearly, reducing the width of the base–collector space charge region W_C would shorten the collector signal delay time, but, if this were accomplished by increasing the collector doping density, then the breakdown voltage and collector junction capacitance C_{BC} would be adversely affected. Trading off speed for improvement in breakdown performance, and vice versa, presents opportunities for novel collector designs. Two structures intended to reduce τ_{CSCR} in GaAs devices are shown in Fig. 3. In the “inverted field” structure of Fig. 3b [12], the field pattern of a conventional collector Fig. 3a is reversed, with the intention of delaying the onset of electron transfer to the lower-mobility, upper conduction bands. This transfer occurs more readily in a conventional collector, as electrons immediately enter a high-field region, in which they are accelerated and rendered more likely to scatter into the upper valleys. This phenomenon is more likely to occur in GaAs than in InP because of the smaller separation between the Γ and L valleys [7]. In the “intrinsic” collector structure shown in Fig. 3c, the high-field zone is restricted to a narrow p^+-n^+ region, and the field remains favorably low in the remaining, weakly doped part of the collector. The first GaAs HBT to register an f_T in excess of 100 GHz was fabricated using such a collector structure [13].

2.3.2. Breakdown Voltage. Turning now to breakdown voltage considerations, the attainment of acceptably high values is difficult in HBTs employing collectors made from

Figure 3. Electric field profiles in different collector structures. The p^+ base is on the left, and the collectors are classified as (a) conventional, (b) inverted, and (c) intrinsic.

narrow-bandgap material, for which the ionization coefficients for electrons and holes are generally high. This is the situation in InP HBTs that have collectors of lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$, which has a bandgap of only 0.75 eV. Solutions to this problem involve making all, or part, of the bulk of the collector from a wider-bandgap material, such as InP, for which the impact ionization coefficients are low. When all the collector is InP, the device is a DHBT. When the collector comprises GaInAs near the base and then InP for the remainder of the layer, as illustrated in Fig. 2c, the device is labeled as a composite-collector HBT. This design is a refinement of the DHBT, with the objective of using just enough n-GaInAs in the collector to ensure that the conduction band spike at the base-collector junction is reduced below the level of the conduction band in the base. In this way, the stored base charge, which strongly influences τ_B and β , and the collector current are not adversely affected by the presence of the conduction band spike.

2.3.3. Kirk Effect. Of all the aspects of collector design, base pushout or the Kirk effect is the most important design consideration. When the electrons injected into the collector becomes comparable to the background donor concentration, the electric field in the collector first decreases and as the injected carriers continue to increase with collector current density J_C , the field reverses and f_T falls off rapidly. An approximate expression for the critical current density J_K at which the onset of Kirk effect occurs is given by

$$J_K = qv_{\text{sat}}N_C \quad (13)$$

where N_C is the collector doping concentration. Above this current density J_K , the collector-base junction becomes forward-biased and holes are injected into the collector. At this point, the base widens into the collector, τ_B increases and β decreases. Even if the base and emitter are designed properly, if the collector is not at its optimum, the device will not yield the best f_T . To overcome this effect and to meet a given f_T , J_K has to be increased, which requires higher collector doping as predicted by Eq. (13). Higher N_C results in lower BV_{CBO} , lower collector depletion layer width W_C , lower τ_{CSCR} , and higher τ_C , due to higher C_{BC} . To prevent large increases in C_{BC} , selectively implanting the collector just below the emitter is often used in silicon technology. The overall result is that f_T improves at the expense of BV_{CBO} . To regain the some of the lost BV_{CBO} , the collector epitaxial thickness can be increased.

2.3.4. Reduction of R_C . If the collector epitaxial-layer (epi) thickness is increased too much, the undepleted portion of the epi contributes significantly to R_C and τ_C increases. Further, the voltage drop in R_C would cause the collector-base junction to be forward-biased, leading to a drop in f_T with increasing I_C . Attention should be paid to the doping and sheet resistance of the subcollector region as this also contributes to R_C . Therefore, the parameters

N_C , J_K , f_T , and BV_{CBO} have to be optimized for a given application.

3. FABRICATION OF HBTs

HBTs using GaAs or InP substrates, or SiGe base layers, have all progressed beyond the experimental device stage to the point that they are being used in commercial circuits. Examples of the fabrication procedures of HBTs representative of various material systems are discussed in this section.

3.1. AlGaAs/GaAs HBTs

HBTs, at least those of the III-V material variety, are invariably fabricated from a stack of epitaxial layers grown on a semiinsulating substrate (see Table 3), and the devices are built by etching away or implanting unwanted regions. Growing the epitaxial layers on a semiinsulating substrate has the beneficial effect of eliminating the parasitic collector-substrate capacitance, which is present in most silicon BJT structures. It also provides an “inert” platform, which may allow fabrication with equal ease of emitter-up and collector-up structures. Collector-up structures are of interest because the smaller dimension of the collector leads to a reduction in collector-base junction capacitance [14]. A more realistic use of collector-up devices might be as the sole transistor type in exceptionally high-speed ICs [15]. We will now focus on the most frequently used emitter-up HBT structures.

AlGaAs/GaAs HBTs were the first to be fabricated by several companies to take advantage of the high frequency capabilities of these devices [4,5,16]. The bandgap of AlGaAs is given by

$$E_g(x) = 1.424 + 1.247x \quad \text{for } x < 0.45 \quad (14)$$

where x is the Al mole fraction. AlGaAs is lattice-matched to GaAs for a wide range of Al mole fractions. With high electron mobility in AlGaAs, this material is well suited for HBTs. Since LEDs and lasers have been fabricated in this material before, this material system has been well researched. The current gain achieved in this material is about 50–100 (unlike 5000 predicted earlier), due to large surface recombination velocity and significant recombina-

Table 3. Typical Epitaxial-Layer Structure for AlGaAs/GaAs HBTs

Layer	Al Composition	Dopant	Doping (cm^{-3})	Thickness (\AA)

tion in the emitter–base space charge region. An example of a manufacturable process for AlGaAs/GaAs HBTs from NORTEL is illustrated in Fig. 4 [17]. The epitaxial layers comprising the device, shown in Table 3, can be grown by molecular-beam epitaxy (MBE) or organometallic chemical vapor deposition (OMCVD), and are shown schematically on the figure by the alternating dark and light bands. From the top, the layers are the heavily doped cap to facilitate ohmic contacting to the emitter metal, the emitter, the base, the collector, and the subcollector.

A dummy dielectric emitter (Si_3N_4) is employed for self-alignment to the base metal, which completely surrounds the emitter in this case (see Figs. 4a and 4b). A deep He^+ ion implantation serves to deactivate the collector layer under most of the base metal area, thereby eliminating most of the extrinsic base–collector capacitance. Obtaining a good ohmic contact to the thin, p-type base, without allowing metal penetration through to the collector, is a crucial step. The procedure here is to first etch off the emitter cap and then deposit PdZnPtAuPd, which is then alloyed through the AlGaAs to the p^+ base. The penetration depth during alloying is controlled by the thickness of the Pd layer below the Pt barrier. The next step (Fig. 4c) is to etch off the cap layer between the edge of the base metal

and the emitter stack. This defines the emitter dimensions and, very importantly, leaves an AlGaAs “shelf” layer on top of the base, thereby reducing the surface recombination velocity in this peripheral region. This helps maintain a high β in small-dimension devices. The peripheral region is protected from the subsequent etch, which exposes the subcollector (Fig. 4d), by a SiON sidewall spacer, which also provides alignment tolerance for the emitter metalization. The fabrication sequence is terminated by providing two levels of metal interconnects and a planarizing layer of benzocyclobutene (BCB).

There are many ways to build HBTs, and a simpler process with fewer masks incorporating 1.4-THz Schottky diodes has been described [16]. Generally, Be is used as a p-type base dopant. There were some initial reliability concerns of the device due to dopant migration. These have been resolved and a median time to failure of $>10^8$ h for discrete devices have been shown [18]. Carbon is considered superior to Be in terms of reliability, and most HBTs today employ carbon doping for the base [19–21]. The shift in HBT device parameters is a function of collector current density [22]. The highest reported f_{max} for AlGaAs/GaAs HBT was 350 GHz and this was achieved using a 50 nm base doped to $6 \times 10^{19} \text{ cm}^{-3}$ using carbon [23].

Figure 4. Fabrication sequence for an AlGaAs/GaAs HBT.

3.2. InGaP/GaAs HBTs

A significant event in AlGaAs/GaAs HBT development was the replacement of the AlGaAs emitter by $\text{In}_{0.49}\text{Ga}_{0.51}\text{P}$. Owing to small conduction band offset (0.16 eV) and large valence band offset (0.29 eV), compositional grading of the emitter–base junction is not required (since V_{offset} is small), and this simplifies the epitaxial layer growth. Also, there are selective etchants to etch the InGaP emitter and stop on GaAs base, unlike the case for the AlGaAs/GaAs system [24]. Oxygen complexes, which are often incorporated in aluminum-containing emitters, are less prevalent when using InGaP. This reduces the emitter–base junction recombination current and allows $\beta > 1$ to be maintained down to very low current densities, showing ideal behavior. In fact, InGaP HBTs provide superior current gains compared to AlGaAs HBTs for a given doping profile and almost independent of device size [24,25], due to reduced surface recombination. A first demonstration of a 60-GHz InGaP/GaAs IC technology with 28 ps ECL gate delay was reported in 1993 by Prasad [26]. A YIG-tuned InGaP/GaAs HBT microwave oscillator with low phase noise was first reported in 1994 [27]. The ease of epitaxial growth, simpler fabrication, better temperature stability, lower $1/f$ noise, and improved D.C. properties of InGaP HBTs have led to rapid growth of this technology. Today, InGaP HBTs are widely used for power amplifier applications in cellphones [28,29]. Hitachi has developed a high-speed InGaP HBT IC technology with f_T of 156 GHz and f_{max} of 255 GHz [30]. As described before, carbon doping of the base results in highly reliable devices with no change in the device performance for 10^4 h of operation at a junction temperature of 264°C at $J_C = 2.5 \times 10^4 \text{ A/cm}^2$ [31,32]. The mean time to failure (MTTF) is an order of magnitude better than that for AlGaAs HBTs, suggesting that the InGaP emitter is the best choice for GaAs HBTs [33,34].

3.3. InP/InGaAs HBTs

It is well known that InGaAs, as used for the base material in InP HBTs, has many desirable properties [7]. For example, with respect to GaAs and Si, InGaAs possesses higher electron mobility, higher electron peak velocity, higher electron saturation velocity, and, compared to GaAs, a higher separation of the Γ and L conduction band minima. These properties are very useful for building high-speed devices. Another variation of this device is to use AlInAs emitter instead of InP emitter.

Another beneficial property of InGaAs is its low bandgap (0.75 eV), which results in a higher minority-carrier electron concentration for a given base doping density. When combined with a graded-emitter junction, a significantly lower emitter–base turnon voltage, V_{BE} can be achieved. For example, V_{BE} of InP/InGaAs HBTs is 0.7 V compared to 1.4 V for AlGaAs/GaAs HBTs. A low V_{BE} permits lower supply voltages to be used, resulting in less power consumption and a more favorable gate delay–power product. InGaAs also has a very low surface recombination velocity, which permits achievement of near-ideal I – V characteristics over a large range of forward bias [7].

A typical process sequence for an InP HBT is illustrated schematically in Fig. 5 [35]. Three mesa etches are required: one to define the emitter, one to define the base and collector regions, and one to etch down to the semiinsulating substrate in order to provide device isolation. The mesa etches are necessary because the InP material system lacks an ion implantation damage process capable of rendering GaInAs sufficiently resistive to provide isolation. To reduce the parasitic base–collector capacitance in a mesa structure, the base–collector mesa must be made as small as possible, necessitating tight self-alignment of the base and emitter metallizations. This is achieved by a slight undercutting of the emitter metal contact, which allows this metal to serve as a mask for the medial edge of the subsequently deposited base metal. The etch used in the undercutting must also be selective to avoid destruction of the thin base material; for GaInAs bases, this can present a problem. If the collector is InP, a selective etch can also be used to define the base–collector mesa. If the collector is GaInAs, the same material as the subcollector, then this convenient etch-stop method cannot be employed. However, the etching is less critical than in the

Figure 5. Fabrication sequence for an InP HBT.

case of the emitter mesa formation because the subcollector is relatively thick. The device structure resulting from a triple-mesa process is highly nonplanar, but can be planarized, to facilitate device interconnection and terminal access, by using a suitable polyimide. This coating also provides some passivation of the exposed GaInAs surfaces. The highest reported f_T for InP HBT is 452 GHz [36], and the highest reported f_{max} is 478 GHz [37]. Recently, Vitesse Semiconductor reported a InP DHBD process with f_T and f_{max} of 325 GHz with the lowest CML gate delay of 1.95 ps [126]. Using a transferred-substrate technology, Lee and others have shown a f_{max} of 820 GHz for AlInAs/InGaAs HBT [38]. Reliability studies on InP HBTs have shown that there are no shifts in device parameters based on accelerated tests at 205°C for 6500 h [39,40].

InP technology allows the monolithic integration of long-wavelength photodetectors with HBTs. Inevitably, there are difficulties associated with the simultaneous realization of high-quality optical and electronic devices from a given stack of epitaxial layers. However, in optoelectronic integrated-receiver front ends, for example, good results have been obtained when using the base-collector of an InP HBT as the photodiode [41]. An example of this embodiment is shown in Fig. 6. The top-illuminated photodiode is constructed from the HBT layers by removing the emitter layers and adding an antireflection coating.

3.4. GaN HBTs

There has been a lot of research in GaN materials and devices since the late 1990s. GaN has a bandgap of 3.4 eV, electron saturation velocity of 2×10^7 cm/s, and a high breakdown field of 2 MV/cm. This material is well suited for high breakdown voltage and high temperature applications. A typical GaN HBT would use Si-doped $\text{Al}_{0.15}\text{Ga}_{0.85}\text{N}$ as the emitter ($E_g = 3.85$ eV) and Mg-doped GaN as base and GaN collector grown on sapphire substrate. At this time, GaN HBT technology is not as mature as other HBTs that we have considered so far. The technology suffers from inability to dope the base heavily, very high V_{offset} of 1–5 V

due to high base contact resistance, low current gains (<10), and high collector–emitter leakage [42].

3.5. SiGe HBTs

Unlike the III–V HBTs discussed in the preceding subsections, the starting material for SiGe HBTs are generally p-type silicon substrates. Since the SiGe is the base layer, SiGe HBTs are normally DHBTs. Further, most SiGe HBTs are fabricated by growing a SiGe base layer and depositing a polysilicon layer on top of it to form an emitter, in sharp contrast to III–V HBTs, where all the device layers are grown at once, forming the starting material.

3.5.1. Material Properties. Germanium has a lattice constant of 5.65 Å, whereas silicon has a lattice constant of 5.43 Å. Therefore, the SiGe layer is not lattice-matched to silicon. However, if the epitaxial film is not too thick and the growth temperature is not too high, the SiGe base layer will conform to the Si collector material on which it is grown. Such a layer is referred to as *pseudomorphic* or *coherently strained*. The strain decreases the SiGe bandgap, fortuitously improving the bandgap differential between the base and the subsequently deposited Si emitter, allowing one to build an HBT with tailored bandgap differences. The bandgap of $\text{Si}_{1-x}\text{Ge}_x$ varies according to the relation [43]

$$E_g(x) = 1.124 - 1.22x + 0.88x^2 \quad \text{for } x < 0.6 \quad (15)$$

Furthermore, the strain in the SiGe film breaks the sixfold degeneracy of the conduction band minima and the twofold degeneracy of the valence band maxima; these phenomena can be exploited to improve the electron mobility (reducing τ_B) and the hole mobility (reducing R_B) [6]. The critical thickness—beyond which the SiGe film becomes unstable, and sufficiently defective for the associated rise in recombination centers to render it useless for bipolar applications—is inversely proportional to the Ge content or, for graded SiGe films, to the integrated Ge content. Maintenance of the coherently strained nature of the film,

Figure 6. Schematic cross section of the elements of a positive–intrinsic–negative (p-i-n)/HBT OEIC photoreceiver.

by not allowing it to relax and assume its bulk lattice constant, is dependent on minimizing the exposure of the film to subsequent high-temperature environments.

3.5.2. Base Profiles. The constraints imposed by the considerations of SiGe film stability lead to a Si/SiGe HBT fabrication process, which is more complicated than those described previously for III-V HBTs. A review of the procedures used to date to achieve high-performance Si/SiGe HBTs can be found in Refs. 44–46, along with a detailed description of the technology that is employed at IBM to produce HBTs in a manner compatible with standard CMOS processing resulting in a BiCMOS technology. With reference to the HBT base, there are two approaches: (1) using a box SiGe profile with a fixed Ge concentration along with a heavily doped base, similar to the III-V HBTs, where a lightly doped Si emitter is also grown, making it a true HBT (the box profile is used by a few companies, e.g., TEMIC); and (2) using a graded Ge profile (lowest Ge at emitter–base junction and highest Ge at base–collector junction) with a lightly doped base and contact it with a heavily doped polysilicon emitter, which integrates well in standard bipolar process. Here, the speed advantage is due to the accelerating field in the base and the device is a drift base transistor, often abbreviated by the misnomer “HBT”. The graded base approach is widely used in the industry as it has several advantages over the box profile [44].

3.5.3. SiGe Epitaxial Growth. Turning our attention now to the epitaxial (epi) growth of the base, we have two options: (1) nonselective epi and (2) selective epi. In the simplistic nonselective epi, the SiGe base grows as a single crystal on the exposed areas of silicon (where we want the base to be formed) and as polysilicon on oxide. The polysilicon naturally contacts the base and facilitates connection to the base. Also, this polysilicon layer can be used as a resistor if needed. In the selective epi, SiGe base is grown only on the exposed areas of silicon and no growth occurs on the oxide. An additional layer of polysilicon is necessary to contact the base. Each of these techniques has its own advantages and disadvantages.

The SiGe base layers in the HBTs from IBM are grown using a UHV/CVD system, but in this case it is of the hot-wall variety [47]. This equipment has been developed specifically for blanket Si and SiGe epitaxy and is consistent with a low-temperature, commercially feasible process. In this process, hydrogen-passivated Si wafers are admitted to the system, in which a vacuum of around 10^{-9} torr is maintained. The residual gas is predominantly hydrogen; other species, which may be chemically active with silicon, are not present at sufficient partial pressures to violate the hydrogen passivation of the wafer. Films are subsequently deposited under vacuum by CVD at temperatures in the range 400–500°C. Precise dimensional control, of the order of one or two atomic layers, is possible with the UHV/CVD process. Reduced-pressure CVD reactors with pressures of the order of 10 torr are also being used for SiGe epi [48]. These are typically single-wafer machines, unlike the high-vacuum batch reactor described earlier.

3.5.4. SiGe HBT Flow. Here we describe a selective epi technology from NEC, Japan which is geared toward high-performance bipolar circuitry and therefore has the same goal as that of the processes described earlier for III-V HBTs. A partial process sequence is illustrated in Fig. 7 [49,50]. To prepare for the SiGe growth and to begin the emitter definition, the top dielectric film (Si_3N_4) and the large-grain p^+ polysilicon layer shown in Fig. 7a is etched and the edge of the resulting feature is covered with a Si_3N_4 sidewall. The bottom dielectric (SiO_2) is then etched and allowed to laterally undercut the sidewall. From this point on, attention must be paid to the thermal budget, so as not to destroy the pseudomorphic nature of the SiGe base. This layer is grown on the exposed Si substrate, simultaneously with a polysilicon film which descends from the underside of the polysilicon layer exposed by the earlier lateral etch. Growth is stopped when the two growing films touch (see Fig. 7b). Growth is carried out by CVD in a

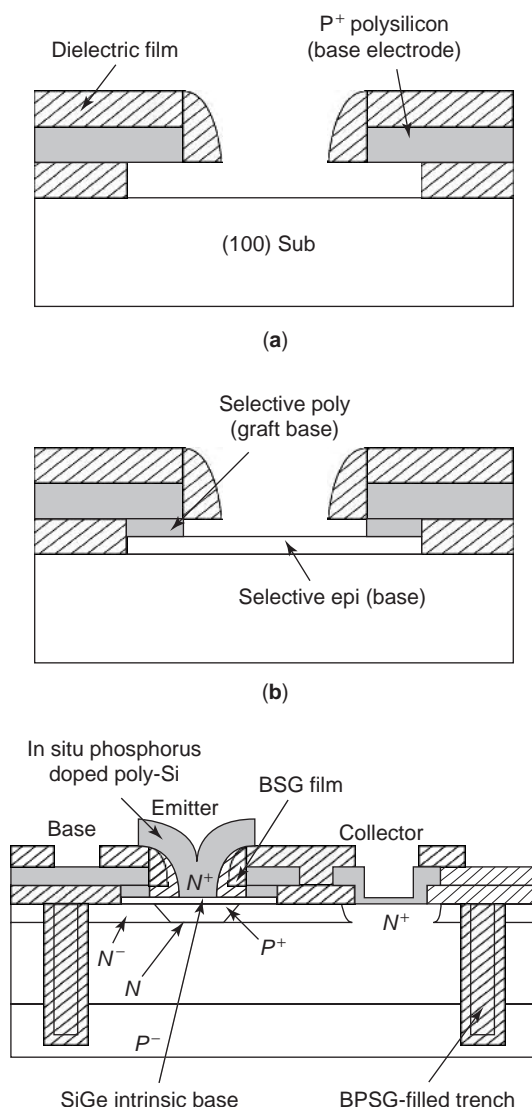

Figure 7. Partial fabrication sequence for SiGe HBT (a) and (b) with the finished device.

cold-wall, ultra-high-vacuum (UHV) system at $\sim 650^\circ\text{C}$. Because films grown by this selective epitaxial growth (SEG) process are very sensitive to the condition of the Si surface, the collector is formed subsequently, using ion implantation. The remaining fabrication steps comprise (1) coating of the Si_3N_4 sidewall with borosilicate glass (BSG), (2) doping of the external SiGe base by driving in boron from the glass at 800°C for 10 min, (3) deposition of phosphorus-doped polysilicon for the emitter, and (4) driving in the emitter at 950°C for 10 s. The finished device, complete with BSG trench isolation, is shown at the bottom of Fig. 7.

3.5.5. SiGe BiCMOS Flow. Most SiGe bipolar processes today incorporate CMOS to take advantage of the high functionality, density, and popularity of several working circuits in standard CMOS. This also helps designing a system on a chip (SoC). In Fig. 8 we show a method of adding bipolar steps to an existing CMOS flow to generate a BiCMOS process flow. The reason for processing the PMOS after the NPN is not to add additional thermal cycles to change the characteristics of the PMOS. It should be noted that if a nonselective epi is used for SiGe base, the SiGe poly layer must be removed from the CMOS areas during base definition. A typical BiCMOS flow with process cross sections is presented in Ref. 45.

One problem associated with thin boron-doped base layers grown by epi is that the dopant diffuses during subsequent device processing, making the base wide and a consequent reduction in f_T , f_{max} , and β . To overcome this problem, the diffusion of boron must be reduced. It has been found that if carbon is added to the SiGe base in concentration of $< 10^{20} \text{ cm}^{-3}$ ($\sim 0.2\%$), the diffusion coefficient of boron is reduced by more than one order of magnitude [51]. Adding carbon to the base thus results in stable DC and AC performance and improved yield. Accelerated testing on SiGe HBTs has shown that the device is very robust and no parametric shifts occur for $> 10^6 \text{ h}$ [52,53].

3.6. Device Performance

The purpose of this subsection is to briefly mention some of the high-performance HBTs that have been reported in the literature and to relate them to the materials constituting the device. Using f_T and f_{max} as figures of merit, Table 4 lists the high-frequency performance of various HBTs reported in the literature. The table also includes data reported in the early 1990s to enable the reader to assess the progress made since that time. It is seen that the InP HBT leads with highest f_T and f_{max} of 370 and 459 GHz, respectively. The highest f_{max} of 820 GHz is obtained on InAlAs/InGaAs HBT transferred to GaAs host substrate and mounted in the collector-up configuration. InGaP HBTs have made a steady progress in f_T from 60 to 156 GHz. The first reported ECL gate delay for InGaP HBT is 28 ps. In the early 1990s, AlGaAs HBTs have shown a f_{max} of 350 GHz. SiGe HBTs have shown performance comparable to III-V HBTs with the lowest CML gate delay of 3.6 ps. More recently, with the regrown emitter process, InP HBTs have shown a f_T of 183 GHz.

The large bandgap of GaAs is also helpful in the attainment of acceptable breakdown voltages. For example, values of BV_{CEO} in the range of 9–15 V are typical of AlGaAs/GaAs HBTs in which the collectors have a doping density of $3 \times 10^{16} \text{ cm}^{-3}$ and thicknesses in the range 300–700 nm. Comparable breakdown voltages in InP HBTs can be obtained only with composite-collector or DHBT structures since the bandgap and breakdown field in InGaAs are smaller than in GaAs. For really high breakdown voltages, InGaP DHBTs are preferred with BV_{CEO} of 47 V [63]. For a given f_T , SiGe HBTs generally have a lower breakdown voltage compared to GaAs HBTs since the collector has to be doped heavily to avoid the Kirk effect.

4. MODELING

The importance of modeling cannot be overemphasized as it forms crucial link between the device physics, device

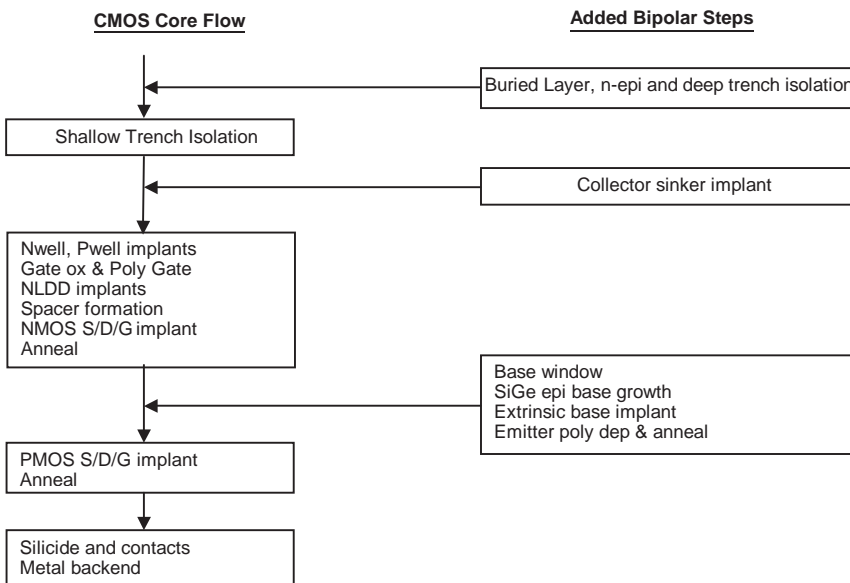

Figure 8. Addition of bipolar steps to a CMOS flow to generate a BiCMOS flow.

structure, process technology, and circuit design. The bipolar compact models have evolved since the Gummel–Poon model to MEXTRAM, high-current model (HICUM), vertical bipolar intercompany (VBIC) model [64–66], and others. Newer models are more complex and take additional computational time, but the advantage is that they are more accurate. This helps in designing complex circuits and better prediction of the performance of a circuit or a system. Some of the newer models have taken into account impact ionization in the collector, quasisaturation, self-heating effects, parasitic substrate transistor effects, and other factors that were not present in the original Gummel–Poon model. A detailed consideration of all these models is beyond the scope of this article. However, in this section, we will present some of the major differences between silicon BJT and HBT models.

4.1. DC and Thermal Effects

Let us now focus on DC properties. III–V HBTs have higher offset voltage (V_{offset}) compared to SiGe or silicon BJT. As mentioned before, V_{BE} for AlGaAs/GaAs and InGaP/GaAs HBT is ~ 1.4 V, whereas V_{BE} for InP/InGaAs and SiGe HBT is close to 0.7 V, comparable to silicon BJT. Due to the presence of the heterojunction at the emitter–base region, the relation between I_C and V_{BE} in a HBT is not as simple as in a BJT, and the ideality factor is greater than unity and varies with V_{BE} . As seen from Eq. (2), the current gain of a HBT decreases with temperature while in a silicon BJT, the current gain increases with temperature. This has to be modeled properly. Typical I_C – V_{CE} characteristics of a silicon BJT slants upward because of (1) lower doping in the base and (2) higher β at higher currents. In HBTs, the I_C – V_{CE} characteristics are generally flat because of higher doping in the base and/or compositional grading across the base. At high currents, the I – V curves droop downward, due to self-heating, which results in a lower current gain and negative Early voltage [67]. Thermal effects are more severe in GaAs HBTs since the thermal conductivity of GaAs is 0.46 W/cm \cdot °C compared to silicon

1.2 W/cm \cdot °C. It should be noted that the thermal effects modeled for DC effects should also model AC thermal effects as it is very important for power amplifier applications.

4.2. AC Effects

Turning our attention now to AC properties, we find that there are new effects in DHBTs. It is well known that at high currents, f_T falls off as a result of the familiar Kirk effect [68], and this also results in a reduction of β with I_C . It is observed that f_T falls off much more rapidly in DHBTs than what is predicted by theory. In addition to the Kirk effect, there is the *heterojunction barrier effect*, which causes this rapid fall of f_T at high currents. In DHBTs, when there is a transition from narrow-bandgap base to wide-bandgap collector, there is a valence band offset at the heterointerface as explained in Fig. 1. Since this barrier is masked by the band bending and the depletion region caused by collector–base (CB) reverse bias, it has negligible effect during low-injection or low-current operation. Under high injection levels, the CB electric field decreases and finally collapses exposing the valence band barrier. This barrier prevents the flow of holes into the collector to maintain charge neutrality when the Kirk effect has set in. These holes pile up at the heterointerface, causing charge imbalance, which results in a conduction band barrier. The conduction band barrier opposes the electron flow into the collector, causing a sudden decrease of f_T [69,70]. This effect is observed in III–V DHBTs and SiGe HBTs. At this point, it is also important to mention another important factor, the *heterojunction barrier effect*, which occurs at low currents as a result of improper base profile design or diffusion of base dopants during subsequent processing, altering the intended base profile. If the transition from narrow-bandgap base to wide-bandgap collector occurs inside a neutral base, parasitic barriers are produced at the conduction band edge, preventing the electron flow into the collector and severely degrading f_T [71,72]. This can be avoided by placing undoped spacers between base and collector. In the case of a SiGe-graded base HBT, if the boron outdiffuses past the Ge profile, it could result in a parasitic conduction band barrier. One method is to set the boron back a certain distance from Ge peak to account for the boron diffusion or use carbon in the base to suppress boron diffusion as explained before.

So far, we have discussed the variation f_T with I_C . We will now consider the variation of f_T with V_{CE} . For a given I_C , as we increase V_{CE} , the collector depletion region width W_C increases and C_{BC} decreases, causing a reduction in τ_C as seen from Eq. (9). This would imply that we have a lower transit time τ_{EC} from Eq. (3) and f_T would increase with increasing V_{CE} . This is what is typically observed in silicon BJTs. However, there is an opposing effect. The transit time in the collector depletion region τ_{CSCR} increases, as seen from Eq. (8). Therefore, the overall variation of f_T with V_{CE} is mixed. Initially, f_T increases with increasing V_{CE} since there is a considerable reduction C_{BC} . Further increase in V_{CE} increases the collector transit time, and f_T decreases with V_{CE} . This has been observed in III–V HBTs. SiGe HBTs do not show this behavior since the collector is very heavily doped.

Since HBTs are increasingly used as power amplifiers in cellphones, the nonlinear behavior such as output power, gain compression, power-added efficiency (PAE), inter-modulation distortion (IMD), and adjacent-channel power ratio (ACPR) have to be modeled for optimizing power amplifier design. Some of the abovementioned effects have been successfully modeled for both III-V and SiGe HBTs [73–78].

4.3. Nonequilibrium Electron Transport

As device dimensions continue to shrink in the never-ending quest for higher speed, transport in the shortened bulk regions of the HBT can no longer be faithfully described by the classical processes of drift and diffusion. The base of modern HBTs is one such region whose width is approaching the length of a mean free path and, therefore, is a region in which quasiballistic transport can be expected to prevail. Quasiballistic transport in the base and velocity overshoot effect in the collector is observed in III-V HBTs. At high values of J_C , the electric field is perturbed by the traveling space charge, leading to very high velocity (even as high as $\sim 7 \times 10^7$ cm/s) near the base-collector junction, leading to very short collector transit time τ_{CSCR} . This results in very high f_T just before onset of the Kirk effect [76–78].

4.4. Parameter Extraction

Once the model is chosen, the next task is to extract device parameters for the model. This task is by no means trivial and creates problems due to the nature of the HBTs and the complexity of the chosen model. For example, the base resistance of a HBT is very low, and conventional DC methods to extract R_B and R_E do not yield correct results [79]. New AC methods have to be used for direct extraction of the model parameters, and there are a variety of papers in the literature [80–82].

5. APPLICATIONS

When AlGaAs/GaAs and SiGe HBTs first came into existence, the main applications were A/D and D/A converters, low-noise amplifiers (LNAs), and power amplifiers. The development and performance of these circuits are described very well in the literature [4–7,45,46]. At the time of this writing, approximately two decades have passed since the first demonstration of these circuits and in the meantime, several new circuits have been developed. Since the applications are widely varied, it will be impossible to cover all of them. We will take a systematic approach to discuss these circuits on the basis of device performance.

5.1. Frequency Dividers

One of the first major building blocks in a digital circuit is the flip-flop, and the speed at which it can be toggled gives a feel for the performance of the circuit. Table 5 shows a summary of various HBT frequency dividers. Static frequency dividers are simple flip-flops. Dynamic frequency dividers make use of a mixer and a lowpass filter in a

regenerative loop. The output of the filter is fed back to the mixer so as to generate an output whose frequency is one-half of the input frequency. These generally run at higher frequency, and the output swing is small. In the dynamic frequency dividers, InP HBT from NTT stands tall at a record frequency of 150 GHz. The SiGe counterpart from Infineon is equally impressive, running at 110 GHz.

Coming now to the static dividers, InP HBT from Hughes Research Labs once again sets the record at 100 GHz. On the other hand, a SiGe divider clocking at 96 GHz was reported by IBM at the 2003 GaAs IC Symposium. InGaP HBT dividers have moved from the humble beginning of 12.5 GHz to 39.5 GHz. The emphasis in InGaP HBT technology today is mostly for power amplifiers for cellphones and base stations. Table 5 also shows a 0.18- μm CMOS dynamic frequency divider operating at 40 GHz.

5.2. Oscillators and VCOs

The next circuit that can be benchmarked against the others is a simple oscillator or voltage-controlled oscillator (VCO). Table 6 compares oscillators from various technologies. Shown in the table is also the phase noise at a given offset frequency. The highest-frequency oscillator reported so far operates at 134 GHz, and the transistor used in this oscillator is a InGaP/InGaAs HBT with a f_{max} of 170 GHz. This record is yet to be broken! The SiGe process from Infineon with a f_{max} of 200 GHz has shown a VCO running at 98 GHz. This is the highest reported frequency for an oscillator in silicon-based technology. The next-highest reported frequency for an InP HBT VCO is from TRW running at 62.4 GHz. The very first YIG-tuned InGaP HBT oscillator was reported by Prasad and Haynes [27]. InGaP HBT VCOs are currently running at 34.2 GHz as reported by Hilsenbeck in the 2003 GaAs IC Symposium. A 0.12- μm CMOS VCO from Infineon is running at 51 GHz, which is very good benchmark for a standard CMOS process.

5.3. Power Amplifiers

The superior high-frequency and high-voltage capabilities of HBTs make them very good candidates for RF power amplifiers. The performance levels of power amplifiers and power transistors in different technologies are listed in Table 7. It is clear that InGaP HBTs tend to dominate RF power amplifier market. A 10-W (40-dBm) InGaP DHBT with a gain of 13 dB at 2 GHz and power-added efficiency (PAE) of 50% was reported by Kurpas et al. [63]. An equally good contender for this was a 230-W (53.6-dBm) SiGe power HBT from Northrop–Grumman. This device had a gain of 6.9 dB at 2.8 GHz and a PAE of 46%. For comparison, we have shown a 1-W AlGaAs HBT with 6 dB gain and 72% PAE from Mitsubishi. These high-power transistors are used mainly in power amplifiers for cellphone base stations.

Turning our attention to power amplifiers, we see a 60-GHz power amplifier with 15 dB gain and 13 dBm power output from Sharp built on InGaP HBT technology. We can compare this with a SiGe HBT power amplifier from Infineon operating at 7–18 GHz. This power amplifier has 14 dB gain, 11% PAE, and an output power of 17.5 dBm. A more recent IS-95B power amplifier for cellphones from Skyworks boasts a 27 dB gain and 40% PAE. The data shown in Table 7 represent only a small sample of power amplifiers and power HBTs reported in technical papers and available on the market.

5.4. LNA and Wideband Amplifiers

The most important functional block in a receiver chain is the LNA as it determines the minimum detectable input signal level. Since the HBTs have high current gain, high f_T , and low base resistance, the noise figure of the device is low. Minimum noise figure as low as 0.2 dB and associated

gain of 14 dB at 10 GHz has been reported for SiGe HBTs [108]. Table 8 summarizes LNA and wideband amplifier performance. The SiGe LNA from STMicroelectronics with 22 dB gain and a noise figure (NF) of 1.6 dB operating at 8.2 GHz is a good example of the performance that can be expected from SiGe HBT technology. An example of CMOS LNA built on 0.18 μm technology is also shown in Table 8. At a frequency of 24 GHz, the LNA has a gain of 12.9 dB and noise figure of 5.6 dB. Coming to wideband amplifiers, the highest record is again set by InP HBT. The amplifier boasts a bandwidth of 140–200 GHz and has a gain of 8.5 dB.

5.5. Digital Communication Circuits

In fiberoptic communication systems, several digital circuit blocks can be built with HBTs because of these transistors' superior high-frequency properties. InP HBT is considered to be the best candidate for this purpose since it is a suitable material for the fabrication of OEICs [124]. Beginning with the receiver chain, these include the transimpedance amplifier (TIA), the limiting amplifier, clock and data recovery (CDR), and the demultiplexer (DMUX). On the transmitter chain, we have the multiplexer, the clock multiplication unit, and the voltage driver and the laser modulator. Over the years, the data rates have steadily increased, and we show some recent examples of circuits operating at 40 Gbps. Table 9 shows digital communication circuits fabricated in InP HBT, SiGe HBT, silicon bipolar, and CMOS. We have also included one example of a TIA in InP and SiGe HBT technologies since it is an integral part of the system. It is interesting to note that 50 Gbps 2–1 multiplexer was demonstrated as early as 1996 in silicon bipolar technology. Some of these high-speed circuits were once considered to be only in the realm

Table 7. Performance Summary of HBT Power Amplifiers

of compound semiconductors. Note that the standard CMOS technology is also advancing rapidly and demonstrating successful 40-Gbps circuits.

6. FUTURE TRENDS AND INDUSTRY OUTLOOK

The heterojunction bipolar transistor has traditionally been the workhorse for ultra-high-speed circuits and will continue to maintain its place at least in the foreseeable future. The HBT is here to stay in spite of the competition from silicon bipolar and deep sub micrometer CMOS. HBTs will dominate in wireless, microwave, fiberoptic communications and test instruments.

The emitter widths of III–V HBTs have scaled down from several micrometers in the mid-1990s to current values of 0.4 μm . On the other hand, the emitter widths of SiGe HBTs have shrunk a lot faster and have reached 0.12 μm . This aggressive scaling of SiGe HBTs is due to the advances in CMOS scaling, lithography, and advanced processes. Base widths will continue to become thin to meet the never-ending need and greed for high f_T . As the base gets thinner, the extrinsic portion of the base also contributes to high R_B . To reduce extrinsic base resistance, a raised extrinsic base (REB) has been employed in 200-GHz SiGe processes [61]. Compared to SiGe HBTs, III–V HBTs will continue to have higher breakdown voltage because of its higher bandgap and breakdown field. The AlGaAs/GaAs HBT, which was dominant at one time, has now been taken over by InGaP HBT. These days, “GaAs HBT” means InGaP HBT, which will play a major role in wireless applications. InP HBT will continue to dominate in high-speed circuits and has a great potential

for developing 160-Gbps fiberoptic communication circuits [124,125].

III–V HBTs have traditionally employed mesa etching of the emitter and a metal liftoff process to form base contacts self-aligned to the emitter. This requires a base (and emitter) that is large enough to be contacted by the ohmic metal and results in high C_{BC} . Higher C_{BC} results in poor device performance, despite the superior material properties of III–V semiconductors. To overcome this problem, regrown emitters are now being used to emulate the double-polytransistor structures in silicon [57].

SiGe HBTs, on the other hand, have used heavily doped polysilicon to form the emitter and contact the SiGe base. This has resulted in lower BV_{EBO} , higher R_E , and a slightly higher $1/f$ noise due to the presence of the interfacial oxide between emitter and base. By using a regrown emitter with the correct amount of doping, BV_{EBO} can be increased and R_E can be decreased [83] with improved $1/f$ noise. Standalone SiGe HBT processes will disappear, and SiGe BiCMOS will be the mainstream process with very high integration levels.

In this fast-moving space age, cost is a deciding factor in making technology decisions. SiGe BiCMOS, which is currently running on 200-mm wafers, with expectations to move to 300-mm wafers, will continue to drive the cost down with improved performance over newer generations. Along with CMOS, BiCMOS offers a very high level of integration and functionality. This fact cannot be denied. Realizing this, many silicon houses (IBM, Infineon, Jazz, National, Maxim, Micrel, Motorola, etc.) have developed their own SiGe processes. For those companies, which do not have their own fabrication facilities, SiGe BiCMOS foundry services are available from IBM, Jazz, TSMC, UMC, and other manufacturers. Comparing this with

Table 9. Performance Summary of Digital Communication Circuits

Material	Circuit	Affiliation	Speed (Gbps)	Ref.
InP/InGaAs	4–1 MUX/DMUX ^a	NTT	40.0	114
InP/InGaAs	CDR ^b /DMUX	Inphi	43.2	115
InP/InGaAs	16–1 MUX	Vitesse	40.0	116
InP/InGaAs	TIA ^c	Vitesse	40.0	117
SiGe	4–1 MUX/DMUX	IBM	50.0	118
SiGe	CDR—Rx/Tx	IBM	43.0	119
SiGe	TIA	Lucent	40.0	120
Si bipolar	2–1 MUX	Siemens	50.0	121
CMOS 0.12 μm	2–1 MUX/DMUX	Infineon	40.0	122
CMOS 0.18 μm	CDR/1–4 DMUX	UCLA	40.0	123

^aMultiplexer/demultiplexer.

^bClock and data recovery.

^cTransimpedance amplifier.

III-V HBTs running on 6- or 4-in. wafers with medium to large-scale integration and higher cost, we find that III-V HBTs have a place in some special applications where SiGe BiCMOS cannot compete. For those competing in the III-V HBT applications who do not have a fabrication facility, foundry services are available from TRW, Knowledge*On, Win Semiconductors, and other companies.

CMOS will continue to catch up with HBTs. However, in applications where $1/f$ noise matters, such as in oscillators, HBTs will dominate. The high-transconductance, high-early-voltage, and high-current-handling capabilities of bipolar technology cannot be ignored. Also, aggressively scaled CMOS can stand only lower supply voltages, and this may be a problem in applications where voltage swing is important. We believe that all the three technologies will coexist and have their own roles to play. It is not too unrealistic for us to witness terahertz transistors in the years to come.

Acknowledgment

The author is deeply grateful to his undergraduate professor, Dr. Sainath, who was instrumental in steering him into the field of semiconductor devices, which was considered a "black art" at that time (and still is!). The author would also like to express his sincere thanks to D. L. Pulfrey for providing an earlier version of this article, which formed a framework on which to build. The author also expresses his heartfelt thanks to the following people for many fruitful discussions on issues pertaining to HBTs: Peter Asbeck, Madhu Gupta, Frank Chang, S. J. Pearton, David Roulston, C. R. Selvakumar, John Cressler, David Hame, Tak Ning, Michael Schroter, Hans-Martin Rein, and the late Greg Stillman. The author was given an opportunity to work and contribute to III-V HBTs at Tektronix with the encouragement and support of Jack Sachitano and Bruce Murdock. Thanks are also due to Reda Razouk (National Semiconductor), Barry Small (Micrel Semiconductor), Viktor Zekeriya, and Vijay Ullal (Maxim) for giving the author an opportunity to contribute to SiGe BiCMOS. Finally, the author would like to thank his wife Chaya and daughter Rama for providing plenty of time during evenings and weekends to complete the deceptively simple task of writing this article.

HETEROSTRUCTURES DEVICES

VICTOR RYZHII
 University of Aizu
 Japan

All semiconductor devices are made of building blocks, consisting of semiconductor structures with different

properties and supplied by some nonsemiconductor parts. This relates to discrete devices and integrated circuits alike. Junctions of semiconductors doped by different impurities are the most important structures of semiconductor devices. If a junction is formed by regions of the same semiconductor material with one of them doped by acceptor impurities, and the other one by donor impurities, such junction is called the *p-n junction*, or the *p-n homojunction*. Semiconductor structures consisting of homojunctions are known as *homostructures*. More generally, homostructures are defined as semiconductor structures in which doping changes with position. Semiconductor structures with a nonuniform chemical composition are called *heterostructures*. The simplest heterostructure includes a single heterojunction, which is an interface between two different semiconductor materials. The size of the region where the chemical composition changes can be both small (about a few periods of the crystal lattice) and relatively large (comparable with the size of the device). The first case corresponds to so-called abrupt heterostructure, in contrast to graded (or graded-gap) heterostructure, in which the chemical composition and, in turn, the semiconductor energy bandgap change smoothly.

The abrupt heterostructures can be formed by almost all combinations of semiconductor materials, although not all combinations yield heterostructures with desirable properties and quality. Examples of heterostructures include Si–Si_{1-x}Ge, GaAs–Al_xGa_{1-x}As, GaSb–InAs, and other heterostructures. Graded heterostructures are formed by many semiconductor compounds, in particular, A₃B₅ compound system.

The main property of heterostructures used in most heterostructure devices is the nonuniformity of spatial distributions of the bandgap and the edges of the valence and conduction bands. This leads to the formation of the so-called quasi-electric field in heterostructure bulk affecting charge carriers, as has been pointed out in a pioneering paper by H. Kroemer (see, e.g., Ref. 1 and references cited therein). The quasi-electric field in graded heterostructures forces electrons and holes to move in the same direction, despite their opposite charges (Fig. 1). In heterostructures with abrupt heterojunctions, the band offsets can form potential barriers or ramps for electrons and holes, shown in Fig. 2. The band offsets are the result of abrupt variations of the chemical composition. Thus, the

Figure 1. Forces on electrons and holes in a graded-gap heterostructure. The forces in electrons and holes are in the same direction.

Figure 2. Energy barriers (a) and ramps (b) for electrons and holes in an abrupt heterostructure. Electrons and holes are rejected from the heterojunction if their energy is smaller than the barrier height. They acquire the energy passing the ramp at the heterojunction.

energy of the carriers at the band edges must change as those carriers pass through the heterojunction.

An important practical constraint is the necessity to select materials with small differences in lattice constants at the required fabrication and operating temperatures. A good lattice match is needed to minimize the density of interface states and strain fields at the heterojunction. A heterostructure with a double heterojunction can form a potential well. If such a well is narrow enough, the energy spectrum of electrons (or holes) becomes quantized (Fig. 3), due to the confinement of the latter in the direction perpendicular to the heterojunction plane. Such potential wells are known as *quantum wells* (QWs).

Heterostructures are the elements of many of the most advanced semiconductor devices currently being developed and fabricated. They are essential parts of modern optoelectronic devices, such as semiconductor lasers, light-emitting diodes, and photodetectors with highest performance. Heterostructures are being employed increasingly in high-speed digital and high-frequency analog devices [2,3]. The advantages of heterostructures are that they provide effective control over the states and motions of charge carriers—electrons and holes in active regions of heterostructure-based devices.

Figure 3. Quantum wells for electron and holes (a) and quantum well for electrons only (b) in double heterostructures.

1. HETEROSTRUCTURE BIPOLAR TRANSISTORS

The principle of a bipolar transistor with heterojunctions is old as the transistor itself. A heterostructure (heterojunction) bipolar transistor (HBT) is the first semiconductor device incorporating heterostructures as it has been patented by W. Shockley as early as 1948. HBTs differ from ordinary bipolar transistors by the utilization of a wide-bandgap semiconductor material for the transistor emitter and, in some cases, for the collector, instead of the same material as for the base. In particular, HBTs are formed by a N-p-n heterostructure with a N-p heterojunction serving as the emitter junction, and a p-n junction for the collector. Such HBTs are single-heterostructure bipolar transistors (SHBTs). SHBTs can be made of P-n-p heterostructures as well. Double heterostructure bipolar transistors (DHBT) consists of both the emitter and collector heterojunctions. They have N-p-N or P-n-P structures. Symbols N and P denote the wide-bandgap semiconductor portions doped by donors and acceptors, respectively, while the symbols n and p correspond to the narrow-bandgap regions with related types of doping.

The basic idea of an HBT is as follows. Consider the energy band structure of an N-p-n HBT with an abrupt or graded-emitter heterojunction, as in Fig. 4. The incorporation of the wide-gap emitter leads to the formation of an additional barrier for the carriers in the base (holes in the example under consideration in Fig. 4) inhibiting their escape to the emitter region. This decreases the current of holes injected from the base into the emitter. A figure of merit for an HBT is the ratio of the collector current I_c to the base current I_b :

$$\beta = \frac{I_c}{I_b} < \frac{I_n}{I_p} \equiv \beta_{\max} \tag{1}$$

Here I_n and I_p are the currents of electrons injected from the emitter into the base and holes injected from the base into the emitter. The ratio of the electron and hole currents, that is, the parameter β_{\max} , is given by the following expression

$$\beta_{\max}^{(HBT)} = \frac{N_e v_{nb}}{p_b v_{pe}} \exp\left(\frac{\epsilon_v}{kT}\right) = \beta_{\max}^{(0)} \exp\left(\frac{\epsilon_v}{kT}\right) \tag{2}$$

for HBTs with an abrupt emitter heterojunction and

$$\beta_{\max}^{(HBT)} = \beta_{\max}^{(0)} \exp\left(\frac{\epsilon_v + \epsilon_c}{kT}\right) \tag{3}$$

in the case of HBTs with a graded heterojunction. Here k is the Boltzmann constant, T is the temperature, N_e and p_b are the electron and hole concentrations in the emitter and the base, respectively, v_{nb} and v_{pe} are the mean velocities of electrons and holes in the related regions, ϵ_v and ϵ_c are the band edge discontinuities related to the valence and conduction bands in the case of an abrupt heterojunction. For a graded heterojunction, ϵ_v and ϵ_c are the fractions of the change of the bandgap in the emitter and base regions related to the valence and conduction bands. In

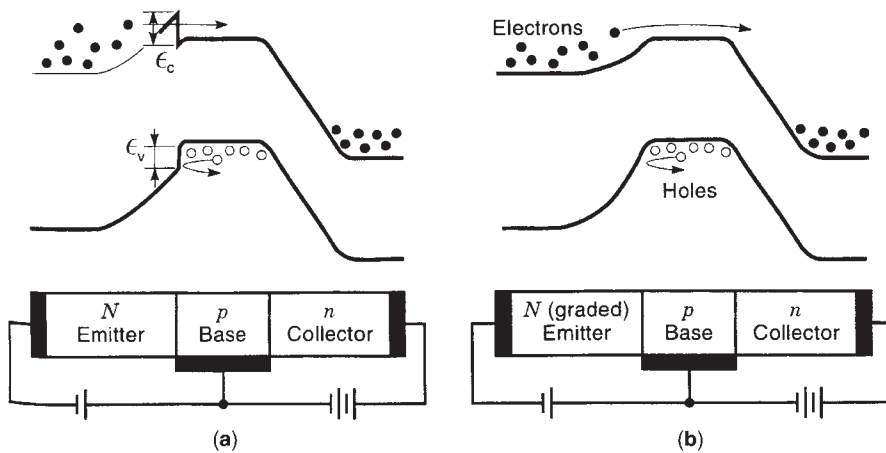

Figure 4. Energy band diagrams of N-p-n HBTs with an abrupt (a) and graded (b) emitter and schematic view of their structure.

the general case $\varepsilon_v + \varepsilon_c = \Delta\varepsilon_g$, where $\Delta\varepsilon_g$ is the difference between the bandgaps in the different parts of the heterostructure. In Eqs. (2) and (3) $\beta_{\max}^{(0)}$ corresponds to a homostructure bipolar transistor ($\varepsilon_v = \varepsilon_c = 0$), with the same doping of all its parts as the HBT under consideration.

For a good transistor, a value β_{\max} should be large. In conventional bipolar transistors the large value of β_{\max} is achieved by significantly higher doping level of the emitter, in comparison to the base ($N_e \gg p_b$). However, very high values of β_{\max} can be realized in HBTs, almost regardless of the doping ratio, due to large value of the exponent in Eqs. (2) and (3). Indeed, if $\Delta\varepsilon_g = 0.2$ eV at $T = 300$ K, one has $\beta_{\max}^{(\text{HBT})} / \beta_{\max}^{(0)} = \exp(\Delta\varepsilon_g / kT) \simeq 3000 \gg 1$. Thus, high β values can be obtained without a high emitter-to-base doping ratio. The increase of the base doping level results in lower base resistance. Simultaneously, a lightly doped emitter region provides smaller capacitance of the emitter. Both high base and low emitter doping promote better high-frequency performance of HBTs, in comparison to homostructure bipolar transistors. This is due to lower base resistance and smaller emitter-base capacitance. High base doping leads to lower noise as well. In addition, high base doping results in higher punch-through voltage.

The conduction band discontinuity in the emitter heterojunction provides the injection of hot electrons from the emitter to the base. If the base is thin enough, the injected electrons can pass it without scattering or enduring a few collisions with impurities and phonons. In the case of such ballistic or near-ballistic transport of electrons in the HBT base, their delay time can be very short. This also contributes to the advantages of HBTs over standard bipolar transistors. Incorporation of the graded-gap base with quasi-electric field yields the acceleration of the injected electrons (or holes) in the base. Such a design provides higher performance as well.

Apart from HBTs with a single heterojunction (usually in the emitter), that is, SHBTs, DHBTs are also considered as prospective components, especially for digital circuits and novel functional devices. The utilization of an additional heterojunction (in the collector) opens up opportunities for separate optimization of the base and the collector—the interchangeability of their functions in some circuits.

The incorporation of more sophisticated heterostructures into the emitter of an HBT or its other parts can substantially extend the diversity of the HBT characteristics. For example, HBTs with a double-barrier heterostructure in the HBT emitter providing resonant-tunneling injection can exhibit N-shape current-voltage characteristics. The utilization of resonant tunneling HBTs (RTHBTs) promises a significant reduction in the logic circuits complexity [4]. HBTs without base contact can be used as phototransistors with very high photoelectric gain, making them rather effective photodetectors for optical fiber communication systems and other applications.

2. HETEROSTRUCTURE HOT-ELECTRON TRANSISTORS

Heterostructure hot-electron transistors (HETs) are made on the base of a double heterojunction structure. Wide-gap regions form the HET emitter and collector. A narrow-bandgap region, sandwiched between the wide-bandgap emitter and collector regions, serves as the HET base. In contrast to HBTs, the HET base is doped by the same type of dopants as the emitter and the collector. Hence HETs are unipolar devices. The energy band diagram of a HET with a N-n-N structure is shown in Fig. 5.

The electron injection from the emitter to the base, and, further, to the collector in HETs with the structure of Fig. 5, is associated with thermionic emission of electrons overcoming the barrier at the N-n interface. Electrons injected from the wide-bandgap emitter have excess kinetic energy in the base. Their motion is directed primarily perpendicular to the heterojunction plane. The directed velocity of electrons significantly exceeds the thermal velocities of both the injected and thermalized electrons in the base. That is why such transistors are called the HETs. The thermalized (or cold) electrons provide electrical neutrality of the base. As the scattering of the injected electrons in the HET base leads to their capture in the latter, and prevents them from the injection into the collector, the electron transport in the base should be either ballistic or near-ballistic.

Different types of HETs have been proposed. The injection of electrons (or holes in P-p-P HETs) from the emitter

Figure 5. Energy band diagram of a N-n-N HET and schematic view of its structure.

can be associated with thermionic or tunneling processes. The energy band diagram of a HET, with tunneling injection of electrons, is shown in Fig. 6.

The main problem connected with the development of high-performance HETs is the tradeoff between the capture rate of hot electrons into the base, which decreases the HET current gain, and the base resistance, which limits high-speed potentials of HETs. The point is that the enhancement of the base doping level necessary for the lowering of the base resistance leads to the increase of the capture probability of hot electrons, due to the reinforcement of their scattering on donors and cold electrons.

In HETs with a thin base, electrons in the latter can be quantized. The quantization of the electron spectrum in the HET base adds an additional complexity to the HET operation. The existence of a bound state in the electron spectrum can result in significant contribution of resonant tunneling processes to the injection of electrons. Further development of the idea of hot-electron transport resulted in the proposal of a HET with a resonant tunneling emit-

Figure 6. Energy band diagram and structure of a HET with tunneling injection of electrons.

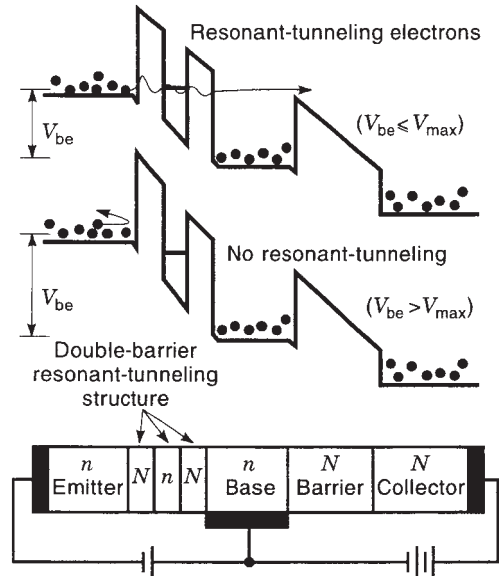

Figure 7. Operational principle and schematic view of the structure of a resonant tunneling HET.

ter. The operation principle of resonant tunneling HETs (RTHETs) is demonstrated in Fig. 7. The most important feature of the RTHET operation is that at some collector-base voltage, the injected electron current has a maximum. The further increase of this voltage leads to a sharp drop of the injected current. Thus, RTHETs are transistors exhibiting negative differential resistance. This property is considered as very promising for future applications in different circuits.

Although HETs of different types are still under investigation, they have no commercial significance, despite very promising features of their characteristics.

3. HETEROSTRUCTURE FIELD-EFFECT TRANSISTORS

Heterostructure field-effect transistors (HFET) are field-effect, three-terminal devices, akin to the metal semiconductor field-effect transistors (MESFETs) with a Schottky gate and metal insulator field-effect transistors (MISFET), taking advantage of electron transport in heterostructure channel. A general name HFET is used for a family of field-effect transistors on the base of different heterostructures. This family includes the modulation-doped field-effect transistor (MODFET), which is also known as the high-electron-mobility transistor (HEMT), the heterostructure insulated-gate field-effect transistor (HIGFET), and some others.

In MODFETs, the wide-bandgap layer beneath the metallic gate is doped, and carriers transfer to the layer of an undoped narrow-gap material. The narrow-bandgap material layer forms the MODFET channel, which is usually undoped. The result of the modulation doping is that electrons (or holes) in the channel are spatially separated from the doped layer. Because of this, they can have extremely high mobility along the heterojunction due to the elimination of impurity scattering. The most common

Figure 8. Cross-sectional view of a MODFET with *n*-channel.

MODFETs utilize $Al_xGa_{1-x}As-GaAs$ heterostructures. A typical view of the MODFET structure cross section is shown in Fig. 8.

Electrons (holes) in the MODFET channel are confined by the heterojunction from one side and by the electric potential creating the electric field, forcing them against the heterointerface. Such confinement of electrons may lead to the quantization of their energy spectrum. If the electron confinement is strong, so that the width of the channel is small enough, electrons form a two-dimensional (2D) electron gas, located near the heterojunction. Sometimes, MODFETs with a 2D electron gas in the channel are called the *two-dimensional electron gas field-effect transistors* (TEGFETs).

The MODFET performance is strictly dependent on the thickness and quality of a very thin undoped layer of a wide-gap material, separating the doped region and the narrow-bandgap channel. This so-called spacer is usually made of $i-Al_xGa_{1-x}As$ (see Fig. 8).

HIGFETs differ from MODFETs, in that both the wide-bandgap and the narrow-bandgap layers are undoped. In some HFETs, the narrow-bandgap channel is doped. Such HFETs lose the advantage of high electron mobility. Their operation is similar to that of MISFETs. Along with the HFETs, in which the channel is formed by a heterojunction and an electrostatic barrier, in some HFETs a double heterostructure is used to form the channel. In the latter case, the HFET channel can be a QW, because of strong electron confinement.

4. HETEROSTRUCTURE LASERS AND LIGHT-EMITTING DIODES

First semiconductor lasers began as homostructure devices comprising a p-n homojunction. Today, semiconductor lasers are usually made of a heterostructure, forming a single or multiple QW. The incorporation of a heterostructure and, especially, a QW in the laser structure provides significant advantages of heterostructure laser diodes (HLDs) over lasers with homojunctions [2,5-7]. The same is true for heterostructure light-emitting diodes (HLEDs) as well. The main of such advantages are much lower threshold current of lasing and higher operational temperatures. The implementation of heterostructures in lasers resulted in the development and wide applications of HLDs operating at room temperature.

The energy band diagrams of HLDs are shown in Fig. 9. The wide-bandgap and N and P regions provide the elec-

Figure 9. Energy band diagrams of HLDs with a narrow-gap active region (a) and narrow-gap active region with a quantum well (b).

tron and hole injection into a narrow-bandgap active region (Fig. 9).

The lasing power is given by the following equation:

$$P = \frac{\hbar\omega}{e}(I - I_{th}) \tag{4}$$

where $\hbar\omega$ is the energy of the lasing photons, \hbar is the reduced Planck constant, ω is the photon angular frequency, e is the electron charge, I is the pumping current, and I_{th} is the threshold current. The latter is defined by the properties of the HLD structure materials, the HLD geometry, quality of the mirrors reflecting generated radiation or reflecting property of the HLD surfaces serving as the mirrors, and so on.

In HLDs with a QW, electrons and holes are captured in the latter and occupy 2D states. Due to the existence of two barriers, there is the electron-hole confinement within a narrow-gap region. So the barriers prevent the leakage of carriers from the HLD active region. It results in higher electron and hole concentrations in the active narrow-bandgap region, in comparison with homostructure lasers at the same values of the injected current. This means that the threshold concentration of electrons and holes sufficient for the change of the absorption coefficient from negative (absorption of photons with the energies close to the energy gap of the active-region material) to positive (amplification) is achieved at lower injected current. As a result, the injected current corresponding to the threshold of lasing (threshold current I_{th}) reduces if a double heterostructure is used. The incorporation of a more narrow-bandgap layer into the HLD active region, which forms a QW, yields an additional improvement in

the laser performance. Smaller density of states in a QW, due to the 2D nature of the latter, leads to their more full occupation by electrons and holes at given value of the injected current. This effect also contributes to the achievement of the lowest possible threshold current I_{th} .

Apart from the electron-hole confinement, HLDs benefit of the confinement of lasing modes, due to the waveguide effect. This effect (termed *optical confinement*) is connected with the larger crystal lattice refraction index of a narrow-gap part of the HLD structure playing a role of the active region. In homostructure lasers, the effect of optical confinement plays some useful role in reducing the diffraction losses of emitted radiation. In such lasers, the optical confinement is associated with the nonuniformity of the electron and hole concentrations near the p-n junction. In HLDs, the optical confinement is much more effective.

The spectrum of radiation emitted by HLDs and HLEDs is determined primarily by the value of the energy gap of the active region material. The energy of the emitting photons $\hbar\omega$ is close to the energy gap of the active-region semiconductor E_g :

$$\hbar\omega \simeq E_g \quad (5)$$

This equation can be rewritten as

$$\lambda \simeq \frac{2\pi\hbar c}{E_g} \quad (6)$$

where λ is the lasing wavelength and c is the velocity of light in vacuum. If E_g is expressed in electronvolts, the lasing wavelength λ in micrometers according to Eq. (6) is given by $\lambda \simeq 1.24/E_g$. For HLDs with a GaAs active region ($E_g = 1.42$ eV) and $\text{Al}_{1-x}\text{Ga}_x\text{As}$ contact regions, one has $\lambda \simeq 0.87$ μm . Utilizing different semiconductor materials, especially binary, ternary, and quaternary compounds, one may fabricate HLDs and HLEDs operating from mid-infrared to blue range of the spectrum. In HLDs with QWs in the active region, the emitted photons are generated due to the transitions from the electron quantum levels to the hole quantum levels in the QWs (see Fig. 9). In such a case, the effective bandgap defining the energy of the lasing photons E_g^{QW} and their wavelength $\lambda \simeq 2\pi\hbar c/E_g^{\text{QW}}$ depend also on the positions of the quantum levels, with respect to the bottom of the conduction and the top of the valence bands in the QWs. One may obtain

$$\hbar\omega \simeq E_g^{\text{QW}} = E_g + \frac{\pi^2\hbar^2}{2w^2} \left(\frac{1}{m_n} + \frac{1}{m_p} \right) \quad (7)$$

where w is the width of the QW and m_n and m_p are the effective masses of electrons and holes, respectively. Growing the HLD structure with appropriate width of the QW in the action region, one may control the lasing wavelength.

HLDs and HLEDs find numerous applications. They are used in consumer electronics, for example, in CD players, optical communications, navigation devices, and other systems. Thanks to the development of HLDs and HLEDs,

operating in relatively long-wavelength range of spectrum from one side, and heterostructure devices, emitting very short-wavelength light (blue light), their applications can be extended to atmosphere monitoring systems, displays, traffic lights, and so on.

5. QUANTUM-WELL PHOTODETECTORS

Conventional photodetectors utilize the transitions of electrons from the valence band ground state to the conduction band excited state. The photocarriers (electrons and holes) created as a result of such interband transitions produce a photocurrent in photodetectors. To create an electron-hole pair, the photon energy $\hbar\omega$ should be greater than the energy gap E_g of a semiconductor material used for a photodetector. By controlling E_g , one may fabricate photodetectors for different ranges of spectrum. It is possible by using a chemical composition chosen in the proper way. For visible or near-infrared ranges of spectrum, A_3B_5 and some other semiconductor materials are used.

Carrier multiplication, which results from impact ionization initiated by electrons and holes generated due to optical interband transitions at high electric fields across the photodetector active region, is used to achieve internal photoelectric gain and, as a result, higher performance. Avalanche photodiodes (APDs), which utilize impact ionization at bias near the breakdown voltage, can be built using both homo- and heterostructures. Two of the crucial performance characteristics of APDs, the gain-bandwidth product and the excess noise arising from the random nature of the avalanche multiplication of electrons and holes, are determined by the electron and hole ionization coefficients and, what is more important, by the ratio of the latter. One approach to achieving low multiplication noise in APDs is the use of heterojunctions to artificially enhance the ionization rate of either electrons or holes. The most successful APD of this type is the APD with a multiple-QW structure. The point is that, for low-noise and high gain-bandwidth product, the ratio of the electron and hole ionization coefficients k should be either large or small ($k \ll 1$ or $k \gg 1$). It means that a large difference in the ionization rates is necessary. As electrons emerge from the wide-bandgap region between the QWs into the narrow-bandgap portion (into the QW), the discontinuity in the conduction band provides sufficient additional energy to initiate ionization. This enhances the ionization rate of electrons. The ionization rate for holes, on the other hand, is not enhanced to the same degree, since the valence band offset is smaller than that of the conduction band [2,8] in many practically important heterostructures.

Heterostructure APDs with QWs are successfully fabricated in $\text{GaAs-Al}_{1-x}\text{Ga}_x\text{As}$ and $\text{InP-In}_{0.53}\text{Ga}_{0.47}\text{As}$ compound material systems, and some others.

To satisfy the condition $\hbar\omega > E_g$ for very important far- and midinfrared ranges of spectrum, corresponding to wavelengths $\lambda = 2\text{--}20$ μm , semiconductor alloys such as $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ are used. There are substantial technological difficulties to grow, process, and fabricate photodetectors made of such materials. The transitions from the impurity states to the conduction or valence band can also

be utilized in photodetectors operating in far and near infrared ranges. However, these photodetectors also have some disadvantages.

Quantum-well intersubband photodetectors (QWIPs), based on semiconductor heterostructures, are considered as a very prospective alternative to both $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ interband photodetectors, as well as impurity photodetectors. QWIPs utilize the intraband electron transitions in the conduction band (in n-type QWIPs) or the intraband hole transitions in the valence band (in p-type QWIPs). By absorbing photons, electrons transfer from the bound states in QWs into states above the barriers between the QWs (continuum states); that is, they transfer between the subbands within a band. Such intersubband transitions result in the occurrence of electrons (holes) in continuum states, where they can freely move, producing a photocurrent. Conventional QWIP consists of a heterostructure with a single or multiple QW, doped either by donors or acceptors. The QW structure is supplied by contact regions of the same type of doping as the QWs. These contacts serve as the QWIP emitter and collector [9]. The conduction band edge profile of the QWIP structure is shown in Fig. 10. Usually QWIPs are made of A_3B_5 or $\text{Si}_{1-x}\text{Ge}_x$ compounds.

QWIPs operate in the range of spectrum, in which the energy of incident photons is sufficient to provide electrons absorbing such photons energy to escape from a QW:

$$\hbar\omega > E_i \quad (8)$$

Here E_i is the ionization energy of the QW, which is the difference between the energy of the barrier top and the bottom of the 2D subband in the QW (see Fig. 10). The ionization energy E_i depends on the depth of the QW, which, in turn, is defined by the difference in the chemical compositions of the barrier and QW materials, and the QW width. Both the depth and width can be easily varied during the QWIP structure growth process, to adjust the range of the sensitivity of the QWIP.

The photoexcited electrons are collected, thereby producing a photocurrent. The escape of electrons from QWs due to their photoexcitation leads to some redistribution of the potential across the QWIP structure and, in turn, to

Figure 10. Conduction band edge profiler of a n-type QWIP under biasing voltage. Arrows show injected, captured, and photoexcited electrons.

the increase of the electric field at the QWIP emitter contact. This results in the injection of extra electrons from the emitter. The current created by the injected electrons can significantly exceed the current produced by the photoexcited electrons, so that QWIPs can exhibit a photoelectric gain. The latter can be markedly greater than unity. The photocurrent in a QWIP is given by the following formula:

$$I_{\text{ph}} = \frac{e\sigma \sum \Phi}{p_c} \quad (9)$$

Here σ is the cross section of the electron photoionization from the QW, Σ is the electron sheet concentration in each QW defined by the sheet concentration of donors, Φ is the photon flux, and p_c is the probability of the electron capture into QWs. It is instructive that the photocurrent according to Eq. (9) does not depend on the number of QWs in the QWIP N . Usually the value p_c is small, so that the photoelectric gain $g = (Np_c)^{-1}$ can be large, even in QWIPs with multiple-QW structure. From Eq. (9), one may obtain the following expression for the QWIP responsivity:

$$R = \frac{e\sigma \Sigma}{p_c \hbar\omega} \quad (10)$$

For a QWIP with typical parameters $\sigma = 2 \times 10^{-15} \text{ cm}^2$, $\Sigma = 10^{12} \text{ cm}^{-2}$, $p_c = 0.01\text{--}0.05$, and $\hbar\omega = 0.1 \text{ eV}$ ($\lambda = 12 \mu\text{m}$), from Eq. (10), one has $R = 0.4$ to 2 A/W .

Relatively simpler and cheaper QWIP technology is not the only advantage making QWIPs potential competitors to standard infrared photodetectors. The QWIP advantages are connected also with their intrinsic high-speed operation and the feasibility of their integration with other A_3B_5 and $\text{Si}_{1-x}\text{Ge}_x$ devices.

Despite the novelty of QWIPs, they already find applications as components for infrared imaging devices with large staring arrays of QWIPs.

6. OTHER HETEROSTRUCTURE DEVICES

Among heterostructure devices not discussed above, there are some others that are considered as very prospective in the future. One may point out the real-space transfer transistors (RSTTs) utilizing the real-space transfer of electrons or holes between two semiconductor materials. The RSTT operation requires a heterostructure in which the semiconductor layer with wider energy gap has much reduced mobility. The $\text{GaAs}\text{--}\text{Al}_{1-x}\text{Ga}_x\text{As}$ heterostructures have been used so far largely for the RSTTs. For detailed discussions on RSTTs, readers are referred to Ref. 4.

Solar cells are also an example of devices in which the utilization of heterostructures provides marked advantages. The advantages of heterostructure solar cells (HSCs) over conventional p-n homojunction SCs are as follows [5]: First, HSCs exhibit enhanced short-wavelength response, if the energy gap of the HSC wide-bandgap layer exceeds the energy of photons to be absorbed inside the depletion region in the narrow-bandgap portion. Apart from this, they have lower series resistance, if the wide-bandgap

region is heavily doped without affecting its transparency. In addition, HSCs can exhibit higher radiation tolerance.

Many of novel devices utilize quantum properties of electrons in heterostructures with QWs. As an example, one may mention resonant tunneling diodes (RTDs) for logic and ultra-high-frequency applications [2,10]. Combining RTDs with HBTs or HFETs allows the fabrication of compact high-speed circuits that operate at room temperature. In the early 1990s, the electron intersubband transitions were utilized for laser generation of midinfrared radiation in QW structures, called *quantum cascade lasers* [11]. The intersubband lasers have many potential applications in the midinfrared range of spectrum.

The integration of heterostructures utilizing both intersubband (intraband) and interband transitions open up additional prospects for the development of new functional QW devices. For example, integrated QWIP-LED devices [12] can be used for effective conversion of far- or midinfrared signals or images into near-infrared or, possibly, visible signals and images. In QWIP-LED devices, their QWIP part, utilizing intersubband electron transitions, serves as an element sensitive to infrared radiation. It produces a photocurrent that, being injected into the LED active region, results in the generation of relatively short-wavelength output radiation, due to radiative recombinations of the injected electrons. High-performance discrete devices and pixelless imagers can be fabricated using integrated QWIP-LED heterostructures.

In QWs electrons or holes are spatially confined in one direction. The energy corresponding to their motion in this direction is quantized, while in other directions it can be considered as classical. Advances in microfabrication technology now permit the building of heterostructures, in which electrons and holes are confined in two or even three directions. In the first case, electrons and holes are confined in a narrow-bandgap semiconductor material region extensive in one direction and buried in a wide-bandgap material. In such heterostructures, usually called *quantum wires* (QWRs), the electron (hole) energy spectrum is characterized by two discrete quantum numbers and one continuous quantum number. The latter is the electron (hole) momentum. Thus, electrons and holes in QWRs are propagating as one-dimensional particles. If the region of a narrow-bandgap semiconductor, material has a form of a small "box" electrons, and holes in the narrow-bandgap box exhibit fully discrete energy spectrum. Small boxes of a narrow-bandgap semiconductor surrounded by a wide-bandgap material with discrete energy spectrum are called the "quantum boxes" or "quantum dots" (QDs). QDs are similar to real atoms, because electrons (holes) in them have discrete energy spectrum as it takes place in atoms. A QD is said to be a zero-dimensional structure. However, sizes of QDs are substantially larger than those of real atoms. This is due to large number of atoms of semiconductor material involved in the formation of a QD. The energy spectrum of a QWR or a QD is defined by the difference in the energy gaps of the QWR or QD material from one side, and surrounding material from another. The most crucial are the QWR or QD sizes. If the QD size is small enough, the QD can have the only one quantum level. Usual size of QWRs (in the direction perpendicular

to the direction of classical electron or hole motion) and QDs is about a few nanometers. Due to energy spectra significantly different from those for conventional heterostructures and even for QWs, the one- and zero-dimensional structures constituting QWRs and QDs are very promising for electronic and optoelectronic devices, especially lasers. More detailed description of the QWR and QD properties, and their possible applications, can be found in Refs. 2 and 13.

HIGH-FIELD EFFECTS

K. HESS
University of Illinois

Electrons and holes contribute to the charge transport in semiconductors, while ordinary charge transport in metals is restricted to electrons only. Another distinctive feature of semiconductor transport is its inherent non-linearity in high electric fields. It is difficult to generate high electric fields in metals because of their high electrical conductivity and the necessity of the presence of high currents according to Ohm's law. In semiconductors, high fields can exist with current densities of the order of 10^5 A/cm², or even much lower, depending on their conductance, which at low temperatures may approach zero. Ryder [1]

and Shockley [2] noticed that semiconductor electron transport was extremely nonlinear in high electric fields. Strong deviations from the proportionality of current density to fields were measured in germanium at room temperature for fields as small as 1000 V/cm.

High-field transport in semiconductors then became an area of considerable research. It was found that the nonlinear behavior (the deviation from Ohm's law) was due to an elevation of the energy of the charge carriers caused by the accelerating force of the electric field. Interactions with the lattice vibrations lower the energy of the charge carriers as Joule heat is transferred to the crystal lattice. However, electric fields always cause a finite rise of charge carrier energy above the equilibrium energy (corresponding to the temperature of the crystal lattice). This excess energy can sometimes also be described by a temperature, the temperature T_c of the charge carriers, which is larger than the temperature T_L of the crystal lattice. One speaks therefore of *hot-carrier transport* in semiconductors.

The rise in charge carrier energy changes the conductance for two reasons. For one, a higher energy gives rise to significant changes in the interactions of the charge carriers with crystal imperfections that form scattering centers. The scattering rate influences the conductance directly. Increases or decreases of this rate lead to decreases or increases of the conductance, respectively. The second reason for variations in conductance with charge carrier energy arise from changes in the $E(\mathbf{k})$ relation. This function gives the connection between the energy E and the wavevector \mathbf{k} of the charge carriers, which corresponds in classical mechanics to the energy-momentum relation. Since conductance is a sensitive function of $\partial E(\mathbf{k})/\partial k$, it changes with the energy of the electrons (or with T_c whenever a temperature of the carriers is well defined).

The most complete existing theory of high-field transport in semiconductors involves the solution of a Boltzmann-type equation [3]. The use of this equation can be justified by invoking the dephasing of quantum coherence over distances that correspond to the feature sizes of semiconductor structures and devices. Consequently, the charge carriers do behave classically and can, in a way, be understood from the principles of classical mechanics. Quantum mechanics has then only a background role and determines, for example, the effective mass or the velocity of the electrons or gives justification for the existence of holes and hole transport. Fermi's "golden rule" of quantum mechanics is used to calculate the scattering rates and thus represents another quantum contribution. It is also easy to include the Pauli principle in such an equation and thus to approach some properties of a Fermi liquid. However, the assumption of weak perturbational interaction of the particles, which is basic to Boltzmann's derivation, must remain true, and indeed is a good approximation for most of the important semiconductor materials.

The basic phenomena of high field transport are nonlinear conductance [3]; changed responses to magnetic fields [4]; changed high-frequency response, including the dielectric function [5]; and changed confinement in potential wells or at heterojunctions between different semiconductors [6].

In semiconductor devices, the high-field effects are based on the same phenomena. For example, in transistors of the field effect family, the electric fields can be as high as 10^5 V/cm², and the corresponding carrier temperatures may reach $T_c = 10^4$ K [7]. Such temperatures cause changes in the conductivity by orders of magnitude (mostly reductions) [3,5]. Remember that T_c is the temperature of the charge carriers and not of the crystal lattice, which would melt at such temperatures. T_L , the temperature of the crystal lattice, can also be raised, but is usually raised orders of magnitude less. This difference is possible because the systems of electrons and crystal lattice are only weakly coupled. Under certain circumstances the conductance can also be raised by hot-electron phenomena, leading to speed advantages in devices (e.g. velocity overshoot phenomena) [8]. Devices made of semiconductor heterojunctions also exhibit various forms of hot-electron transfer (e.g., real-space transfer) between the different materials. These effects often give rise to a device performance degradation, but also can be used advantageously [6].

In the following, a general theory of high-field transport is developed. The next section describes high-field transport in bulk semiconductors (theory and experimental results), and finally an overview of major effects in devices is given.

1. THE BOLTZMANN EQUATION FOR HIGH-FIELD SEMICONDUCTOR TRANSPORT

The following is a top-down approach to the theory of high-field phenomena. The next section derives a modern Boltzmann equation including the most important quantum effects as derived from the energy band structure. The relevance of the various terms of this equation to hot-electron phenomena are discussed and general ways to obtain solutions are briefly reviewed and referenced. Subsequently a more phenomenological discussion and analytical approximation of several high-field effects is given.

1.1. Derivation of a Modern Boltzmann Equation

The Boltzmann equation derived here is more general than the original equation derived by Boltzmann. The only cases of weakly interacting charge carriers in solids that cannot be understood from this modified equation are those that involve macroscopic feature sizes (e.g., device boundaries) that are smaller than the quantum dephasing length under the given conditions. This dephasing length in silicon at room temperature is of the order of several hundred angstroms, but can be much smaller in high electric fields, approaching 20 Å for electron energies of about 1.5 eV. This means that for conventional devices operating with high fields, hot-electron transport can be understood extremely well with the theory developed below even if the feature sizes are below 100 Å. Quantum effects such as tunneling can often be added to this theory by the Bardeen transfer Hamiltonian formalism [3,9].

The following derivation lacks complete mathematical rigor but is valid under widely varying circumstances. For example, we need not assume conservation of the number

of particles, which is important in that electrons and holes can annihilate each other or can be created by light. We follow Boltzmann, but replace the velocity in seven-dimensional phase space by the wavevector \mathbf{k} in the definition of a distribution function $f(\mathbf{k}, \mathbf{r}, t)$, meaning as usual the probability of finding charge carriers at \mathbf{k}, \mathbf{r} and at time t in the volume elements $d\mathbf{k}, d\mathbf{r}, dt$. Consider then a cube in \mathbf{r} space and in \mathbf{k} space as shown in Fig. 1.

We first calculate how many electrons arrive from the left and enter the cube through the left dy - dz plane, and how many leave at the corresponding plane on the right, all during a time period dt . Since the x -direction travel distance of electrons with velocity \mathbf{v} is $v_x dt$, we have

$$\text{Incoming : } f(\mathbf{k}, \mathbf{r}, t) d\mathbf{k} dy dz v_x dt \tag{1}$$

$$\text{Outgoing : } f(\mathbf{k}, (x + dx, y, z), t) d\mathbf{k} dy dz v_x dt \tag{2}$$

and the net particle gain is

$$\begin{aligned} & -v_x [f(\mathbf{k}, (x + dx, y, z), t) - f(\mathbf{k}, \mathbf{r}, t)] dy dz d\mathbf{k} dt \\ &= -v_x \frac{\partial f}{\partial x} dx dy dz d\mathbf{k} dt \\ &= -\mathbf{v} \cdot \nabla f d\mathbf{k} d\mathbf{r} dt \end{aligned} \tag{3}$$

in three dimensions. Note that the velocity \mathbf{v} here is equal to the group velocity and is related to \mathbf{k} by $\mathbf{v} = \nabla_{\mathbf{k}} E(\mathbf{k})/\hbar$ (3).

Figure 1. Cubes in (a) \mathbf{r} space and (b) \mathbf{k} space to illustrate the balance of incoming (e.g., into the y - z face) and outgoing (e.g., at $x + dx$) electrons (or change carriers in general). The changes in \mathbf{r} space are due to carrier velocity, those in \mathbf{k} space due to acceleration by a force.

This balance depends on the velocity and \mathbf{k} vector of the electrons and therefore on how “hot” the electrons are. It also describes diffusion, since concentration gradients enter this term. The relation between diffusion and electron heating is actually a complicated one and will be discussed below phenomenologically.

In an analogous manner, we obtain the change of the number of electrons at \mathbf{k} in \mathbf{k} space because of accelerations. Replacing dx by dk_x and so on as illustrated in Fig. 1, and replacing $dx/dt = v_x$ as used in Eq. (1) by dk_x/dt , one gets

$$-\frac{d\mathbf{k}}{dt} \cdot \nabla_{\mathbf{k}} f d\mathbf{k} d\mathbf{r} dt \tag{4}$$

where $d\hbar/dt = -e\mathbf{F}$ (3) and \mathbf{F} is the electric field. This term represents the major energy supply to the electrons and therefore the root cause of the heating and hot-electron effects.

There is still another possibility to change the number of electrons with wavevector \mathbf{k} at \mathbf{r} . The electrons can be scattered and change their wavevector from \mathbf{k} to \mathbf{k}' at a given point \mathbf{r} in real space. Figure 2 shows the two infinitesimal volumes in \mathbf{k} space to illustrate the scattering events. The outgoing (out of state \mathbf{k}) electrons are

$$\text{out} = -\sum_{\mathbf{k}'} S(\mathbf{k}, \mathbf{k}') f(\mathbf{k}, \mathbf{r}, t) d\mathbf{k} d\mathbf{r} dt \tag{5}$$

The factor $f(\mathbf{k}, \mathbf{r}, t)$ is necessary because an electron has first to be in the \mathbf{k} state to be scattered out. In degenerate systems (Fermi statistics), an additional factor $1 - f(\mathbf{k}', \mathbf{r}, t)$ arises from the Pauli principle. The incoming (into the \mathbf{k} state) electrons are

$$\text{in} = \sum_{\mathbf{k}'} S(\mathbf{k}', \mathbf{k}) f(\mathbf{k}', \mathbf{r}, t) d\mathbf{k} d\mathbf{r} dt \tag{6}$$

Again, the Pauli principle will call for a factor $1 - f(\mathbf{k}, \mathbf{r}, t)$. The in and out scatterings lead to a (more or less) random distribution of the \mathbf{k} vector. The energy gained from the

Figure 2. Schematic of a scattering process. The charge carrier scatters from a volume $dk_x dk_y dk_z$ at \mathbf{k} to another such volume at \mathbf{k}' .

field is therefore distributed in \mathbf{k} space and thus receives a random temperaturelike component. The interaction with lattice vibrations is inelastic and also changes the energy (magnitude of \mathbf{k}). This energy loss represents Joule heat and determines, together with the force, the actual average electron energy (temperature).

The Boltzmann equation describes all of these heating-cooling dynamics and is obtained by balancing the particle numbers and the change in f given by the net change of incoming and outgoing particles. Therefore, we have

$$\begin{aligned} \frac{\partial f(\mathbf{k}, \mathbf{r}, t)}{\partial t} = & -\mathbf{v} \cdot \nabla f(\mathbf{k}, \mathbf{r}, t) - \frac{1}{\hbar} \mathbf{F}_0 \cdot \nabla_{\mathbf{k}} f(\mathbf{k}, \mathbf{r}, t) \\ & + \sum_{\mathbf{k}'} [f(\mathbf{k}', \mathbf{r}, t)S(\mathbf{k}', \mathbf{k}) - f(\mathbf{k}, \mathbf{r}, t)S(\mathbf{k}, \mathbf{k}')] \end{aligned} \quad (7)$$

where \mathbf{F}_0 is the force ($-e\mathbf{F}$ for an electric field \mathbf{F}).

If we include the factors arising from the Pauli principle as discussed above, we arrive at

$$\begin{aligned} \frac{\partial f(\mathbf{k}, \mathbf{r}, t)}{\partial t} = & -\frac{1}{\hbar} \nabla_{\mathbf{k}} E(\mathbf{k}) \cdot \nabla f(\mathbf{k}, \mathbf{r}, t) - \frac{1}{\hbar} \mathbf{F}_0 \cdot \nabla_{\mathbf{k}} f(\mathbf{k}, \mathbf{r}, t) \\ & + \sum_{\mathbf{k}'} \{f(\mathbf{k}', \mathbf{r}, t)[1 - f(\mathbf{k}, \mathbf{r}, t)]S(\mathbf{k}', \mathbf{k}) \\ & - f(\mathbf{k}, \mathbf{r}, t)[1 - f(\mathbf{k}', \mathbf{r}, t)]S(\mathbf{k}, \mathbf{k}')\} \end{aligned} \quad (8)$$

This equation is very general and includes automatically, for example, effects of the energy band structure as described by $E(\mathbf{k})$. Of course, it describes transport in one band only [3]. The functional form of this band, however, can be arbitrary. Effects of strain in the solid, for example, need only be included in the band structure and then are automatically taken into account in the distribution function f once the Boltzmann equation is solved. From the distribution function, one can in turn obtain macroscopic quantities such as the electronic current in the usual prescribed way.

To summarize, all terms of this equation have special significance for hot-electron effects. The second term on the right-hand side (RHS) of Eq. (8) represents the driving force, the electric field \mathbf{F} , and signifies the heating of the electrons. The third term on the RHS describes the scattering and how momentum and energy are distributed. This term signifies the influence of hot electrons on the classical conductivity. Electrons are scattered out of a given range of the wavevector \mathbf{k} or scattered into that range from all other possible values of \mathbf{k} , denoted by \mathbf{k}' . This scattering term makes the Boltzmann equation an integrodifferential equation. Therefore, to solve it, one needs a tenfold integral over time, space \mathbf{r} , and \mathbf{k} , as well as \mathbf{k}' . The tenfold numerical integration can probably be done best by Monte Carlo methods, although approximations in lower dimensions may permit the use of computationally more efficient numerics. The first term on the RHS represents space-dependent effects such as diffusion and indicates that the hot-electron diffusion not only is dependent on the heating of the electrons but in turn influences the heating. This term is relevant to the question of how the force heats the electrons. For example, a confining force

that does not give rise to a current (as, e.g., at a potential minimum) may not heat the electrons, since for this case the accelerating drift (second term on RHS) and diffusion (first term on RHS) can cancel exactly [3,10,11].

The energy band structure enters the Boltzmann equation through the $E(\mathbf{k})$ relation in the first term on the RHS. It also enters indirectly through the sum over \mathbf{k} , since this sum includes the density of states. Finally, if one wants to calculate a current, one needs to integrate the product of velocity and distribution function over all \mathbf{k} space, where the velocity is given by $\mathbf{v} = \nabla_{\mathbf{k}} E(\mathbf{k})/\hbar$.

A full solution of the Boltzmann equation as derived above does describe all hot-electron phenomena currently known in semiconductors. It can be and has been achieved numerically in bulk semiconductors [12] and in devices [13]. We refer the reader to these references and to software and explanations available on Websites [14]. Here we continue with discussions of important experimental results in terms of approximate concepts and solutions.

1.2. Approximate Solutions of the Boltzmann Equation and Hot Electrons

Since the Boltzmann equation is an integrodifferential equation, precise and explicit solutions can be found only under very special circumstances. The best-known example is the time-independent solution for homogeneous systems (no space-dependent terms) in the relaxation-time approximation. Under the assumption of weak forces (electric fields), one can write the distribution function as a sum of a function f_0 that is even in the wavevector \mathbf{k} and an odd function f_1 . Assuming that the Pauli terms are negligible, as they are for not too high carrier concentrations, the whole collision integral of Eq. (8) reduces to

$$\text{Collision integral} = f_1/\tau_{\text{tot}} \quad (9)$$

with

$$\frac{1}{\tau_{\text{tot}}} = \sum_{\mathbf{k}'} S(\mathbf{k}, \mathbf{k}') \quad (10)$$

and f_0 is equal to the equilibrium Boltzmann distribution given by

$$f_0 = \exp(E_{\text{F}}/kT_{\text{L}}) \exp(-E/kT_{\text{L}}) \quad (11)$$

The odd part of the distribution function that determines the electric current is then

$$f_1 = -\tau_{\text{tot}} \frac{\mathbf{F}_0}{\hbar} \cdot \nabla_{\mathbf{k}} e^{(E_{\text{F}}-E)/kT} \quad (12)$$

where E_{F} is the Fermi level. The electric current density j is then obtained from

$$j = -\frac{e}{4\pi^3} \int \mathbf{v} f_1 d\mathbf{k} \quad (13)$$

The high field or hot-electron term is neglected in this approach, which describes only low fields and ohmic

behavior. The reason is the approximation of f_0 by the equilibrium distribution. To allow for high electric fields, one needs to solve the full Boltzmann equation or at least the coupled equations resulting for both f_0 and f_1 in the relaxation-time approximation. As described above, the force accelerates the electrons (holes), and the scattering randomizes, thus causing f_0 to contain more energetic electrons and therefore changing its form away from the equilibrium.

As mentioned, the complete solution of Eq. (8) has been achieved by so-called Monte Carlo methods, which are related to the Monte Carlo integration known from numerical mathematics [3,5]. These solutions have been described at length in the literature and form a vast field [5,12–14].

Approximate solutions of the Boltzmann equation for high electric fields are also well known. Of particular importance is the electron temperature approximation, which is described in the next section together with typical experimental results for high field transport in bulk (homogeneous) semiconductors.

2. HOT-ELECTRON EFFECTS IN SEMICONDUCTORS AND APPROXIMATE THEORY

2.1. Electron Temperature and Scattering Rate

A first glimpse of how important hot electrons would be in semiconductor transport was given by the work of Shockley (1951) [2] and Ryder (1953) [1], who found a saturation of the electron current in germanium at electric fields around 1000 V/cm as shown in Fig. 3. This current saturation is basic to hot-electron phenomena and has been shown to arise from the increase of average electron energy $\langle E \rangle$. Under certain assumptions that are approximately satisfied in n-type silicon and germanium for intermediate electric fields [3], one can represent the average energy by a temperature T_c , which, for not too high electron densities, can be approximated

by a Boltzmann-type formula

$$\langle E \rangle = \frac{3}{2} k_B T_c \quad (14)$$

where k_B is Boltzmann's constant. The actual solution of the Boltzmann equation to arrive at the electron temperature concept is involved, and the reader is referred to Ref. 3 for detailed information.

An approximate formula for T_c is [3]

$$T_c \approx T_L \left[1 + \left(\frac{F}{F_c} \right)^2 \right] \quad (15)$$

F_c is a critical electric field that is around 10^4 V/cm for silicon at room temperature. The carrier temperature T_c can therefore become extremely high. For example, at the field $F = 2 \times 10^4$ V/cm, which can easily be reached and indeed is routinely reached in modern transistors, we have $T_c = 1500$ K for $T_L = 300$ K. Such temperatures have indeed been measured by various methods that can sense the electron energy inside the semiconductor [15]. An outside touch does not reveal a temperature increase of the electrons because of the large workfunction that the electrons would need to overcome in order to propagate out of the semiconductor [16]. Equation (11) is not valid for electric fields much higher than 3×10^4 V/cm for silicon because of band structure effects such as non-parabolicity [5]. For very high fields, a full-band Monte Carlo approach is again necessary to calculate the average energy and distribution functions of the electrons reliably.

The rise of the electron temperature (or energy) causes a change in the scattering rate that enters the mobility μ of the charge carriers and therefore the conductivity $\sigma = en\mu$ (n being the carrier concentration). The mobility derives from the relaxation time as defined in Eq. (10) if the scattering in randomizing (independent of the wavevector). Otherwise τ_{tot} needs to be replaced by the so-called momentum relaxation time [3]. This relaxation time usually exhibits a significant energy dependence. For phonon scattering it decreases typically with increasing energy, while for scattering by weakly screened Coulomb charges it increases. The mobility μ is proportional to a weighted energy average of the relaxation time, and the conductivity therefore increases or decreases proportionally.

A typical dependence of the mobility on the electron temperature is then (for the case of scattering by phonons) [3]

$$\mu \approx \mu_0 \left(\frac{T_L}{T_c} \right)^{1/2} \quad (16)$$

where μ_0 is the mobility at zero electric field, that is, for $T_L = T_c$. Using, then, the equation for the current density of a homogeneous semiconductor, $j = en\mu$, one gets from Eqs. (16) and (15)

$$j = en\mu_0 \left(\frac{F}{1 + (F/F_c)^2} \right)^{1/2} \quad (17)$$

Figure 3. Current density (or drift velocity) versus electric field in bulk n-type germanium for three temperatures (as indicated). Notice the saturation at electric fields above 10^3 V/cm. (After Ref. 1.) Reprinted with permission, © 1953 by the American Physical Society.

This equation shows immediately the essential feature of current saturation (nonlinear transport) at high electric fields and is quite general. For example, the square root in Eq. (16) derives from the density of states. Equation (17) is valid even for a more general density of states; it can be proved easily for any density of states that is proportional to E^p for any $p > 0$. The dependence of the electron phonon scattering rate on the density of states is illustrated in Fig. 9. Note, however, that in devices other scattering mechanisms such as surface roughness scattering are of great importance. Some of these mechanisms are reviewed in Ref. 16.

2.2. Effects of Band Structure and the Gunn Effect

The derivation of Eq. (17) contains only changes in the scattering rate with carrier temperature. As mentioned above, however, the band structure influences not only the scattering rate (via the density of states) but also the velocity v of the electrons, since in the one-band approximation we have [3]

$$\mathbf{v} = \frac{1}{\hbar} \nabla_{\mathbf{k}} E(\mathbf{k}) \quad (18)$$

For the typical band structure of some III–V compounds, this leads to pronounced effects in the current–voltage characteristics. For GaAs, the effective mass is small at low energies ($m^* = 0.067m_0$) and $E(\mathbf{k}) = \hbar^2 k^2 / 2m^*$. Correspondingly, the velocity of electrons becomes very high at moderate energies. However, the band structure changes drastically only 0.3 eV above the conduction band edge, exhibiting there additional minima with much higher effective mass (close to the germanium type conduction), and above 0.5 eV, even higher effective masses (close to the silicon conduction mass). In simple terms, GaAs contains three “highways,” each one becoming available as the energy increases and each one exhibiting higher mass. If the electrons are heated by electric fields, they initially are on the fastest highway, exhibiting a high mobility and conductance. At higher fields they are heated enough to transfer to the germanium like conduction band minimum (highway 2) and at still higher fields to the siliconlike minimum (highway 3). This decreases their speed so drastically that GaAs actually shows a range of negative differential resistance, that is, the current drops as the electric field is increased. This phenomenon leads to the Gunn effect, which manifests itself by high-frequency current oscillations, since the situation of negative differential resistance is not stable [7]. These phenomena have received considerable attention, and a large framework of research exists [7,18].

The current–field characteristic of GaAs is shown in Fig. 4 and compared with the characteristics of silicon (both for electron transport). It is evident that the low-field current behavior of GaAs transforms into silicon like behavior at high electric fields, with a region of negative differential resistance in between. The reader is referred to the literature [3,5,7] for more information.

A word of caution should be added here. There is a lack of direct experimental verification of band structure and

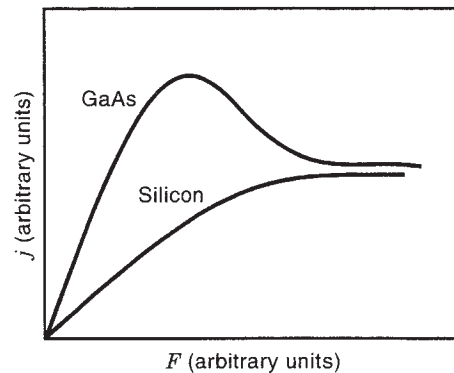

Figure 4. Schematic of current density versus electric field for homogeneous (bulk) GaAs and silicon. Notice the negative differential resistance of GaAs (which leads to instabilities [7] and inhomogeneities of the carrier density). Also note that at very high fields the GaAs and silicon curves approach each other. Depending on temperature and electric field, they can even cross. However, they are always close at very high fields.

related semiconductor parameters for high-field transport. Optical measurements and femtosecond spectroscopy [19] do give detailed information on the density of states.

2.3. Real-Space Transfer

The negative differential resistance of GaAs and the Gunn effect are determined mostly by the structure of the $E(\mathbf{k})$ relation, that is, by effects in \mathbf{k} space. The terms of the Boltzmann equation signifying real-space operations have not been discussed yet. From the discussions following Eq. (8) it is clear, however, that real-space effects complicate hot-electron transport significantly. The prime reason for this complication is the real-space transfer effect [6], which is described here.

The transfer of electrons between two different solids is known from Bethe’s thermionic emission theory [3]. This type of transport includes only electric fields perpendicular to the different layers of semiconductors. However, electric fields parallel to semiconductors can energize the charge carriers (hot-electron effect) and lead to a redistribution of them in the different layers that depends sensitively on the difference of the conduction band edges of the various materials. (Readers not used to solid-state concepts should think of the conduction band edge as the minimum kinetic energy of conduction electrons, which is different in different materials, the electrons thus having different potential energy in each material.) The effect of redistribution of electrons or holes due to electric fields parallel to different layers of semiconductors is called *real-space transfer* (RST) and is shown schematically in Fig. 5. This transfer of electrons (heated by parallel fields) over barriers is more complicated and more difficult to understand than other effects basic to nonlinear semiconductor transport and device operation. The reason is that RST can be visualized only the combination of two concepts related to the energy distribution of electrons. The first concept is that of quasi-Fermi levels [3], and the second is the concept of a charge carrier temperature T_c as already

Figure 5. Electrons in a material with lower conduction band edge (e.g., GaAs) neighboring two layers with higher conduction band edge (e.g., AlAs) accelerated by a force F_0 . The electrons gain energy and are scattered and then transfer out of the central material layer, thus exhibiting real-space transfer.

discussed above. For RST problems, both concepts matter, and both the carrier temperature and the quasi-Fermi levels are a function of space coordinate and time.

Imagine, for example, electrons residing in a layer of high-mobility GaAs neighboring, on either side, two layers of low-mobility AlAs (Fig. 5). The GaAs equilibrium distribution function f_0 is

$$f_0 = \exp(-E/kT_L) \quad (19)$$

while in the AlGaAs we have

$$f_0 \propto \exp\left(-\frac{\Delta E_c + E}{kT_L}\right) \quad (20)$$

Here the energy is measured from the GaAs conduction band edge, and ∇E_c is the band edge discontinuity between AlAs and GaAs.

If now the electrons are heated by an external field parallel to the layers, we have to replace T_L in Eqs. (19) and (20) by a space-dependent carrier temperature T_c . It is clear that for $T_c \rightarrow \infty$ the difference between the AlAs and the GaAs population densities vanishes. In other words, the electrons will spread out into the AlAs layers. This also means that even perpendicular to the layers (z direction) a constant Fermi level cannot exist, and E_F has to be replaced by the quasi-Fermi level $E_{QF}(z)$ as the density of electrons becomes a function of $T_c(z)$. This is unusual, since commonly the quasi-Fermi levels differ only in the direction of the applied external voltage V_{ext} (by the amount eV_{ext}). In the present case, a voltage is applied parallel to the layers, the electrons redistribute themselves perpendicularly to the layers, and a field (and voltage perpendicular to the layers) develops owing to the carrier redistribution. Basic to the calculation of this process are the thermionic emission currents [3] of hot electrons from one layer to the other. Since the external voltage is applied parallel to the layers, we have in steady state a precise balance of currents flowing from left to right and right to left, which determines the z -dependent carrier population.

A complication of the theory is presented by the necessity (in most cases) of having to solve Poisson's equation as charge is transferred. For typical parameters of the GaAs-AlAs material system and electric fields of the order of 10^3 to 10^4 V/cm parallel to the layers, one obtains time

constants of the order of picoseconds for the transfer, which gives the RST effect importance for device applications (RST transistors as developed by [6]).

The real-space transfer effect is also of general importance in all situations when electrons are confined in potential wells and parallel fields are applied (and accelerate the charge carriers), even if the electrons do not propagate out of the wells but merely redistribute themselves within each well. This is of relevance for the understanding of the influence of transverse fields (such as the gate field) in a transistor [10]. The RST effect and the spreading of the electrons are then determined by the transverse field. The quantum analog of this classical picture is the redistribution of hot electrons in the different quantized subbands of a quantum well.

2.4. Time Dependences, Velocity Overshoot, and Ballistic Transport

As complex as the considerations of nonlinear transport in \mathbf{r} space and \mathbf{k} space are already, time dependences add to the richness of hot-electron effects. All the discussions above were essentially valid for the steady state only. On short timescales, however, the mode of transport changes its type because of transitions from the ballistic to the overshoot regime and to diffusive transport.

Diffusive transport is the well-known mode for which the mobility is proportional to the average of τ_{tot} . This proportionality implies the validity of the Boltzmann equation, which, as discussed at the beginning, involves the dephasing of the wave function. For times much shorter than τ_{tot} , the transport is essentially *ballistic*, which means that in crystalline semiconductors the accelerations are described by the equation

$$\hbar \frac{d\mathbf{k}}{dt} = -e\mathbf{F} \quad (21)$$

where \mathbf{F} is the electric field and $\hbar\mathbf{k}$ is the crystal momentum. This equation becomes invalid at extremely short times, as described in Ref. 20, but is applicable under most circumstances. Neglecting the basic thermal motion of the electrons (due to T_L), this means that all electrons are accelerated in the direction of the force and gain speed according to Eqs. (18) and (21). Since all electrons move in the same direction, the average velocity is very large compared to the thermal case where electrons move in all directions and have just a small average drift velocity on top of the thermal motion. In high electric fields, and with high values of T_c , the thermal velocity (pointing randomly in all directions) can be as high as 10^8 cm/s, while the saturated drift velocity is (in silicon) a factor of 10 below this value. A visualization of these facts is given in Fig. 6.

The range between the high-velocity ballistic transport and the low-velocity diffusive transport is called the range of velocity overshoot. Imagine transport in a semiconductor switched on at time $t_0 = 0$ by application of a high field F . The electrons are then accelerated ballistically for about 100 fs and may reach a velocity well above 10^7 cm/s (the value of the saturated velocity in silicon and other important semiconductors). Then, as time goes on, scattering

Figure 6. Schematic of the development of average drift velocity versus time, assuming that a high electric field F is suddenly applied at $t=0$. The electrons are accelerated to high velocities and high average drift velocities. Their random velocity (indicated by arrows pointing in all directions) is at first small but is steadily increased because of randomizing scattering. At a certain point the average drift velocity approaches a maximum. From here on the random component of the velocity increases because of the very strong scattering at the high energies that the charge carriers now have, and the average drift velocity decreases. Finally, steady state is reached, where the scatterings and accelerations balance each other. The large random arrows indicate then a high electron temperature, and the drift velocity is saturated (at 10^7 cm/s in silicon).

events randomize the velocity to all directions, which leads, typically after a picosecond or so, to the saturated average velocity. At the times in between, the velocity is higher and exhibits the overshoot. In GaAs these effects are accentuated by the changes in effective mass at high energy, and the overshoot can be considerable [8]. This is shown in Fig. 7.

A similar effect is also achieved for transport in short semiconductor sections sandwiched in between contacts. As soon as the electrons enter the semiconductor from the contact, they are accelerated by high electric fields into the overshoot or even the ballistic regime and leave the semiconductor, entering the second contact, before scattering can randomize their motion. Thus the velocity in short semiconductor diodes can overshoot the saturated value (now for all times), which in some devices gives a speed advantage [22].

2.5. Changes of Carrier Concentration and Hot Electrons: Impact Ionization

Up to now, all the conductivity changes we have discussed have arisen from changes in the carrier velocity and a redistribution of charge carriers in energy. The total number of electrons or holes was not affected by hot-electron effects. There exists, however, an important phenomenon that causes considerable changes of conductance because of changes in the total number of charge carriers. This is the occurrence of impact ionization, the exact inverse of the Auger effect [3]. A heated electron in the conduction band (the same can be argued for holes) gains energy from the applied electric field and collides with an electron in the valence band, lifting this electron up to the conduction band, with the net result of two conduction electrons

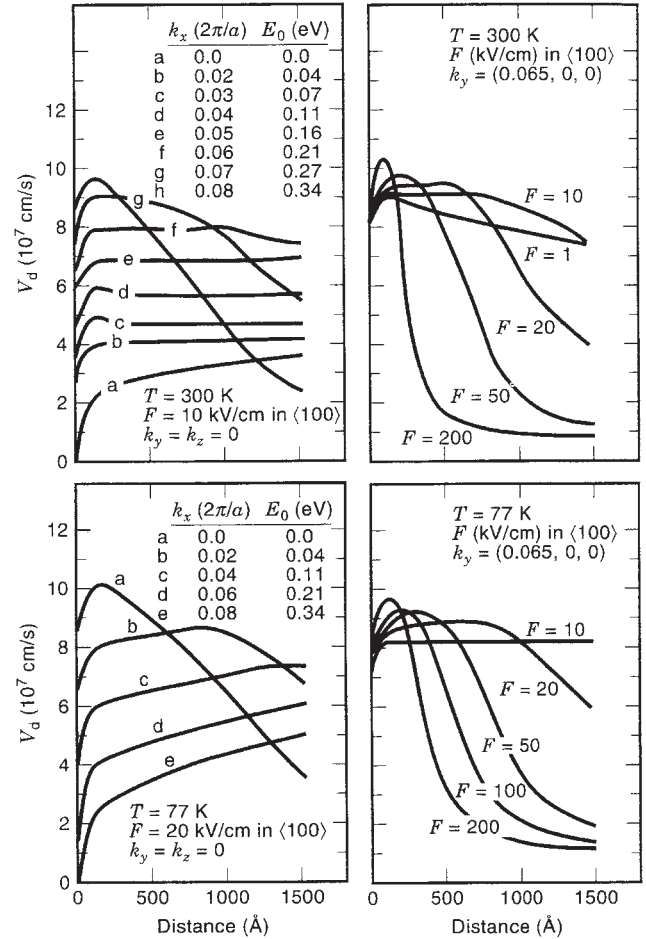

Figure 7. Overshoot of electrons injected with certain wavevectors k_x in the x direction and with certain energies E_0 into GaAs. A field F subsequently accelerates them and leads to velocity overshoot (19).

and a hole. The primary electron and the secondary electron plus hole all now contribute to the conduction, and the electronic current density \mathbf{j} therefore increases with time according to the equation

$$\frac{d\mathbf{j}}{dt} = \alpha_t \mathbf{j} \quad (22)$$

This increase of current with time also gives rise to a spatial increase of the current as

$$\nabla \cdot \mathbf{j} = \alpha_r \mathbf{j} \quad (23)$$

The coefficient α_r is in general a matrix. However, for a constant electric field impact ionization is mostly isotropic and α_r is a scalar [12,23].

We will concentrate, in the following on the theory of α_t . The theory of α_r proceeds very similarly, and one can almost always use $\alpha_t v_d = \alpha_r$, where v_d is the average (drift) velocity of the electrons. The multiplication of electrons (and holes) with time depends physically on two quantities. One is the actual ionization probability, that is, the probability for an electron with given energy to create an

electron-hole pair. This probability per unit time is called the impact ionization rate R_I . The second quantity is the actual probability of having such an electron at a given energy, which is, of course, given by the distribution function. α_t is then the average product of these two probabilities.

$$\alpha_t = \frac{\int_{-\infty}^{\infty} dk R_I f}{\int_{-\infty}^{\infty} dk f} \quad (24)$$

The calculation of R_I involves the quantum mechanics of three particles (two electrons, one hole) in two different bands (conduction and valence) with different (Bloch) wavefunctions and $E(\mathbf{k})$ relations. Even using the approximate "golden rule" of time-dependent perturbation theory involves then a difficult numerical simulation with multiple integrations. Most of the theories of the past are therefore oversimplified and of very limited use, including the formula derived by Keldysh [24]. The only theory in reasonably close agreement with experiments is the Monte Carlo integration of the "golden rule" formulae by Kane [25], the result of which is shown in Fig. 8.

An even greater numerical problem is the calculation of the distribution function entering Eq. (24). The reason is that R_I starts to become appreciably large only at relatively high energies, as shown in Fig. 8. Typically, in silicon, ionization becomes important only for electron energies of 3 eV above the conduction band edge. If this were the average electron energy, it would correspond to a temperature of 24,000 K, which is seldom reached before catastrophic damage occurs. Therefore it is the high-energy

Figure 8. Impact ionization rate α_t (multiplied by \hbar) as a function of conduction electron energy according to the theory of Kane [25]. (Reprinted with permission, © 1967 by the American Physical Society.)

Figure 9. Electron energy distribution as a function of electron energy (in the conduction band), according to Ref. 24, for various constant electric fields. Also shown is the electron-phonon scattering.

tail of the distribution function that matters for impact ionization. This high-energy tail depends sensitively on the band structure and also on spatial and temporal changes of the electric field and can be reliably obtained only from a full-band solution of the Boltzmann equation such as the full-band Monte Carlo [12]. An example of the distribution at high energies is given in Fig. 9 for a constant electric field. Figure 9 also shows the phonon scattering rate in silicon at room temperature as a function of conduction band energies. Note that this rate becomes of the order of 10^{14} s^{-1} at energies above 1.5 eV.

A discussion of all of these complexities and the corresponding results for α_r are given in Refs. 15 and 27. The best results are obtained for theories of R_I à la Kane and

Figure 10. Theoretical electron impact ionization coefficients α_r versus $1/F$ for constant electric fields F and various materials after Bude and Hess [28]. Solid line—GaAs; dashed line—InAs; dotted-dashed line—InP; dotted line— $\text{Ga}_{0.43}\text{In}_{0.57}\text{As}$. The electron ionization coefficient for silicon is roughly a factor of 2 above the coefficient of GaAs. The hole ionization coefficients of GaAs and InP are close to the electron ionization coefficients, while the hole ionization coefficient for silicon is much below the curve for electrons (factors of > 10). (Reprinted with permission, © 1992 by the American Physical Society.)

for distributions from full-band Monte Carlo integrations of the Boltzmann equation (25). Typical theoretical results of α_r are shown in Fig. 10.

The presence of layers of different semiconductors, as occurs in quantum-well structures and superlattices, adds another dimension to the science and engineering of impact ionization and has been discussed extensively in the literature. Examples are given in Refs. 29 and 30.

A simplified approach of great usefulness and parametrized expressions for α_r have been derived by Baraff and others using his theory [7,31]. These are excellent for estimates and for an appreciation of contributory physical parameters. Note, however, that all the simplified analytical expressions given in most textbooks for the threshold, phonon scattering mean free path, and other parameters are quantitatively incorrect and cannot replace the integration of Boltzmann's equation, including the band structure.

3. HOT ELECTRONS IN DEVICES

The special status of hot electrons in semiconductor devices arises from the time and space dependences of electric field and carrier concentrations. These dependences require special care in the theory of average velocity (overshoot, real-space transfer, and transport including abrupt interfaces) and impact ionization. The nonlocality of these effects deserves special attention [32]. Consistency with Gauss law also needs to be satisfied. In fact, numerical solutions of Poisson's equation are a fixed part of any predictive device simulation. The field of hot electrons in devices is therefore a vast one and cannot be reviewed within this limited space. For a general appreciation the reader is referred to discussions of Gunn devices, IMPATT diodes, hot-electron diodes and transistors, real-space transfer devices, and avalanche photodiodes in Ref. 18. All of these devices are based on hot-electron effects. Many of the most important devices, such as metal-oxide-semiconductor field-effect transistors (MOSFETs), involve hot electrons in their operation. Often, hot electrons are felt to cause great disadvantage because they reduce speed (current and velocity saturation), lead to degradation and aging of devices [33], and can cause various instabilities (e.g., through negative differential resistance). However, there are two counts in favor of hot electrons in devices that have led to the continual involvement of hot electrons in chip technology. For one, hot electrons lead to a large scattering rate by phonons as discussed above. This large rate gives rise to dephasing of the wavefunction on the length scale of $0.003\ \mu\text{m}$. Therefore it is possible to reach feature sizes down to $0.1\ \mu\text{m}$ without major transitions from classical to quantum transport. The second point in favor of hot electrons arises from the need for aggressive designs, particularly with respect to switching speed. One needs to use the highest possible current densities, and this means in semiconductors also high electric fields. Frequent predictions that hot-electron effects will be scaled away soon have therefore often not come true. Since hot-electron effects are important in so many devices and of such variable

consequences, we will discuss here only major effects that appear in many variations.

3.1. Hot Electrons in Field-Effect Devices

Field-effect transistors exhibit a large number of hot-electron effects. It has been known since the 1960s [34] that velocity saturation is important in these devices. The saturation was at first only encountered close to the drain, in the so-called pinchoff region [7]. As the device sizes decreased, the velocity saturation spread all over the channel, at least for the highest drain voltages used [7]. This effect reduces some of the figures of merit of the transistors (as, e.g., the transconductance) and was therefore seen as an unwelcome side effect; it was simulated by use of Eqs. (16) and (15) or similar equations but with space-dependent electric fields. This local dependence on a varying electric field is, of course, valid only if the field varies so slowly that the transport is always diffusive without the nonlocal velocity overshoot or ballistic components. These latter effects become important for transistor channel length of the order of $0.1\ \mu\text{m}$ [20]. Then the overshoot effects counteract and undo part of the velocity saturation and generally contribute to higher device speed. This has been proved in MOSFETs, as discussed in Ref. 20.

The documentation of overshoot effects in silicon-based devices is a nontrivial task, since they always appear in connection with velocity degradation in other regions of the devices, and they are small (around a factor of 2 for $T_L = 300\ \text{K}$). Overshoot effects are larger in III-V compound field-effect transistors such as metal-semiconductor transistors (MESFETs). Ordinary MESFETs exhibit much scattering in the conducting channel due to the charged donors or acceptors, in addition to the always present scattering by the polar optical phonons [3,7]. The overshoot effects are therefore more pronounced in modulation-doped field effect transistors (MODFET), which contain the dopants in a layer of a different semiconductor (e.g., AlGaAs) neighboring the channel (e.g., GaAs) as described in Ref. 35. These transistors exhibit, therefore, a significant speed advantage over MESFETs, as shown by numerous works [36,37]. Typical values of the overshoot in such devices, as deduced from Monte Carlo simulations, correspond to those shown in Fig. 7. We note that real-space transfer can, of course, be also of importance in these devices and may reduce some of their advantages.

Impact ionization is an important limiting factor in field-effect transistors, since its presence usually will disturb device operation. The theory of impact ionization in devices proceeds along the lines discussed above. However, nonlocal effects are of great significance because of the presence of rapidly varying electric fields in the conducting channels of field-effect devices. One then needs to allow for dead spaces of the ionization [32,38].

As discussed above, the probability of impact ionization is very small for electron energies below a certain energy in the conduction band. Of course, the minimum energy the electron needs is the energy of the gap E_G . Even above this energy, the threshold for significant ionization is often not reached for energies of 2 or 3 times E_G , as can be seen

from Kane's results in Fig. 8. This energy needs to be reached to start significant ionization.

With a space-dependent electric field $F(z)$ in the z direction, the electron needs to traverse a certain distance d to reach effective threshold. Typically d can be obtained from an equation such as

$$\int_0^d F(z) dz = cE_G \quad (25)$$

where c is a constant determining the effective threshold (normally of the order of 2). Over such a distance, ionization cannot occur, even if the electric field is very high. Ionization in very short field-effect transistors with highly peaked electric fields is therefore smaller than one would expect from an integration of the ionization probability over all fields not counting the dead space of length d . This explains the fact that ionization is not a function of the local electric field alone (nonlocality).

Anisotropies of impact ionization, which have not been found for constant electric fields [23], can occur when ballistic acceleration over short distances is important, mainly because of anisotropies of the effective threshold [39]. These further complicate the simulation of impact ionization in devices. It is the conviction of this author that a quantitative understanding of impact ionization in devices is possible only with a full-band solution of the Boltzmann equation consistent with the solution of Poisson's equation, as can be done with various simulation tools [13,14]. Some of the controversies in the literature can be tracked to oversimplified simulation.

The hot-electron effects discussed above are reversible in the sense that after turning off the electric fields, the hot electrons cool down to the ambient temperature within picoseconds without any structural changes of the crystal lattice. However, hot electrons can also cause structural changes. A particularly well-known hot-electron degradation occurs at the MOSFET interface between the silicon and the silicon dioxide [33]. This damage is linked to the breaking of silicon-hydrogen bonds that are always present at this interface. A clear proof was given by damage measurements involving the isotope deuterium [40]. When the silicon-hydrogen complex was replaced by silicon-deuterium, a much-reduced hot-electron degradation of MOSFETs was found, which has the beneficial effect of increasing the device lifetime [41]. A large framework of experimental and theoretical contributions to this area exists in the literature and is reviewed in Ref. 42.

3.2. Hot Electrons in Quantum-Well Laser Diodes

Hot electrons in quantum-well laser diodes have an origin and consequences different from what they have in field-effect devices. The electrons here are not heated by the electric field but by other electrons propagating into the quantum well and exhibiting suddenly high kinetic energy as shown in Fig. 11. These electrons, originating from outside the well, can now transfer their energy in essentially two ways to the electrons in the quantum well. For one, they can transfer the energy through direct electron-electron interaction (electron-hole interactions can also be

Figure 11. Electron propagating over a semiconductor hetero-junction and acquiring significant kinetic energy (in the GaAs).

important in laser diodes because of the presence of both electrons and holes with approximately equal density). The incoming electron beam therefore heats the quantum-well electrons. Another pathway of energy transfer is by polar optical phonons. Electrons at high energies in the quantum wells emit polar optical phonons (within about 10^{-13} s). These phonons cannot propagate out of the quantum well and decay relatively slowly (typically within 3–10 ps). The phonons therefore accumulate, giving rise to a nonequilibrium (heated) phonon distribution. The quantum-well electrons at low energy can then in turn absorb phonons and heat up themselves. This gives rise to a nonequilibrium electron temperature T_c .

A completely consistent calculation of these effects has been made [43] and shows that the modulation of electron

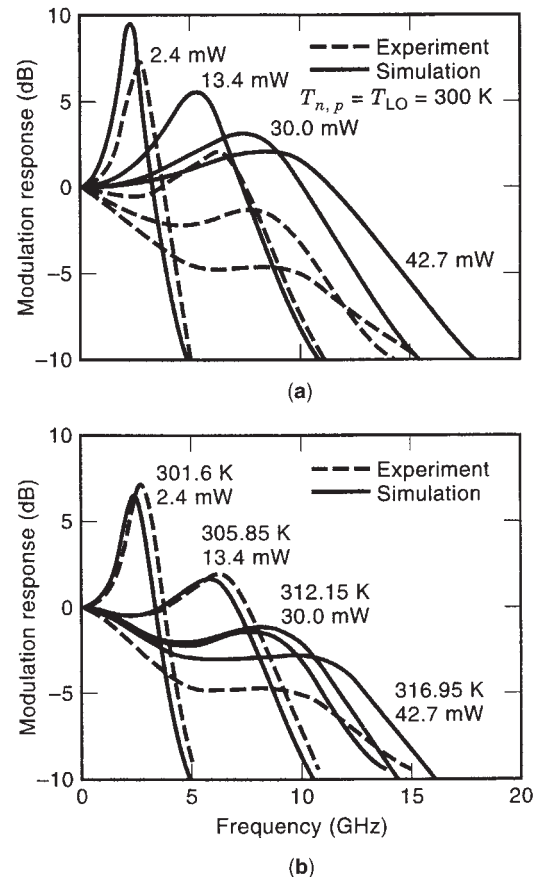

Figure 12. Modulation response of quantum-well laser diodes for various driving currents corresponding to the power indicated: (a) theory without hot-electron effects—the agreement with experiments is weak, particularly at higher power levels; (b) theory including hot-electron effects (temperatures indicated above curves) shows excellent agreement with experiments [38].

density in quantum-well laser diodes is always accompanied by a modulation of the electron temperature and therefore influences the laser performance and modulation response sensitively through very small temperature rises. While field-effect devices operate at electron temperatures of several thousand kelvins caused by the heating of the electric field, laser diodes cease to operate for dynamic electron heating of a few kelvins, as shown in Fig. 12, which depicts the modulation response of a typical semiconductor laser diode. The static heating is also important in lasers and degrades their performance. For the static case electron temperatures around 100 K above room temperature may be tolerated—still much less than the T_c values reached in field-effect devices.

HIGH-FREQUENCY BROADCASTING

KIM ANDREW ELLIOT

High-frequency (HF) broadcasting, more commonly known as *shortwave broadcasting*, employs the long-distance capabilities of skywave propagation for transmissions over long distances. HF is used for international broadcasting. Some international broadcasters additionally use the mediumwave broadcast band (standard AM) to reach audiences in nearer target countries. HF is also used for domestic broadcasting in countries with large remotely populated regions (e.g., Russia, China, Canada, Australia) and in tropical countries, where the effectiveness of

mediumwave broadcasting is reduced by poor soil conductivity and static from lightning.

International HF broadcast stations generally transmit in a number of languages, including the language of the broadcasting country, plus a selection of major world languages or languages of countries of particular interest to the broadcasting country. For example, the Broadcasting Service of the Kingdom of Saudi Arabia has international HF transmissions in Arabic, Bambara, Bangali, Indonesian, Persian, Somali, Swahili, Turkmen, Turkish, and Urdu—languages of major Islamic populations. Unlike domestic radio, which remains on the air throughout the day, international HF broadcasts in a particular language usually have a duration of a half-hour to 90 min because most international radio stations have a limited number of broadcasters proficient in each language. The fluid nature of the ionosphere also requires that frequencies be changed several times during the day.

1. HISTORY

1.1. Early Years

By the 1920s, the establishment of voice modulation and the discovery of the long-distance properties of the HF frequencies enabled the development of HF broadcasting. In 1927 the Philips company in the Netherlands established a permanent high-frequency broadcasting station to send programs to the Dutch colonies [1]. Soon after, Britain and France began HF broadcasts to their colonies.

During the 1930s, Italy and Germany conducted the first sustained use of radio for international propaganda. Italy transmitted in Arabic to the Middle East in an attempt to turn opinion in that region against the British. Germany broadcast to German communities abroad, adding Spanish, Portuguese, and English to the Americas, and other languages to other targets. The British Broadcasting Corporation (BBC) reacted by supplementing its Empire Service with broadcasts in many of the same languages already transmitted by Germany and Italy [2].

1.2. World War II

Axis broadcasting during World War II had two main strategies. One involved attempts to convince neutral countries to remain neutral or to join with the Axis. The second was to demoralize or confuse the civilian populations or armed forces of countries that had already joined the war against the Axis powers [3]. The BBC countered the Axis broadcasts with a more factual presentation of news. This was also largely the policy of the Voice of America (VoA), created by the United States government in 1942 by consolidating the several private HF broadcast stations that existed in the United States before the war [4].

1.3. The Cold War Years

At the end of World War II, there was a sudden reduction in the amount of international HF broadcasting. However, the advent of the Cold War led to a growth of international broadcasting that was sustained through the 1980s. The Soviet Union's Radio Moscow set the pace with an increas-

ing number of transmitters, transmission hours, and broadcast languages through the Cold War years. All other communist countries, and even some Republics of the Soviet Union, maintained their own international radio services. China's Radio Peking (later, Radio Beijing, and now Voice of China) and its ally Radio Tirana (Albania) were among the largest HF broadcast operations.

From the West, Voice of America and BBC overseas broadcasts expanded. In 1953, West Germany created its Deutsche Welle, which grew to be one of the major international radio services. Also in the early 1950s, the United States created Radio Liberation, later Radio Liberty, directed to the Soviet Union, and Radio Free Europe directed to the other communist countries of Europe. These stations were later merged to form Radio Free Europe/Radio Liberty, Inc.

1.4. The Post-Cold War Period

Radio Moscow, which led the expansion of international broadcasting after World War II, also led the post-Cold War reduction of international broadcasting. In 1990, Radio Moscow broadcast in 61 languages. In 1998, its successor, Voice of Russia, had 33 language services. Western broadcasters also reduced some of their operations and shifted operations from direct HF broadcasts to rebroadcasting within the target country (rebroadcasting is described later). Radio Free Europe/Radio Liberty moved from Munich to Prague. The station closed its Hungarian service and began privatization of its Czech and Polish services. Voice of America HF broadcasts in Russian were reduced from 16 h per day in 1989 to 6 h per week in 1998.

Many of the HF transmitters active during the Cold War are now leased to religious and other radio programmers. In 1997, BBC sold its UK-based HF broadcast transmitters to Merlin Communications International Ltd., which leases the transmitters back to the BBC. Merlin leases spare transmitter time, as do Deutsche Telekom in Germany, Sentech in South Africa, and the transmission companies in many of the former Soviet republics.

Other countries have been considering the future of their international radio services in the post-Cold War era. In late 1996, the Canadian government announced that Radio Canada International would be closed. Public and political support kept the station on the air. In 1997, the Australian government planned to close Radio Australia, the international service of the Australian Broadcasting Corporation. After much debate, Radio Australia remained on the air, but its operations were reduced by about half. Its broadcasts in Cantonese, Thai, and French were dropped, and its main HF transmission site near Darwin was put into mothballs.

The United States has created new international broadcasting services that reflect the shift from the old U.S.–Soviet Cold War theater. Radio Martí to Cuba began broadcasting in 1985. Radio Free Asia was inaugurated in 1997, transmitting to China, Tibet, North Korea, Vietnam, Laos, Cambodia, and Burma (now Myanmar). Congress has allocated funds for new Radio Free Europe/Radio Liberty broadcasts to Iran and Iraq and for a new Radio Democracy for Africa to be operated by the Voice of America.

The use of HF for domestic broadcasting has receded in recent decades. For example, the 1973 *World Radio TV Hand book* listed about 250 stations in the 90-m tropical broadcast band (3200–3400 kHz). The 1998 issue of the *Handbook* lists about 150 stations in that same band [5]. However, investment in domestic HF broadcasting continues in some countries. In 1994, the Zimbabwe Broadcasting Corporation revived its domestic HF broadcasting by putting the first of four new 100 kW HF transmitters into service.

2. PRESENT BROADCASTING ACTIVITY

International radio broadcasting can be divided into three broad types: government-funded, religious, and commercial. Government-financed stations comprise, by far, the

largest share. According to the 1998 *World Radio TV Hand book* [5], some 85 national governments operate international radio stations. Most religious international stations are Protestant evangelical, but there are also Catholic and Islamic stations. Commercial HF international broadcasting has not been successful in selling spot advertisements because of a lack of audience ratings data, but a number of stations make some profit by selling blocks of time to religious and special-interest organizations.

Table 1 shows the top forty international radio stations by frequency hours.

2.1. International Broadcasting from the United States

The United States originates every type of international HF broadcasting. The Voice of America is a government

Table 1. International Radio Broadcasters: Top 40 Stations Ranked by Program Hours per Week^a

	Country	Station	Type ^b	Hours per Week
1	USA	Trans World Radio	R	939
2	United Kingdom	BBC World Service	G	929
3	China	China Radio International	G	893
4	USA	Voice of America	G	870
5	USA	Far East Broadcasting Co	R	809
6	Germany	Deutsche Welle	G	708

37	Italy	RAI International	G	218
38	Ukraine	Radio Ukraine International	G	203
39	Poland	Polish Radio Warsaw	G	200
40	Cuba	Radio Havana Cuba	G	195

^aThis table shows program hours rather than frequency hours. Many religious broadcasters transmit in a language on only one frequency. Government-funded international broadcasters use more than one HF frequency per language broadcast, and as such they may have a better chance of delivering an audible signal in the target country or countries. Hours per week include mediumwave and HF transmissions. Program hours reflect simultaneous transmission in more than one language. (Source: BBC Monitoring, World Media Unit.)

^bStation types: G—government-funded; R—religious; C—commercial.

agency (at present part of the U.S. Information Agency) that broadcasts worldwide in 51 languages. Radio Free Europe/Radio Liberty and Radio Free Asia (to China and the other communist countries of Asia, plus Burma) are U.S. government-financed corporations that focus their programming on the domestic affairs of their target countries. The United States also has more than 20 private HF broadcast stations. Some, such as WEWN, Worldwide Catholic Radio in Birmingham, Alabama, are purely religious operations. Others, such as WWCR in Nashville, sell time to religious and special-interest program producers.

2.2. Clandestine Broadcasting

A special category of government-funded HF broadcasting is clandestine broadcasting [6]. These are stations that do not reveal the location of their transmitters or studios. Clandestine stations accompany most wars and revolutions and are used by opposition groups (genuine or contrived by unfriendly countries) to provide an alternative to state-controlled domestic media. Often, a clandestine station claims to be operating from within the target country, as the voice of the people of that country, but actually is transmitting across boundaries. During World War II, the Germans transmitted a “station debunk” on HF to the United States. The station attempted to represent itself as a voice of disenchanting Americans. More recently, opposition groups have been relying less on secret transmitters. Instead, they increasingly lease time from

commercial shortwave transmission companies or disseminate their messages via the Internet. In addition to political clandestine stations, low-powered hobby pirate HF stations are also active, especially in Europe and North America.

2.3. Transmitters and Relays

HF broadcasting requires a significant investment in transmitters and antennas. In the 1990s, HF transmitters typically have power from 100 to 500 kW. Large directional antenna systems are necessary to focus power to the desired target (Fig. 1). Major transmitter manufacturers include Thomcast (France) and Continental (USA, recently merged with Telefunken of Germany).

Despite the long-distance capabilities of HF, attempts to broadcast halfway around the world are generally disappointing. As such, major international radio stations have established relay stations outside their home countries. Until the 1970s, the signals reached the relays by way of HF single-sideband feed transmissions. The signal received by the audience was never better than the weakest HF link. Now, with satellite feeds, transmissions from HF relays begin with a studio-quality signal. A more recent variation of HF relays is transmitter exchanges in which two international stations use each other's transmitters. China Radio International (Beijing) exchanges transmitter time with Radio Canada International, Radio France International, Spanish Foreign Radio, Swiss Radio International, and Voice of Russia.

Figure 1. High-frequency broadcast antenna arrays at the Voice of America's Edward R. Murrow transmitting station near Greenville, NC. Guyed masts up to 100 m support arrays of folded dipoles in front of wire reflecting screens. (Courtesy of USIA International Broadcast Bureau.)

Table 2. HF Frequencies Allocated by the International Telecommunications Union for Broadcasting

Frequencies (kHz)	Meter Band	Notes
2300–2495	120	For domestic broadcasting in tropical regions; actually in the “medium frequency” (300–3000-kHz) range
3200–3400	90	For domestic broadcasting in tropical regions
3900–4000	75	Europe and Asia only
4750–5060	60	For domestic broadcasting in tropical regions
5950–6200	49	
7100–7300	41	Eastern Hemisphere only
9500–9990	31	
11,650–12,050	25	
13,600–13,800	22	
15,100–15,600	19	
17,550–17,900	16	
21,450–21,850	13	
25,670–26,100	11	

3. FREQUENCY ASSIGNMENTS

Table 2 shows the HF frequencies allocated for broadcasting. Channels within these bands are spaced 5 kHz apart, that is, 9505, 9510, 9515, and so on. Administrations register frequencies with the Radio Communications Bureau of the International Telecommunications Union that HF broadcast stations within their jurisdictions intend to use. The ITU has a number of procedures for resolving interference. Also useful in preventing interference are frequency coordination meetings held periodically among many international HF broadcasting stations.

Many stations escape interference by broadcasting on frequencies outside (but usually near) the allocated HF broadcast bands. This “out of band” broadcasting is allowed by a provision of the ITU regulations, if users of communications services for which the frequencies are primarily allocated do not complain of interference.

4. PROGRAM CONTENT

HF broadcasters transmit a variety of programs, including news, current affairs analyses and commentaries, cultural and special-interest programs, and music. The most important distinction in programming is propaganda versus a balanced and objective presentation of news and information. One of the pivotal decisions in international broadcasting was that of the BBC not to follow the Axis broadcasters’ propagandistic approach but to maintain the BBC domestic broadcasting policy of (mostly) balanced and factual reportage.

A propagandistic approach to international broadcasting would include one-sided news and current affairs reporting in conjunction with commentaries that are direct attempts to persuade the audience to a certain political viewpoint. This approach, created by the Axis broadcast-

ers before and during World War II, was followed by the international broadcasting of the Communist stations through the 1980s. Propaganda continues to exist—Radio Havana and Radio Pyongyang are two notable examples—but it is less prevalent now that many former communist countries and other dictatorships are experimenting with democracy.

The decision to broadcast balanced, objective news corresponds to the main motivation to listen to foreign broadcasts. Generally, persons seek out foreign broadcasts to get the news and information they want, especially about their own countries and regions, which they cannot get in reliable form from their domestic media. The most important evidence that a balanced presentation of news and information has been more successful than propaganda is that Radio Moscow, during its decades of dominance in terms of broadcast hours, number of languages, and kilowattage, generally had audiences no larger than about 10% the size of those for the BBC World Service or the Voice of America [8]. The international broadcasters of the Western democracies have determined that even if news is embarrassing or negative to their own governments, it attracts audiences and counters the misinformation, disinformation, and withheld information of the state-controlled media in authoritarian countries.

The use of HF broadcasting to transmit music has always been a matter of debate. Some maintain that HF is too unreliable for the enjoyment of music. Many listeners, however, have depended on shortwave for the types of music they wish to hear, but cannot receive from radio stations in their own countries. Willis Conover’s jazz programs on the Voice of America are an important example.

One of the most important programming functions of HF broadcasting is to provide news, information, and entertainment to compatriots living abroad. Virtually all international radio stations transmit in their own languages for emigrants or citizens living or studying in other countries. Often this programming consists of relays of domestic radio programming. This programming fulfills a need—information about the homeland in the language of the homeland—unmet by the domestic broadcasting in the countries where the expatriates live. In 1998, Radio Portugal dropped the last of its foreign-language broadcasts (except for Tetum, a language spoken in former Portuguese East Timor), in favor of a schedule devoted almost exclusively to broadcasts in Portuguese for Lusophone communities worldwide.

5. THE AUDIENCE

Most government-funded international radio stations conduct little or no audience research. They exist largely as a matter of national obligation. So the documentation of an audience is not as vital as for a commercial station, which must provide statistics about its audience to sell advertising.

The largest audience research office is operated by the BBC World Service. The Voice of America, Radio Free Europe/Radio Liberty Inc., Deutsche Welle, and Radio France International also have significant audience

research offices. No global estimate of the number of all international HF broadcast listeners has been attempted because of the impossibility of conducting research in all countries. The best benchmark of the size of the international radio audience is the audience size of the most popular international broadcaster. The BBC estimates that 138 million people listen to BBC World Service at least once a week. This is a conservative estimate because it does not include countries where BBC is unable to commission surveys. Although the estimate includes all listening by way of the BBC's own HF, mediumwave, and FM transmitters, most of the World Service audience still listens via HF [9].

In general, the main predictor of audience size is the nature of the domestic media. Countries that have media that are deficient because of government control, poor economies, or both have the largest international radio audiences.

Some international radio stations cite the volume of audience mail as evidence of an audience. However, there is no reliable way to determine the size of an audience from the number of letters received. Audience mail is more useful to determine audience reaction to programming and reception quality.

A statistic commonly cited in the international broadcasting profession is the existence of 600 million shortwave radios worldwide. This originates from a 1986 study by the Academy for Educational Development [10]. However, an accurate and up-to-date estimate is difficult because of the many radios and "boomboxes" that contain perfunctory shortwave bands. There is no doubt a high mortality rate among these appliances. Radios with shortwave coverage have become less prevalent in general merchandise stores, even in developing countries [11]. In these countries, there is a shift from the number of models with mediumwave and one shortwave band toward those with mediumwave and an FM band.

The quality of shortwave radios varies widely. The typical shortwave available and affordable in a developing country would be a single-conversion model containing a mediumwave band, one or two shortwave bands, and, increasingly, an FM band. Tuning is across large segments of the HF spectrum, from, say 4–12 MHz or 3–22 MHz. Broadcast stations are crowded into the small dial spaces that correspond to the HF broadcast bands. A step up in quality and increasingly available in developing countries are multiband radios that tune only the segments of the HF spectrum devoted to broadcasting, plus mediumwave and FM. This affords better band spread and station separation. Portable shortwave radios with digital frequency readout are less available and more expensive in the developing countries, but they are favored among consumers in the industrialized countries. The highest level receiver is the communications receiver, a tabletop model usually costing from \$700 to more than \$2000. These have digital frequency readout and many technical features that facilitate the reception of marginal signals.

Many of the users of high-end communications receivers are "DXers." DXers are a significant segment of the HF broadcast audience, especially in industrialized countries. The term "DX" comes from the old radiotelegraph abbreviation for "distance." DXing listeners try to receive as

many stations as possible in as many countries as possible. They verify their reception of these stations by sending reception reports and receiving a QSL (another radiotelegraph abbreviation for "confirmation") card.

6. PROBLEMS OF HF BROADCAST RECEPTION

Good, reliable reception of HF broadcasts is limited by the nature of the ionosphere. Conditions of the ionosphere vary day-to-day in weatherlike fashion. They also vary in accordance with the eleven year sunspot cycle. During ebbs in the sunspot cycle, frequencies above, roughly, 12 MHz are less useful for long distance broadcasting. Nearer the peaks of the cycle, the higher HF frequencies become useful, and the lower frequencies remain so. This gives the many international radio broadcasters more room to distribute themselves and avoid interference.

One impediment to good reception is the tendency of many international radio stations to exceed the capabilities of HF. Stations that do not have relay stations or exchange agreements may attempt to send their signals to target countries halfway around the world. These attempts generally produce poor results and, in the process, cause interference in areas short of the target.

Most of the problems of HF reception are of human rather than ionospheric origin. There are too many broadcast stations for the number of frequencies available. Despite some ITU regulation, many stations commence use of frequencies with impunity. As already mentioned, shortwave signals are usually heard outside their target areas. They are not causing interference "on paper," but in reality they are. Interference can be cochannel or adjacent-channel. Theoretically, short-wave stations do not broadcast to the same target on channels less than 10 kHz apart. However, stations 5 kHz apart are heard on any shortwave radio. Often typical inexpensive shortwave radios cannot separate strong signals on adjacent channels.

6.1. Jamming

Most interference is not intentional. Intentional interference is known as jamming. Jamming dates back before World War II. During the Cold War, the Soviet Union maintained an intensive program of jamming the broadcasts of Radio Free Europe, Radio Liberty, the Voice of America, the BBC World Service, and other Western stations. The jamming usually consisted of a raucous buzzing noise. This would be accompanied by a Morse code identifier used by Soviet engineers to track the performance of their jamming transmitters. Because of the tendency of HF signals to be heard better over long distances than shorter distances, skywave jamming is not completely effective in blocking transmissions from abroad. The Soviets remedied this by ringing major cities with HF transmitters close enough to propagate groundwave signals within these cities. Soviet jamming ended in 1989, a manifestation of Mikhail Gorbachev's *glasnost* policy.

Today, China is the country most actively engaged in jamming. China interferes with the broadcasts of the Voice

of America, the U.S. Radio Free Asia, BBC World Service, and transmissions from Taiwan. In addition to noise jamming China transmits overmodulated audio from its domestic radio programs on the frequencies of these external broadcasts. Cuba, North Korea, Vietnam, and Burma (Myanmar) are also presently of recently jamming external broadcasts. Jamming is also often heard from a number of Middle Eastern countries.

7. PROSPECTS FOR HF BROADCASTING

A number of new media technologies are now vying with HF to transmit broadcasts over long distances and across national boundaries. These media are satellite broadcasting, the Internet, and rebroadcasting. Radio was the original medium of international broadcasting because only radio could travel long distances and across national boundaries. New media allow text, graphics, video, and the traditional audio. Most international broadcasters are maintaining most of their efforts in their traditional radio medium. Nevertheless, they will have to decide which medium is most appropriate for each of their broadcasting missions. Since the 1970s or so, international radio broadcasts have consisted largely of news, commentaries, and current affairs talks, with a minimum of production. Such content might more efficiently be transmitted as text.

7.1. Satellite Broadcasting

With terrestrial broadcasting, radio developed first, then television. In satellite broadcasting, television has already started, but direct satellite *radio* systems for domestic and international use are still in development. WorldSpace Corporation of Washington, DC is planning to launch the first of its three direct radio broadcasting satellites in late 1998. The WorldSpace system will transmit radio broadcasts to small receivers in Africa, the Middle East, Asia, the Caribbean, and Latin America. Each WorldSpace satellite will have three beams, each with a capacity of 96 AM-quality channels. The company plans to provide transmissions services for both international and domestic radio broadcasting.

Many international radio broadcasters are already using audio subcarriers of direct-to-home *television* satellite systems. This is most prevalent on the Astra satellite television system in Europe. World Radio Network of London combines the programs of several international radio stations into 24 hour services, using subcarriers of Astra in Europe and other satellites in other parts of the world.

7.2. The Internet

Now the advent of RealAudio and other audiostreaming software it possible for persons to receive foreign broadcasts via the Internet. Audio fidelity is usually not even AM-quality, but reception is more reliable than via HF. An important advantage of Internet audio is that a listener can hear a specific program, say, a weekly half-hour pro-

gram about science, at any convenient time, rather than having to be at the radio at the scheduled time of the program. Some international broadcasters also present "live" streams of their 24-h schedule. The BBC World Service in English is available via Broadcast.com, a commercial World Wide Web service.

At present, however, computers with Internet access are much less common in homes than are shortwave radios, especially in the developing countries, where audiences for international radio are largest. Also, access to certain World Wide Web sets can be interdicted. The Chinese government controls Internet gateways in that country and currently blocks access to some foreign news-oriented sites, including those of the Voice of America and the Cable News Network. Inbound electronic mail is more difficult to stop, and now the Voice of America has a Mandarin-language e-mail news service delivered to computer users in China. This service uses the most popular software in China to convert from ASCII to Chinese characters.

7.3. Rebroadcasting

Now many international broadcasters use satellites to feed complete programs of brief reports to radio stations in the target country, which rebroadcast this content to local audiences. When given the choice, listeners certainly prefer to hear foreign broadcasts via a nearby FM or mediumwave transmitter than by way of a distant and unreliable HF signal. Rebroadcasting also facilitates international television because terrestrial television transmission is limited to relatively short distances and direct-to-home satellite opportunities are still limited and expensive.

To some extent, however, rebroadcasting is a self-negating enterprise. The fact that a country could allow foreign broadcasts to be transmitted from its own territory indicates that the country tolerates a free and diverse domestic media environment. This reduces much of the incentive to listen to foreign broadcasts, whether via local or external transmitters. At present, there is no rebroadcasting (at least of news and current-affairs programs) in some of the most important target countries for international radio such as China, Nigeria, Indonesia, India, and Cuba. During crises, private radio stations are also sometimes banned from rebroadcasting international programs or are themselves taken off the air. The Voice of America, BBC, and Radio France International have experienced a temporary loss of local rebroadcasting during turbulent periods in the Democratic Republic of the Congo, Liberia, Niger, and other countries.

7.4. Digital HF Broadcasting

In the 1980s, it was widely assumed that satellites would replace HF as the medium for international broadcasting. Two events in the 1990s have caused international broadcasters to temper their optimism about the new technologies. BBC World Service Television was broadcast to East Asia, including China, as part of the Star TV service of the AsiaSat satellite. The English-language television service was accompanied by a Mandarin-language translation on

an audio subcarrier. Media entrepreneur Rupert Murdoch purchased Star TV in 1994. Murdoch, pursuing media opportunities in China, yielded to Chinese government pressure and removed BBC World Service Television from the Star TV beam, which reached most of China. BBC's Arabic Television Service was shut down in 1996 when the Saudi-owned Orbit Radio and Television Network, which beamed the service into the Middle East, objected to BBC's coverage of Saudi domestic affairs.

Therefore, international broadcasters are reconsidering the future of HF for international broadcasting. The main incentive for listening to foreign broadcasts is to get news that the audience wants but cannot get from their domestic state-controlled media. Therefore international broadcasting must rely on noninterdictable, direct-to-home media. HF is not encumbered by the politicocommercial links which affect the owners of satellite transponders. And HF transmissions are not as easy to block as World Wide Webpages.

A coalition of international radio broadcasters and manufacturers of HF transmitters and shortwave receivers have formed Digital Radio Mondial (DRM) to develop a system for digital broadcast transmission on HF and in the mediumwave and longwave broadcast bands [12]. The DRM inaugural meeting was held, remarkably, in China at Guangzhou City in March 1998. A DRM statement proclaims that HF digital broadcasting will allow listeners to hear "shortwave programs free of fading and interference." This will require new and, at least initially, more expensive receivers. It remains to be seen if digital transmission will overcome the degradations of HF reception. An important question is whether digital HF transmission will help overcome or facilitate attempts by authoritarian governments to block broadcasts from abroad.

FURTHER READING

A description of international and domestic radio broadcasting in all countries, including schedules for HF broadcasts in all broadcast languages, is in the annual *World Radio TV Handbook*, published until 1998 by Billboard Publications. Beginning with the 1999 issue, the book will be published by WRTH Publications, Milton Keynes, UK (editor@wrth.demon.co.uk).

Schedules of English-language HF broadcasts, plus reviews of receivers and other information for the listener is in Lawrence Magne, ed., *Passport to World Bank Radio*, International Broadcasting Services Ltd., Penns Park, PA (<http://www.passport.com>).

Schedules and general articles about HF broadcasting and other radio topics are contained in *Monitoring Times* magazine, published monthly by Grove Enterprises, Brasstown, NC (<http://www.grove-ent.com>). Schedules and information are also published in the monthly *Journal of the North American Shortwave Association* (<http://www.anarc.org/naswa>). English-language HF broadcast schedules are updated weekly by FineWare.

A comprehensive compilation of news about and schedules of world broadcasting stations, including HF broadcasting, is contained in the *World Media* and *Schedules* publications of BBC Monitoring, Reading, England (marketing@mon.bbc.co.uk).

A listing of most of the world's HF broadcast transmitters by country, location, manufacturer, power, date of inauguration, and (if applicable) decommission, is in L. Maes, *Transmitter Documentation Project*, 5th ed., Rijkvevorse, Ludo Maes, Belgium, 1998 (<http://www.ping.be/tdp>). A comprehensive discussion of HF receivers is F. Osterman, *Shortwave Receivers Past and Present: Communications Receivers 1942 to 1977*, 5th ed., Universal Radio Research, Reynoldsburg, OH, 1998 (<http://www.universal-radio.com>).

General descriptions and the history of international broadcasting include D. R. Browne, *International Broadcasting: The Limits of the Limitless Medium*, Praeger, New York, 1982; H. L. Childs and J. B. Whitton, eds., *Propaganda by Short Wave*, Princeton Univ. Press, 1942; M. Nelson: *War of the Black Heavens: Western Broadcasting in the Cold War*, Syracuse Univ. Press, 1997; C. J. Rolo, *Radio Goes to War: The "Fourth Front,"* Putnam, New York, Peter 1942; J. Wood, *History of International Broadcasting*, Peregrinus, London, 1993.

Several World Wide Websites contain information for the shortwave listener about international broadcasting. Among the most useful (with links to other sites) are TRS Consultants (<http://www.trsc.com>), Shortwave/Radio Catalog (<http://itre.ncsu.edu/radio>), Association of North American Radio Clubs (<http://www.anarc.org>), Radio Netherlands Real Radio (<http://www.rnw.nl/realradio/index.html>), and the IBB Monitoring Homepage (<http://voa.his.com/>).

1. INTRODUCTION

Transmission lines are used to guide electromagnetic waves from one place to another. They are used for a wide range of applications, and different types of lines are suitable for different applications. The power transmission lines that supply electricity do not transmit signals, but just the power required to run the various electrical devices. As a result, power lines are designed to minimize the various losses incurred in traversing great distances. There are also transmission lines that carry high-frequency signals varying in a nonrepetitive fashion for communication purposes. These are called *high-frequency transmission lines*. The impetus in the design of such lines is to maximize the operable frequency bandwidth and minimize the attenuation of the signals. The former preserves the quality of the signal being transmitted, while the latter increases the spacing between repeater stations, reducing the cost of transmission. Transmission of signals is not limited to physically long lines. Transmission lines are also used to send signals within a computer or to feed an antenna from its source.

1.1. Historical Perspective

The earliest device to use electrical transmission lines was the telegraph. The first message was sent by Morse in the year 1844. By the year 1866, a cable was laid across the Atlantic Ocean, making it possible to send messages across continents. A few years later, with the invention of the telephone, transmission lines with a wider bandwidth were employed. By 1890, as electricity became more important, power lines were developed to transmit power from the generators to the consumers. These lines which use just a simple wire to transmit signals are referred to as *single-wire transmission lines*.

The first experiments involving two-conductor transmission lines were carried out by Heinrich Hertz [1] toward the end of the nineteenth century. His experiments with the coaxial line demonstrated the validity of the electromagnetic theory of Faraday and Maxwell [2]. In 1897, Lord Rayleigh [3] proved mathematically that it is possible to transmit waves through a hollow waveguide of rectangular or circular cross section. A different type of wave propagation based on surface waves was analyzed by

Sommerfeld in 1899 [4]. This work was extended to analyze wave propagation along dielectric cylinders by Hondros and Debye in 1910 [5]. Marconi was the first to demonstrate wireless communication by sending signals across the Atlantic Ocean in 1901. The primary function of transmission lines in wireless communication is in transferring the signal from the transmitter to the antennas.

With the development of the radar in the 1930s, the frequency of the signals were approaching the gigahertz range. At these frequencies, the hollow waveguides provide a more practical, low-loss way of transferring energy. Even though it was theoretically proved that it was possible to transmit waves through a hollow waveguide, no experimental results were forthcoming until the year 1936. It was then that two men, George C. Southworth and Wilmer L. Barrow, independently demonstrated wave transmission through the waveguide [6]. The period during World War II saw a steady growth in both theoretical and experimental work on transmission lines and waveguides as practical communication devices.

After World War II, rectangular waveguides became the dominant waveguiding structure. However, as engineers sought components with larger bandwidths, other structures were investigated. The next major milestone in the history of transmission lines was the development of the microwave printed circuit [7,8]. The microstrip line was introduced to alleviate the bandwidth problem since its fundamental mode operated at all frequencies. The ease of fabrication was another attractive feature of the microstrip line.

By the 1970s, most long-distance communication lines were simple two-conductor transmission lines. As the demand for high capacity and long-distance transmission systems increased, optical fibers were developed to replace the existing copper wire system [9]. Optical fibers had a much wider bandwidth than did the simple coaxial line since they operated at optical frequencies. Their inherent low loss also made it possible to achieve a much higher repeater spacing than conventional copper-based transmission lines.

1.2. Comparison of Transmission Lines

Several factors need to be considered when choosing a transmission line for a particular application. The most important factors to be considered when comparing transmission lines are

1. Frequency range and bandwidth
2. Attenuation
3. Power-handling capability
4. Ease of fabrication

Since there is no single transmission line that gives the optimal performance in all these areas, the line that has the best tradeoff for the given application must be chosen. For low-frequency applications like power transmission, a simple wire can be used to connect the source and the receiver. The frequency range of such lines is limited to low frequencies because they start radiating energy as the frequency is increased. At higher frequencies, the field is

Table 1. Comparison of Transmission Lines

Type	Advantages	Disadvantages
Single-wire transmission lines	High power, inexpensive	Low-frequency range, lossy
Coaxial lines	Large bandwidth, small size	Low power, high attenuation
Hollow waveguides	Low attenuation, high power	Limited bandwidth, large size
Optical waveguides	Large bandwidth, low loss	Radiate at bends, low power
Microstrip lines	Large bandwidth, ease of fabrication	Low power, high attenuation

usually transmitted using coaxial lines that consist of a wire inside a cylindrical outer conductor. The outer conductor acts as a shield to minimize radiation losses. Such coaxial lines can be used to send signals up to a few gigahertz. Even though the coaxial lines have large bandwidth, they suffer from high attenuation and low power-handling capability. A hollow metallic waveguide is more efficient at high frequencies because of its high power-handling capability and low attenuation. However, unlike coaxial lines, waveguides have a much smaller bandwidth.

It is also possible to transmit energy through dielectric slabs and rods, without any conducting walls. Such waveguides are referred to as *open* or *dielectric waveguides*. For example, an optical fiber is a dielectric waveguide. As their name suggests, they operate at optical frequencies. Since they operate at such high frequencies, they have a very large bandwidth. They also tend to radiate energy at discontinuities and bends.

The last transmission line to be discussed in this section is the microstrip. A microstrip line consists of a thin metallic strip placed on top of a dielectric substrate that is supported from below by a conducting plate. Just like the coaxial lines, microstrip has a large bandwidth but suffers from high attenuation and low power-handling capability. But their primary advantages are their ease of fabrication and integration with complicated microwave circuits. The properties of the various transmission lines discussed

above are summarized in Table 1. Some of them are illustrated in Fig. 1.

1.2.1. Two-Conductor Transmission Line. Different types of two-conductor transmission lines are available for different applications. The simplest of them is the single-wire transmission line with Earth acting as the implicit ground plane. Such lines are useful for low-frequency applications. At higher frequencies, the radiation losses make it impractical to use a single wire transmission line. At such frequencies, it is desirable to use a coaxial line that consists of a wire surrounded by an external cylindrical conductor. The outer conductor acts as a shield that prevents radiation losses. The principal mode of operation in such lines is the TEM mode: a mode in which both the electric and the magnetic fields are perpendicular to the direction of wave transmission. The TEM mode can propagate at all frequencies, giving the coaxial line a large bandwidth. Besides the coaxial line, there also exists the two-wire balanced line that consists of two identical lines placed next to each other. The twisted-pair transmission line is another type of two-conductor transmission line. In these lines, two insulated wires are twisted together and encased, along with other similar pairs, inside a metallic sheath. These lines are popular for transmission of both analog and digital data. The twisting in the wire reduces low-frequency interference, and the

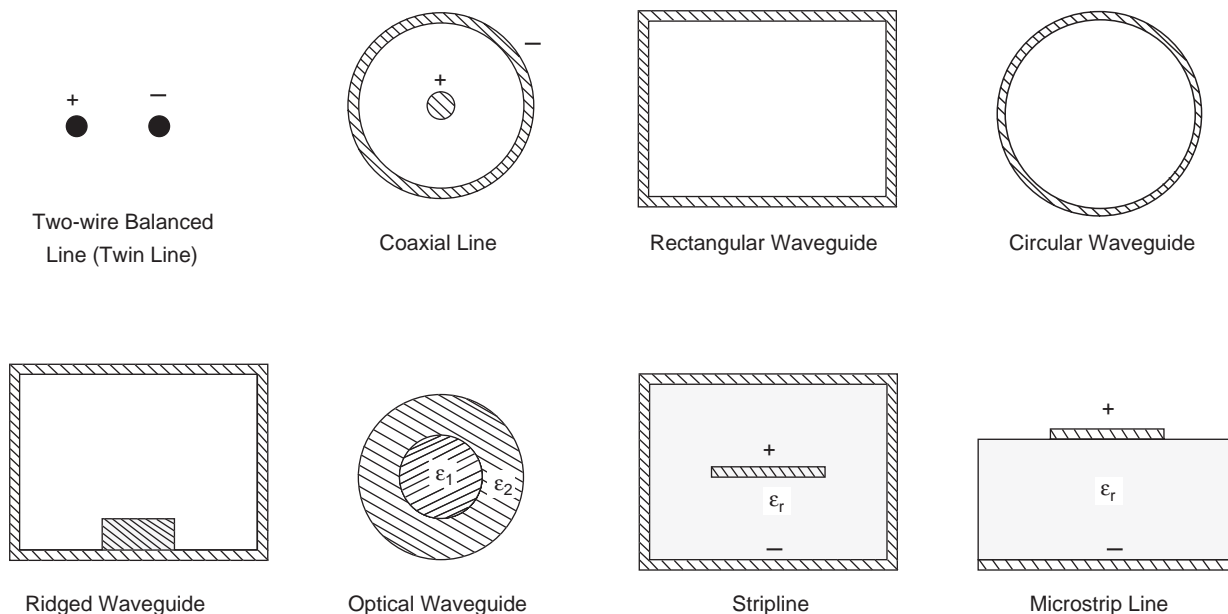

Figure 1. Cross-sectional view of typical transmission line structures.

use of different twist lengths in adjacent pairs reduces crosstalk. The bandwidth of such twisted-pair lines used in transmission of digital signals is presently around 6 MHz.

1.2.2. Hollow Waveguides. Hollow waveguiding structures are more efficient at transmitting high-frequency signals. A simple hollow waveguide is a hollow metallic cylinder filled with air or any dielectric medium. Such waveguides, unlike coaxial lines and other simple transmission lines, do not have a central conductor. As we shall see later, these waveguides cannot support the TEM mode. Instead, the wave propagates by bouncing between the perfectly conducting walls. The modes inside a hollow waveguide can be classified into TE and TM modes. In a TE mode, the electric field is transverse to the direction of propagation. In TM modes, it is the magnetic field that is transverse to the direction of propagation. The TE and TM modes are decoupled from each other. Any arbitrary field distribution within the waveguide can be expressed as a linear combination of a TE component and a TM component. Typically the field inside the waveguide is a combination of several modes. For each waveguide mode, there is a critical frequency below which the waveguide will not propagate that mode. This critical frequency, also known as the *cutoff frequency*, is inversely proportional to the size of the waveguide cross section. Therefore, to propagate low-frequency signals, the waveguide must be made bigger. This tends to restrict the bandwidth of the signal in a waveguide.

1.2.3. Open Waveguides. The simplest form of an open waveguide is the dielectric slab waveguide. It consists of a dielectric coating on top of a ground plane. To simplify the analysis of such a structure, the coating is usually assumed to have an infinite width with no field variation along that direction. For the wave to propagate within a dielectric waveguide, its permittivity should be higher than the permittivity of the surrounding medium. The wave is then guided by total internal reflection. As in the case of hollow waveguides, the field inside a dielectric slab waveguide can also be decomposed into TE and TM modes. However, the field is not localized to the waveguiding structure. Since these waveguides are not enclosed by conducting walls, there exists a residual field outside the slab waveguide. The field outside the guiding structure decays exponentially, and hence the energy is localized to the waveguide.

Apart from the slab waveguides, there also exist circular and rectangular dielectric waveguiding structures. The optical fiber is a simple and very popular example of a circular dielectric waveguide. It has a dramatic impact on modern telecommunications. Dielectric waveguides are also very important in integrated optics and at the shorter millimeter-wave frequencies. Unlike the closed waveguides, the TE and TM modes are coupled to each other in circular and rectangular open waveguides; thus, none of the modes are strictly TE or TM. Instead, the *EH* notation is sometimes used to denote a mode whose TE component dominates over its TM component, and vice versa for the *HE* notation.

1.2.4. Microstrip Lines. Microwave integrated circuit (MIC) transmission lines in general and microstrip lines in particular have become popular for high-frequency applications because of their ease of fabrication and large bandwidth. Moreover, they can be easily integrated with microwave and millimeter-wave integrated circuits. A microstrip line consists of a thin metallic strip on top of a dielectric substrate backed by a ground plane. The dielectric substrate material needs to have a low-loss tangent and a relatively large dielectric constant. The principal mode of operation is not strictly TEM since the dielectric does not uniformly surround the conducting strip. Instead, the fundamental mode is an approximation to the TEM mode and is commonly referred to as the *quasi-TEM mode*. Microstrip lines can be designed for frequencies ranging from a few gigahertz, or even lower, to many tens of gigahertz.

2. PROPAGATION IN GUIDING STRUCTURES

When the transmission lines [10–16] are small in terms of the wavelengths of the transmitted signal, they can be satisfactorily analyzed in terms of circuit theory parameters, such as currents and voltages. In this case, the line is treated using a distributed circuit model. However, as the frequency increases and the operating wavelength becomes comparable with the dimensions of the transmission line, a more general analysis is necessary. The most general approach to study the energy propagation along transmission lines is based on Maxwell's equations. By solving the associated boundary-value problem defined by the geometry and material of the transmission line, one can, in principle, completely characterize the electrical properties of the transmission line. In many cases, an analytical solution is not possible, requiring the use of numerical techniques.

In this section, we shall describe the basic properties of the electromagnetic fields on a transmission-line structure using Maxwell's equations, and discuss how they can give rise to the concepts of current and voltage along the transmission line.

If the regions between the conductors in the transmission line are filled with a homogeneous material, it can support purely transverse electric (TE), transverse magnetic (TM), or transverse electromagnetic (TEM) modes. A TE wave is such that the electric field \mathbf{E} is everywhere transverse to the direction of propagation, which will be assumed to be the z axis. This is equivalent to saying that, in the TE mode, the \mathbf{E} field is completely confined to the transverse plane (cross section) of the waveguide. Analogously, for the TM wave, the magnetic field \mathbf{H} is transverse to z , and for the TEM wave, both fields are transverse to z . If the wave is TEM, it is customary to say that the waveguide is operating in the *transmission-line mode*. (*Note:* The term *transmission line* is occasionally reserved for structures that support the TEM mode. Here, we consider transmission lines as any structure capable of guiding waves; hence, the terms waveguides and transmission lines are used interchangeably.) It can be shown that a

hollow waveguide cannot support a TEM wave. For the transmission-line mode to exist, there needs to have at least two conductors (one of them can be a ground plane). In our analysis, we will assume harmonic fields and adopt the $e^{-i\omega t}$ time convention.

2.1. TE and TM Modes

Because the fields of a general uniform transmission line can be decomposed into TE and TM types, we can characterize the TE wave with the \hat{z} component of the magnetic field or H_z , since $H_z \neq 0$ for this type of wave. Similarly, we can characterize the TM wave with the \hat{z} component of the magnetic field or E_z since $E_z \neq 0$ for this type of wave.

We shall first derive the equations governing the E_z and H_z components of the fields in a uniform transmission line with a general geometry filled with a homogeneous material.

We start from Maxwell's equations

$$\nabla \times \mathbf{E} = i\omega\mu\mathbf{H} \quad (1)$$

$$\nabla \times \mathbf{H} = -i\omega\varepsilon\mathbf{E} \quad (2)$$

and let

$$\mathbf{E} = \mathbf{E}_s + \hat{z}E_z, \quad \mathbf{H} = \mathbf{H}_s + \hat{z}H_z \quad (3)$$

where the subscript s represents the transverse to z components. Substituting Eq. (3) into Eqs. (1) and (2), we have

$$\left(\nabla_s + \hat{z} \frac{\partial}{\partial z}\right) \times (\mathbf{E}_s + \hat{z}E_z) = i\omega\mu(\mathbf{H}_s + \hat{z}H_z) \quad (4)$$

$$\left(\nabla_s + \hat{z} \frac{\partial}{\partial z}\right) \times (\mathbf{H}_s + \hat{z}H_z) = -i\omega\varepsilon(\mathbf{E}_s + \hat{z}E_z) \quad (5)$$

where ∇_s stands for the transversal part of the nabla operator:

$$\nabla_s \equiv \hat{x} \frac{\partial}{\partial x} + \hat{y} \frac{\partial}{\partial y}$$

Equating the s components of Eqs. (4) and (5), we have

$$\nabla_s \times \hat{z}E_z + \frac{\partial}{\partial z} \hat{z} \times \mathbf{E}_s = i\omega\mu\mathbf{H}_s \quad (6)$$

$$\nabla_s \times \hat{z}H_z + \frac{\partial}{\partial z} \hat{z} \times \mathbf{H}_s = -i\omega\varepsilon\mathbf{E}_s \quad (7)$$

Substituting for \mathbf{E}_s from Eq. (7) into Eq. (6), we have

$$\omega^2\mu\varepsilon\mathbf{H}_s = -i\omega\varepsilon\nabla_s \times \hat{z}E_z + \frac{\partial}{\partial z} \hat{z} \times \left(\nabla_s \times \hat{z}H_z + \frac{\partial}{\partial z} \hat{z} \times \mathbf{H}_s\right) \quad (8)$$

Using the vector identities $\hat{z} \times \nabla_s \times \hat{z} = \nabla_s$, $\hat{z} \times \hat{z} \times \mathbf{H}_s = -\mathbf{H}_s$, and assuming that the field has $e^{\pm ik_z z}$

dependence, so that $(\partial^2/\partial z^2) \rightarrow -k_z^2$, we can rewrite Eq. (8) as

$$\mathbf{H}_s = \frac{1}{k^2 - k_z^2} \left[\frac{\partial}{\partial z} \nabla_s H_z + i\omega\varepsilon \hat{z} \times \nabla_s E_z \right] \quad (9)$$

where $k^2 = \omega^2\mu\varepsilon$. By the same token, we have

$$\mathbf{E}_s = \frac{1}{k^2 - k_z^2} \left[\frac{\partial}{\partial z} \nabla_s E_z - i\omega\mu \hat{z} \times \nabla_s H_z \right] \quad (10)$$

The factor k_z is called the *propagation constant*. Equations (9) and (10) allow us to derive all the other components of the field in a waveguide once we know the z components of the field.

If we equate the \hat{z} components of Eqs. (4) and (5), we have

$$\nabla_s \times \mathbf{E}_s = i\omega\mu H_z \quad (11)$$

$$\nabla_s \times \mathbf{H}_s = -i\omega\varepsilon E_z \quad (12)$$

Substituting Eqs. (9) and (10) into Eqs. (11) and (12), we have

$$(\nabla_s^2 + k_s^2)H_z = 0 \quad \text{for TE waves} \quad (13)$$

$$(\nabla_s^2 + k_s^2)E_z = 0 \quad \text{for TM waves} \quad (14)$$

where $k_s^2 = k^2 - k_z^2$. Therefore, H_z and E_z satisfy a two-dimensional scalar wave equation, also known as the *reduced-wave equation*. Once E_z and H_z are solved for from Eqs. (13) and (14), we can derive all the other field components using Eqs. (9) and (10).

2.2. TEM Mode of a Transmission Line

For TEM waves, both E_z and H_z are zero. According to Eqs. (9) and (10), \mathbf{H}_s and \mathbf{E}_s will be nonzero only if $k_z = k$. Therefore, all TEM waves, or TEM modes in a waveguide, have e^{ikz} dependence, where the propagation constant in the guiding structure is equal to that in free space. Furthermore, from Eqs. (11) and (12), we conclude that, for TEM waves

$$\nabla_s \times \mathbf{E}_s = 0, \quad \nabla_s \times \mathbf{H}_s = 0 \quad (15)$$

These equations state that both the \mathbf{E}_s and \mathbf{H}_s are irrotational fields in the xy plane. Any irrotational field can be written as the gradient of a scalar function, as in the case of the electrostatic field $\mathbf{E} = -\nabla\phi$, where ϕ is the electric potential. In other words, \mathbf{E}_s is electrostatic in the xy plane while \mathbf{H}_s is magnetostatic in the xy plane. Hence, we can let

$$\mathbf{E}_s = -\nabla_s \phi_s(x, y)e^{ikhz}, \quad \mathbf{H}_s = -\nabla_s \psi_s(x, y)e^{ikhz} \quad (16)$$

Since $\nabla \cdot \mathbf{E}_s = 0$ and $\nabla \cdot \mathbf{H}_s = 0$ in the waveguide, ϕ_s and ψ_s satisfy Laplace's equations

$$\nabla_s^2 \phi_s(x, y) = 0, \quad \nabla_s^2 \psi_s(x, y) = 0 \quad (17)$$

If we have perfect electric conductors, the boundary conditions are $\hat{\mathbf{n}} \times \mathbf{E}_s = 0$, and $\hat{\mathbf{n}} \cdot \mathbf{H}_s = 0$ on the metallic surfaces. These boundary conditions translate to

$$\phi_s = \text{constant} \quad (18)$$

$$\hat{\mathbf{n}} \cdot \nabla_s \psi_s = \frac{\partial}{\partial n} \psi_s = 0 \quad (19)$$

Equation (18) is known as the *Dirichlet boundary condition*, while Eq. (19) is the *Neumann boundary condition*. The constants in Eq. (18) are the potentials on the conductors, which may differ for different conductors.

At this point, it seems that ϕ_s and ψ_s are decoupled, and hence, the electric field and the magnetic field are independent of each other. This could not be true, as the coupling is expressed in Eqs. (6) and (7) (if we set $E_z = H_z = 0$ for discussing TEM modes). Hence, the coupling of the fields is only through the \hat{z} variation of the fields:

$$\frac{\partial}{\partial z} \hat{z} \times \mathbf{E}_s = i\omega\mu\mathbf{H}_s \quad (20)$$

$$\frac{\partial}{\partial z} \hat{z} \times \mathbf{H}_s = -i\omega\epsilon\mathbf{E}_s \quad (21)$$

Furthermore, from these equations, we deduce that \mathbf{H}_s and \mathbf{E}_s are mutually orthogonal in the TEM mode. Since the fields have e^{ikz} dependence, we conclude that

$$\hat{z} \times \mathbf{E}_s = \sqrt{\frac{\mu}{\epsilon}} \mathbf{H}_s = \eta \mathbf{H}_s \quad (22)$$

if we assume that the wave is propagating in only one direction, then η is also known as the *intrinsic impedance* of the medium, and all TEM waves satisfy Eq. (22).

We can integrate Eq. (20) about a line contour around one of the conductors that made up the transmission line to obtain

$$\frac{\partial}{\partial z} \oint_C \hat{z} \times \mathbf{E}_s \cdot d\mathbf{l} = i\omega\mu \oint_C \mathbf{H}_s \cdot d\mathbf{l} \quad (23)$$

By Ampere's law, we have $\oint_C \mathbf{H}_s \cdot d\mathbf{l} = I$, the total current on one of the conductors. For the left-hand side, we have

$$\begin{aligned} \oint_C \hat{z} \times \mathbf{E}_s \cdot d\mathbf{l} &= - \oint_C d\mathbf{l} \cdot \hat{z} \times \nabla_s \phi_s \\ &= - \int_S dS \hat{z} \cdot \nabla_s \times \hat{z} \times \nabla_s \phi_s. \end{aligned} \quad (24)$$

The second equality follows from Stokes' theorem. Using $\hat{z} \cdot \nabla_s \times \hat{z} \times \nabla_s \phi_s = \nabla_s^2 \phi_s = 0$, we have

$$\oint_C \hat{z} \times \mathbf{E}_s \cdot d\mathbf{l} = - \int_S dS \nabla_s^2 \phi_s \quad (25)$$

$\nabla_s^2 \phi_s = -\rho/\epsilon$, the right-hand side of Eq. (25) evaluates to Q/ϵ , where Q is the total charge per unit length on one conductor. Hence, Eq. (25) becomes

$$\oint_C \hat{z} \times \mathbf{E}_s \cdot d\mathbf{l} = \frac{Q}{\epsilon} \quad (26)$$

Therefore, Eq. (23) becomes

$$\frac{d}{dz} Q = i\omega\mu\epsilon I \quad (27)$$

Since the transverse field is purely static, we can define $Q = CV$, where C is the capacitance per unit length and $V = V_1 - V_2$. Hence, Eq. (27) becomes

$$\frac{d}{dz} V = i\omega \frac{\mu\epsilon}{C} I \quad (28)$$

Since $\mu\epsilon/C$ has the dimension of henries per meter, we can define $L = \mu\epsilon/C$, an inductance per unit length, and Eq. (28) becomes

$$\frac{dV}{dz} = i\omega LI \quad (29)$$

With manipulations similar to $\hat{z} \times (21)$, we obtain

$$\frac{dI}{dz} = i\omega CV \quad (30)$$

Equations (29) and (30) are the telegraphist equations for a transmission line, which can also be derived from a circuits viewpoint.

Since the fields, and hence the voltage and current, have e^{ikz} dependence, where $k = \omega\sqrt{\mu\epsilon} = \omega\sqrt{LC}$, we deduce either from Eq. (29) or (30) that

$$\frac{V}{I} = \sqrt{\frac{L}{C}} = Z_0 \quad (31)$$

if the wave is propagating only in the positive z direction. Z_0 is also known as the *characteristic impedance* of a transmission line. Since C and L are dependent on the geometry of the transmission line, Z_0 is a geometry-dependent impedance. This is unlike η , the intrinsic impedance. It can be easily shown from Eqs. (29) and (30) that

$$\frac{d^2 V}{dz^2} + \omega^2 LCV = 0 \quad (32)$$

$$\frac{d^2 I}{dz^2} + \omega^2 LCI = 0 \quad (33)$$

which are one-dimensional scalar wave equations, whose solutions are given by

$$V(z) = V^+ e^{ikz} + V^- e^{-ikz} \quad (34)$$

$$I(z) = I^+ e^{ikz} - I^- e^{-ikz} \quad (35)$$

These constants are related through $V^+/I^+ = V^-/I^- = Z_0$. The velocity of the wave on the line is given by

$$v = \frac{1}{\sqrt{\mu\epsilon}} = \frac{1}{\sqrt{LC}} \quad (36)$$

The time-average energy stored per unit length in a transmission line for a single propagating wave is given by

$$\langle W_e \rangle = \frac{1}{4} \epsilon \int_S \mathbf{E}_s \cdot \mathbf{E}_s^* dS = \frac{1}{4} \epsilon \int_S (\nabla_s \phi_s)^2 dS \quad (37)$$

$$\langle W_m \rangle = \frac{1}{4} \mu \int_S \mathbf{H}_s \cdot \mathbf{H}_s^* dS = \frac{1}{4} \mu \int_S (\nabla_s \psi_s)^2 dS \quad (38)$$

where $\langle W_e \rangle$ and $\langle W_m \rangle$ are the time average energy stored in the electric field and the magnetic field, respectively. Using the fact that $\nabla \cdot (\phi \nabla \phi) = (\nabla \phi)^2 + \phi \nabla^2 \phi$, we can write

$$\langle W_e \rangle = \frac{1}{4} \epsilon \oint_{C_1+C_2} \phi \frac{\partial}{\partial n} \phi dl = \frac{1}{4} (V_1 - V_2) Q = \frac{1}{4} CV^2 \quad (39)$$

where $V = V_1 - V_2$, $Q = CV$. This equation could also be derived from circuits theory. As we have shown before, $|\mathbf{E}_s| = \sqrt{\frac{\epsilon}{\mu}} |H_s|$; hence the time-average energy stored in the magnetic field is

$$\langle W_m \rangle = \langle W_e \rangle = \frac{1}{4} CV^2 \quad (40)$$

Since $V^2 = Z_0^2 I^2 = \frac{L}{C} I^2$, and $\mu\epsilon = LC$, we can also write

$$\langle W_m \rangle = \frac{1}{4} LI^2 \quad (41)$$

Equation (41) can also be established by circuit theory. It also establishes our definition of L as an inductance per unit length.

The time-average power flow down a transmission line is given by

$$\langle P \rangle = \frac{1}{2} \Re \int_S dS \hat{z} \cdot (\mathbf{E}_s \times \mathbf{H}_s^*) \quad (42)$$

Since $\mathbf{H}_s = \sqrt{(\epsilon/\mu)} \hat{z} \times \mathbf{E}_s$ from Eq. (22), we have

$$\langle P \rangle = \frac{1}{2} \sqrt{\frac{\epsilon}{\mu}} \int_S dS |\mathbf{E}_s|^2 = 2v \langle W_e \rangle = v \langle W_e + W_m \rangle \quad (43)$$

Hence, the time-average stored energy $\langle W_e + W_m \rangle$ moving at velocity v contributes to power flow. Equation (43) is also valid for non-TEM modes and more general (but loss-

less) situations, if v is replaced by v_g , the *group velocity*. The group velocity is defined as $v_g = (dk_z/d\omega)^{-1}$. In the TEM case, $k_z = k = \omega\sqrt{\mu\epsilon}$, so that $v_g = v$. The group velocity is the velocity of energy propagation in a waveguide, and it is also the signal velocity. Equations (29) and (30) can be also derived from a simple circuits model assuming distributed inductances and capacitances along the line.

2.3. Lossy Transmission Lines

To characterize a lossy transmission line, we replace the series impedance per unit length $-i\omega L$ by $-i\omega L + R$, and the shunt admittance per unit length $-i\omega C$ by $-i\omega C + G$, where R is the series resistance per unit length in the conductor, while G is the shunt conductance per unit length in the dielectric insulator. The series resistance results from the finite conductivity of the (imperfect) conductors, while the shunt conductance results from the imperfect insulation of the dielectrics. Usually, the series resistance is a much more important attenuation factor than the shunt conductance.

Figure 2 illustrates the distributed circuit model for the transmission line. Together with L and C , R and G constitute the *primary* transmission-line constants. In contrast, the velocity of propagation v and the characteristic impedance of the line Z_0 are usually called *secondary* constants. The telegraphist equations then become

$$\frac{dV}{dz} = (i\omega L - R)I = -ZI \quad (44)$$

$$\frac{dI}{dz} = (i\omega C - G)V = -YV \quad (45)$$

The characteristic impedance is now

$$Z_0 = \sqrt{\frac{Z}{Y}} \quad (46)$$

while the propagation constant becomes

$$k^2 = -(i\omega L - R)(i\omega C - G), \quad (47)$$

$$k = \omega \sqrt{LC \left(1 + \frac{iR}{\omega L}\right) \left(1 + \frac{iG}{\omega C}\right)}$$

Hence k is complex and the wave e^{ikz} is attenuating. Moreover, with loss, even if the primary constants are independent of frequency, the secondary parameters will be frequency-dependent.

Note that, strictly speaking, when we have a lossy transmission line due to conductor losses, a pure TEM wave cannot exist. This is because the axial current flow meets a resistance, and hence, an axial component of the electric field is necessary now to drive a current in the conductor. Therefore, the field is only quasi-TEM. However, the conductor loss can be regarded as a small perturbation of the perfect conductor case, and the electromagnetic field in the lossy line will not differ much from that of a lossless case.

Figure 2. Distributed equivalent circuit representation of a transmission line supporting the TEM mode. Each section Δl is modeled by a resistance R per unit length (Ω/m), an inductance L per unit length (H/m), a capacitance C per unit length (F/m), and a conductance G per unit length (G/m).

The shunt conductance G in a lossy line can be found as follows. If the capacitance per unit length between two conductors is given by the formula

$$C = \epsilon K \quad (48)$$

where K is a geometry-dependent factor, the shunt admittance would be given by $Y = -i\omega C = -i\omega\epsilon K$. If now the dielectric medium is lossy so that $\epsilon = \epsilon' + (i\sigma/\omega)$, then the shunt admittance is given by

$$Y = -i\omega\epsilon'K + \sigma K \quad (49)$$

Hence, we identify $G = \sigma K$. Note that the derivations in Eqs. (20)–(30) hold true even if ϵ is complex. For this reason, Y in Eq. (33) is exact.

The series resistance R can be found by calculating the resistance of the conductor in a perturbative manner when it is lossy. The skin effect will confine the current to flow only on the surface of the conductor. Since the skin depth in a conductor is $\delta = \sqrt{2/\omega\mu\sigma}$, the current is confined to flow in a thinner region at higher frequencies, hence increasing this series resistance.

Another way of calculating transmission-line loss is via a perturbation argument and the use of energy conservation. If a transmission line is lossy such that $k = k' + ik''$, and

$$V, I \sim e^{ik'z - k''z} \quad (50)$$

then, the power flow in a line, which is proportional to $|V|^2$ or $|I|^2$, is

$$P \sim e^{-2k''z} \quad (51)$$

By energy conservation, we obtain

$$\frac{dP}{dz} = -P_d = -2k''P \quad (52)$$

where P_d is the power dissipated per unit length on the line. Therefore, the attenuation constant k'' can be derived to be

$$k'' = \frac{P_d}{2P} \quad (53)$$

if we know P_d . We can assume P to be close to that of a lossless line in using Eq. (53) in a perturbative concept.

2.4. Distributed Parameters

From Eqs. (34) and (35), the impedance of a lossless transmission line at any given point is given by

$$Z(z) = \frac{V(z)}{I(z)} = Z_0 \frac{e^{ikz} + \Gamma_0 e^{-ikz}}{e^{ikz} - \Gamma_0 e^{-ikz}} \quad (54)$$

where $\Gamma_0 = V^-/V^+$ is the reflection coefficient, which can be found by using a known value of $Z(z)$ at some point on the line. For instance, if the line is terminated with a load Z_L at $z = 0$, then $Z(0) = Z_L$ and, substituting in Eq. (54), we have

$$\Gamma_0 = \frac{Z_L - Z_0}{Z_L + Z_0} \quad (55)$$

Furthermore, the line impedance can be written at any location along the line

$$Z(z) = Z_0 \frac{Z_L + iZ_0 \tan \beta z}{Z_0 + iZ_L \tan \beta z} \quad (56)$$

with $z < 0$, while the reflection coefficient everywhere along the line (generalized reflection coefficient) $\Gamma(z)$ is given by Eq. (55) with Z_L substituted by $Z(z)$ above. The representation of the variation of the normalized impedance along the line with the angle of the generalized reflection coefficient, that is, the relation

$$\Gamma = \frac{Z - Z_0}{Z + Z_0}$$

for all Z , such that $\text{Re}[Z] \geq 0$, in the Γ plane, is called the *Smith chart* [17,18]. It provides a useful graphical aid to the analysis of transmission-line and matching problems that are otherwise cumbersome if treated in analytical form.

The addition of two waves, V^+ and V^- , propagating in opposite directions gives rise to a standing-wave pattern along the line. The ratio of the minimum and maximum values of the voltage of the standing-wave pattern defines

the *voltage standing-wave ratio* (VSWR), given by

$$\text{VSWR} = \frac{1 + |\Gamma_0|}{1 - |\Gamma_0|} \tag{57}$$

Transmission lines are usually designed to maximize transmission and minimize reflection over the frequency band of interest. Therefore, in practical design situations, we have $\text{VSWR} \approx 1$.

2.5. Transformation Matrices

In a circuit, a transmission line may interact with other transmission lines, either by design, as in microwave integrated circuits (MICs), or as a result of undesired effects, as in closely packed, high-frequency circuit interconnections [19,20] on computer boards. We use the term *coupling* when such property is desired, or planned by design [21,22]. Coupled integrated transmission lines form the basic building blocks for a series of passive microwave elements such as filters and directional couplers [15]. In the case of an undesired interaction, we usually employ the term *crossstalk*. In both cases, one can analyze the N -transmission-line problem as a general microwave circuit consists of many ports. A convenient way to characterize an N -port network is to describe the network in terms of *impedance matrices* or *admittance matrices*. For example, if the N -port network can be characterized by a voltage-current pair at each port (flowing into), then a column vector of voltages can be defined and also a column vector of currents. We can express a relationship between the voltages and the currents as

$$\mathbf{V} = \begin{bmatrix} V_1 \\ V_2 \\ \vdots \\ V_N \end{bmatrix} = \begin{bmatrix} Z_{11} & Z_{12} & \cdots & Z_{1N} \\ Z_{21} & Z_{22} & \cdots & Z_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ Z_{N1} & Z_{N2} & \cdots & Z_{NN} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ \vdots \\ I_N \end{bmatrix} = \bar{\mathbf{Z}} \cdot \mathbf{I} \tag{58}$$

By the same token, we can express

$$\mathbf{I} = \bar{\mathbf{Y}} \cdot \mathbf{V} \tag{59}$$

where $\bar{\mathbf{Y}}$ is the admittance matrix, which define the Y parameters. For reciprocal circuits, it can be shown that $\bar{\mathbf{Z}}$ and $\bar{\mathbf{Y}}$ are symmetric matrices, so that there are only three independent matrix elements in a two-port network. For lossless circuits, it can be shown that these matrices have pure imaginary elements.

For high frequencies, however, it is more pertinent to think about waves. Then, at each port, we can define an incident and a reflected wave. For instance, we can define an incident voltage wave V^+ and a reflected voltage wave V^- . A relationship can then be express between the reflected waves at all the ports to the incident waves at all

the ports. This constitutes the *scattering matrix*:

$$\mathbf{V} = \begin{bmatrix} V_1^- \\ V_2^- \\ \vdots \\ V_N^- \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} & \cdots & S_{1N} \\ S_{21} & S_{22} & \cdots & S_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ S_{N1} & S_{N2} & \cdots & S_{NN} \end{bmatrix} \begin{bmatrix} V_1^+ \\ V_2^+ \\ \vdots \\ V_N^+ \end{bmatrix} = \bar{\mathbf{S}} \cdot \mathbf{V}^+ \tag{60}$$

It can be proved that the matrix $\bar{\mathbf{S}}$ has to be symmetric for reciprocal circuits, and that it has to be unitary if the circuit is lossless. The S_{ij} are called *scattering* or simply *S-parameters*. S parameters are very important in the characterization of a microwave circuits. CAD (computer-aided design) packages for the analysis of complex networks are usually based on the availability of S parameters (or Y parameters) for each of their building blocks (such as the transmission lines).

When one needs to cascade a series of two-port networks, it is more convenient to work with chain matrices or transmission matrices. A voltage-current transmission matrix, usually called an *ABCD matrix*, relates the voltage and current at one port to the voltage and current at the second port.

Written explicitly, we have

$$\begin{bmatrix} V_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A_1 & B_1 \\ C_1 & D_1 \end{bmatrix} \begin{bmatrix} V_2 \\ I_2 \end{bmatrix} \tag{61}$$

Notice that in the convention for the *ABCD* matrix, the current at port 2 is flowing out of the port rather than into the port. In this manner, if we have a second transmission matrix of a second network that relates V_2, I_2 to V_3, I_3 namely

$$\begin{bmatrix} V_2 \\ I_2 \end{bmatrix} = \begin{bmatrix} A_2 & B_2 \\ C_2 & D_2 \end{bmatrix} \begin{bmatrix} V_3 \\ I_3 \end{bmatrix} \tag{62}$$

then, when these two networks are cascaded together, the resultant transmission matrix is the product of the two matrices

$$\begin{bmatrix} V_2 \\ I_2 \end{bmatrix} = \begin{bmatrix} A_1 & B_1 \\ C_1 & D_1 \end{bmatrix} \begin{bmatrix} A_2 & B_2 \\ C_2 & D_2 \end{bmatrix} \begin{bmatrix} V_3 \\ I_3 \end{bmatrix} \tag{63}$$

For a two port network, it can be shown that

$$A = \frac{Z_{11}}{Z_{12}}, \quad B = \frac{Z_{11}Z_{22} - Z_{12}^2}{Z_{12}} \tag{64a}$$

$$C = \frac{1}{Z_{12}}, \quad D = \frac{Z_{22}}{Z_{12}} \tag{64b}$$

for a reciprocal network. It is also readily verified that

$$AD - BC = 1 \tag{65}$$

for this case. Hence, the determinant of a chain matrix is always 1 for a reciprocal network.

3. HOLLOW WAVEGUIDES

In this section, we will focus on a typical class of high-frequency transmission line, the hollow waveguide [10,23]. Hollow waveguides are specially useful in low-loss and high-power systems, such as the feeding system of an antenna. Hollow waveguides do not support a TEM mode, and the analysis of the previous section deriving the circuit parameters (line and voltage) along the line in terms of the TEM fields does not apply in this case. The absence of a TEM mode in a hollow waveguide can be proved by contradiction as follows. If we assume that it does, then the magnetic field $\mathbf{H} = \mathbf{H}_s$ has to end on itself due to the absence of magnetic charges. It is clear that $\oint_C \mathbf{H}_s \cdot d\mathbf{l} \neq 0$ about any closed contour following the magnetic field lines. This is clearly in violation of Eq. (15) for a TEM mode, which implies that if $\oint \mathbf{H}_s \cdot d\mathbf{l} = 0$ if C does not enclose any conducting current. These two results are contradictory, implying the absence of a TEM mode in a hollow waveguide.

3.1. Rectangular Waveguides

The rectangular waveguide is the most commonly used hollow waveguide. It is illustrated in Fig. 3. By adjusting the aspect ratio, a to b , of the waveguide, one can obtain a good bandwidth for single-mode propagation (the aspect ratio of $\frac{1}{2}$ is used in most practical waveguides). Furthermore, the analysis of this waveguide is the simplest.

3.1.1. TE Modes (H Modes). A TE mode in a rectangular waveguide is characterized by H_z satisfying Eq. (13) with the requisite Neumann boundary condition. An H_z that will satisfy Eq. (13) with $(\partial/\partial n)H_z = 0$ on the waveguide wall is

$$H_z = H_0 \cos\left(\frac{m\pi}{a} x\right) \cos\left(\frac{n\pi}{b} y\right) e^{ik_z z} \quad (66)$$

where $k_s^2 = (m\pi/a)^2 + (n\pi/b)^2$, $k_z = \sqrt{k^2 - k_s^2}$. This last relation is called the *dispersion relation*. A dispersion relation gives the propagation constant as function of frequency: $k_z = k_z(\omega)$. The transverse fields can be found using Eqs. (9) and (10). The mode becomes *evanescent* or

Figure 3. Geometry of a rectangular hollow waveguide.

nonpropagating when $k_s^2 > k^2$, that is, when k_z becomes imaginary. Since $k^2 = \omega^2 \mu \epsilon$, the *cutoff frequency* (i.e., the frequency below which the mode is evanescent) is given by

$$\omega_{mn,c} = \frac{1}{\sqrt{\mu \epsilon}} \left[\left(\frac{m\pi}{a} \right)^2 + \left(\frac{n\pi}{b} \right)^2 \right]^{1/2} \quad (67)$$

The corresponding mode is usually labeled as TE_{mn} (or H_{mn}) mode. Note that this is in marked contrast for the case of TEM propagation. For the TEM mode, no cutoff frequency exists. The wavelength of a wave at ω_c in the medium denoted by μ , ϵ is the cutoff wavelength:

$$\lambda_{mn,c} = \frac{2}{[(m/a)^2 + (n/b)^2]^{1/2}} \quad (68)$$

In waveguide conventions, a is assumed larger than b . Then, the dominant mode (fundamental mode) with the lowest cutoff frequency is the $m=1$, $n=0$ mode, also known as the TE_{10} mode (or H_{10} mode). The TE_{00} mode is nonexistent because, otherwise, $k_s = 0$, and \mathbf{E}_s and \mathbf{H}_s would diverge from Eqs. (9) and (10) when $k_s \rightarrow 0$. The waveguide usually operates at those frequencies where only the fundamental mode can propagate.

3.1.2. TM Modes (E Modes). A TM mode in a rectangular waveguide is characterized by E_z satisfying Eq. (14) with the requisite Dirichlet boundary condition. An E_z that will satisfy Eq. (14) with $E_z = 0$ on the waveguide wall is

$$E_z = E_0 \sin\left(\frac{m\pi}{a} x\right) \sin\left(\frac{n\pi}{b} y\right) e^{ik_z z} \quad (69)$$

where $k_s^2 = (m\pi/a)^2 + (n\pi/b)^2$, $k_z = \sqrt{k^2 - k_s^2}$. The TM_{mn} mode has the same cutoff frequency as the TE_{mn} mode. However, when either $m=0$, or $n=0$, the mode does not exist since $E_z = 0$ then. Therefore, the lowest TM mode is the TM_{11} mode with a cutoff frequency above that of the TE_{10} mode. Given the z components of the fields, all other field components of a waveguide can be derived.

3.2. Circular Waveguides

Certain modes of a circular waveguide have less attenuation from wall loss compared to a rectangular waveguide. Hence, circular waveguides are sometimes preferred over a rectangular waveguide. The geometry of a circular hollow waveguide is illustrated in Fig. 4.

3.2.1. TE Modes (H Modes). The E_z component of a TE mode satisfies Eq. (13) in cylindrical coordinates

$$\left[\frac{1}{\rho} \frac{\partial}{\partial \rho} \rho \frac{\partial}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2}{\partial \phi^2} + k_s^2 \right] H_z = 0 \quad (70)$$

with the boundary condition that $(\partial/\partial \rho)H_z = 0$, $\rho = a$, where a is the radius of the waveguide. If we assume that H_z has $e^{\pm in\phi}$, $\sin n\phi$ or $\cos n\phi$ dependence, where n is an integer, we can replace $\partial^2/\partial \phi^2$ by $-n^2$. The solution of

Figure 4. Geometry of a cylindrical hollow waveguide.

Eq. (70) then becomes

$$H_z = H_0 J_n(k_s \rho) e^{\pm i n \phi + i k_z z} \tag{71}$$

where J_n is the Bessel function. We require that $(\partial/\partial\rho)H_z = 0$ at $\rho = a$, implying that

$$J'_n(k_s a) = 0 \tag{72}$$

with $k_z = \sqrt{k^2 - k_s^2}$. If the m th zero of $J'_n(x)$ is defined to be β_{nm} such that $J'_n(\beta_{nm}) = 0$, then the values of possible k_s are

$$k_s = \frac{\beta_{nm}}{a} \tag{73}$$

The subscript n denotes the orders of the Bessel function $J_n(x)$ and the circular harmonic $e^{\pm i n \phi}$. The subscript m denotes the m th zero of $J'_n(x)$ discounting the zero at the origin. The corresponding mode is usually denoted as the TE_{nm} mode. Cutoff occurs when $k = \omega \sqrt{\mu\epsilon} < k_s$. From the tabulated data for β_{nm} , it follows that the TE_{11} modes corresponding to the first zero of $J'_1(x)$ have the lowest cutoff frequency. The cutoff frequency for the TE_{nm} mode is given by

$$\omega_{nm,c} = \frac{1}{\sqrt{\mu\epsilon}} \frac{\beta_{nm}}{a} \tag{74}$$

and the corresponding cutoff wavelength is

$$\lambda_{nm,c} = \frac{2\pi}{\beta_{nm}} a \tag{75}$$

3.2.2. TM Modes (E Modes). Similar to a TE mode, the E_z component of a TM mode has $e^{\pm i n \phi}$ dependence, satisfying the equation

$$\left[\frac{1}{\rho} \frac{\partial}{\partial \rho} \rho \frac{\partial}{\partial \rho} - \frac{n^2}{\rho^2} + k_s^2 \right] E_z = 0 \tag{76}$$

with the boundary condition $E_z(\rho = a) = 0$. Hence

$$E_z = E_0 J_n(k_s \rho) e^{\pm i n \phi + i k_z z} \tag{77}$$

with $J_n(k_s a) = 0$. If we denote the m th zero of $J_n(x)$ by α_{nm} , then k_s has possible values of

$$k_s = \frac{\alpha_{nm}}{a} \tag{78}$$

where the subscript n denotes the order of the Bessel function $J_n(x)$ and the subscript m denotes the m th zero of $J_n(x)$, discounting the zero at the origin. The corresponding mode is known as the TM_{nm} mode. The cutoff frequency of the TM_{nm} mode is given by

$$\omega_{nm,c} = \frac{1}{\sqrt{\mu\epsilon}} \frac{\alpha_{nm}}{a} \tag{79}$$

and the corresponding cutoff wavelength is

$$\lambda_{nm,c} = \frac{2\pi}{\alpha_{nm}} a \tag{80}$$

From the tabulated data for α_{nm} , it follows that the lowest TM mode is the TM_{01} mode, but it has a higher cutoff frequency compared to the TE_{11} mode.

It can also be shown that the TE_{01} mode has the lowest loss at high frequencies. The TE_{01} is axially symmetric with $\mathbf{E} = \phi \mathbf{E}_\phi$. An interesting property of this mode is that, contrary to other modes, the loss decreases monotonically as frequency increases.

The transverse field components of a circular waveguide are easily obtained given the axial components. One disadvantage of circular waveguides is that, because of its circular symmetry, the wave polarization on the transversal plane may change as the wave propagates, as a result of small perturbations. One way to combat this problem is to employ elliptical waveguides [24].

3.3. Other Closed Waveguides

If a metallic waveguide has an arbitrary cross section whose shape does not fall on any of the curvilinear coordinates, one has, in general, to resort to numerical techniques to find the modes and dispersion curves. These will be discussed later. Among these other waveguides, ridge waveguides are commonly used [25,26]. They are attractive because the frequency range of their dominant mode exceeds that of a rectangular waveguide of same external dimensions (the cutoff is lowered). The tradeoff is for an increased loss from the walls.

When a uniform waveguide is filled with inhomogeneous materials [27], the guided modes of the structure cannot be decomposed into TE and TM waves, except for some very special cases. In other words, the E_z and H_z components of the fields are always coupled together. Such modes are also called the *hybrid modes*. This coupling can be shown from Maxwell's equations [10]. The fact that the E_z and H_z waves are in general coupled at a dielectric interface is also known as the *depolarization effect*.

In general, inhomogeneous filled waveguides can be used to make variable phase shifters and attenuators. If the inhomogeneity filling the waveguide is nonreciprocal (like ferrite), then isolators, gyrators, and attenuators can be made.

An example of inhomogeneous filled waveguide is the dielectric-slab-loaded waveguide. The dispersion relation for this structure can be easily derived using the transverse resonance condition [10].

4. OPEN WAVEGUIDES

In an open waveguide [28–32] a wave is guided along a structure, but the field is not enclosed completely in the structure—the field extends to infinity. However, the field decays exponentially away from the guiding structure; hence, the energy of the wave is still localized around the guiding structure. The guiding structure is often filled with inhomogeneous medium. Therefore, many properties of inhomogeneously filled waveguides are also true in open, inhomogeneously filled waveguides.

4.1. Dielectric Waveguides

An example of an open waveguide is a dielectric slab waveguide. The waveguide is made with dielectric coating on a ground plane, or in the case of optical thin-film waveguides, it is a coating of an optically more dense medium on top of an optically less dense substrate, as illustrated in Fig. 5.

Because of the symmetry of the geometry, we can decompose the field inside such a waveguide into TM and TE types [33]. The mode is guided by total internal reflection. This is possible only if $\epsilon_1 > \epsilon_0$ and $\epsilon_1 > \epsilon_2$. At total internal reflection, the fields in regions 0 and 2 are evanescent, and hence they decay exponentially away from the structure. Therefore, most of the energy of the mode is still trapped and localized in the vicinity of the structure.

If a TM wave is in a dielectric slab, we can write the field in region 1 as

$$\mathbf{H}_1 = \hat{y}[A_1 e^{ik_{1x}x} + B_1 e^{-ik_{1x}x}]e^{ik_z z} \quad (81)$$

Equation (1) has the physical meaning that the wave in region 1 is representable as bouncing waves. At $x = 0$, the upgoing wave is the reflection of the downgoing wave; hence, we have

$$A_1 = R_{12}^{\text{TM}} B_1 \quad (82)$$

where R_{12}^{TM} is the TM reflection coefficient at the 1–2 interface. If there are subsurface layers, R_{12}^{TM} could be the generalized reflection coefficient that includes subsurface reflections. Otherwise, it is just the single interface, Fresnel reflection coefficient for a TM wave. At the upper interface at $x = d$, we require that the downgoing wave be a reflection of the upgoing wave:

$$B_1 e^{-ik_{1x}d} = R_{10}^{\text{TM}} e^{ik_{1x}d} A_1 \quad (83)$$

For nontrivial A_1 and B_1 , Eqs. (82) and (83) imply that

$$1 - R_{10}^{\text{TM}} R_{12}^{\text{TM}} e^{2ik_{1x}d} = 0 \quad (84)$$

This is the guidance condition, sometimes known as the transverse resonance condition for TM modes in a dielectric slab, with

$$R_{ij}^{\text{TM}} = \frac{\epsilon_j k_{ix} - \epsilon_i k_{jx}}{\epsilon_j k_{ix} + \epsilon_i k_{jx}}, \quad k_{ix} = \sqrt{k_i^2 - k_z^2} \quad (85)$$

Because of Eq. (85), the guidance condition expressed by Eq. (84) can be expressed entirely as a function of k_z . We can solve Eq. (84) either graphically or numerically on a computer. Once the value of k_z that satisfies Eq. (84) is found, it can be used in Eq. (82) or (83) to find a relationship between A_1 and B_1 . The fields in region 0 and 2 can be found easily:

$$\mathbf{H}_0 = \hat{y} T_{10}^{\text{TM}} A_1 e^{ik_{0x}(x-d) + ik_z z} \quad (86a)$$

$$\mathbf{H}_2 = \hat{y} T_{12}^{\text{TM}} B_1 e^{-ik_{2x}x + ik_z z} \quad (86b)$$

In other words, the field in region 0 is a consequence of the transmission of the upgoing wave in region 1, while the field in region 2 is a consequence of the transmission of the downgoing wave in region 1. In the above, T_{ij} is a transmission coefficient with

$$T_{ij}^{\text{TM}} = 1 + R_{ij}^{\text{TM}} \quad (87)$$

In order for a mode to be trapped, the field has to decay exponentially in the x direction. Therefore, k_{0x} and k_{2x} have to be purely imaginary. In other words, we can find the values of k_z for guidance only in the ranges $k_z > k_0$ and $k_z > k_2$.

For a symmetric waveguide where regions 0 and 2 are the same, the first few modes of the waveguides are as sketched in Fig. 6. These modes are, in general, better

Figure 5. Geometry of a dielectric slab waveguide. The electromagnetic field is guided by total internal reflection. This is possible only if $\epsilon_1 > \epsilon_2$ and $\epsilon_1 > \epsilon_3$.

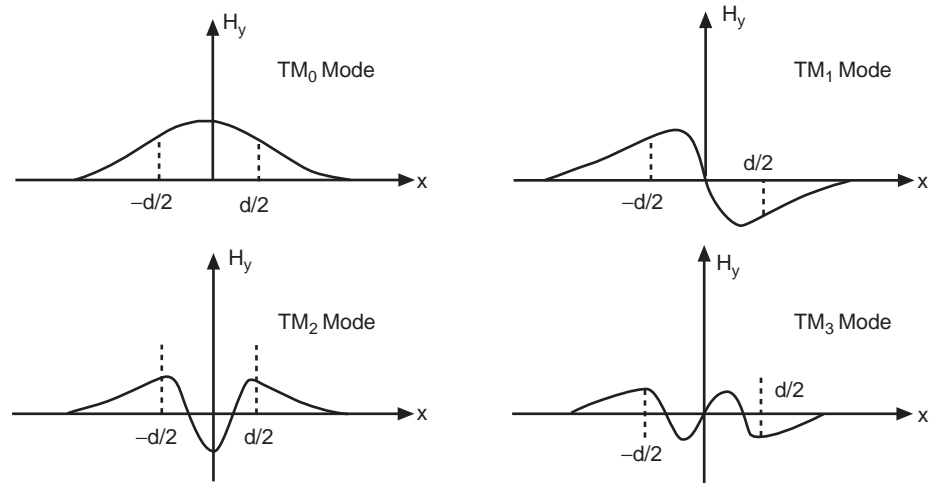

Figure 6. Field distribution for different modes in a dielectric slab waveguide. The amplitude scale is arbitrary. The TM_0 has no cutoff frequency, but the other modes have a finite cutoff frequency.

trapped when the contrast is high between region 1 and regions 0 and 2, or when the frequency is high. We can study the guidance of a TE mode that is the dual of a TM mode in a similar fashion.

By a further manipulation of Eq. (84), and using the definition of Fresnel reflection coefficients, Eq. (84) can be written as

$$\alpha_{0x} \frac{d}{2} = \frac{\varepsilon_0}{\varepsilon_1} k_{1x} \frac{d}{2} \tan\left(\frac{k_{1x}d - m\pi}{2}\right) \quad (88)$$

where $\alpha_{0x} = \sqrt{k_z^2 - k_0^2}$, $k_{1x} = \sqrt{k_1^2 - k_z^2}$, and $m = 1, 2, 3, 4, \dots$. The left-hand side of Eq. (88) can be expressed in terms of the $k_{1x}d$ variable

$$\frac{d}{2} \sqrt{k_z^2 - k_0^2} = \sqrt{(k_1^2 - k_0^2) \left(\frac{d}{2}\right)^2 - \left(\frac{k_{1x}d}{2}\right)^2} \quad (89)$$

which is the equation of a circle. Equation (88) can hence be solved graphically by plotting both sides of Eq. (88) as a function of $k_{1x}d$.

A mode in a dielectric has a part of its energy outside the waveguide and inside the waveguide. Hence, the group velocity of the mode is between that of the slab region and the outer region. When the frequency is very low, the mode is weakly evanescent outside the dielectric slab and the group velocity of a mode is closer to that of the outer region because most of the energy of the mode is outside the waveguide. When the frequency is high, the mode is strongly evanescent outside and most of the energy of the mode is trapped inside the slab. Hence, the group velocity of the mode is close to that of the dielectric slab.

The TM_0 mode has no cutoff, since continuity of the slope and field amplitude can be satisfied for all frequencies, and yet the field is evanescent outside. This is not true of the higher-order modes. For high frequencies, the higher-order modes are well trapped inside the dielectric waveguide. When the frequency is lowered, however, the field may cease to be evanescent outside the dielectric

slab. At the frequency when the field becomes constant outside, we have the cutoff. At frequencies lower than the cutoff frequency, the mode leaks energy to outside the slab, it becomes a leaky mode and is not guided at all.

Many other configurations of dielectric waveguides are possible. Dielectric waveguides found many applications in the millimeter-wave and optical frequency ranges. One problem of these waveguides is the radiation loss incurred at bends and discontinuities. This can be minimized by utilizing a higher dielectric constant, but at the expense of a much smaller size of the structures, which leads to manufacturing problems. Analytical solutions in general are not available for these structures, and a numerical analysis is necessary to find the modes and dispersion relations. Moreover, in these structures, the TE and TM modes are coupled by the boundary conditions at the dielectric boundaries. For this reason, none of the modes are strictly TE or TM, and the *EH* notation is used to denote a mode whose TE component dominates over its TM component, and vice versa for the *HE* notation.

A very popular geometry of dielectric waveguides is the circular dielectric waveguide, which is discussed next.

4.2. Circular Dielectric Waveguide

The geometry of a circular dielectric waveguide is illustrated in Fig. 7. An optical fiber is a kind of circular dielectric waveguide. Usually, an optical fiber has a protective cladding as well. In the ensuing analysis, we will ignore the protective cladding, letting $b \rightarrow \infty$.

In order for a mode to be guided, we require that $\varepsilon_1\mu_1 > \varepsilon_2\mu_2$. In other words, the light velocity in the core region has to be slower than the light velocity in the cladding. The field outside the core region is evanescent for a guided mode. Therefore, letting $b \rightarrow \infty$ affects the guided mode slightly, especially if the mode is tightly bound to the core; hence, it is a good approximation.

In the optical fiber modes, except for the axisymmetric modes, the TE and TM fields are coupled to each other by the boundary conditions as in an inhomogeneously filled waveguide. The z components of the field are solutions to

Figure 7. Geometry of a circular dielectric waveguide. To obtain a guided mode, the dielectric constant in the core should be greater than in the cladding, $\epsilon_1 > \epsilon_2$. The field is guided by total internal reflection. An optical fiber is an example of circular dielectric waveguide. In this case, the contrast between the dielectric constants ϵ_1 and ϵ_2 is usually very low.

the wave equation in cylindrical coordinates for each of the homogeneous regions.

We will analyze next the circular dielectric waveguide using the weakly guided approximation [34]. The weakly guided approximation is quite useful in analyzing optical fibers, since the dielectric constant contrast from core to cladding is usually very low.

4.3. Weakly Guided Approximation

Starting from Maxwell's equations, we can derive the vector wave equations governing electromagnetic fields in an inhomogeneous waveguide

$$\nabla \times \mu_r^{-1} \nabla \times \mathbf{E} - \omega^2 \mu_0 \epsilon_0 \epsilon_r \mathbf{E} = 0 \quad (90a)$$

$$\nabla \times \epsilon_r^{-1} \nabla \times \mathbf{H} - \omega^2 \mu_0 \epsilon_0 \mu_r \mathbf{H} = 0 \quad (90b)$$

where $\mu_r = \mu(\mathbf{r})/\mu_0 = f_1(\mathbf{r})$, and $\epsilon_r = \epsilon(\mathbf{r})/\epsilon_0 = f_2(\mathbf{r})$. If we find a solution to Eq. (90a), the solution to the dual problem is obtained by letting $\mathbf{E} \rightarrow -\mathbf{H}$, $\mathbf{H} \rightarrow \mathbf{E}$, $\mu_r \rightarrow \epsilon_r$, $\epsilon_r \rightarrow \mu_r$. However, if $f_1(\mathbf{r}) \neq f_2(\mathbf{r})$, the dual problem corresponds to a different waveguide with $\mu_r = f_2(\mathbf{r})$ and $\epsilon_r = f_1(\mathbf{r})$. In order for a dual problem to be itself, we require that $f_1(\mathbf{r}) = f_2(\mathbf{r})$. If this is the case, then a mode and its dual are degenerate. Therefore, we can associate every mode in a waveguide with a dual mode. However, $f_1(\mathbf{r}) = 1$ usually, while $f_2(\mathbf{r}) \neq 1$; therefore, a mode is not exactly degenerate with its dual.

However, in the case of a weakly guided dielectric waveguide, $\epsilon_r \rightarrow 1$; hence, a mode is nearly degenerate with its dual. Furthermore, we can show that the vector nature of the wave is unimportant. If $\mu_r = 1$, we can rewrite Eqs. (90a) and (90b) as

$$\nabla \times \nabla \times \mathbf{E} - \omega^2 \mu_0 \epsilon_0 \epsilon_r \mathbf{E} = 0 \quad (91a)$$

$$\nabla \times \nabla \times \mathbf{H} - (\nabla \ln \epsilon_r) \times \nabla \times \mathbf{H} - \omega^2 \mu_0 \epsilon_0 \epsilon_r \mathbf{H} = 0 \quad (91b)$$

where $\nabla \ln \epsilon_r = \nabla \epsilon_r / \epsilon_r$ is the effect of the polarization charges at the dielectric interface. If the transverse and longitudinal components of Eqs. (91a) and (91b) are extracted, the following equations ensue:

$$\nabla^2 \mathbf{E}_s + \nabla_s [\nabla_s \ln \epsilon_r \cdot \mathbf{E}_s] + k^2 \mathbf{E}_s = 0 \quad (92a)$$

$$\nabla^2 E_z + ik_z (\nabla_s \ln \epsilon_r) \cdot \mathbf{E}_s + k^2 E_z = 0 \quad (92b)$$

$$\nabla^2 \mathbf{H}_s + (\nabla_s \ln \epsilon_r) \times (\nabla_s \times \mathbf{H}_s) + k^2 \mathbf{H}_s = 0 \quad (93a)$$

$$\begin{aligned} \nabla^2 \mathbf{H}_z + (\nabla_s \ln \epsilon_r) \times (\nabla_s \times \mathbf{H}_z) + (\nabla_s \ln \epsilon_r) \\ \times (\hat{z} ik_z \times \mathbf{H}_s) + k^2 \mathbf{H}_z = 0 \end{aligned} \quad (93b)$$

In the limit when $\epsilon_r \rightarrow 1$, and $\omega \rightarrow \infty$, the polarization charge terms in Eqs. (92a) and (93a), which are proportional to the first derivative of the field, can be ignored with respect to the other terms, yielding

$$\nabla^2 \mathbf{E}_s + k^2 \mathbf{E}_s = 0 \quad (94a)$$

$$\nabla^2 \mathbf{H}_s + k^2 \mathbf{H}_s = 0 \quad (94b)$$

In other words, the wave guidance problem by a fiber of weak contrast in the high-frequency limit reduces to a scalar problem.

In the limit when the contrast $\epsilon_r \rightarrow 1$, the wave that propagates in the fiber is a TEM wave where $E_z = 0$. When $\epsilon_r > 1$, we see from Eq. (92b) that $E_z \sim |\mathbf{E}_s|/\omega$. Therefore, when $\omega \rightarrow \infty$, then $|E_z| \ll |\mathbf{E}_s|$. By the same token, $|H_z| \ll |\mathbf{H}_s|$ when $\omega \rightarrow \infty$. Therefore, when the contrast is very low, and the frequency is very high, the mode is quasi-TEM, and $\nabla_s \cdot \mathbf{E}_s \approx 0$ and $\nabla_s \cdot \mathbf{H}_s \approx 0$.

Equations (94a) and (94b) are equivalent to

$$(\nabla^2 + k^2)\phi = 0 \quad (95)$$

where ϕ is either E_x , E_y , H_x or H_y .

For example, if we assume cylindrical geometry, we can let

$$\phi = \begin{cases} AJ_n(k_{1\rho}\rho)e^{in\phi + ik_z z}, & \rho < a \\ BK_n(\alpha_2\rho)e^{in\phi + ik_z z}, & \rho > a \end{cases} \quad (96)$$

The boundary conditions for ϕ at the interface where $k^2 = \omega^2 \mu_0 \epsilon_0 \epsilon_r$ displays a step discontinuity is

$$\phi_1 = \phi_2 \quad (97a)$$

$$\hat{n} \cdot \nabla \phi_1 = \hat{n} \cdot \nabla \phi_2 \quad (97b)$$

These boundary conditions are derivable from Eq. (95) alone.

Imposing these boundary conditions at $\rho = a$ for the weakly guided dielectric waveguide, whose field is given

by Eq. (96), we have

$$AJ_n(k_{1\rho}a) = BK_n(\alpha_2 a) \quad (98a)$$

$$AK_{1\rho}J'_n(k_{1\rho}a) = B\alpha_2 K'_n(\alpha_2 a) \quad (98b)$$

which yields

$$\frac{k_{1\rho}J'_n(k_{1\rho}a)}{J_n(k_{1\rho}a)} = \frac{\alpha_2 K'_n(\alpha_2 a)}{K_n(\alpha_2 a)} \quad (99)$$

Using the recurrence relationship that $J'_n(x) = -J_{n+1}(x) + \frac{n}{x}J_n(x)$, and that $K'_n(x) = -K_{n+1}(x) + \frac{n}{x}K_n(x)$, we can transform this to

$$\frac{k_{1\rho}J_{n+1}(k_{1\rho}a)}{J_n(k_{1\rho}a)} = \frac{\alpha_2 K_{n+1}(\alpha_2 a)}{K_n(\alpha_2 a)} \quad (100)$$

Similarly, using the recurrence relationship that $J'_n(x) = J_{n-1}(x) - (n/x)J_n(x)$, and $K'_n(x) = -K_{n-1}(x) - (n/x)K_n(x)$, we have

$$\frac{k_{1\rho}J_{n-1}(k_{1\rho}a)}{J_n(k_{1\rho}a)} = -\frac{\alpha_2 K_{n-1}(\alpha_2 a)}{K_n(\alpha_2 a)} \quad (101)$$

We can solve Eq. (11) graphically. The modes thus found are collectively designated the LP_{nm} mode. The lowest order mode is the LP_{01} mode (where LP stands for “linearly polarized”). These LP modes can be shown to be a linear combination of the EH and HE modes mentioned before.

The term “weakly guided dielectric waveguide” is a misnomer. When V is large, a mode can be tightly bound as demonstrated by the phase velocity approaching that of a core. Also, E_x and E_y are not independent of each other since $\nabla_s \cdot \mathbf{E}_s = 0$. The same statement applies to H_x and H_y .

5. MICROWAVE INTEGRATED CIRCUITS (MIC) TRANSMISSION LINES

With the advent of integrated circuits at microwave and millimeter-wave frequencies, microwave integrated circuit (MIC) transmission lines have become increasingly important [15]. They are easily integrated with other microwave integrated circuits, and have a low cost and better reproducibility/reliability than do conventional lines. Some examples are shown in Fig. 8. Not presented on this figure but also representative of MICs lines are the stripline and the inverted microstrip line [11]. Along with some configurations of dielectric waveguides for millimeter waves and integrated optics [29,32], such transmission lines belong to a class usually called *planar transmission lines* because the characteristics of these lines can be determined from the dimensions on a single plane.

5.1. Quasi-TEM Approximation

The usual integrated circuits waveguiding structures cannot support a TEM mode (an exception is the stripline, whose design data can be determined exactly from an electrostatic analysis for the TEM mode), for if they do, the

Figure 8. Cross-sectional view of different kinds of microwave integrated circuit (MIC) waveguides.

phase-matching condition will be violated at the interface between the inhomogeneities (i.e, between the two dielectrics). This is because a TEM wave has the same phase velocity of the medium in which the wave is traveling.

However, if the wavelength under consideration is much larger than the transverse structure of the waveguide, we can show that the fundamental mode of such a structure is almost TEM or quasi-TEM. A “fundamental” mode is the mode that is propagating when $\omega \rightarrow 0$ or $\lambda \rightarrow \infty$. The analysis under such assumptions is usually called *quasistatic* analysis.

We can write Maxwell’s equations by separating out the transverse and longitudinal components as

$$\nabla_s \times \mathbf{E}_s = ik\eta \mathbf{H}_z \quad (102)$$

$$\nabla_s \times \mathbf{H}_s = -ik\eta^{-1} \mathbf{E}_z \quad (103)$$

$$\frac{\partial}{\partial z} \hat{z} \times \mathbf{E}_s - \hat{z} \times \nabla_s E_s = ik\eta \mathbf{H}_s \quad (104)$$

$$\frac{\partial}{\partial z} \hat{z} \times \mathbf{H}_s - \hat{z} \times \nabla_s H_z = -ik\eta^{-1} \mathbf{E}_s \quad (105)$$

where $\eta = \sqrt{\mu/\epsilon}$. For a structure whose dominant transverse dimension is much smaller than the wavelength, the transverse variation of the field would be more rapid than the longitudinal variation. The x and y variations will vary on the length scale of δ . To emphasize this fact, we can perform a coordinate stretching transformation by letting

$$x = \delta x', \quad y = \delta y' \quad (106)$$

Under such a coordinate stretching transformation, we obtain

$$\nabla_s \rightarrow \frac{1}{\delta} \nabla'_s \quad (107)$$

Equations (104) and (105) become

$$ik_z \delta \hat{z} \times \mathbf{E}_s - \hat{z} \times \nabla'_s E_z = ik\eta \delta \mathbf{H}_s \quad (108)$$

$$ik_z \delta \hat{z} \times \mathbf{H}_s - \hat{z} \times \nabla'_s H_z = -ik\eta^{-1} \delta \mathbf{E}_s \quad (109)$$

where we have assumed $e^{ik_z z}$ dependence of the field. When $\delta/\lambda \rightarrow 0$, then $k\delta \rightarrow 0$. Since $k_z = \sqrt{k^2 - k_s^2} < k$, we also expect $k_z \delta \rightarrow 0$, when $\delta/\lambda \rightarrow 0$. Therefore, in the long-wavelength limit, we obtain

$$(\mathbf{E}_z, \eta \mathbf{H}_z) \sim O(k\delta)(\mathbf{E}_s, \eta \mathbf{H}_s) \quad (110)$$

In other words, $|E_z| \ll |\mathbf{E}_s|$, $|H_z| \ll |\mathbf{H}_s|$, implying that the field is quasi-TEM. Therefore, we can write Eqs. (102) and (103) as

$$\nabla_s \times \mathbf{E}_s = 0 \quad (111)$$

$$\nabla_s \times \mathbf{H}_s = 0 \quad (112)$$

Taking the divergence of Eqs. (104) and (105) and making use of Eqs. (111) and (112), we have

$$\nabla_s \cdot \epsilon \mathbf{E}_s = 0 \quad (113)$$

$$\nabla_s \cdot \mu \mathbf{H}_s = 0 \quad (114)$$

Consequently, the transverse field of a quasi-TEM mode is essentially static. For this reason, the waveguide can be analyzed as if a TEM mode were propagating on it. We can solve the electrostatic problem to find the line capacitance C of the line. The line inductance L can be obtained by solving the magnetostatic problem. Then, k_z , the axial wavenumber, can be found by

$$k_z = \omega \sqrt{LC} \quad (115)$$

The preceding analysis indicates that when the wavelength is long, the axial variation of the field is slow compared to the transverse variation. The transverse variation of the field has to be such that the field can match the boundary condition on the metallic conductors, which is much smaller in dimension than the wavelength. Hence, the transverse variation of the field must balance itself, resulting in Eqs. (111) to (113), which are the static equations.

5.2. Capacitance and Effective Dielectric Constant of MIC Lines

We shall discuss how the line capacitance of a MIC line, such as a microstrip line, can be found. For other MIC lines, the analysis follows in a similar manner [15]. There is no closed-form solution for such a class of problem. When $\epsilon_r = 1$ (i.e., the conductors are surrounded by homogeneous space and no dielectric interface is present), the structure supports the TEM mode and one may solve such problems by conformal mapping (as in the stripline case) [35]. When $h/w \ll 1$, the problem can be solved by asymptotic matching [36]. However, to get an accurate value of C for all w/h , a numerical analysis is preferable.

To find the line capacitance of the MIC line, one can first solve for the charge distribution on the line. Then, the capacitance can be easily found from the equation $Q = CV$, where Q is the total charge per unit length on the line and V is the voltage applied between the strip and the ground

plane. To find the charge distribution, we can first formulate an integral equation governing the charge distribution, and then solve it by numerical techniques [37]. Approximate closed-form formulas for C_{eff} as a function of line geometry and substrate material are also available [38,39]. A potential ϕ can be defined such that $\mathbf{E}_s = -\nabla_s \phi$ and $\nabla_s^2 \phi = 0$, because \mathbf{E}_s is an electrostatic field in the long-wavelength limit.

To find L , we make use of the fact that if $\epsilon_r = 1$, a pure TEM mode propagates on the MIC line. In this case

$$k_z = k_0 = \omega \sqrt{L_0 C_0} \quad (116)$$

Therefore, L_0 can be found once C_0 , the line capacitance with $\epsilon_r = 1$, is known. C_0 can be also found by solving an integral equation. Since L_0 remains unchanged when $\epsilon_r \neq 1$, we have

$$k_z = \sqrt{\frac{C}{C_0}} k_0 \quad (117)$$

An *effective* relative dielectric constant can be defined such that

$$\epsilon_{\text{eff}} = \frac{C}{C_0} \quad (118)$$

which is a function of frequency. The physical meaning for ϵ_{eff} is simple. It is the dielectric constant with which one can fill the space homogeneously around a MIC line to yield the same line capacitance as the inhomogeneously filled line.

A characteristic impedance can also be defined as

$$Z_0 = \sqrt{\frac{L_0}{C}} = \sqrt{\frac{\mu_0 \epsilon_0}{C_0 C}} = \frac{Z_0^a}{\sqrt{\epsilon_r}} \quad (119)$$

where Z_0^a is the characteristic impedance of the air-filled line.

For the most commonly employed geometries and materials, closed-form empirical formulas for ϵ_{eff} and Z_0 are available for design purposes and easy incorporation into CAD algorithms [39].

5.3. Frequency-Dependent (Full-Wave) Theory of MIC Lines

The quasi-TEM model triumphs in predicting the value of k_z or the phase velocity in the long-wavelength limit. However, k_z is in general frequency-dispersive. To obtain a k_z that is valid at high frequencies as well (above a few GHz), we need to solve the full-wave solution to the MIC line problem. Approximate closed formulas (some essentially empirical formulas, backed up by accurate characterizations) for the frequency-dispersive $\epsilon_{\text{eff}}(\omega)$ (and hence, k_z and C) as a function of the static ϵ_{eff} , geometry, substrate, and frequency are available [39]. These formulas are useful for CAD applications, but have a number of drawbacks, such as being applicable to only a specific class of MIC lines (e.g., those based on alumina substrates) and sometimes requiring accurate static (TEM) data.

On the other hand, numerical methods [37] are the only means of solving the full-wave problem for the general microwave and millimeter-wave transmission-line problem. This is also true for integrated optics waveguides. With the advances in computer technology, these methods have become increasingly important. The most popular numerical methods include the finite-difference and finite-difference time-domain (FD and FDTD) methods, the transmission-line method (TLM), the finite-element method (FEM), the boundary-element method (BEM), the method of lines (MoL), the method of moments (MoM), the beam propagation method (BPM), the effective index method, and the spectral domain approach. There is no such a thing as *the* best universal numerical method available. Each of these methods has its advantages and limitations and is best suited for some given applications. Each has its own variations and improvements. For a discussion of each and example applications, the reader is referred to the texts by Sorrentino [37] and Huang and Kong [40].

HIGH-TEMPERATURE SUPERCONDUCTORS

RAAFAT R. MANSOUR
University of Waterloo
Waterloo, Ontario, Canada

1. INTRODUCTION

Superconductors, as opposed to normal or conventional conductors, have the ability to conduct electrical current with very small resistance, very small power loss, very small generation of heat, and greatly reduced noise levels. The resistance is very small but finite at microwave frequencies and is truly zero at DC. Superconductivity was first understood as a very-low-temperature phenomenon and was explained by John Bardeen, Leon Cooper, and Robert Schrieffer in what has become known as the BCS theory. According to this theory, at a particular low temperature, called the *transition temperature* or *critical temperature* (T_c), the electrons in certain materials pair up and form a single quantum state, acting like a frictionless fluid, and become superconducting.

While conventional low-temperature metallic superconductors have been known since the beginning of the twentieth century, the extremely high cost of refrigeration has limited their use in many applications. Until 1986 researchers could not identify any materials that could become superconducting with a critical temperature higher than 23 K. The materials discovered up to that time, which had critical temperatures lower than 23 K, were commonly known as *low-temperature superconductor* (LTS) materials. A new era in superconductivity began in 1986 with the discovery of a new class of ceramic materials that are superconductive at temperatures as high as 125 K. Referred to as *high-temperature superconductor* (HTS) materials, these materials generally have significant advantages over LTS materials because they can be cooled at economically and commercially feasible temperatures.

Superconductivity is certainly a multidisciplinary field. It spans almost the entire realm of electrical engineering including microwave, power, electronic, and power and computer engineering [1]. In microwave applications, the

HTS technology offers major breakthroughs in performance of components and subsystems. Light weight, small volume, and high performance, which are the properties of the superconducting technology, are also the main drivers in the design and construction of microwave systems. The feasibility of using this technology to design microwave components such as filters, multiplexers, receivers, delay lines, couplers, antennas, and phase shifters with superior performance has been already demonstrated. A review of progress since 1990 is given in three IEEE-MTT Special Issues on HTS microwave applications published in 1991 [2], 1996 [3], and 2000 [4]. Three books have also been published on microwave superconductive devices [5–7].

Although the quest for room-temperature superconductor materials goes on, the quality of today's materials is adequate for the development of advanced superconductive systems with superior RF performance for wireless and space applications. In this article we provide first a brief historical overview summarizing the key development milestones of the technology. We discuss the basic material characteristics, highlighting the unique features that are relevant to microwave applications. We then cover the progress to date in various microwave applications of high-temperature superconductivity.

2. HISTORY AND PHENOMENA OF SUPERCONDUCTIVITY

The history of superconductivity can be divided into two eras. The first era started with H. Kamerlingh Onnes, a Dutch physicist, who successfully liquefied helium in the early twentieth century at around 4.2 K. While investigating the effect of such low temperatures on the properties of various metals in 1911, Onnes observed that the ohmic resistance for mercury vanishes at about 4 K. He made the same discovery with lead and tin shortly after. The progress in understanding superconductivity and in developing superconductors with transition temperatures higher than 4 K was agonizingly slow. By switching from single elements to alloys, researchers were eventually able in 1941 to raise the transition temperature to 15 K, for niobium nitride. It took, however, more than 30 years to further raise the transition temperature to 23 K with the discovery of the niobium germanium alloy in 1973. A number of systems already use low-temperature superconducting devices. A comprehensive review of the applications of low temperature superconductivity is given in a special issue published in January 1973 in the *Proceedings of the IEEE*. The LTS materials are still being used today in various applications. It was not until 1957 that a theory finally emerged to give an acceptable microscopic picture explaining why metals become superconductors at low temperatures. Three physicists at the University of Illinois, John Bardeen, Leon Cooper, and Robert Schrieffer, introduced what is now known as the BCS theory, named after the initial letters of their surnames. The theory was criticized from the start for failing to provide predictions that match experiments. Numerous revisions and even quite different models were proposed.

The second era commenced in 1986 with the discovery of a new class of superconducting materials with a then recordbreaking temperature of 35 K by Alex Muller and George Bednorz of IBM Zurich. The compound was a ceramic with a complex structure: an oxide of lanthanum, barium, and copper. Muller and Bednorz were awarded the 1987 Nobel Prize in Physics for their discovery.

Early in 1987, Paul Chu and his colleagues at the University of Houston reported the real breakthrough in high-temperature superconductivity (HTS), a yttrium–barium–copper–oxide compound ($\text{YBa}_2\text{Cu}_3\text{O}_7$) with a transition temperature of 94 K. The material is commonly known as YBCO. These new materials operate well at 77 K, allowing the use of liquid nitrogen rather than liquid helium. Liquid nitrogen is much cheaper and denser and has a heat vaporization that is 60 times larger than that of liquid helium. The ability to use liquid nitrogen rather than liquid helium reduces the cost of cooling by a factor of 1200.

In December 1987, Hiroshi Maeda’s group at Tsukuba laboratories in Japan reported the bismuth–strontium–calcium–copper–oxides (BiSrCaCuO), which have a T_c of 110 K. The next breakthrough was announced in February 1988 at the World Congress on Superconductivity in Houston. Zhengzhi Sheng and Allen Hermann from the University of Arkansas reported success with a thallium compound (TlBaCaCuO) having a transition temperature of 120 K.

In 1993, Paul Chu’s group at the Texas Center for Superconductivity at the University of Houston announced the discovery of a mercury compound HgBaCaCuO having a transition temperature of 161 K. For the first time, superconductors could conceivably be cooled by the household coolant Freon, which exists in liquid form at 147 K. The stability of this compound is still however, in question since it was developed in a procedure that involves a static pressure of 150,000 atm. It is believed that chemical

substitution may be used to achieve the same result the high pressure is now achieving. Figure 1 summarizes the history of the superconductor materials.

Shortly after the discovery of the YBCO materials at temperature near 90 K, scientists and engineers became very interested in the prospects of employing the HTS technology in the design of microwave components and subsystems. The U.S. Naval Research Laboratory (NRL) established a program known as the “high-temperature superconductivity space experiment” (HTSSE) in 1989. This program was a major catalyst to the development of microwave superconductivity. It consisted of two phases: the focus of the first-phase HTSSE-I (1989–1992) was to develop microwave HTS components such as resonators and filters [8], while the focus of the second phase HTSSE-II (1992–1996) was to develop advanced HTS subsystems [9]. More than 30 organizations from the United States, Canada, and Europe provided devices and subsystems to the HTSSE program [8–11]. The results obtained from this comprehensive research program did conclusively demonstrate that viable and robust HTS subsystems could be developed, fabricated, and cryogenically packaged for both ground and space applications [11].

In addition to the HTSSE program, several other focused programs were led by government agencies in the United States, Japan, Canada, and Europe on advancing HTS microwave technology. In particular, the U.S. Defense Advanced Research Projects Agency (DARPA), which sponsored several research programs in this field [12].

Another key factor that helped advance the development of HTS microwave devices was the rapid progress of the wireless industry in the 1990s. Several startup companies emerged in the United States, Europe, and Japan since the mid-1990s [13–16] with a focus on the commercialization of HTS microwave devices for wireless applications.

Figure 1. History of superconductor materials.

3. CHARACTERISTICS AND THEORIES OF SUPERCONDUCTORS

Superconductors have unique characteristics that differ from those of normal conductors. A much lower loss can be obtained with superconductors corresponding to lower RF losses. The surface resistance of superconductor materials at microwave frequencies is typically two orders of magnitude smaller than that of normal conductors. While the surface resistance of a normal conductor varies with frequency as $(f)^{1/2}$, that of superconductors varies with frequency as $(f)^2$ [7]. This frequency dependence is seen experimentally and can be easily deduced from theory.

Superconductors have a surface resistance that is dependent on the applied field. The dependence is more pronounced at high levels of fields, leading to nonlinearities and generation of intermodulation products. The nonlinearity exists even at low power levels but is more pronounced at high power levels. Such nonlinear characteristics have a negative impact on the power-handling capability of microwave superconductive devices [17–21]. The same nonlinear characteristics, however, were exploited to develop novel HTS devices such as mixers [7] and nonlinear transmission lines (NLTLs) [22]. Another characteristic of superconductor materials is that they have frequency-independent penetration depth that determines field penetration into the materials rather than the skin depth of normal conductors.

There are two other unique characteristics of superconductor material: the Meissner effect and flux quantization. The Meissner effect relates to the superconductor's ability to expel magnetic field; specifically, superconductors are perfect diamagnets. This characteristic makes it possible to suspend a magnet in midair over a piece of superconductor. The Meissner effect also implies that the transition to the superconducting state is sensitive to the magnetic field, and for increasing magnetic fields the flux first penetrates into and then ultimately destroys the superconducting state. Correspondingly, a superconducting transmission line can be driven into the normal state by a sufficiently large current that exceeds the critical current J_c .

The flux quantization relates to the phenomenon that magnetic field generated from a current circulating in a superconducting loop is quantized. The unit of quantization is known as the fluxon, or flux quantum and is given by 2.07×10^{-15} Wb. The characteristic of flux quantization makes it possible to build extremely sensitive magnetometer devices capable of measuring extremely low

levels of magnetic fields. Such magnetometers are known as *superconductor quantum interference devices* (SQUIDs) [23]. Table 1 summarizes the differences between superconductors and normal conductors.

For microwave applications, the two most important parameters of HTS materials are the surface resistance R_s and the critical current density J_c , which represents the maximum current that can be carried by the superconductor before switching to the normal state. There are several techniques available to measure these two parameters [5–7]. Typical values for R_s and J_c for HTS thin films are 100–200 $\mu\Omega$ and 10^6 A/cm², respectively.

The HTS thin films are deposited on a low loss dielectric substrate and are processed using standard photolithographic techniques. The most widely used substrate is lanthanum aluminate (LaAlO₃) with a dielectric constant of $\epsilon_r = 24$ and a loss tangent of $\tan \delta = 3 \times 10^{-5}$. One challenge with the LaAlO₃ substrate is that its crystal structure exhibits twinning, which makes the substrate effectively inhomogeneous. This can affect the ability to set the frequency correctly in narrowband filter applications. Another commonly used substrate for HTS films is magnesium oxide (MgO) with $\epsilon_r = 9.5$. MgO does not suffer from twinning problems, but on the other hand it does not offer the same miniaturization, which the LaAlO₃ substrate offers, because of its high dielectric constant. Sapphire substrates have also been used with various buffer layers to provide the appropriate lattice match to HTS films. However, the surface resistance R_s and current density J_c are inferior to films on LaAlO₃ or MgO substrates.

Dielectric materials typically exhibit a considerable improvement in loss tangent $\tan \delta$ on cooling to cryogenic temperatures. For example, high-purity sapphire ($\epsilon_r = 9.4$) at X-band frequencies exhibits $\tan \delta$ of 10^{-5} at 300 K and $\tan \delta$ of 10^{-7} at 77 K [24]. MgO and LaAlO₃ exhibit a similar loss tangent improvement at cryogenic temperatures [25] as compared to room-temperature operation. This is considered a fringe benefit of operating at cryogenic temperatures.

The HTS films are deposited on 2- and 3-in. wafers, which can vary in substrate thickness from 0.010 to 0.1 in. (standard substrate thicknesses are 0.01 and 0.02 in.). The HTS films are typically deposited either by laser ablation or by sputtering techniques [26]. Currently, 2- and 3-in.-diameter wafers with HTS films on one or both surfaces are commercially available from various sources at prices that are almost one-tenth the prices of the early 1990s.

The BCS theory deals with superconductors from a microscopic point of view. Two other well-known theories

Table 1. Differences between Superconductors and Normal Conventional Conductors

Characteristic	Normal Conductor	Superconductor

were developed to deal with the macroscopic properties of superconductors: the London theory [27] and Ginzburg–Landau (GL) theory [28]. These two theories have been used in conjunction with Maxwell’s equation to model the electromagnetic characteristics of superconductive microwave devices [29–31]. The London theory is based on the two-fluid model [27], which assumes that the current in superconductor is carried by two parallel pathways, one of the normal electrons and one of the superconducting electrons whose densities are a function of temperature. The London theory has been successful in explaining several of the characteristics of superconductor materials. It does not however, take into consideration the field dependence of the constituent parameters of the superconductor materials. The GL theory, on the other hand, is a more comprehensive macroscopic theory that accounts for field dependence allowing the characterization of the nonlinear behavior of the superconductive materials.

4. HTS MICROWAVE FILTERS

Microwave filter networks represent a critical and substantive portion of any communication system. Such a system, whether wireless or satellite, requires filters to separate the signals received into channels for amplification and processing. The phenomenal growth in the telecommunications industry has brought significant advances in filter technology as new communication systems emerged, demanding equipment miniaturization while requiring more stringent filter characteristics. The emergence of the HTS technology has offered the possibility, for the first time, to build filters that can compete with traditional waveguide and dielectric resonator filters not only in size but also in Q (quality factor).

Figure 2 illustrates a pictorial comparison between microwave filters realized using rectangular single-mode waveguide technology, circular dual-mode waveguide technology, dielectric resonator technology, and superconductor technology [32]. Two types of superconductive filters are included in this figure: one using the hybrid

Figure 2. A comparison between various microwave filters.

DR/HTS technology and the other based on HTS thin-film technology. All filters have the same order and are designed to operate at the same center frequency of 4 GHz. It is clear that a significant reduction in size and mass can be achieved with the use of HTS technology.

In addition to size and mass reduction, HTS filters also offer improvement in the in-band insertion loss. The unloaded Q of a microwave resonator in general can be written as $Q_u = (R_s/G + F \tan \delta)^{-1}$, where G is a factor determined by the resonator’s geometry, which typically increases as the resonator dimensions increase, while F is a factor determined by the fraction of the electrical energy of the cavity stored in the dielectric materials; R_s is the surface resistance and $\tan \delta$ is the loss tangent of the dielectric material. It is clear that reducing either R_s or $\tan \delta$ or both of them can increase the unloaded Q_u . Three main types of HTS filter are reported in the literature:

1. HTS thin-film planar filters
2. Hybrid dielectric/HTS filters
3. HTS thick-film-coated filters

In both HTS thin-film planar filters and thick-film-coated filters, the Q improvement is attributed mainly to the reduction of R_s by replacing normal metals with HTS materials. On the other hand, the improvement in Q in hybrid dielectric/HTS filters is attributed to the reduction of R_s as well as to the reduction of the loss tangent of the substrate due to cooling.

4.1. HTS Thin-Film Planar Filters

Planar filters such as stripline, microstrip, and coplanar line filters have been known since the mid-1970s [33]. These filters, however, have very limited applications because of their low Q values. Effectively any known planar filter configuration can be realized in HTS technology by replacing metal films with HTS films. This in turn would increase the filter Q value by several orders of magnitude. For example, a half-wavelength microstrip resonator made of gold films on lanthanum aluminate substrate would typically have an unloaded Q value of 400. Replacing the gold films with HTS films while using the same substrate would provide an HTS resonator with an unloaded Q value of $\sim 30,000$.

The emergence of the HTS technology has created the opportunity for more innovation in planar filter configurations. Several novel filter configurations have been proposed allowing the realization of quite advanced filter functions [34–38]. Figure 3 illustrates a packaged HTS 10-pole elliptic function self-equalized planar filter. The basic building block of this filter is a dual-mode lumped-element resonator, which makes it easy to create elliptic and self-equalization functions [39].

The emergence of several commercial computer software packages for simulation and design of planar circuits in the early 1990s played a key role in advancing the development of HTS planar filters. Even though these commercial packages do not factor in the physical characteristics of the superconductor materials, they

Figure 3. A 10-pole HTS thin-film filter.

have been successfully used in the design of planar HTS filters, particularly for low-power applications.

4.2. Hybrid Dielectric/HTS Filters

For the conventional dielectric resonator shown in Fig. 4a, the tangential electric field of the HEE_{11} mode vanishes at the plane $z=0$ [40]. As a consequence, introducing a conducting wall at this plane will only slightly perturb the field distribution of this mode. Thus the size of the dielectric resonator filter operating in the HEE_{11} mode may be reduced by supporting the resonator directly on a conducting surface (image plate) as shown in Fig. 4c. With the use of dielectric support that fills the whole cavity, further size reduction can be achieved as shown in Fig. 4d.

A normal-conducting image plate, however, significantly degrades the Q of the resonator, which in turn makes the approach unfeasible for high- Q applications. On the other hand, if the image plate is replaced by a surface made of high-temperature superconductor materials, the original unloaded resonator Q will be only slightly affected, allowing the use of this resonator structure to realize compact size filters with a superior loss performance for cryogenic applications [41,42]. The reduction in size is attributed to the use of the image plate, while the improvement in loss performance is attributed to the use of the

Figure 5. A layout of the eight-pole hybrid DR/HTS filter. The 38s are dielectric resonators; the 40s are HTS wafers diced from a standard 2-in. wafer; the 36s are dielectric supports; the 44s are spring washers; the 26s, 102, and 104, are elements of the filter housing; and the 28s are input/output probes.

HTS image plate as well as to the increase in the unloaded Q of the dielectric resonator as the temperature is lowered from 300 to 77 K.

Several hybrid DR/HTS filters, which utilize the concept illustrated in Fig. 4, were built and tested [21,38, 41,43]. Figure 5 shows a detailed configuration of an eight-pole hybrid DR/HTS filter [29]. The filter consists of four dielectric resonators operating in image-type dual modes. The resonators are supported inside the filter housing using two blocks made of low-loss low-dielectric constant ceramic materials. The HTS material is in the form of

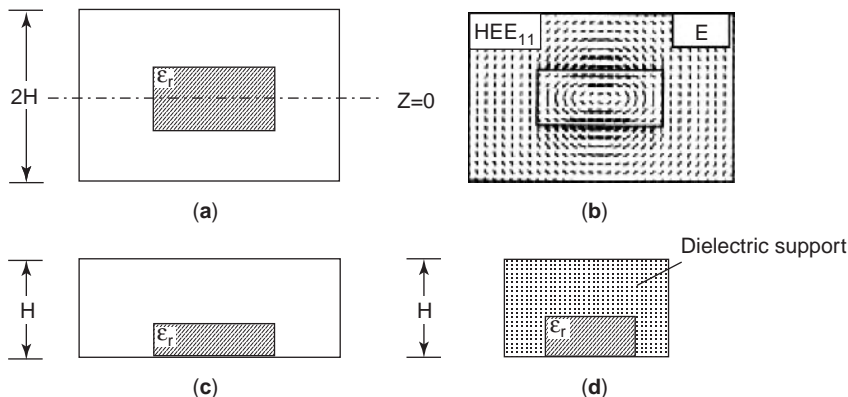

Figure 4. Transition from conventional DR cavity to an image DR cavity: (a) conventional DR resonator; (b) field distribution; (c) image DR resonator; (d) image DR resonator with a DR support.

small wafers (0.5×0.5 in. at C band), which are diced from a standard 2-in. HTS thin film deposited on 0.02-in.-thick wafer of LaAlO_3 . The HTS films are kept in contact with the dielectric resonators using springs and metallic plates bolted to the filter housing. A detailed description of this type of filter is given in [44].

The drawback of hybrid DR/HTS filters is the mechanical design complexity. These filters do, however, have several advantages over their counterparts HTS thin-film planar filters:

1. No etching is required for the HTS material. Etching may reduce the power-handling capability of the HTS material and degrade its surface resistance. The design also eliminates the need to deposit gold contacts, which are required for thin-film filters. Also there is no need to generate circuit and contact masks.
2. In patterned thin-film filters, a good portion of the HTS material is wasted as a result of the etching process, while in hybrid DR/HTS filters the wafer is diced into small pieces called “shorting [short-circuiting] plates.” The wafer is used efficiently.
3. The filter has a good spurious performance. The image plate helps not only in reducing the filter size but also in eliminating spurious modes, making it possible to design filters of this type with a spurious-free window of more than 2 GHz width centered at a frequency of 4 GHz.

4.3. HTS Thick-Film-Coated Filters

Melt-processed YBCO thick films were used to coat three-dimensional structures for microwave applications [45,46]. YBCO thick films typically have a current density of 2000 A/cm^2 and a relatively low value of surface resistance of approximately $0.5 \text{ m}\Omega$ (5 GHz at 77 K). The feasibility of constructing a thick-film YBCO 5.66-GHz cavity resonator operating in TE_{011} modes with unloaded Q values of 715,000 at 77 K has been demonstrated [47]. Measured results of cavities operating at 10 and 7.5 GHz have also been reported [48]. However, the TE_{011} cavities are too bulky to be used at frequencies below $\sim 1\text{--}2$ GHz. At lower frequencies, two resonator structures have been proposed for thick-film coating: coaxial resonators and split-ring resonators [49]. Thick-film coaxial resonators have found limited use because of the need to coat all surfaces in the cavity to achieve reasonably high Q values. On the other hand, the split-ring resonator has been adopted by Illinois Superconductor Corporation to manufacture thick-film HTS filters for wireless applications [51].

Figure 6 illustrates a 3-pole HTS filter employing split-ring resonators coated with HTS thick films. Coupling between resonators is achieved through the use of irises to provide the right coupling between resonators. Details on this type of filter can be found in Ref. 50.

5. CRYOGENIC RECEIVERS

A layout of a typical receiver is shown in Fig. 7. In addition to signal amplification, the receiver typically provides fre-

Figure 6. A three-pole filter employing split-ring resonators coated with HTS thick films.

quency conversion to the transmit band. It consists of an input filter, a low-noise amplifier (LNA), an oscillator, and a downconverter. The input filter limits the noise bandwidth and provides a high rejection of out-of-band signals. The insertion loss of this filter is a very critical parameter since it adds directly to the overall noise figure of the receiver. In most applications, these filters are typically built using high- Q filter structures to minimize the insertion loss. For example, a C-band input filter in satellite receivers is typically configured as a cascade of a waveguide lowpass filter and a waveguide bandpass filter. An HTS filter with a similar performance would have $\frac{1}{16}$ th the mass and $\frac{1}{100}$ th the volume of the conventional C-band waveguide input filter. It will also provide a 50% reduction in insertion loss.

The LNA benefits from cryogenic operation in two ways [51,52]. The use of HTS-matching structures results in decreased loss at the input of the LNA, which directly improves the attainable noise figure. Additionally, a fringe benefit of operation at 77 K is the reduction in the inherent noise of the active component. The improvement is more pronounced at high frequencies. Table 2 summarizes the typical measured noise figure results of C-band and Ka-band LNAs. The oscillator could also benefit from using HTS technology by employing high- Q HTS resonator as the frequency-determining element. The benefit in this case would be phase noise reduction. However, cooling the

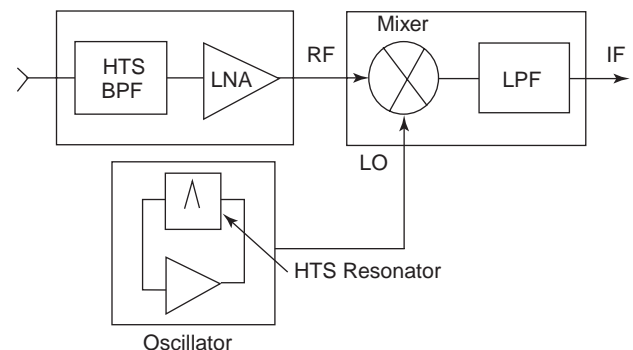

Figure 7. A block diagram for an RF receiver.

Table 2. Measured Noise Figure Results of Ka-Band and C-Band LNAs

Component	Measured Noise Figure

C-band LNA	1.0	0.25

remaining oscillator components will have a negligible impact on overall oscillator performance while adding a large heat load on the system. Therefore the use of cryogenic technology has been limited in most applications to the input filters and the first LNA stage.

6. HTS DELAY LINES

Delay lines are useful devices in realizing transversal filters for analog signal processing applications. Current technologies for delay lines include surface acoustic wave (SAW) devices and electromagnetic coaxial cables in the form of coils. However, the small acoustic wavelength and the minimum achievable linewidth limit the SAW delay devices to low-frequency applications. Electromagnetic coaxial transmission lines with much larger wavelengths can yield much higher frequency limits. On the other hand, coaxial delay lines are bulky and have high insertion losses. Often the use of amplifiers and equalizers is necessary to restore the original signal.

Superconducting delay lines [53–55] offer the highest bandwidth with the lowest loss in highly compact designs. Several HTS planar transmission lines such as striplines and microstrip and coplanar lines could be used to realize delay lines. The high dielectric constant of lanthanum aluminate substrates ($\epsilon_r = 24$) allows a significant amount of delay to be placed on a single substrate, while the low

conductor loss of the HTS material keeps insertion loss to a minimum. Figure 8 illustrates a delay line realized using an HTS coplanar delay line [56]. A 100-ns HTS delay line of this type measures $90 \times 96 \times 12$ mm. A 100-ns delay line realized using RG-141 cables would have a length of 70 ft. Even with a cryocooler, the size and weight reductions offered by the HTS technology are very attractive.

7. ANTENNA AND BEAMFORMING NETWORKS

High-temperature superconductors offer new opportunities for the designers of antenna systems. Examples include antenna-matching elements, feed networks, microstrip antennas, and superdirective arrays [57–59]. In particular, beamforming networks can benefit from HTS technology in areas of both insertion loss reduction and miniaturization. The current designs for beamforming networks use either multilayer stripline technology or coaxial technology. The stripline designs are compact in size but exhibit very high insertion loss. The coaxial designs, on the other hand, exhibit low loss but are known to be very heavy and bulky.

Figure 9 illustrates a layout of an HTS 8×8 Butler matrix designed to operate at L band [59]. The matrix consists of folded thin-film 90° hybrids and delay lines. The size of the overall matrix is $75 \times 50 \times 12$ mm. The HTS Butler matrix is two orders of magnitude smaller than its coaxial counterpart.

8. WIRELESS APPLICATIONS

Mobile communication systems require improved sensitivity and selectivity to support the constant growth in services, increased coverage, and larger numbers of subscribers. Several companies have taken advantage of

Figure 8. A layout of an HTS delay line.

Figure 9. An 8×8 HTS Butler matrix.

Figure 10. A cryogenic package consisting of an HTS filter and an LNA.

technical innovations in cryoelectronics to address these improvements. Cryoelectronic solutions have matured to the point where numerous field trials under the auspices of both RF equipment manufacturers and PCS carriers have been proved to be successful [60–63].

The performance of wireless base stations can be considerably enhanced by incorporating cryogenic LNAs with high-temperature superconductor filters. The HTS technology presents a viable solution of realizing small-size high-order filters with low insertion loss. The overall size of multiple HTS transceiver chains, including the associated cryocooler, is considerably less than that of an equivalent conventional transceiver.

The capacity and coverage of a base station receiver are determined primarily by the receiver selectivity and sensitivity on the up-link and in part by the base station transmitter power of the downlink. The selectivity can be significantly increased with the use of high-order filters as shown in Fig. 10. However, high-order filters, built using conventional technology, would exhibit a very high pass-band insertion loss, resulting in a reduced signal-to-noise ratio and hence degrading the sensitivity performance of the receiver.

A significant improvement in receiver sensitivity can be achieved by designing the receiver to operate in a cryogenic environment. This virtually eliminates thermal noise from the LNA and potentially improves the filter loss performance. Although conventional dielectric resonator filters can be cooled with some improvement in performance, integrated receivers of this type are too large for tovertop mounting.

The low resistance of the HTS materials makes it possible to use the planar thin-film technology to provide HTS filters that are two orders of magnitude smaller in size than conventional dielectric resonator filters. This significant reduction in physical size makes valuable space available for other required electronic components, enabling service providers to enhance the utilization of existing base stations instead of developing additional base stations. In addition, miniaturization can decrease deployment costs for new base stations, as less real estate is required to support base station. Figure 11 illustrates a comparison between a conventional transceiver and an HTS transceiver [63].

9. SPACE APPLICATIONS

The mass, volume, and power consumption of payload electronic equipment are significant contributors to the overall cost of space systems. HTS technology offers the potential of large reductions in mass and volume of electronic equipment, leading to significant cost reduction of satellite systems [39,64,65]. Today's space segment represents a market of many billions of dollars for commercial and military applications and is growing. HTS technology has the potential to accelerate the development and implementation of new advanced satellite systems. It also represents the potential of performance enhancements of strategic defence communications systems.

Mass reductions have a dramatic impact on the economics of a satellite program because launch costs are related to satellite weight. Similarly, mass reductions can be exploited to increase the capacity (by adding payload electronics) or extending operational life (by increasing station maintenance fuel). As a result, market factors have constantly been pushing hardware suppliers to reduce mass and size of their products.

The current technology for satellite input multiplexers is the dielectric resonator technology. A 60-channel HTS

Figure 11. A comparison between a conventional dielectric resonator transceiver (left) and an HTS transceiver (right).

Figure 12. A 60-channel HTS multiplexer integrated with cryocoolers.

multiplexer was built [39] to duplicate the requirements of the Intelsat 8 C-band dielectric resonator multiplexer. The channel filters are 10-pole self-equalized planar HTS thin-film filters of the type shown in Fig. 3.

Figure 12 illustrates the overall 60-channel HTS multiplexer, while Fig. 13 shows the experimental results of four channel HTS filters having bandwidths of 34, 41, 72, and 112 MHz, which meet the bandwidth requirements of the Intelsat 8 program. More than 50% reduction in mass and 50% reduction in size were achieved with the use of HTS technology [39]. It should be mentioned that the reductions in mass and size include the cryogenics (two cryocoolers for redundancy).

There have also been efforts dedicated to the development of high-power HTS output multiplexers [43,65]. Figure 14 illustrates the layouts of a four-channel superconductive C-band output multiplexer and a similar conventional waveguide output multiplexer. For the conventional C-band multiplexer, both the channel filters and the manifold are built using the waveguide technology. For the superconductive multiplexer, the channel filters are hybrid DR/HTS filters, while the manifold is realized using coaxial technology. The superconductive multiplexer

Figure 13. Experimental results of four channels of the HTS 60-channel C-band input multiplexer.

Figure 14. A comparison between a C-band four-channel HTS output multiplexer and its waveguide counterpart.

occupies less than 5% of the volume of the waveguide multiplexer (without the cryocooler).

The potential advantages of using HTS technology in the design of output multiplexers are mass and volume reduction as well as insertion loss improvement. The insertion loss improvement can translate into improvement in satellite EIRP or reduction in the DC power required for power amplifiers. However, the mass penalty of the currently available cryocooler and associated electronic controller may overshadow any advantages gained with the use of HTS technology for high-power-output multiplexer applications [43].

10. CRYOCOOLER TECHNOLOGY AND CRYOPACKAGING

Several cryocooler techniques exist that could meet the temperature needs for microwave HTS devices and subsystems. These techniques can be divided into two main categories: open-cycle and closed-cycle [66]. The open-cycle techniques include cooling with a stored cryogen such as liquid nitrogen or through Joule–Thomson gas expansion. Open-cycle coolers are bulky and dissipate materials, requiring frequent fillup of the cryogen or compressed gas. Therefore, they are ideal for laboratory environments or in applications where regular equipment maintenance is possible.

Closed-cycle coolers are self-contained refrigerators that consume only electrical power, requiring no maintenance over the designed lifetime. Closed-cycle cryocoolers have been primarily developed for infrared devices and military applications. The main design considerations for a closed-cycle cryocooler are DC power consumption, size, and reliability. In particular, the reliability of the cryocooler remains the primary barrier to the widespread commercial acceptance of superconducting devices.

In addition to the cryocooler, it is also essential to provide a cryopackage with a means to mechanically and thermally attach the HTS microwave device to the cold head of the cryocooler within an evacuated enclosure, while providing electrical and RF cabling through the enclosure. One major challenge is to ensure low loss in the

electrical connections without allowing too much heat to travel from the outside room-temperature environment to the HTS component. It is difficult to find commercially available RF cables that can reasonably meet the two conditions described above. For example, having a cable with low conduction heat load requires the use of a small-diameter cable. On the other hand, small-diameter cables typically have a high RF insertion loss. The choice of the RF and electrical connections to the package has a major impact on the size and cooling power of the cryocooler. Another major design issue is to guarantee that the enclosure maintains its vacuum over the operational lifetime of the system. Cryopackaging is typically one of the main issues in the design of microwave HTS subsystems.

11. CONCLUSIONS

The HTS technology offers the potential of large reduction in mass and volume of microwave equipment. It could also provide performance discrimination not attainable with other technologies. The technology has grown very fast and merged with commercial and defense applications. This article has presented a summary of the main HTS microwave applications. I strongly urge newcomers to the field to continue reading about the subject to understand more about the potential challenges and limitations of this revolutionary technology.

HISTORY OF WIRELESS COMMUNICATION

PATT LEGGATT

In the earlier decades of the nineteenth century, magnetic and electric forces were believed to act instantaneously at a distance, a view prevalent in continental Europe and especially in Germany. But the obvious philosophical difficulties inherent in instantaneous action at a distance made this concept less acceptable to a few in the United Kingdom in general and to Michael Faraday in particular.

1. FARADAY'S WAVES

In 1831 Faraday conducted a series of experiments on the magnetic effects of electric currents, during which he made his important discovery of electromagnetic induction, whereby an electric potential was induced in a conductor subjected to a changing magnetic field. In the course of these experiments, Faraday came to the conclusion that magnetic and electrostatic forces were not instantaneously effective at a distance but required a finite time for their transmission. We know now that electromagnetic energy is transmitted at the speed of light, but while continuing his experiments into 1832, Faraday had no means of detecting or measuring the very small time intervals necessary to confirm his theories. Furthermore he suggested, with remarkable intuition, that transmission of such forces took the form of some kind of wave motion. To establish his prior claim to the notion of wave motion, Faraday deposited a written statement in a sealed envelope with the Royal Society in 1832. The envelope was finally opened more than 100 years later in 1937 by the then-president of the Royal Society, and found to contain, *inter alia*, the following words: "I am inclined to compare the diffusion of magnetic forces from a magnetic pole to the vibrations upon the surface of disturbed water, or those of air in the phenomenon of sound."

Faraday, the son of a blacksmith, was a brilliantly imaginative experimenter and theoretician but had only self-taught scientific education and no knowledge of mathematics. Because of this, his theories were regarded with some disdain by many contemporary scientists. However, there was one young mathematician, James Clerk Maxwell, who was most impressed by Faraday's concepts of magnetic fields and lines of force as set out in his paper "Experimental researches in electricity," read to the Royal Society in 1851.

2. MAXWELL'S ANALYSIS

Maxwell already had an interest in this area, triggered while he was at Cambridge by the ideas of William Thomson, afterward to become Lord Kelvin; and Maxwell determined to submit Faraday's concepts to detailed mathematical analysis. As his studies continued, he concentrated his attention on the possible nature of the medium through which electromagnetic forces could be propagated, wishing to devise a mechanical model exhibiting appropriate characteristics. This was a complex task, but by about 1862 he came up with a system of very minute rapidly spinning eddies or vortices, each surrounded by a layer of even more minute particles revolving in a direction opposite to that of the vortices themselves.

The vortices, with their outer layers of particles, could interact with one another in a manner analogous to a train of gear wheels, so that energy imparted to one vortex would be transferred to others and so progress through the medium.

Maxwell devised this mechanical model as one that could exhibit the sort of behavior necessary to embrace

Faraday's concepts of lines of force and wavelike transmission of energy; but it was a convenient model only, and he was not so fanciful as to suggest that it represented anything much related to reality. Nevertheless it served his purpose of enabling rigorous mathematical analysis, culminating in his 1864 paper to the Royal Society, "A dynamical theory of the electro-magnetic field." One of Maxwell's main hopes had been to derive the electromagnetic nature of light and heat, and this was triumphantly achieved in particular by one of the consequences of his theories, that electromagnetic wave propagation would travel at a velocity very close to the value for the speed of light that had been experimentally determined by others at the time.

3. THE MAXWELLIANS

Maxwell's analysis was deeply mathematical, making use of Hamiltonian quaternionic calculus and high-order differential equations, and at the time of his final publication in 1873, there were very few physicists with the intellectual ability to understand it. There were only three of note: Oliver Lodge and Oliver Heaviside in England, and the Irish professor George Francis FitzGerald of Trinity College, Dublin.

In 1873 Oliver Lodge, then a student at University College, London, attended a lecture by Maxwell at a meeting of the British Association and obtained a copy of his *Treatise* published in that year. Lodge did not study this closely until 1876, but when he did he quickly came to realize that Maxwell's equations implied not only the electromagnetic nature of light and heat but also that there could be a whole spectrum of radiation with wavelengths both above and below those of visible light. Lodge was probably the first to appreciate that such electromagnetic waves could perhaps be generated electrically; and in 1879, after Maxwell's death, he began to give serious attention to this possibility.

FitzGerald too was studying Maxwell's theories at about this time and, in a paper to the Royal Dublin Society in 1882, suggested that electromagnetic radiation of about 10 wave-length could be generated by discharging a condenser (Leyden jar) through a circuit of very low resistance and low inductance. Furthermore, he clarified Maxwell's analysis to the extent of showing that the equations also led to the laws of reflection and refraction that had already been developed in the wave theories of light.

Another physicist who contributed significantly in this way was Oliver Heaviside, now best remembered for his 1902 theory of a reflecting ionized layer in the upper atmosphere, which, when physically verified some 20 years later, was named after him. Heaviside was a first-class mathematician and was already interested in Maxwell's papers. He reformulated much of the analyses in appreciably simpler terms, changing Maxwell's rather convoluted systems into notation of his (Heaviside's) own devising. He developed his own operational calculus and vector algebra and although contemporary mathemati-

cians found it difficult to grasp at first, it is in this form that Maxwell's equations are familiar to students of today.

These three adherents and interpreters of the equations called themselves *Maxwellians*. They were scientists, and what was crucial to them was that the electromagnetic radiation implicit in the equations indicated that the unsatisfactory theories of instantaneous action at a distance could be discarded. While the theoretical analyses were their prime interest, they naturally hoped for experimental verification of the real existence of such radiation, and it was Lodge who pursued this most effectively.

4. OLIVER LODGE

Oliver Lodge was born in Staffordshire, England in 1851, the son of a pottery merchant. He received his scientific education at University College, London and while there attended a lecture by James Clerk Maxwell showing that oscillatory electrical discharges resulted in electromagnetic wave radiation propagating with the velocity of light. This fired Lodge with an abiding interest in what was eventually to become *wireless*.

Lodge quickly rose to be an eminent physicist, gaining his D.Sc. degree in 1877 and being appointed Professor of Experimental Physics at the University College of Liverpool in 1881. In 1887 he was elected Fellow of the Royal Society, the highest honor in British science, and he was knighted as Sir Oliver Lodge in 1902. He died at age 89 in 1940.

In 1887 Lodge undertook a series of investigations into lightning discharges and protection against them. He found by experiment that lightning flashes were oscillatory and followed this up with further experiments involving spark discharges from Leyden jars. In early 1888 he developed a famous experiment that he called the *recoil kick*. This involved generating oscillations by discharge of a Leyden jar capacitor into a long pair of wires and observing that a much greater spark would occur at the end of the wires when they were of a suitable length. He correctly surmised that this was due to a standing-wave pattern along the wires with a voltage anti-node at the end. Furthermore, he understood that this condition would be satisfied when the wires were a half-wavelength long (or a multiple of this) and was thus able to determine experimentally the wavelength of the oscillations.

It can be seen therefore that he was conversant with the principles of resonance and tuning—or *syntony* as he called it—saying in 1888, “The natural period of oscillations in the wires will then agree with the oscillation period of the discharging circuit, and the two will vibrate in unison, like a string or a column of air resounding to a reed.”

Although his experiments were largely confined to oscillations along wires, Lodge knew well that the electromagnetic waves were propagated in the space surrounding the wires rather than in the wires themselves. He knew also, being familiar with Clerk Maxwell's mathematical analysis, that the waves would be radiated into space and travel at the speed of light.

Thus we can see that Lodge had demonstrated experimentally the existence of electromagnetic waves as predicted by Maxwell's equations. But he had dealt only with waves guided along wires, since he had not then devised any means of detecting such radiation in free space.

In fact Lodge was not the first to observe electromagnetic waves along wires. In 1870 Wilhelm von Bezold observed such phenomena, detecting the waves by patterns formed by dust particles under the influence of electrostatic fields. However, he did not relate these observations to Maxwell's theories and his work attracted little notice.

5. HEINRICH HERTZ

At the same time that Lodge was undertaking his experiments, there were even more effective investigations being carried out by Heinrich Hertz in Germany. Hertz, the son of a lawyer, was born in February 1857. He turned eventually to science with a year's course at Munich, transferring in 1878 to the University of Berlin. Here he studied under Professor von Helmholtz, who gave much encouragement to one he recognized as an outstanding pupil. Finally, having been awarded his doctorate, Hertz was appointed assistant professor at the Physics Institute of Berlin in 1880.

Hertz had been brought up in the “instantaneous action at a distance” school of thought, but fairly early in his career he was introduced to Maxwell's theories by professor von Helmholtz, who encouraged him to attempt experimental proof of Maxwell's postulated *displacement current* in air or empty space. Hertz did not immediately take this up, but he was intrigued by the possibility that the concepts of displacement currents and electromagnetic waves could fundamentally change action at a distance theories.

A few years later he had been appointed professor at the Technical High School at Karlsruhe and found there in a collection of old physical apparatus a pair of Knochenhauer spirals, flat coils wound in wooden frames. Experimenting casually with these, he noticed that discharging a Leyden jar through one of the coils gave rise to a small spark across the open terminals of the other some distance away. This revived his earlier interests, and he began to devote effort to theoretical clarification of Maxwell's equations. He became increasingly convinced that the equations could indeed give the true explanation of electric and magnetic field phenomena, and by 1884 he wrote “I think we may infer without error that if the choice rests only between the usual system of electromagnetics and Maxwell's, the latter is certainly to be preferred.” But the physical existence of electromagnetic waves, and especially their finite velocity of propagation, needed to be established by practical demonstration, so Hertz undertook a series of experiments culminating in the famous ones of 1887/88 that proved the point beyond all doubt. It is true that others before him had, rather accidentally, observed electromagnetic radiation, notably Mahlon Loomis in the United States in 1872 and David Hughes in England in 1879, but neither of them under-

stood what was happening or were familiar with Maxwell's work.

Hertz's investigations into the subject had involved generation, detection, and measurement of waves in free space, rather than along wires. Lodge generously acknowledged that Hertz experiments were superior to his own and a more convincing proof of the validity of Clerk Maxwell's theories.

After his experiments Hertz undertook further theoretical interpretation and development of the Maxwell concepts, much helped by his correspondence with FitzGerald, Lodge, and Heaviside, which revealed significant earlier work by these Maxwellians that he had not previously heard of. Hertz's papers in 1890 were particularly important in the field of theoretical physics and were influential in setting the scene for the later achievements of Lorentz and Einstein. Hertz died in 1894 at the early age of 36.

Hertz was not primarily an experimentalist seeking to demonstrate the existence of electromagnetic waves. He was a theoretical physicist who conducted his famous experiments as a means of justifying his firm conclusion on a matter of fundamental scientific importance. The waves were not important to Hertz for their own sake; he saw them simply as affording proof that Maxwell's equations gave the true picture and that hitherto accepted theories of action at a distance must therefore be regarded as obsolete.

The three Maxwellians, Lodge, FitzGerald, and Heaviside, were of a like mind. They were satisfied with the fact that Hertz had experimentally demonstrated the real existence of electromagnetic radiation, and neither they nor Hertz himself concerned themselves with any possible practical applications such as communication.

Someone soon did, however; Richard Threlfall, as president of the Australasian Association for the Advancement of Science, proposed in 1890 using Hertzian waves for communication purposes. But no one else saw this as a practical proposition at the time, the range of a few yards achieved by Hertz in his Karlsruhe laboratory not seeming to offer very much.

6. WIRELESS TELEGRAPHY BEGINS WITH MARCONI

Five or six years went by with nothing very significant happening until Hertz' death in 1894. But ironically, this was one further event involving Hertz that had a most profound impact, for in that year the 20-year-old Guglielmo Marconi, on holiday in the Italian Alps, read an obituary describing the work of Hertz. He was immediately inspired to consider whether Hertzian waves might not form the basis of a wireless telegraph communication system, and dedicated himself to this idea for the rest of his life.

At the end of his holiday Marconi returned to the family home in the Villa Griffone near Bologna, and at once commenced experiments in his attic workshop, where he had long since occupied himself with the electrical devices that had fascinated him from boyhood.

It is a well-known story how Marconi improved his apparatus and techniques to achieve greater and greater ranges during 1894/95; how he came to England in 1896 to make further progress; and how he spanned the Atlantic with the letter "S" in Morse in 1901. This story need not be told again here, but Marconi's relationship with Oliver Lodge is perhaps less well known and may usefully be described.

7. LODGE AND COHERERS

Although it was Hertz who first contrived to demonstrate the existence of electromagnetic waves in free space and that they exhibited reflection and refraction in the same way as light, it is true to say that Lodge knew and understood as much or more about the nature and behavior of the waves than did anyone else in the latter years of the nineteenth century.

As already mentioned, Lodge was thoroughly conversant with resonance and tuning, and he also well understood the principles underlying radiation from antennas of various configurations. Although he knew that waves must be radiated into free space, he lacked any means of detecting them; and it was use of the crude, but just adequate, resonant sparkgap detector that enabled Hertz to effect his splendidly successful experiments.

But in 1889, the year after Hertz' demonstrations, Lodge made a discovery that was to prove a crucial step forward on the path to a practical wireless communication system. During his investigations into lightning and the analogous effects of spark discharges from Leyden jars, Lodge observed that two iron spheres or other metal surfaces very close together would at times fuse together to form a conducting path when subjected to a Hertzian wave pulse. He called this arrangement a *coherer*, saying that it formed "an astonishingly sensitive detector of Hertzian waves." Later, in 1893, he was made aware of the work of Edouard Branly in France, who had observed similar cohering effects with a glass tube filled with metal filings. Lodge immediately tried this for himself and found it very much more sensitive than his own iron spheres. In fact the phenomenon of coherence resulting from nearby spark discharges had been independently noticed by others some years earlier, including Guitard in 1850, Varley in 1866, and Onesti in 1874; but these predecessors had not in fact ascribed the effects to Hertzian waves, and neither had Branly in his 1890 experiments. In 1902 Lodge, in conjunction with Alexander Muirhead, invented a new form of coherer in which a knife-edged steel wheel grazed the surface of a small pool of mercury covered with a film of oil: an incoming radio pulse ruptured the thin oil film and allowed low-resistance contact between the steel and the mercury. This type of coherer was at least as sensitive as any other and a good deal more stable in operation.

Lodge did not at the time attempt to put his coherers to practical use, but Marconi used a filings version in his early apparatus. It was this, plus the use of elevated antennas and connection to Earth, which enabled Marconi to develop and steadily improve his equipment to the point

where it could be seen as a workable wireless communication system.

8. LODGE VERSUS MARCONI

Marconi came to England in 1896 as a young man of nearly 22, with little theoretical knowledge of wireless principles but full of enthusiasm and dedication. He had a flair for publicity and in December gave a demonstration to members of the public, carrying a blackbox around the audience that rang a bell whenever a key at the end of the hall was depressed. Representatives of the press were present, and the next day Marconi was headline news, hailed as the inventor of wireless. In fact Marconi was always quite modest and did not claim to be an inventor but rather that he “took up others people’s ideas and inventions and improved them.” But Lodge, and other scientists who had made significant contributions in the field, was naturally indignant about the adulation of a young Italian upstart: Lodge may thus be forgiven his testy comment in later years that “It was stale news to me and to a few others,” but he then added more generously, “But whereas we had been satisfied that it *could* be done, Marconi went on enthusiastically and persistently till he made it a practical success.”

Another area of interplay between Marconi and Lodge was tuning. As already mentioned, Lodge had a full understanding of the principles of resonance and tuning and in May 1897 he applied for a patent on his *syntony* ideas.

Tuning, and the resultant ability to separate one transmission from another, was of course a vital necessity for the development of Marconi’s wireless system and he tried many different circuit arrangements with gradually increasing success. Finally in 1900 his famous “four sevens” patent was granted. It may appear strange that he was granted this patent when Lodge had registered his some years earlier; but it seems that it was not considered that one infringed the other, and it was ruled in court that the two were complementary rather than duplications. Nevertheless the existence of Lodge’s patent was seen as an embarrassment by the Marconi Company, especially when its validity was extended in 1911 by a further 7 years. Accordingly, the Marconi Company negotiated with Lodge and bought his patent for a considerable sum.

9. THE LODGE–MUIRHEAD SYNDICATE

Another source of rivalry was the appearance of the Lodge–Muirhead Syndicate with a competing wireless telegraphy system. Although Lodge was basically uninterested in commercial exploitation of his Hertzian wave experiments and discoveries, such a venture was suggested to him by Dr. Alexander Muirhead after he had attended one of Lodge’s lectures in 1894. This eventually resulted in formation of the Lodge–Muirhead Syndicate in which Lodge provided the scientific ideas and Muirhead—a very able telegraph engineer—the design of practical equipment.

By 1903 the Syndicate was ready with a well-designed and effective system incorporating the Lodge steel–mercury coherer, but they found themselves up against the Marconi Company’s monopoly of coastal stations in the United Kingdom that it had negotiated with Lloyds of London from 1901, and the company’s contracts with many shipping lines for exclusive use of Marconi equipment and operators.

Faced with this situation, the Syndicate could find only limited markets in the military field and in a few overseas countries. So despite its technical excellence, the Lodge–Muirhead system was not a commercial success and was wholly bought out by the Marconi Company in 1911, together with the Lodge tuning patent referred to previously.

10. CONTINUOUS-WAVE TELEGRAPHY

Early radiotelegraphy was effected by spark trains produced as Morse signals by a telegraph key. The spark-induced oscillation bursts making up a dot or dash were randomly phased.

It was realized that continuous wave trains could be advantageous in offering narrower bandwidth transmission and hence the possibility of more precise tuning of transmitter and receiver, and various developments were undertaken to achieve this. The first was Marconi’s synchronous spark discharger wherein multiple sparkgaps on a rotating disk ensured that the oscillations from one gap would be so phased as to continue the oscillations from the preceding gap, giving a reasonable approximation of a continuous wave.

An alternative approach was the Poulsen system, based on earlier work by Duddell, using the negative resistance characteristic of an arc to generate continuous oscillation in a parallel resonant circuit. This was quite widely used by the German Telefunken company for a radiotelephone system, but was not always successful due to the difficulty of maintaining a steady arc discharge.

Another alternative was the high-frequency alternator. Difficulties here arose from the very high rotational speeds necessary to produce even quite modest radio-frequencies; but Ernst Alexanderson of American General Electric designed very successful machines capable of 100 kHz at powers of hundreds of kilowatts. A later development in Germany was the Goldschmidt HF, alternator, which reduced the need for excessive rotational speed by an ingenious system of frequency multiplication within the machine. With suitable coils and pole pieces, and moderate speed, the rotor could produce a frequency of perhaps 15 kHz; this would be induced in the stator, setting up a rotating field therein. The stator field was arranged to rotate in the direction opposite that of the rotor, so that an oscillation of double the frequency, 30 kHz was induced in the stator and $30 + 15 = 45$ kHz in the rotor. This 45 kHz was selected by a tuned filter resulting in a frequency of 60 kHz in the stator; the latter frequency was applied to the aerial for transmission. The Goldschmidt patents were bought up by the Marconi Company in 1913.

A difficulty with any of these machines was to maintain very precise alternator rotational speed, since even a small fluctuation would seriously detract from the potential for exact frequency stability and receiver selectivity. Particularly difficult was avoidance of speed changes with electrical load when the Morse key was operated; and this was compensated to some extent by a subsidiary key contact adjusting the alternator driving motor field when the key was depressed.

A final problem was that a continuous wave would by itself produce no sound in receiver headphones. To render Morse signals audible required the wave to be modulated at audiofrequency. Crude modulation could be provided by a "ticker," a chattering contact that broke up the continuous wave into audiofrequency groups. A better solution was to modulate the signals with a frequency about 1 kHz different from the main carrier to produce an audible "beat" note. This was achieved by Fessenden's heterodyne arrangement or by Goldschmidt's tonewheel.

11. RADIOTELEPHONY

Most early workers were content to communicate in Morse code telegraphy, but Reginald Fessenden, a Canadian working in the United States, considered radiotelephony much preferable. In 1900 he achieved speech transmission over a distance of 1 mi using a spark transmitter with a spark repetition frequency of 10,000/s. But modulating speech on a spark signal has been memorably described as "like printing a newspaper on a roll of stair carpet," and articulation and background noise were very unsatisfactory.

Fessenden realized that a continuous wave carrier was necessary for satisfactory speech modulation, and he initially experimented with arc-based oscillators, but found a HF alternator more satisfactory. On Christmas Eve 1906, and again on New Year's Eve, he successfully transmitted speech and music from his Brant Rock station using a HF alternator. Remarkably, his experimental speech transmissions shortly before these two events were heard by chance at Fessenden's receiving station at Machrihanish in Scotland.

In the very early years of the twentieth century the only radiowave detector was the coherer; but this, which was an ON/OFF device, was suitable only for reception of Morse transmissions. Fessenden sought a continuously operating detector that would be suitable for demodulating speech signals on a continuous-wave carrier, and in 1903 invented his "liquid barretter," an electrolytic gas generator that did indeed respond continuously to the amplitude of a received carrier. This was used in conjunction with his 1906 speech and music transmissions, although by this time the Marconi magnetic detector was also in use and capable of amplitude demodulation, as were Fleming's diode of 1904 and the crystal detectors introduced by Braun, Austen, Pickard, Pierce, and Dunwoody from 1906.

Lee de Forest developed an arc-based radio telephone in 1907/08, which was supplied in some quantity to the U.S. Navy.

12. VACUUM TUBES

On the basis of Thomas Edison's discovery in 1883 of unilateral conduction or electric current between an incandescent filament and an adjacent "plate" electrode, John Ambrose Fleming in England devised his "oscillation valve" in 1904. In 1906 de Forest introduced a third "grid" electrode between filament and plate, thus inventing the triode tube: but he had little understanding of the operating principles of his invention, and it was the detailed studies of Howard Armstrong and Irving Langmuir that developed it into a reliable and practical device by 1915.

Also in 1915, Armstrong developed the regeneration principle and hence the triode oscillator, and this finally fulfilled the need for convenient and stable generation of continuous radiofrequency oscillations that could readily be amplitude modulated for radiotelephony applications. Furthermore, the triode could be configured as a sensitive detector of such signals.

Thus was opened the way to modern electronics and, a few years later, to entertainment broadcasting of speech and music.

HORN ANTENNAS

EDWARD V. JULL
 University of British Columbia
 Vancouver, British Columbia
 Canada

A “horn” antenna is a length of conducting tube, flared at one end, and used for the transmission and reception of electromagnetic waves. For an efficient transition between guided and radiated waves, the horn dimensions must be comparable to the wavelength. Consequently horns are used mostly at centimeter and millimeter wavelengths. At lower or higher frequencies they are inconveniently large or small, respectively. They are most popular at microwave frequencies (3–30 GHz), as antennas of moderate directivity or as feeds for reflectors or elements of arrays.

Since acoustic horns have been in use since prehistoric times, the design of horns as musical instruments was a highly developed art well before the appearance of the first electromagnetic horns. This occurred shortly after Hertz in 1888 first demonstrated the existence of electromagnetic waves. Experimenters placed their sparkgap sources in hollow copper tubes (Figs. 1a, 5a). These tubes acted as highpass filters for microwave and millimeter-wave radiation from the open end. In London in 1897 Chunder Bose used rectangular conducting tubes with “collecting funnels,” or pyramidal horns (Fig. 1d) in his demonstrations at 5 and 25 mm wavelengths [1]. Thus the electromagnetic horn antenna was introduced but this early beginning of microwave invention closed with Marconi’s demonstration that longer wavelengths could be received at greater distances. Horns were too large to be practical at those wavelengths, and it was almost 40 years before microwave horns reappeared with the need for directive antennas for communications and radar. Horns alone were often not sufficiently directive but combined in an array or with a lens (Fig. 4a), or more often a parabolic reflector (Figs. 4b, 4c) highly directive antenna beams are obtained.

1. RADIATING WAVEGUIDES AND HORNS

Horns are normally fed by waveguides supporting only the dominant waveguide mode. For a rectangular waveguide (Fig. 1a) with TE_{01} mode propagation only, these dimensions in wavelengths λ are $\lambda/2 < a < \lambda$ and $b \approx a/2$. Open-ended waveguides have broad radiation patterns, so when used as a feed for a reflector, there is substantial spillover, or radiation missing the reflector and radiation directly backward from the feed. To increase the directivity of a radiating waveguide and its efficiency as a reflector feed, for example, its aperture dimensions must be enlarged, for the beamwidth of an aperture of width $a \gg \lambda$ is proportional to λ/a radians.

Figure 1. (a) Open-ended rectangular waveguide; (b) E -plane sectoral horn; (c) H -plane sectoral horn; (d) pyramidal horn.

This waveguide enlargement by a flare characterizes horns. The aperture fields of a horn are spherical waves originating at the horn apex (Fig. 2). The path from the horn apex to the aperture plane at a distance x from the aperture center of a horn of slant length ℓ is

$$\rho = ((\ell \cos \alpha)^2 + x^2)^{1/2} \approx \ell \cos \alpha + \frac{x^2}{2\ell \cos \alpha} \quad (1)$$

Figure 2. Effect of horn flare on the aperture field phase of a horn.

when $x \ll l \cos \alpha$. Thus the phase variation in radians across the aperture for small flare angles α is approximately $kx^2/(2\ell)$, where $k = 2\pi/\lambda$ is the propagation constant. This quadratic phase variation increases with increasing flare angle, thus reducing directivity increase due to the enlarged aperture dimension. It is convenient to quantify aperture phase variation by the

parameter

$$s = \frac{\ell(1 - \cos \alpha)}{\lambda} \approx \frac{d^2}{8\lambda\ell}, \quad d \ll \ell \tag{2}$$

which is the approximate difference in wavelengths between the distance from the apex to the edge ($x = d/2$) and the center ($x = 0$) of the aperture. The radiation patterns of Figs. 3a, 3b [2] show the effect of increasing s on the E - and H -plane radiation patterns of sectoral and pyramidal horns. The main beam is broadened, the pattern nulls are filled, and the sidelobe levels are raised over those for an in-phase aperture field ($s = 0$). With large flare angles radiation from the extremities of the aperture can be so out of phase with that from the center that the horn directivity decreases with increasing aperture width.

The adverse effects of the flare can be compensated by a lens in the aperture (Fig. 4a), but because that adds to the weight and cost and because bandwidth limitations are introduced by matching the lens surfaces to reduce reflections, it is seldom done. Instead, a combination of aperture width and flare length in wavelengths is chosen that provides maximum axial directivity or minimum beamwidth. This is an “optimum” horn design. To achieve higher directivity or narrower beamwidth for a given aperture width, a longer horn is required.

Figure 3. Universal radiation patterns of sectoral and pyramidal horns flared in the (a) E and (b) H planes. The parameter $s = b^2/8\lambda\ell_E$ in (a) and $a^2/8\lambda\ell_H$ in (b); $2\pi s/\lambda$ is the maximum phase difference between the fields at the center and the edge of the aperture. (Copyright 1984, McGraw-Hill, Inc. from Love [2].)

Figure 4. (a) Horn aperture field phase correction by a lens; (b) parabolic reflector fed by a horn; (c) horn reflector antenna (f =focal length of the lens or reflector).

Sectoral horns (Figs. 1b, 1c) are rectangular waveguides flared in one dimension only. The incident waveguide mode becomes a radial cylindrical mode in the flared region of the horn. Since radiation pattern beamwidths are inversely proportional to aperture dimensions in wavelengths, sectoral horns have beams that are narrow in the plane containing the broad dimension. Such fan-shaped beams may be useful for illuminating elongated parabolic reflectors or parabolic cylinder reflectors.

A pyramidal horn (Fig. 1d) is flared in both waveguide dimensions and so is more adaptable both as a reflector feed and on its own. The forward radiation pattern may be

calculated quite accurately from Kirchhoff diffraction theory for all except small horns. The TE_{01} rectangular waveguide mode yields an aperture field uniform in one dimension (in the E plane) and cosinusoidal in the other (the H plane). A comparison of parts (a) and (b) of Fig. 3 shows that this results in a higher sidelobes in the E plane and, for a square aperture, a narrower beam. Pyramidal horns are relatively easily constructed, and for all except small horns their axial gain can be predicted accurately. Consequently, they are used as gain standards at microwave frequencies; that is, they are used to experimentally establish the gain of other microwave antennas by comparing their response to the same illuminating field.

Most of the preceding remarks on open-ended rectangular waveguides and pyramidal horns also apply to open-ended circular waveguides and conical horns (Figs. 5a, 5b). For propagation of the lowest-order mode (TE_{11}) only in a circular waveguide, the interior diameter must be $0.59\lambda < a < 0.77\lambda$. This mode has a uniform aperture field in the E plane and a cosinusoidal distribution in the orthogonal H plane. This appears, modified by a quadratic phase variation introduced by the flare, in the aperture field of the horn. Consequently the E -plane radiation pattern of the horn is narrower, but with higher sidelobes than the H -plane pattern and the radiated beam is elliptical in cross section. In addition, cross-polarized fields appear in pattern lobes outside the principal planes.

2. HORN FEEDS FOR REFLECTORS

Many refinements to horns arise from their use as efficient feeds for parabolic reflectors, particularly in satellite and space communications and radio astronomy. The phase center, where a horn's far radiation field appears to originate, must be placed at the focus of the reflector (Fig. 4b). This phase center is within the horn on the horn axis and depends on the flare angle and aperture distribution. For both rectangular and conical horns the position of the phase center is not the same in the E and H planes, or planes containing the electric and magnetic field vectors, respectively. A phase center can be calculated from the average of the positions of the E - and H -plane phase centers or determined from the position of the feed that maximizes the gain of the reflector antenna.

For efficient aperture illumination the feed horn radiation pattern should approximately match the shape of the aperture, and illuminate it essentially uniformly and with minimal spillover, or radiation missing the reflector. Pyramidal horns may seem suitable for rectangular apertures because their beams are rectangular in cross section, and conical horns may seem a natural choice for a circular aperture, but efficient aperture illumination is not obtained in either case, because their principal plane patterns differ. Both horns have high E -plane pattern sidelobes and low H -plane sidelobes. A dual (TE_{11}/TM_{11})-mode conical horn provides equal E - and H -plane beamwidths and equally low sidelobes, and is an efficient feed for a circular aperture over a narrow frequency band (see Love [3], p. 195; Ref. 3 also contains reprints of most earlier significant papers on horn antennas). A broadband

Figure 5. (a) Open-ended circular waveguide; (b) conical horn; (c) corrugated horn; (d) circular waveguide with corrugated flange.

solution achieves an axisymmetric beam with annular corrugations on the interior surfaces of a conical horn (Fig. 5c). These produce a horn aperture field distribution that is approximately cosinusoidal across the conical horn aperture in all directions and hence an axisymmetric radiation pattern with low sidelobes. Such corrugations in the E -plane interior walls only of a pyramidal horn will produce a cosinusoidal E -plane aperture distribution, and consequently similar E -plane and H -plane radiation patterns for a square horn aperture.

A feed for a small circular reflector that is more easily constructed than a corrugated conical horn but with a less axisymmetric radiation pattern, is an open-ended circular

waveguide ringed by a recessed disk of approximately quarter-wavelength-deep corrugations (Fig. 5d). These corrugations suppress backradiation from the feed and so improve the aperture illumination over that of a simple open circular waveguide [3, pp. 181, 226]. Combined with dual-mode excitation, this arrangement provides a simple and efficient feed for a front-fed paraboloidal reflector.

3. RADIATION FROM APERTURES

The far-field radiation pattern of an aperture can be calculated exactly from the Fourier transform of the tangential fields in the entire aperture plane. Either electric or magnetic aperture fields may be used but for apertures in space, a combination of the two gives the best results from the usual assumption that aperture plane fields are confined to the aperture and negligible outside it. This aperture field is assumed to be the undisturbed incident field from the waveguide. For apertures with dimensions larger than several wavelengths, a further simplifying assumption usually made is that the aperture electric and magnetic fields are related as in free space.

3.1. Rectangular Apertures

With the abovementioned assumptions, at a distance much greater than the aperture dimensions, the radiated electric field intensity of a linearly polarized aperture field $E_x(x, y, 0)$ in the coordinates of Fig. 6a is

$$\bar{E}(r, \theta, \phi) = \bar{A}(r, \theta, \phi) \int_{-(b/2)}^{b/2} \int_{-(a/2)}^{a/2} E_x(x, y, 0) e^{j(k_1 x + k_2 y)} dx dy \quad (3)$$

Here

$$\left. \begin{aligned} k_1 &= k \sin \theta \cos \phi \\ k_2 &= k \sin \theta \sin \phi \end{aligned} \right\} \quad (4)$$

and

$$\bar{A}(r, \theta, \phi) = j \frac{e^{-jkr}}{2\lambda r} (1 + \cos \theta) (\hat{\theta} \cos \phi - \hat{\phi} \sin \phi) \quad (5)$$

is a vector defining the angular behavior of the radiation polarization for an aperture in space. For an aperture in a conducting plane, it is more accurate to use

$$\bar{A}(r, \theta, \phi) = j \frac{e^{-jkr}}{\lambda r} (\hat{\theta} \cos \phi - \hat{\phi} \sin \phi \cos \theta) \quad (6)$$

which, since it is based on the aperture plane electric fields only, fully satisfies the assumption of a vanishing tangential field in the aperture plane outside the aperture. Consequently radiation fields of open-ended waveguides and small horns can be calculated accurately from (3) with (6) if they are mounted in a conducting plane. Clearly (5) and (6) differ significantly only for large angles θ off the beam axis.

Figure 6. Coordinates for radiation from (a) rectangular and (b) circular apertures.

If the aperture field is separable in the aperture coordinates—that is, if in (3), $E_x(x, y, 0) = E_0 E_1(x) E_2(y)$, where $E_1(x)$ and $E_2(y)$ are field distributions normalized to E_0 , the double integral is the product of two single integrals

$$E(r, \theta, \phi) = \bar{A}(r, \theta, \phi) E_0 F_1(k_1) F_2(k_2) \quad (7)$$

where

$$F_1(k_1) = \int_{-(a/2)}^{a/2} E_1(x) e^{jk_1 x} dx \quad (8)$$

$$F_2(k_2) = \int_{-(b/2)}^{b/2} E_2(y) e^{jk_2 y} dy \quad (9)$$

define the radiation field.

4. OPEN-ENDED WAVEGUIDES

4.1. Rectangular Waveguides

With the TE_{10} waveguide mode the aperture field

$$E_x(x, y, 0) = E_0 \cos \frac{\pi y}{a} \quad (10)$$

in (7) yields the following equations for (8) and (9):

$$F_1(k_1) = b \frac{\sin\left(\frac{k_1 b}{2}\right)}{\frac{k_1 b}{2}} \quad (11)$$

$$F_2(k_2) = a \left(\frac{\cos\left(\frac{k_2 a}{2}\right)}{\pi^2 - (k_2 a)^2} \right) \quad (12)$$

This defines the radiation pattern in the forward hemisphere $-\pi/2 < \theta < \pi/2$, $0 < \phi < 2\pi$. If the aperture is in space, then (5) is used for $\bar{A}(r, \theta, \phi)$, but this is not an accurate solution since the aperture dimensions are not large. Rectangular waveguides mounted in conducting planes use (6) for $\bar{A}(r, \theta, \phi)$ in (7), which then accurately provides the far field. The pattern has a single broad lobe

with no sidelobes. For large apertures plots of the normalized E -plane ($\phi = 0$) and H -plane ($\phi = \pi/2$) patterns of (7) appear in Figs. 3a and 3b for those of a horn with no flare ($s = 0$), but without the factor $(1 + \cos \theta)/2$ from (5) or $\cos \theta$ from (6).

4.2. Circular Waveguides

The dominant TE_{11} mode field in circular waveguide produces an aperture field distribution, which in the aperture coordinates ρ', ϕ' of Fig. 6b is

$$\bar{E}(\rho', \phi') = E_0 \left[\hat{\rho}' \frac{J_1(k_c \rho')}{k_c \rho'} \cos \phi' + \hat{\phi}' J_1'(k_c \rho') \sin \phi' \right] \quad (13)$$

where J_1 is the Bessel function of the first kind and order, J_1' is its derivative with respect to its argument $k_c \rho'$, and $k_c a/2 = 1.841$ is its first root; E_0 is the electric field at the aperture center ($\rho' = 0$). Since (13) is not linearly polarized, its use in (3) provides only part of the total radiated far field. The total field

$$\bar{E}(r, \theta, \phi) = jka E_0 J_1(1.841) \frac{e^{-jkr}}{r} \left\{ \hat{\theta} \cos \phi \frac{J_1\left(\frac{k'a}{2}\right)}{\frac{k'a}{2}} + \hat{\phi} \sin \phi \cos \theta \frac{J_1\left(\frac{k'a}{2}\right)}{1 - \left(\frac{k'a}{3.682}\right)^2} \right\} \quad (14)$$

in which $k' = k \sin \theta$.

In the E and H planes ($\phi = 0$ and $\pi/2$) the cross-polarized fields cancel and the patterns shown in Fig. 14a are similar to those of (11) and (12), respectively, but with slightly broader beams and lower sidelobes for the same aperture dimensions. As with rectangular waveguides, open-ended circular waveguide apertures are insufficiently large for (14) to represent all the radiated fields accurately. In the principal planes ($\phi = 0, \pi/2$), it can give a reasonable approximation for the copolarized fields but fails to accurately represent the cross-polarized field patterns in $\phi = \pi/4$. This is evident from a comparison of

numerical results from approximate and exact solutions [4, p. 233].

5. PYRAMIDAL AND SECTORAL HORNS

5.1. Radiation Patterns

A pyramidal horn fed by a rectangular waveguide supporting the TE_{10} mode has an incident electric field in the aperture of Fig. 6a that is approximately the mode distribution modified by a quadratic phase variation in the two aperture dimensions:

$$E_x(x, y, 0) = E_0 \cos\left(\frac{\pi y}{a}\right) \exp\left(-jk\left(\frac{x^2}{2\ell_E} + \frac{y^2}{2\ell_H}\right)\right) \quad (15)$$

With (15), Eq. (3) becomes

$$\bar{E}(r, \theta, \phi) = \bar{A}(r, \theta, \phi) E_0 I_1(k_1) I_2(k_2) \quad (16)$$

where (5) is used for $\bar{A}(r, \theta, \phi)$ and

$$I_1(k_1) = \int_{-(b/2)}^{b/2} \exp\left(-j\left(\frac{\pi x^2}{\lambda \ell_E} - k_1 x\right)\right) dx \quad (17)$$

$$I_2(k_2) = \int_{-(a/2)}^{a/2} \cos\left(\frac{\pi y}{a}\right) \exp\left(-j\left(\frac{\pi y^2}{\lambda \ell_H} - k_2 y\right)\right) dy \quad (18)$$

The E -plane ($\phi = 0$) and H -plane ($\phi = \pi/2$) radiation patterns are, respectively

$$\frac{E_\theta(r, \theta)}{E_\theta(r, 0)} = \frac{1 + \cos \theta}{2} \frac{I_1(k \sin \theta)}{I_1(0)} \quad (19)$$

$$\frac{E_\theta(r, \theta)}{E_\theta(r, 0)} = \frac{1 + \cos \theta}{2} \frac{I_2(k \sin \theta)}{I_2(0)} \quad (20)$$

These integrals can be reduced to the Fresnel integrals

$$C(u) - jS(u) = \int_0^u e^{-j(\pi/2)t^2} dt \quad (21)$$

which are tabulated and for which computer subroutines are available. For example, we obtain

$$\frac{I_1(k \sin \theta)}{I_1(0)} = \frac{e^{j(\pi \ell_E / \lambda) \sin^2 \theta} C(u_2) - C(u_1) - j[S(u_2) - S(u_1)]}{C(u) - jS(u)} \quad (22)$$

with

$$u = \frac{b}{\sqrt{2\lambda \ell_E}} \quad (23)$$

$$u_1^2 = \pm u - \sqrt{\frac{2\ell_E}{\lambda}} \sin \theta \quad (24)$$

Figure 3a shows plots of the magnitude of (22) for various values of the E -plane flare parameter $s = b^2/8\lambda \ell_E$, while

Fig. 3b shows corresponding plots of $|I_2(k \sin \theta)/I_2(0)|$ for the H -plane flare parameter $s = a^2/8\lambda \ell_H$. For no flare ($s = 0$) the patterns are those of a large open-ended rectangular waveguide supporting only the TE_{10} mode. The effect of the flare is to broaden the mainbeam, raise the sidelobes, and fill the pattern nulls. For larger values of s , there is enhanced pattern beam broadening and eventually a splitting of the mainbeam on its axis.

These curves also represent the radiation patterns of the E/H -plane sectoral horns of Figs. 1b and 1c. For an E -plane sectoral horn ($\ell_H \rightarrow \infty$), the E -plane pattern is given by (19) and the H -plane pattern approximately by (12). For an H -plane sectoral horn ($\ell_E \rightarrow \infty$), the E -plane pattern is given approximately by (11) and the H -plane pattern by (20).

In comparing parts (a) and (b) of Fig. 3 it is evident that E -plane beamwidths of a square aperture are narrower than H -plane beamwidths. For horns of moderate flare angle and optimum horns the E -plane half-power beamwidth is $0.89\lambda/b$ radians and the H -plane half-power beamwidth is $1.22\lambda/a$ radians. E -plane patterns have minimum sidelobes of -13.3 dB below peak power, while H -plane pattern minimum sidelobes levels are -23.1 dB.

The universal patterns of Fig. 3 can also be used to predict the approximate near-field radiation patterns of horns by including the quadratic phase error; which is a first-order effect of finite range r . This is done by including

$$\exp\left(-j\frac{\pi}{r\lambda}(x^2 + y^2)\right) \quad (25)$$

in (15). Then the near-field principal plane patterns of a pyramidal horn are given by (17) and (18) with ℓ_E, ℓ_H replaced by

$$\ell'_H = \frac{r\ell_H}{r + \ell_H} \quad (26)$$

and

$$\ell'_E = \frac{r\ell_E}{r + \ell_E} \quad (27)$$

These near-field effects are analogous to decreasing the flare length of a horn with a fixed aperture width. The mainbeam broadens, nulls are filled in, and sidelobes rise.

5.2. Limitations and Extensions

Results from (16) do not apply to small horns and are limited to the forward direction ($\theta < 90^\circ$). They are most accurate on and around the beam axis ($\theta = 0$), becoming progressively less accurate as θ increases. The simplest method for extending the analysis is by the uniform geometric theory of diffraction [e.g., 3, p. 66], which provides the edge-diffracted fields in the lateral and rear directions, which receive no direct illumination from the aperture. Only the edges normal to the plane of the pattern contribute significantly to the E -plane pattern, but the rear H -plane pattern requires contributions from all four aperture edges and so is difficult to calculate this way.

While the geometry of the pyramidal horn defies rigorous analysis, numerical methods have been used with some success for open waveguides and small horns. For larger horns this approach becomes computationally intensive, but some results from Liu et al. [5] are shown in Fig. 7 and compared with measurements and approximate computations. Their numerical computations and measurements by Nye and Liang [6] of the aperture fields show that higher-order modes need to be added to the dominant mode field of (15) and that the parabolic phase approximation of (1) improves as the aperture size increases.

5.3. Gain

Pyramidal horns are used as gain standards at microwave frequencies because they can be accurately constructed and their axial directive gain reliably predicted from a relatively simple formula. The ratio of axial far-field power density to the average radiated power density

from (16) yields

$$G = G_0 R_E(u) R_H(v, w) \quad (28)$$

where $G_0 = 32ab/(\pi\lambda^2)$ is the gain of an in-phase uniform and cosinusoidal aperture distribution. The reduction of this gain due to the phase variation introduced by the E -plane flare of the horn is

$$R_E(u) = \frac{C^2(u) + S^2(u)}{u^2} \quad (29)$$

where the Fresnel integrals and their argument are defined by (21) and (23). Similarly the gain reduction factor due to the H -plane flare of the horn is

$$R_H(v, w) = \frac{\pi^2}{4} \frac{[C(v) - C(w)]^2 + [S(v) - S(w)]^2}{(v - w)^2} \quad (30)$$

Figure 7. Calculated and measured (a) E -plane and (b) H -plane radiation patterns of a pyramidal horn of dimensions $a = 4.12\lambda$, $b = 3.06\lambda$, $\ell_E = 10.52\lambda$, $\ell_H = 9.70\lambda$ (Copyright 1993, IEEE, from Liu et al. [5].)

where

$$\frac{v}{w} = \pm \frac{a}{\sqrt{2\lambda\ell_H}} + \frac{1}{a} \sqrt{\frac{\lambda\ell_H}{2}} \quad (31)$$

A plot of R_E and R_H in decibels as a function of the parameter $2d^2/\lambda\ell$, where d is the appropriate aperture dimension b or a and ℓ the slant length ℓ_E or ℓ_H , respectively, is shown in Fig. 8. Calculation of the gain from (28) is accurate to about ± 0.1 dB for 22 dB standard gain pyramidal horns: optimum horns with dimensions of at least 5λ . For 18-dB-gain horns, the accuracy is about ± 0.2 dB, and for 15-dB horns, ± 0.5 dB. Since optimum gain pyramidal horns have an aperture efficiency of approximately 50%, the gain is approximately

$$G = 0.5 \frac{4\pi}{\lambda^2} ab \quad (32)$$

For an E -plane sectoral horn $\ell_H \rightarrow \infty$ and $R_H(v, w) \rightarrow 1$ the axial gain is then $G_E = G_0 R_E(u)$, an inaccurate formula because aperture dimension a is less than a wavelength. A result that includes the fact that aperture electric and magnetic fields are not related by free-space conditions and that interaction occurs across the narrow aperture of the horn is

$$G_E = \frac{16ab}{\lambda^2(1 + (\lambda_g/\lambda))} R_E(u') \exp\left[\frac{\pi a}{\lambda} \left(1 - \frac{\lambda}{\lambda_g}\right)\right] \quad (33)$$

Figure 8. E - and H -plane flare and near-field gain reduction factors R_E and R_H of pyramidal and sectoral horns in decibels. (Copyright 1981, IEE, from Jull [11].)

where

$$u' = \frac{b}{\sqrt{2\lambda_g\ell_E}} \quad (34)$$

and

$$\lambda_g = \frac{\lambda}{\sqrt{1 - (\lambda/2a)^2}} \quad (35)$$

is the guide wavelength. The accuracy of (33) is comparable to that of (28) for the horns of similar b dimension.

The gain of an H -plane sectoral horn, obtained by letting $\ell_E \rightarrow \infty$ so that $R_E(u) \rightarrow 1$, is $G_H = G_0 R_H(v, w)$. It probably is reasonably accurate, but there appears to be no experimental evidence available to verify it.

The near-field gain of pyramidal and sectoral horns can be calculated from the preceding expressions by replacing ℓ_E and ℓ_H by (26) and (27), respectively.

6. CONICAL HORNS

The aperture field of a conical horn fed by a circular waveguide supporting the TE_{11} mode is approximately

$$E(\rho', \phi') \exp\left(\frac{-jk\rho'^2}{2\ell}\right) \quad (36)$$

where $\bar{E}(\rho', \phi')$ is given by (13) and ℓ is the slant length of the horn. Numerical calculation of the radiation patterns is necessary. In the example of Fig. 9 [7] with a flare angle $\alpha = 5^\circ$ and aperture width $a = 4\lambda$, the E -plane ($\phi = 0$)

Figure 9. Copolar and cross-polar radiation patterns for a conical horn with dimensions $a = 4\lambda$, $\ell = 23\lambda$ --- E -plane, - - - H -plane - . . . cross-polarization. (Copyright 1994, IEE, from Olver et al. [7].)

pattern is narrower than the H -plane ($\phi = \pi/2$) pattern as in square rectangular horns. The cross-polar ($\phi = \pi/4$) radiation pattern peak level is -18.7 dB relative to the copolar pattern peak levels, a level typical of conical horn apertures large than about 2λ . Smaller conical horns can have more axisymmetric patterns. E - and H -plane patterns have equal beamwidths for an aperture diameter $a = 0.96\lambda$, and cross-polarized fields cancel for $a = 1.15\lambda$. This makes small conical horns efficient as reflector feeds and as array elements with high polarization purity.

Larger conical horns are similar to rectangular horns in their lack of axial pattern symmetry. Optimum gain conical horns have an aperture efficiency of about 54% and half-power beamwidths in the E and H planes of $1.05\lambda/a$ and $1.22\lambda/a$ radians, respectively, for aperture diameters of more than a few wavelengths.

7. MULTIMODE AND CORRUGATED HORNS

Lack of axisymmetric radiation patterns make rectangular and conical horns inefficient reflector feeds. Conical horns also have unacceptably high cross-polarization levels if used as reflector feeds in a system with dual polarization. Multimode and corrugated horns were developed largely to overcome these deficiencies. In a dual-mode horn in [3, p. 195], this is done by exciting the TM_{11} mode, which propagates for circular waveguide diameters $a > 1.22\lambda$, in addition to the TE_{11} mode, which propagates for $a > 0.59\lambda$. The electric field configuration of these modes in a waveguide cross section is shown in Figs. 10a and 10b. Added in phase and in the right proportion, cross-polarized and aperture perimeter fields cancel, while the copolar fields around the aperture center add, yielding the aperture field configuration of Fig. 10c. These mixed mode fields are linearly polarized and taper approximately cosinusoidally radially across the aperture. This yields the essentially linearly polarized and axisymmetric radiation patterns desired.

Partial conversion of TE_{11} to TM_{11} fields can be effected by a step discontinuity in the circular waveguide feed, as

Figure 10. Excitation of axisymmetric linearly polarized aperture fields in a stepped conical horn. (Copyright 1984, McGraw-Hill, Inc. from Love [2].)

in Fig. 10d, or by a circular iris or dielectric ring in the horn. The TM_{11}/TE_{11} amplitude ratio depends on the ratio of waveguide diameters, and the relative phase of the modes depends on the length of larger-diameter circular waveguide and the horn. This dependence limits the frequency bandwidth of the horn to about 5%. A multimode square pyramidal horn has similarly low sidelobe levels in its E - and H -plane radiation patterns because of an essentially cosinusoidal aperture distribution in both E and H planes [2]. This is achieved by excitation of a hybrid TE_{21}/TM_{21} mode either by an E -plane step discontinuity or by changes in the E -plane flare. With their bandwidth very limited, dual-mode horns have largely been replaced by corrugated horns in dual-polarization systems, except where a lack of space may give an advantage to a thin-walled horn.

Corrugated horns have aperture fields similar to those of Fig. 10c and consequently similar radiation patterns, but without the frequency bandwidth limitations of the multimode horn. This is achieved by introducing annular corrugations to the interior walls of a conical horn. There must be sufficient corrugations per wavelength (at least 3) that the annular electric field E_ϕ is essentially zero on the interior walls. The corrugations make the annular magnetic field H_ϕ also vanish. This requires corrugation depths such that short circuits at the bottom of the grooves appear as open circuits at the top, suppressing axial current flow on the interior walls of the horn. This groove depth is $\lambda/4$ on a plane corrugated surface or a curved surface of large radius. For a curved surface of smaller radius, such as near the throat of the horn, the slot depths need to be increased; for example, for a surface radius of 2λ , the depth required is 0.3λ . Usually slots are normal to the conical surface in wide-flare horns but are often perpendicular to the horn axis with small flares. To provide a gradual transition from the TE_{11} mode in the waveguide to a hybrid HE_{11} mode in the aperture, the depth of the first corrugation in the throat should be about 0.5λ so that the surface there resembles that of a conducting cone interior. Propagation in corrugated conical horns can be accurately calculated numerically by mode matching techniques. The aperture field is approximately

$$E_x(\rho') = AJ_0(k_c \rho') \exp\left(\frac{-jk \rho'^2}{2\ell}\right) \quad (37)$$

where $k_c a/2$ is 2.405, the first zero order Bessel function J_0 ; ℓ is the slant length of the horn; and A is a constant. This aperture field is similar to that of Fig. 10c, and the resulting E and H patterns are similarly equal down to about -25 dB. Some universal patterns are shown in Fig. 11. Cross-polarization fields are also about -30 dB from the axial values, but now over a bandwidth of 2–1 or more.

Broadband axisymmetric patterns with low cross-polarization make corrugated horns particularly attractive as feeds for reflectors. Low cross-polarization allows the use of dual polarization to double the capacity of the system. Another notable feature for this application is that the position of the E - and H -plane pattern phase centers coincide. Figure 12 shows the distance of the phase center

Figure 11. Universal patterns of small-flare-angle corrugated horns as a function of the parameter $s = a^2/8\lambda l$. (Copyright 1984, McGraw-Hill, Inc. from Love [2].)

from the horn apex, divided by the slant length, of small flare angle conical [8] and corrugated [9] horns for values of the phase parameter s given by (2). For a conical horn the E -plane phase center is significantly farther from the aperture than the H -plane phase center. Thus, if a conical horn is used to feed a parabolic reflector, the best location for the feed is approximately midway between the E - and H -plane phase centers. With a corrugated horn such a compromise is not required, so it is inherently more efficient.

Corrugated horns may have wide flare angles, and their aperture size for optimum gain decreases correspondingly.

Figure 12. Normalized distance of the phase center from the apex of conical (--- E plane, - · - · - H plane and corrugated (—) horns). (Data from Milligan [8] and Thomas [9].)

For example, with a semiflare angle of 20° , the optimum aperture diameter is about 8λ , whereas for a semiflare angle of 70° it is 2λ . Wide-flare corrugated horns are sometimes called “scalar horns” because of their low cross-polarization levels.

For radio astronomy telescope feeds and other space-science applications, efficient corrugated horns have been made by electroforming techniques for frequencies up to 640 GHz. Their axisymmetric radiation patterns with very low sidelobe levels resemble Gaussian beams, which is often essential at submillimeter wavelengths.

8. PROFILE HORNS

Most corrugated horns are conical with a constant flare angle. Figure 13 shows a profile conical horn in which the flare angle varies as on a sine-squared or similar curve along its length. This arrangement provides a horn shorter than a conical corrugated horn of similar beamwidth, with a better impedance match due to the curved profile at the throat and an essentially in-phase aperture field distribution due to the profile at the aperture. Consequently the aperture efficiency is higher than that of conical corrugated horns. The phase center of the horn is near the aperture center and remains nearly fixed over a wide frequency band. Radiation patterns of a short profile horn similar to that of Fig. 13, but with hyperbolic profile curves, are shown in Fig. 14 [10]. A Gaussian profile curve has also been used. All produce patterns similar to those of a Gaussian beam, such as is radiated from the end of an optical fiber supporting the HE_{11} mode. The performance of this small horn as a feed seems close to ideal, but larger-profile horns may exhibit higher sidelobe levels due to excitation of the HE_{12} mode at the aperture.

9. HORN IMPEDANCE

Antennas must be well matched to their transmission lines to ensure a low level of reflected power. In microwave communications systems levels below -30 dB are commonly required.

Figure 13. A profile corrugated horn. (Copyright 1994, IEE, from Olver et al. [7].)

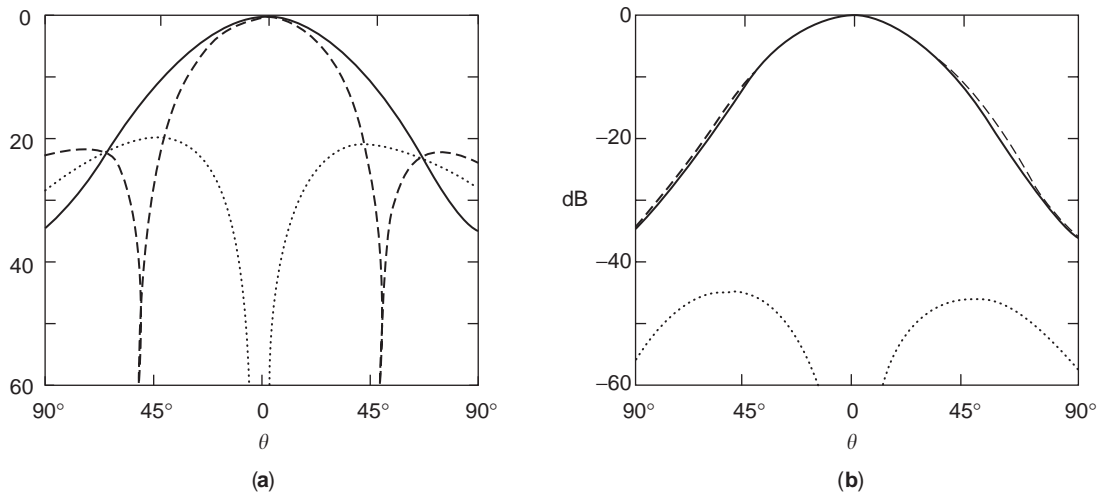

Figure 14. (a) Far field radiation patterns of TE₁₁ mode and (b) radiation patterns of a profile corrugated horn of aperture $a = 15.8$ mm and length $L = 26.7$ mm at 30 GHz (--- E -plane, ____ H -plane cross-polarization). (Copyright 1997, IEEE, from Gonzalo et al. [10].)

The impedance behavior of a horn depends on the mismatch at the waveguide/horn junction and at its aperture. For an E -plane sectoral horn, reflections from these discontinuities are comparable in magnitude, and since they interfere, the total reflection coefficient oscillates with frequency and the input voltage standing-wave ratio (VSWR) may vary from 1.05 at high frequencies to 1.5 at the lowest frequency. With E -plane sectoral horns aperture reflection is much stronger than junction reflection, so their VSWRs increase almost monotonically with decreasing frequency. An inductive iris in the waveguide near the E -plane horn junction can match its discontinuity. A capacitive iris may be similarly used for an H -plane sectoral horn. Aperture reflections in these horns may be matched with dielectric covers.

Pyramidal horns of sufficient size and optimum design tend to be inherently well matched to their waveguide feeds because the E/H -plane aperture and flare discontinuities partially cancel. For example, a 22-dB-gain horn has a VSWR of about 1.04 and an 18 dB horn a VSWR of less than 1.1.

Conical horns fed by circular waveguides supporting the dominant TE₁₁ mode have an impedance behavior similar to that of pyramidal horns of comparable size fed by rectangular waveguides. The waveguide/horn discontinuities of both horns may be matched by an iris placed in the waveguide near the junction. A broader bandwidth match is provided by a curved transition between the interior walls of the waveguide and the horn. Broadband reduction of aperture reflection may be similarly reduced by a curved surface of a few wavelengths' radius. Such "aperture-matched" horns also have lower sidelobe levels and less backradiation in their E -plane patterns than do conventional pyramidal and conical horns. Their H -plane flare patterns are affected little by such aperture matching because the electric field vanishes at the relevant edges.

For dual-mode and corrugated horns there are also negligible fields at the aperture edges and hence little diffraction there. Corrugated horns with initial groove

depths near the throat of about a half-wavelength and which gradually decrease to a quarter-wavelength near the aperture, as in Fig. 13, are well matched at both throat and aperture. For most well-designed corrugated horns a VSWR of less than 1.25 is possible over a frequency range of about 1.5–1. Dual-mode horns using a step discontinuity as in Fig. 10d may have a VSWR of 1.2–1.4. If an iris is required for a match, the frequency bandwidth will, of course, be limited. Conical and pyramidal horns using flare angle changes to generate the higher-order modes can have VSWRs less than 1.03 and require no matching devices.

HTS FILM GROWTH

KOOKRIN CHAR
VLADIMIR MATIJASEVIC
Conductus, Inc.

Thin films of superconductors are of interest primarily for electronics applications. High-performance superconducting thin films are essential, for example, for high-frequency passive devices and Josephson junction circuits. Thin films are also important for fundamental studies of superconducting materials, where specially designed experiments can take advantage of the thin-layer geometry and the capability of layering various combinations of materials, as well as lithographically defining fine features in them. Additionally, there is currently growing interest in using thin-film deposition technology for deposition of thick films on polycrystalline substrates for power applications.

In the decade since the discovery of high-temperature superconductivity (HTS) in cuprate compounds, thin-film materials have played an important role in the evolution of this field. The discovery of HTS has led to a rapid development of many different thin film deposition techniques. HTS thin films are now routinely made in hundreds of laboratories around the world, and thin-film research is actively pursued in areas such as new superconducting materials and epitaxial oxide heterostructures. More recently, advances in deposition processes have brought about the synthesis of larger-area HTS films, making fabrication less expensive and allowing for high-throughput manufacturing of single-superconducting-layer films.

In this article, we review the physical vapor deposition (PVD) techniques most frequently used for HTS thin-film synthesis. Chemical vapor deposition techniques are reviewed in another article of this encyclopedia. Here, we review only the methods and issues that are relevant for film deposition. This does not cover the details of the film growth processes, nor the physical properties of HTS films and their applications. The reader is referred to other references for a more complete discussion of HTS thin films and their applications [1,2].

1. MATERIALS

The HTS material of choice for applications is still $\text{YBa}_2\text{Cu}_3\text{O}_7$ (YBCO), the first cuprate discovered to superconduct above 77 K. There are several compelling reasons why this material is still the most suitable for many of the applications. Some of the fundamental ones are its smaller conduction anisotropy, higher superconducting critical

currents in a magnetic field, and greater chemical stability than in other HTS compounds. However, the most important reason is the ease of fabricating high-quality, single-phase YBCO thin films.

In this review, YBCO will be considered the canonical high- T_c superconductor, and the discussion will be limited to this example, partly for reasons of conciseness and partly because of the prominence of this compound in the HTS community. Additionally, unless otherwise mentioned, one is generally considering growth of *c*-axis-oriented films, i.e. where the CuO_2 layers are parallel to the substrate.

Table 1 reviews the HTS compounds and methods used to date to prepare these thin films. For a review of materials, we refer the reader to Refs. 2 and 3. There has been a substantial effort related to Bi–Sr–Ca–Cu–O thin films (2212 and 2223 phases) by a variety of techniques, particularly in Japan. Some industrial work in the United States has also focused on Tl–Ba–Ca–Cu–O (mostly 2212), primarily for passive electronics applications. One of the obvious reasons for looking at these other compounds is their higher critical temperatures. Nevertheless, the advantages of YBCO have been hard to surpass, particularly at temperatures below 65 K. Substantial thin-film work has also been devoted to La–Sr–Cu–O, Nd–Ce–Cu–O, Hg–Ba–Ca–Cu–O, and infinite-layer compounds, mostly driven by academic interest in basic properties of these HTS materials.

2. THERMODYNAMIC ISSUES

Film growth is inherently a nonequilibrium process. Nevertheless, thermodynamic stability is important as a driving force for the reactions taking place during growth. HTS compounds possess large unit cells that can have additional complications, such as a wealth of metal atom defects and oxygen nonstoichiometries. These complex structures require temperatures for formation close to their melting points, typically (0.8–0.9) T_m , much higher

Table 1. HTS Materials Systems, Methods Used to Fabricate Thin Films, and Applications of the Thin Films

Material	T_c (K)	Thin-Film Deposition Technique	Applications
Y(R)BaCuO 123	85–95	In situ: sputtering, PLD, evaporation, MOCVD; ex situ	RF devices, Josephson Junctions
BiSrCaCuO 2201, 2212, 2223	10–115	In situ: sputtering, PLD, evaporation	Josephson junctions
TlBaCaCuO 1201, 1212, 1223, 2201, 2212, 2223	20–125	1212: in situ sputtering; ex situ	RF devices
HgBaCaCuO 1201, 1212, 1223	95–133	Ex situ	
LaSr(Ba)CuO	20–40	In situ	
NdCeCuO	20–30	In situ	

Figure 1. Thermodynamic stability diagram for YBCO in oxygen pressure and temperature. The shaded elliptical areas indicate regimes where in situ film growth for YBCO has been reported successful. The rectangles show ex situ film growth regimes.

than is usual for growth of epitaxial metals and semiconductors. The intricacies of film growth and the thermodynamics of phases produced are certainly not sufficiently well understood at present. Below, we summarize some of the key thermodynamic issues as they are currently accepted.

2.1. Oxygen Stability

HTS compounds are oxides and, as such, require the presence of oxygen during synthesis. Although it is technically possible to deliver oxygen through the substrate, in practice, oxygen is delivered as a gas impinging on the growth surface together with the cation species. Figure 1 shows the pressure–temperature thermodynamic stability diagram for the bulk YBCO compound. One can see from the diagram that a certain minimum pressure must be maintained for the stability of YBCO. Below that oxygen pressure, depicted by the line labeled d_1 , the YBCO compound is not stable and will decompose. For the typical temperatures during film formation, this translates into a minimum oxygen pressure of about 100 mPa (1 mtorr). At higher oxygen pressures, there is another decomposition line for YBCO, labeled d_2 , seldom not reached during in situ growth of thin films. During cooldown of films to room temperature, this second decomposition is seldom observed because it is strongly limited by diffusion kinetics. However, the stability diagram also implies that the YBCO compound is metastable at room temperature and pressure. In fact, most HTS compounds are believed not to be thermodynamically stable at lower temperatures. References 4 and 5 have a more detailed discussion of the YBCO stability lines. Hammond and Bormann [6] argued

that growth of thin films is optimal close to the high-temperature thermodynamic decomposition line of the compound. In fact, the empirical data confirm this, as can be seen also in Fig. 1, where successful film growth regions are denoted. For processes that possess a more reactive form of oxygen, such as atomic oxygen or ozone, the equivalent decomposition line is shifted compared with that in Fig. 1. Such activated oxygen species have been proven helpful for growth of YBCO when the total pressure is lower than about 1 Pa (10 mtorr).

2.2. Compositional Phase Diagram

The HTS compounds contain typically three to five different metal species in addition to oxygen. Some of these materials are line compounds (and this is presumed to be the case for YBCO) and, as such, do not accept a solid solution of atoms in their chemical formula. This means that one will always be synthesizing a number of phases in addition to the desired HTS material. For YBCO, the Gibbs phase rule implies two other compounds as impurity phases. Figure 2 shows the present understanding of the ternary phase diagram for Y–Ba–Cu oxides at the low oxygen pressures relevant for in situ thin-film growth [7,8]. The corners of the triangles define the phases which will be present for any composition in that triangle.

There are some caveats to the description given above. First, as already stated, film growth is not an equilibrium process, and therefore metastable phases could be formed during synthesis. Second, the HTS material that is formed during film growth may not be, and probably is not, exactly like the bulk material. This has now been well documented in the literature for YBCO films. In fact, it is also fairly well established that YBCO film growth does not match exactly the thermodynamic phase diagram shown in Fig. 2. In particular, the Y_2BaCuO_5 phase has not been observed in in situ-grown films. On the other hand, CuO and Y_2O_3 second phases are commonly observed in YBCO films prepared close to 1:2:3 stoichiometry and are not predicted by the phase diagram.

Figure 2. Thermodynamic ternary phase diagram for Y–Ba–Cu oxides at temperatures below 850°C and oxygen pressures below one atmosphere.

3. EPITAXY

Due to the significant anisotropy of the HTS materials, the easy direction for electrical current flow is in the ab plane, along the Cu-O_2 planes. For devices which require current to flow parallel to the substrate, the growth direction of the HTS films has to be in the c -axis direction. In order to achieve c -axis-oriented growth, good epitaxial growth of all grains is necessary. Furthermore, a high-angle, in-plane grain boundary of two c -axis-oriented grains has been found to behave as a superconducting weak link. This implies that one needs to align all grains in the plane of the substrate as well as out of the plane. The requirements of in-plane epitaxy are very well illustrated in the case of yttria-stabilized zirconia (YSZ) substrates where the YBCO films grow in the c direction, but the c axis grains can have two major different orientation in the ab plane, 45° apart [15]. In the case of applications that require the current flow to be perpendicular to the substrate, a -axis growth has been implemented. Many multilayer Josephson devices have been tried in this way; a -axis growth is typically initiated with a lower substrate temperature, which in turn reduces the mobility of ions necessary for the c -axis growth. Because of the lower growth temperature, films are formed that are structurally less perfect. To overcome this problem, many workers have used a technique of starting growth at a lower temperature for a -axis nucleation, making a template, and then raising the temperature for the remainder of film deposition [16].

3.1. Substrates

The most frequently used substrate for fundamental research is SrTiO_3 because of its good thermal and lattice constant match with most HTS materials. However, high dielectric loss, small wafer size, and high cost of SrTiO_3 render it unfavorable for technological applications. LaAlO_3 has emerged as an alternative to SrTiO_3 as a low-loss perovskite substrate, although its critical dielectric properties are not under complete control. MgO substrates, on the other hand, have an even lower loss for microwave applications. However, the reproducibility of the MgO surface quality has been a problem in the earlier days, but more recently, the surface quality has improved. For applications where very low loss is required, MgO is the best HTS substrate at present. MgO and LaAlO_3 are commercially available in wafer sizes larger than 5 cm (2 in.). More conventional substrates such as Si and sapphire have been used and found to be incompatible with thick HTS thin films, mainly due to microcracking in the HTS films resulting from the thermal expansion mismatch between the substrates and the HTS materials. The maximum thickness of YBCO one can grow without significant microcracking is about 50 nm on Si and about 600 nm on sapphire. Table 2 lists the substrates most commonly used today for growth of HTS films. References 17 and 18 more extensively discuss HTS-compatible substrates and buffer layers.

In most cases, excellent epitaxial alignment can be achieved by depositing oxide buffer layers, such as CeO_2 ,

Table 2. Substrates and Buffer Layer for HTS Thin Films

Substrate	Orientation	Buffer Layer
SrTiO_3	(1 0 0)	None CeO_2
LaAlO_3	(1 0 0) Pseudocubic	CeO_2 None
MgO	(1 0 0)	None SrTiO_3
YSZ	(1 0 0)	CeO_2 Y_2O_3
Al_2O_3	(1 $\bar{1}$ 0 2)	CeO_2 MgO
Si	(1 0 0)	$\text{YSZ}/\text{Y}_2\text{O}_3$ YSZ/CeO_2

before HTS growth. The CeO_2 buffer layer has been found to suppress the unwanted a -axis nucleation for the c -axis growth on substrates such as SrTiO_3 and LaAlO_3 . On substrates such as YSZ and r -plane sapphire, the CeO_2 buffer layer promotes in-plane alignment of each c -axis grain, thereby eliminating potential high-angle grain boundaries. In fact, by using an appropriate buffer layer and a seed layer, one can create a process to produce 45° -angle grain boundaries in a controlled fashion. On Si substrates, the YSZ buffer layer was found to grow epitaxially and to be very effective in preventing chemical reaction between HTS materials and Si.

3.2. Ion-Beam-Assisted Deposition

More recently, a new technique, ion-beam-assisted deposition (IBAD), has been implemented to grow HTS layers on polycrystalline substrates. By bombarding the growing film surface with an ion beam incident at a specific angle to the substrate, one is able to achieve partial in-plane crystalline alignment of the deposited material where the substrate has none. Iijima et al. [19] first utilized this technique to grow in plane textured zirconia buffer layers on substrates made of polycrystalline Ni-based alloys. YBCO was then deposited by PLD. Due to the absence of high-angle grain boundaries in YBCO, the critical currents attained are much higher than without the IBAD process. Other groups, including the one at Los Alamos National Laboratory, has followed on this work and achieved critical currents over 10^6 A/cm^2 at 77 K [20]. More recently a group at Stanford University has demonstrated very good IBAD results with 10 nm thick MgO films [21]. While more development is needed to establish whether the IBAD process is a viable one for large-scale applications, it certainly opens up a whole new range of substrate materials for HTS film growth.

4. FILM GROWTH METHODS

Most of the methods currently employed for fabrication of HTS thin films involve formation of the cuprate crystal structure during film deposition. These are usually called "in situ processes," and they will represent most cases covered in this review. Chemical vapor deposition processes, which are also in situ growth, are covered in another

chapter of this volume. Historically, the processes that were developed first, required a postdeposition anneal, or simply postanneal, in order to crystallize the material. Such methods are now less frequently utilized, since they are not well suited for fabrication of multilayer structures and are thus technologically more limiting. However, they are still used for compounds such as TlBaCaCuO or HgBaCaCuO, where the in situ processes are often impractical because of the required high vapor pressures of Hg and Tl. Finally, there are other processes such as sol-gel, plasma spray deposition, and liquid-phase epitaxy that are generally used for fabrication of thick films (thicker than 1 μm); these also will not be covered in this brief review.

4.1. Postanneal Growth Methods

In the postanneal, or ex situ, growth process, the metallic elements are deposited on a substrate in the correct composition as an amorphous or multilayer film, usually in compound form with oxygen and possibly fluorine. Subsequent annealing in air or oxygen at a high temperature, typically $\geq 850^\circ\text{C}$ for YBCO, forms an epitaxial film of the desired HTS phase [9]. A very commonly used postanneal method for growth of YBCO films is achieved by using BaF_2 in the precursor film. Water is then required in the annealing step in order to eliminate the fluorine and start the HTS growth process. Since the critical growth step takes place separately from deposition, the actual technique used to deposit the layers is of secondary importance. Sputtering and evaporation are typically used.

Ex situ methods have initially focused on synthesis under atmospheric oxygen pressure and correspondingly high temperatures. This region of phase space is depicted in Fig. 1 with the rectangle in the upper left corner. Later work has shown that lower-temperature ex situ growth can also be achieved if the oxygen pressure is reduced at the same time (see also the lower rectangle in Fig. 1). Such films grown under lower oxygen pressures were observed to have properties closer to the in situ grown films [10,11].

4.2. In situ Growth Methods

Dominant methods in use today for physical vapor deposition of HTS are sputtering and laser ablation [also referred to as *pulsed-laser deposition* (PLD)]. Both of these methods are most commonly done from a single target and as such, became rather popular mostly because they are relatively simple to implement and fairly reproducible in the films they produce. In addition, targets for PLD are relatively inexpensive and easy to fabricate, and hence, the technique is well suited for investigation of many different materials. Less widespread today, but currently growing in popularity, are coevaporation and molecular beam epitaxy. After the initial slow start in contending with a sufficiently oxidizing environment in high vacuum, evaporation methods have now emerged as an established way to grow high-quality HTS films.

The following is a list of in situ physical vapor deposition techniques used for deposition of HTS compounds,

which will be covered in this review:

1. Sputtering
 - On-axis magnetron
 - Off-axis magnetron
 - Inverted cylindrical magnetron
 - Ion-beam sputtering
2. Laser ablation
 - On-axis
 - Off-axis
 - Laser-MBE
3. Evaporation
 - Flash evaporation
 - Reactive coevaporation
 - Reactive-MBE

For more discussion on various PVD techniques, we also refer the reader to Refs. 12–14.

5. SPUTTERING

Sputtering is a very commonly used technique for metal deposition in semiconductor and magnetic storage industries. As such, it was applied early on to HTS materials. The first event of significance was the use of a single composite target, which became commonplace for HTS materials because of the inherent difficulty of reproducing the metal atom stoichiometry. The major complication compared to more conventional sputtering of metals is the energetic negative-ion (oxygen) bombardment of the substrate, due to the ionic nature of the oxide target. This causes resputtering and degradation of the sample. This has been recognized even before the advent of HTS and has been fully investigated by Rossnagel and Cuomo [22]. Two types of solution emerged: (1) Using a higher gas pressure in order to thermalize the energetic species [23] and (2) off-axis sputtering, where one eliminates the high-energy particles coming directly from the target [24,25]. Figure 3 shows a schematic of the two processes. Other variations include on-axis unbalanced-magnetron sputtering [26] and inverted cylindrical magnetron (ICM) sputtering [27].

Figure 3. Schematic for the (a) on-axis and (b) off-axis sputter deposition processes.

The energies of ejected atoms from the sputtered targets are in the range of tens of electron volts, and they get scattered by the background Ar and O₂ gas. The angular distribution of each cation species is different, and the *sweet spot* for the proper cation composition is relatively small. In order to cover a 5-cm (2-in.) Wafer uniformly from a single 5-cm target in an off-axis geometry, one has to resort to some sort of scanning method, such as rotation of the wafer. The deposition rate is very low, not only because the deposition rate for oxides is much lower than for metals but also because of the off-axis geometry. It takes several hours to deposit a few hundred nanometers of film. Larger targets and a number of sputter guns depositing simultaneously have been used at several laboratories to increase the deposition rate. When all the deposition conditions are optimum, sputtering has demonstrated a capability to produce YBCO films of excellent crystallinity and surface condition. However, the deposition conditions have to be changed as the targets erode, because the changing target surface geometry results in a different plasma distribution. In addition, the substrate heating method for off-axis sputtering is not as simple as in the case of the off-axis laser ablation or evaporation, which will be described later.

6. LASER ABLATION

Laser ablation, or pulsed-laser deposition (PLD), is a relatively new technique that gained much popularity because it is ideally suited for deposition at a high oxygen pressure. The relative ease of this technique in depositing multicomponent oxides (and nitrides) has made it especially effective in exploring new materials for HTS electronics, such as epitaxial dielectrics or barrier layers. A short-wavelength (170–260-nm) excimer laser is focused onto a rotating target of the material to be deposited. Under the energy of the laser beam (0.1–2 J per pulse), the matter emitted from the target forms a plume that carries it to the substrate at supersonic velocities. In general, a higher gas pressure is required during laser ablation, due to the very high energy of the vaporized material from the surface of the target. The laser plume glows brightly from the target, and deposition is usually done near the end of the plume, about 5 cm away (see Fig. 4). Again, as in the case of sputtering, the various species scatter differently, and therefore the *sweet spot* of the deposition process is relatively small, usually one to two centimeters, depending on the geometry. The deposition rate per laser pulse ranges from a fraction of an angstrom to a few angstroms. The technique was found to be fairly reproducible from the early days and has been used extensively for research and development purposes since 1989. Even though other techniques are potentially more manufacture-friendly, laser ablation is still very actively used for prototyping devices made up of several complex materials, such as superconductors, ferroelectric oxides, and magnetic oxides.

A particular problem associated with PLD is the deposition of micrometer-sized droplets, so-called *boulders*, on the grown film. These particles originate at the target and

Figure 4. Schematic for the (a) on-axis and (b) off-axis laser ablation processes.

are emitted from the action of the laser pulse. A variety of procedures have been utilized to reduce this problem, so that the boulder density can be very low in the best films. Such procedures include target preparation (such as frequency polishing), defocusing the laser spot, mechanically chopping the plume, and spatially filtering the beam.

Although PLD can produce high deposition rates (up to tens of nanometers per second), the area on which one deposits is small. A straightforward way to increase the deposition area is to scan wafers over the plume either by moving the substrate vertically and horizontally or by rotating the substrate. This method has been tried in several laboratories and is still pursued. Another scheme utilizes a rotating cylindrical target with a linear laser profile to obtain larger deposition areas.

Another major difficulty of these techniques is uniform heating of large wafers. Most of the heating methods for small-area laser ablation have been to mount a substrate on a heated metal surface with silver paste, which is difficult to extend to larger sizes. In order to overcome this difficulty of heating a large wafer, an off-axis laser ablation technique has been developed (see Fig. 4b). A large wafer (5–8 cm) can be mounted parallel to the direction of the plume inside a relatively simple blackbodylike heater. The deposition takes place when the atoms collide with the background pressure and are scattered to the surface of the wafer. By rotating the wafer and selecting an appropriate pressure for the geometry, a fairly uniform deposition was achieved over 5-cm wafers. This technique allows for simultaneous deposition on both surfaces of the wafer, which is an important benefit for microwave applications requiring a ground plane. A drawback of this technique is its low deposition rate because of the off-axis geometry. Typical conditions for deposition of a 5-cm wafer resulted in a deposition rate about a factor of 10 lower than for the on-axis deposition.

By using laser fluence just enough to evaporate a few atomic layers of the target in a low-oxygen environment (less than 10^{-2} Pa $\approx 10^{-4}$ torr) and at the same time using a sequence of metal or metal oxide targets, one can obtain a process similar to molecular-beam epitaxy (MBE) by evaporation, here called “laser MBE.” Some in situ diagnostic tools can then be used to characterize the growth of

the materials. This technique has mainly been used to grow artificially layered superconducting materials, such as the infinite-layered superconductor [28,29].

7. EVAPORATION AND MOLECULAR-BEAM EPITAXY

Deposition of HTS thin films by evaporation follows a tradition of such deposition of metal films. The added complexity here is the required partial pressure of oxygen during growth. One can distinguish several variations in the evaporation approaches: flash evaporation, reactive coevaporation of metals, and sequential deposition by MBE. Except for the first process, these evaporation techniques utilize individual metallic sources. However, in attempting to control individual sources, two difficulties arise. One is the need for very fine control of individual sources, including development of species-specific sensors. The second is the need to work at a low enough pressure to minimize beam scattering and at the same time achieve the highly oxidizing thermodynamic conditions required for the growth of these compounds. For an in situ process, one is confined to work at a pressure of molecular oxygen above 100 mPa (1 mtorr) or to use a more reactive form of oxygen supply than molecular oxygen.

7.1. Flash Evaporation

The simplest approach to evaporation of HTS materials is to evaporate the compound in small batches, namely, in flashes of evaporant material. Since the material does not melt congruently, it is not possible to establish a continuously constant rate of metal fluxes, but for short enough intervals, one can average out the compositional variations. Usually, the evaporant material is a powder of YBCO located in a feed mechanism that drops small quantities onto an evaporation source [30]. In most cases, the films require a postannealing treatment to oxidize the film sufficiently, since the fast deposition does not allow for sufficient incorporation of oxygen. This method is at present less significant.

7.2. Reactive Coevaporation

Historically, the first attempts to make films by evaporation utilized a high molecular oxygen pressure. The problems associated with a high background oxygen pressure are rate control of the individuals species and the degradation of the sources. In order to circumvent this difficulty, several approaches were taken. One was to accommodate a high differential pressure between the sources and the sample by introduction of nozzles in close proximity to the sample. Another method is to utilize a more reactive species for oxygen incorporation, such as atomic oxygen or ozone.

The evaporation technique allows one to tune the composition of the film by adjusting the relative rates of the sources. Several groups have worked over the past years on developing process control for coevaporation and studying YBCO film properties as a function of metal atom composition. Figure 5 shows SEM micrographs of films with various metal compositions. The general finding is

Figure 5. Morphology of YBCO films as a function of their composition during reactive coevaporation.

that films that are grown slightly Y- and Cu-rich have better performance than films with exactly 1:2:3 stoichiometry. This is true for a majority of in situ techniques and not just evaporation. The reasons for this are still not completely clear—in particular, whether it is a materials issue or a process control issue. It is known that superconducting properties of films degrade significantly as one goes into the Ba-rich composition. It is possible that process fluctuations around the desired metal atom stoichiometry are responsible for degradation of films close to 1:2:3 composition.

Probably the most technologically significant advance in HTS thin-film evaporation has been the large-area heater developed for coevaporation by the group of H. Kinder at the Technical University of Munich (Germany) and depicted in Fig. 6. They used a blackbody-type rotating-disk heater, similar to the one used by others in PLD deposition, but they added an *oxidation pocket* [31]. This heater has a narrow slit that allows for a differential pressure between the oxidation pocket and the rest of the chamber of about 1000:1. The deposition and the oxidation processes are therefore separated, and a low pressure in the chamber improves the stability of thermal evaporation sources. Uniform YBCO films were grown on wafers up to

Figure 6. Schematic of the heater for large-area HTS deposition by evaporation.

20 cm in diameter using this technique. More importantly, this method is significantly more cost-effective and has higher throughput than any of the other PVD processes.

7.3. Molecular-Beam Epitaxy

In general, one can distinguish between reactive molecular-beam epitaxy (MBE) approaches to HTS film deposition and mere reactive evaporation by the lower background pressure of the former technique. Another difference is that MBE deposition is usually done sequentially rather than simultaneously. Typically, MBE systems have multiple sources with individual shutters, as well as some in situ monitoring tools (see Fig. 7). Reference 32 has a thorough discussion of relevant issues in reactive MBE of HTS films. The work by a number of groups in this field has focused on careful atomic layering to produce very smooth films, as well as customized growth of new materials and heterostructures containing these phases. The reactive MBE technique also lends itself to careful control of chemical doping of these materials, an issue that is very important for the superconducting properties of the cuprates.

7.4. In situ Monitoring Diagnostics

Evaporation and, especially, MBE, with their inherent low background pressure, lend themselves well to vacuum techniques for in situ deposition monitoring and film diagnostic tools such as reflection high-energy electron diffraction (RHEED). RHEED has been shown to be particularly helpful in controlling deposition of Bi-Sr-Ca-Cu-O films, where the growth occurs in blocks of sub-unit cells, but where many similar phases are possible. RHEED has been less helpful to date in the growth of YBCO, which occurs in blocks of unit cells and where intergrowths are more difficult to tailor, due to the higher stability of the primary phase. Terashima and coworkers [33] have shown that growth of YBCO can exhibit oscilla-

tions in the RHEED pattern commensurate with unit cell deposition, suggesting that growth proceeds in a unit-cell-by-unit-cell fashion, rather than in smaller building blocks. More recently, RHEED has also been extended to high-pressure processes such as PLD [34].

Another area of technological development has been in the use of optical absorption techniques for measurement and control of atomic fluxes. Both hollow-cathode lamp systems [35] and tunable diode lasers [36] have been used to monitor fluxes in situ in close proximity to the substrate. Such monitoring of individual fluxes is a prerequisite for careful control of HTS growth.

8. CONCLUDING REMARKS

In spite of a wealth of research, growth of cuprate films has remained a complicated matter. This is due to the materials' rather complex multicomponent crystal structures. They are prone to a variety of defects and growth morphologies. Much work still remains to be done until films are better understood and more reproducible.

As already described, HTS films are now routinely made with out-of-plane as well as in-plane alignment on single-crystalline substrates. Aligned films are still not routine on polycrystalline substrates, but there has been progress in this area as well. This has been manifested in high critical currents in films, particularly for YBCO. Typical critical currents in good quality YBCO films are over 2×10^6 A/cm² at 77 K and above 10^7 A/cm² at low temperatures. There has been much work in characterizing defect structures, but a good understanding of their influence on physical properties is still lacking. One growth structure that seems to be nearly ubiquitous in YBCO films is the spiral, which forms during growth and at the core of which is a screw dislocation [36]. Figure 8

Figure 7. Schematic for the reactive MBE process used in HTS film growth.

Figure 8. An STM image of a laser ablated YBCO film, showing spiral growth structures. (Image courtesy of Prof. Darrell Schlom.)

shows a scanning tunneling microscopy (STM) image of a surface of a YBCO film with a spiral. Steps in this image have a height of one unit cell of YBCO. Such spirals have been identified as contributing of pinning of vortices, important for high critical currents.

Maximally oxygen-doped YBCO bulk materials, made at higher temperatures than thin films, have a superconducting transition temperature of 92 K and a resistivity of $35 \mu\Omega \cdot \text{cm}$ at 100 K. Although having nominally the same crystal structure as the bulk material, YBCO films often have different electronic properties. For example, lower T_c (85–90 K) and expanded c -axis lattice constants (1.170–1.172 nm) are frequently found in thin films. Additionally, flux-pinning centers appear to be highly dispersed in in situ-grown films of YBCO, although the structural origin of these centers has not yet been identified. It is important to have a close feedback loop between film deposition and structural and electrical characterization in order to further improve HTS films.

Technology for deposition and monitoring of HTS thin films has developed significantly since the late 1980s. At the same time, the materials understanding of film nucleation, growth, and oxide interfaces has started to unfold. Together, these developments in the future will bring new capabilities for HTS film growth.

HYBRID CAD TECHNIQUES

F. ARNDT
University of Bremen
Bremen, Germany

1. INTRODUCTION

To meet the increasing demand for enhanced waveguide components and antennas in wireless terrestrial and satellite-based communications, and for radar applications, accurate *and* efficient CAD tools are required. Due to efforts during the 1990s—the decade of global 3D electromagnetic (EM) field solvers—the task of accurate analysis of components can be considered as being largely solved. Current challenges for CAD software relate to a new quality of efficiency and speed that allow direct, fast component optimizations in order to meet desired specifications within reasonable timeframes.

Many approaches to improve the efficiency of EM-based field solvers have been reported so far, such as reduced-order models (ROMs) applied for finite-element (FE) [1] or finite-difference (FD) [2] methods, fast multipole and adaptive integral methods (FMM, AIM) for method-of-moment (MoM) solutions of scattering and microstrip circuit problems [3–10], or combined subgrid conformal techniques for FD methods [11,12].

The issue discussed in this article is the utilization of advanced hybrid MM/FE/MoM/FD techniques, which typically can go beyond the efficiency possibilities of the involved single methods.

In computational electromagnetics, the idea of combining different variations to “hybrid techniques” or “hybrid methods” to expand their capabilities is not new.

Hybrid techniques have already been utilized long ago for handling electromagnetic scattering and radiating problems for large structures [7,13,14]. Examples are the combination of MoM with an “asymptotic” method [e.g., geometric theory of diffraction (GTD)], [7,13–16], or the combination of FE with the boundary integral equation method [7,17,18].

We apply in our article the “hybrid” notation for combining the fast mode-matching (MM) method with EM-based space or surface discretization methods, such

as the finite-element (FE) and finite-difference (FD) methods and the method-of-moments (MoM), to combine the efficiency of the MM with the flexibility of the FE, MoM, and FD techniques.

Due to its efficiency, the mode-matching (MM) method [19–45] has been widely employed for designing waveguide components, where modal expansions can be derived analytically. For structures that are not separable in Cartesian, cylindrical, or elliptical coordinate systems, FE, FD, or MoM techniques provide the desired flexibility. However, because of rather high requirements concerning central processing unit (CPU) time for the CAD of components using pure FE, MoM, or FD methods, for reasonably fast optimizations of typical industrial components, which often require a high number of iterations to meet given specifications, more efficient techniques are desirable. A very effective approach for solving this problem utilizes hybrid methods based on MM/FE/MoM/FD techniques, hence retaining the specific advantages of all proven EM methods while largely avoiding their disadvantages.

Hybrid mode-matching/method-of-moment (MM/MoM) techniques have been applied for horn antennas for a long time [46,47], where the inner horn structure is calculated by the MM method and the radiation problem is solved by MoM [46–50]. Hybrid MM/FE techniques have been introduced more recently for the analysis of dual-mode filters [51–53]. In these applications, the cross section eigenvalue problem of arbitrarily shaped homogeneous waveguide structures (e.g., cross-iris) is solved by a 2D FE method while the MM is applied for the calculation of the scattering parameters at the discontinuities with arbitrary contour. The full-wave combination of all discontinuities is achieved by the generalized scattering matrix (GSM). A more detailed overview on the MM/FE method is given in Ref. 54. More recent applications describe the MM/FE CAD of waffle-iron, evanescent-mode, and combine filters [55–57], of coaxial feeds [58,59], and the analysis of some discontinuities [60,61]. Modal expansion FDTD and transmission-line matrix (TLM) techniques have been proposed [62,63], and a hybrid MM/FD-FD method has been presented [64]. The extension of hybrid methods to MM/FE/MoM and MM/FE/FD has been presented [65,66], and hybrid techniques exploiting the full efficiency and flexibility spectrum of MM/FE/TransFE/MoM/FD methods have been introduced [67,68].

In this article, we describe the recent state of the art of hybrid MM/FE/MoM/FD techniques employed for the rigorous, efficient CAD and optimization of waveguide components, coupled horns, and waveguide slot array antennas, and discuss some typical applications and advanced aspects. Representative application examples will demonstrate the versatility and computational speed of these hybrid methods. Their accuracy is verified by available measurements or reference calculations.

2. THEORY

2.1. MM/FE Method

A very large class of waveguide components in microwave techniques is typically composed of stepwise homogeneous

Figure 1. Step discontinuity between two homogeneous waveguides.

waveguide sections (Fig. 1). Because of its high numerical efficiency, the mode-matching (MM) CAD technique has long been advantageously applied for the design of corresponding components such as for iris or metal-insert-coupled filters, junctions, couplers, diplexers, multiplexers, polarizers, transformers, and orthomode transducers [19–45]. An overview of many of the earlier research work in MM techniques is given in Ref. 36.

The basic principle of the MM technique can be elucidated at a step discontinuity (Fig. 1). Matching the tangential \mathbf{E} - and \mathbf{H} -field components along the transverse surface of the general step discontinuity, which is assumed to be located at $z = 0$, yields the relation between the incident and scattered modal wave amplitude coefficients \mathbf{a} and \mathbf{b}

$$\sqrt{Z_i^I}(a_i^I + b_i^I) = \sum_{j=1}^{\infty} C_{ij} \sqrt{Z_j^{II}}(a_j^{II} + b_j^{II}) \quad i = 1 \dots \infty \quad (1)$$

$$\sum_{i=1}^{\infty} C_{ij} \sqrt{Y_i^I}(a_i^I - b_i^I) = \sqrt{Y_j^{II}}(a_j^{II} - b_j^{II}) \quad j = 1 \dots \infty$$

where $Z = 1/Y$ are the modal wave impedances and C_{ij} are the elements of the frequency independent coupling matrix

$$C_{ij} = \int_{S_{II}} \int \mathbf{e}_i^{\text{Tr}} \mathbf{e}_j^{\text{II}} dS = \int_{S_{II}} \int \mathbf{h}_i^{\text{Tr}} \mathbf{h}_j^{\text{II}} dS, \quad (2)$$

\mathbf{e} and \mathbf{h} are the transversal eigenvectors

$$\mathbf{e} = \begin{cases} \mathbf{u}_z \cdot \nabla_t \Psi & \text{TE modes} \\ -\nabla_t \Psi & \text{TM and TEM modes} \end{cases} \quad (3)$$

$$\mathbf{h} = \mathbf{u}_z \times \mathbf{e}$$

with \mathbf{u}_z the unit vector in the z direction, and the potentials Ψ are solutions of the 2D Helmholtz equation

$$\nabla_t^2 \Psi + k_c^2 = 0 \quad (4)$$

in case of TE and/or TM modes, with the separation condition

$$k_c^2 + \beta^2 = k^2 \quad (5)$$

where $j\beta = \gamma$ is the propagation factor and k the free-space wavenumber; $\nabla_t^2 = \nabla^2 - (\partial^2/\partial z^2)$ denotes the transversal Laplace operator. For TEM modes, Ψ are solutions of the Laplacian equation

$$\nabla_t^2 \Psi = 0 \quad (6)$$

The potentials Ψ are suitably normalized

$$\iint_S \nabla_t^T \Psi_i \nabla_t \Psi_j dS = 1 \quad (7)$$

The Dirichlet and Neumann boundary conditions are

$$\begin{aligned} \Psi^{\text{TM}} &= 0 \quad \Gamma_E & \frac{\partial \Psi^{\text{TM}}}{\partial n} &= 0 \quad \Gamma_M \quad (\text{TM modes}) \\ \frac{\partial \Psi^{\text{TE}}}{\partial n} &= 0 \quad \Gamma_E & \Psi^{\text{TE}} &= 0 \quad \Gamma_M \quad (\text{TE modes}) \\ \Psi_i^{\text{TEM}} &= \begin{cases} \text{const} \neq 0 \quad \Gamma_{E,i} \\ 0 \quad \text{else} \quad \Gamma_E \end{cases} & \frac{\partial \Psi_i^{\text{TEM}}}{\partial n} &= 0 \quad \Gamma_M \quad (i\text{th TEM mode}) \end{aligned} \quad (8)$$

where Γ denotes an electric (E) or magnetic (M) wall. Equation (1) is represented in form of a matrix equation

$$\begin{aligned} \mathbf{a}^I + \mathbf{b}^I &= \mathbf{V}(\mathbf{a}^{II} + \mathbf{b}^{II}) \\ \mathbf{V}^T(\mathbf{a}^I - \mathbf{b}^I) &= \mathbf{a}^{II} - \mathbf{b}^{II} \\ \mathbf{V} &= [\sqrt{\mathbf{Y}^I}][\mathbf{C}][\sqrt{\mathbf{Z}^I}] \\ \sqrt{\mathbf{Y}^I} &= \text{diag}(\sqrt{Y^I}) \\ \sqrt{\mathbf{Z}^I} &= \text{diag}(\sqrt{Z^I}) \end{aligned} \quad (9)$$

which can be solved with regard to the amplitudes of \mathbf{b} in order to yield the generalized scattering matrix (GSM)

$$\mathbf{b} = \mathbf{S}\mathbf{a} \quad (10)$$

In case of rectangular, circular, circular coaxial, and elliptical waveguide discontinuities, the cross section eigenvectors required for the MM technique are given

analytically [19–45]. For more general cross sections, the corresponding eigenvalue problem has to be solved numerically, where formulations by a 2D FE method [52–57] are preferred, leading to a fast convergent direct solution without requiring search algorithms that are usually necessary for cross section field matching [69] or for boundary integral equation techniques [70].

2.1.1. 2D FE Scalar Approach (Nodal Elements) for Waveguides with Ideally Conducting Boundaries. Nodal function expansion of scalar potentials achieves—according to the author’s experience—the most efficient approach (and free of spurious modes) for metallic boundaries and homogeneous cross sections, such as for typical waveguide discontinuities shown in Fig. 1.

A standard generalized matrix eigenvalue problem for the considered waveguide cross sections of more general shape is obtained [51,52] as follows

$$[\mathbf{K} - k_c^2 \mathbf{M}] \vec{\Psi} = 0 \tag{11}$$

where

$$\mathbf{K}_{JK} = \int_{\Omega} \int \nabla_t N_J \nabla_t N_K d\Omega$$

$$\mathbf{M}_{JK} = \int_{\Omega} \int N_J N_K d\Omega, \quad \vec{\Psi} = (\Psi_1, \Psi_2, \dots, \Psi_N)^T$$

and the potentials $\vec{\Psi}$ are approximated by their nodal values Ψ_K and first-order Lagrangian interpolation polynomials $N_K(x, y)$ by

$$\Psi(x, y) \approx \sum_K \Psi_K N_K(x, y) \tag{12}$$

The generalized eigenvalue problem (11) is transformed into standard form by a Cholesky separation technique, and is solved iteratively by the Lanczos algorithm after suitable preconditioning, which includes the boundary problem for the TEM wave of coaxial sections as a special case.

Matching the transverse fields at the common interface of the general waveguide step discontinuity leads to the corresponding generalized scattering matrix (GSM) [52,54], which achieves the stable, reliable, and efficient full-wave combination of all involved parts.

2.1.2. Line Integral Formulation of Coupling Integrals. The frequency independent coupling integrals of the MM technique can be formulated in terms of line integrals by using the common definitions of the trans-

versal eigenvectors [54]

$$\begin{aligned} \frac{k_{cII}^2}{k_{cI}^2 - k_{cII}^2} \oint_{\Gamma_{II}} \Psi_{II} \frac{\partial \Psi^I}{\partial n} dc & \quad \text{TE - TE} \\ 0 & \quad \text{TE - TM, TE - TEM} \\ - \oint_{\Gamma_{II}} \Psi_{II} \frac{\partial \Psi^I}{\partial \tau} dc & \quad \text{TM - TE, TEM - TE} \\ \frac{k_{cI}^2}{k_{cI}^2 - k_{cII}^2} \oint_{\Gamma_{II}} \Psi^I \frac{\partial \Psi_{II}}{\partial n} dc & \quad \text{TM - TM} \\ \oint_{\Gamma_{II}} \Psi^I \frac{\partial \Psi_{II}}{\partial n} dc & \quad \text{TM - TEM, TEM - TEM} \\ 0 & \quad \text{TEM - TM} \end{aligned} \tag{13}$$

In case of degenerate modes ($k_{cI} = k_{cII}$), an adequate expression for the limiting case $k_{cI} \rightarrow k_{cII}$ is formulated.

Line integral formulations (13) of coupling integrals are applied for discontinuities, which consist—at least at one port side—of waveguides providing analytical expressions for the eigenvectors. The accuracy is nearly identical to the corresponding area integral formulations, and there is a slight reduction in calculation time concerning the individual coupling integrals.

However, for discontinuities of waveguides with arbitrary cross section on both sides, where the eigenvectors are numerical solutions of the corresponding 2D FE eigenvalue problem, the accuracy of line integral calculations can typically be one order of magnitude lower than for results using area integral formulations. This is due mainly to errors caused by finite discretization in the numerical approximations of the line integral contour. Moreover, the factor $(1 - k_{cI}^2/k_{cII}^2)$, which occurs in the line integral formulations (13), can increase the error still further, since the determination of eigenvalues k_c is also of only limited accuracy. Hence, in such cases, in contrast to the opinion presented in Ref. 61, area integral formulations [54] are preferable.

2.1.3. 2D FE Vector Approach (Edge Elements) for Inhomogeneous Cross Sections. For inhomogeneous cross sections, such as for waveguide structures containing dielectrics (Fig. 2), triangular edge elements for transversal field expansion are preferred because of their useful features such as eliminating spurious modes (which can occur at inhomogeneous cross sections containing dielectrics), closely approximating material boundaries, and reducing effects of singularities.

Following the approach in Refs. 71 and 72, we expand the vector field within a triangular edge element (Fig. 2) as

$$\mathbf{E}^e = \sum_{i=1}^3 \mathbf{N}_i^e E_i^e \tag{14}$$

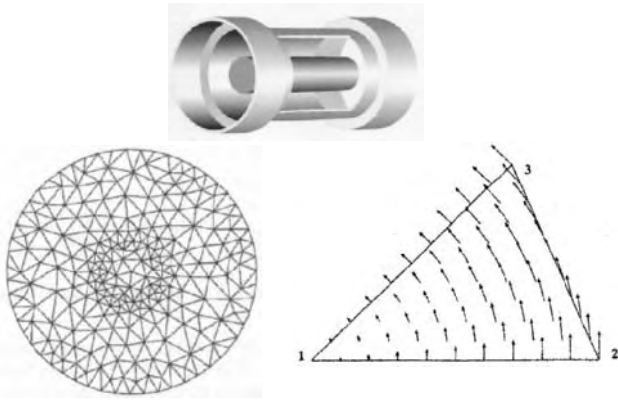

Figure 2. Step discontinuity to waveguide with inhomogeneous cross section (circular waveguide containing dielectric cylinder); mesh; vector basis function for a triangular element.

where E_i^e denotes the tangential field along the i th edge and \mathbf{N} the normalized vector function

$$\mathbf{N}_i^e = l_i^e (L_i^e \nabla L_j^e - L_j^e \nabla L_i^e) \quad (15)$$

where l_i is the length of i th edge and $L_j(x, y)$ the area coordinate of the j th node [71]. The Ritz procedure [71] is applied to formulate the generalized eigenvalue problem, which is reduced to tridiagonal form by the Lanczos procedure [72,73]. The system of equations arising in each Lanczos iteration step is solved by sparse matrix Cholesky decomposition using the minimum-degree algorithm [73].

It should be noted that in contrast to the opinion expressed in Ref. 60, for homogenous cross sections (containing only metallic boundaries), the scalar nodal element approach [52,54] achieves the most efficient formulation for this kind of problem.

2.2. MM/Transfinite FE Method for Planar Waveguides with Arbitrary Contour

Many waveguide components (such as a T-junction with septum, Fig. 3) are planar in the H or E plane with arbitrary contour. Instead of solving the complete structure by the transfinite element (TransFE) method [74], for

such components, a hybrid MM/TransfiniteFE method is applied [67], which combines again the efficiency and flexibility advantages of the involved methods. For the planar element under consideration, the 2D Helmholtz equation can be expressed by an adequate functional [74]. Its solution area is subdivided into an inner region to be discretized and the port region. The fields are approximated by a suitable set of basis functions, which are solutions of the Helmholtz equation in either the H or in the E plane. Assuming that the fields at the ports are expressed in terms of normalized forward- and backward-traveling modes, an expression containing the modal S parameters can be derived. The resulting equation system is solved by the iterative biconjugate gradient (BCG) procedure.

2.3. MM/MoM Method for Apertures and Arbitrarily Shaped 3D Waveguide Discontinuities

For horn antenna structures with arbitrarily shaped outer contour, and for arbitrary 3D metallic N -port waveguide structures (Fig. 4), a hybrid MM/MoM is advantageously applied [46–50,76]. Enforcing the continuity of the tangential magnetic field at the aperture(s) in the usual way [75–78] yields the following equation for the magnetic surface current density \mathbf{M}

$$\mathbf{H}_t^i = \mathbf{H}_t^I(\mathbf{M}) + \mathbf{H}_t^{II}(\mathbf{M}) \quad (16)$$

where \mathbf{H}_t^i denotes the tangential magnetic field incident from the waveguide side(s), and $\mathbf{H}_t^I, \mathbf{H}_t^{II}$ are the tangential fields in regions I and II, respectively (Fig. 4) caused by the magnetic surface current density.

For the solution of (16), the MoM is employed. The magnetic surface current density on the aperture surface is approximated by Q linear independent basis functions \mathbf{M}_q on S_a

$$\mathbf{M}(\mathbf{r}) = \eta_0 \sum_{q=1}^Q V_q \mathbf{M}_q(\mathbf{r}) \quad (17)$$

where V_q are the expansion coefficients and η_0 denotes the free-space impedance. Introducing a set of $P=Q$ linear

Figure 3. Planar waveguide structure with arbitrarily shaped contour solved by the MM/transfinite FE method. Example: T junction with septum.

Figure 4. Definitions of regions I and II for the investigated horn and arbitrarily shaped 3D waveguide structures.

independent test functions \mathbf{W}_p on S_a results in a system of linear equations, which leads to the elements of the modal admittance matrix for region I [46,50,76].

Calculation of the admittance matrix for region II is based on the Kirchhoff–Huygens principle. The electromagnetic field is calculated using the magnetic surface current densities on S_a and the electric surface current densities on S_a and S_b :

$$\mathbf{M}(\mathbf{r}) = \begin{cases} -\mathbf{n} \times \mathbf{E}(\mathbf{r}) & \mathbf{r} \text{ on } S_a \\ 0 & \mathbf{r} \text{ on } S_b \end{cases} \quad (18a)$$

$$\mathbf{J}(\mathbf{r}) = \mathbf{n} \times \mathbf{H}(\mathbf{r}) \quad \mathbf{r} \text{ on } S_a \text{ and } S_b \quad (18b)$$

For numerical calculations, the electric field integral equation (EFIE) is preferred:

$$\begin{aligned} \mathbf{E}(\mathbf{r}) = & -\text{rot} \int_S \mathbf{M}(\mathbf{r}') G_0(\mathbf{r}, \mathbf{r}') dS' \\ & + \frac{1}{j\omega\epsilon_0} \text{rot rot} \int_S \mathbf{J}(\mathbf{r}') G_0(\mathbf{r}, \mathbf{r}') dS' \end{aligned} \quad (19)$$

Advantages include the possibility of direct applicability of numerically available eigenvectors \mathbf{e}_i in region I as basis functions $-\mathbf{u}_z \times \mathbf{e}_i$ for the magnetic surface current density. In (19), G_0 is the free-space Green's function, and the electric surface current densities are expanded in

$$\mathbf{J}(\mathbf{r}) = \sum_{s=1}^S I_s \mathbf{J}_s(\mathbf{r}) \quad \mathbf{r} \text{ on } S_a \text{ and } S_b \quad (20)$$

For the electric surface current densities, the Rao–Wilton–Glisson (RWG) basis functions [79] for triangular patches are chosen, which yields the required high flexibility. The Galerkin method is applied for the numerical solution [46–50,76], which results in the modal admittance matrix of region II.

Using the orthonormality of the eigenvectors, the following expression for the scattering coefficients is derived [50,76]

$$s_{ij} = -\eta_0 \sum_{q=1}^Q A_{iq} V_{qj} - \delta_{ij} \quad (21)$$

where V_{qj} is the expansion coefficient for the basis function \mathbf{M}_q for excitation with mode j , δ_{ij} is the Kronecker delta, and

$$A_{iq} = \int_S \mathbf{M}_q \cdot (\hat{\mathbf{z}} \times \mathbf{e}_i) dS \quad (22)$$

2.4. MM/FD Method

For arbitrary 3D structures containing dielectric material, such as the example of Fig. 5, the MM/finite-difference (FD) method is applied. When calculating the structure as a whole, the FD time-domain (FDTD) method is used; when combining parts with the MM, the FD frequency domain (FDFD) method is preferred [109].

Microwave structures, such as filters and feeds, often include dielectric 3D objects of arbitrary shape, as well as areas of rather different field intensities. Hence, the numerical effort for the FD computation can be high for accurate results if no additional refinement approaches are utilized. Several subgrid techniques have been reported [11,12,80–84]. Whereas usual subgrids mostly typically require additional interpolations schemes at the grid interfaces that can reduce flexibility, the literature [11,12,64,80,81,108,109] presents an efficient direct subgrid method without interpolation.

For the corresponding CAD applications described in this article, the direct subgrid FD technique is generalized to include both arbitrarily curved metallic and dielectric surfaces by a formulation based on combining the subgrid with a locally conformal FD algorithm [85] and with a modified intersection approach [86] for arbitrary dielectric

Figure 5. Arbitrary 3D structures containing dielectric material. Example: Lateral coax feed with dielectric coating and compensation posts.

boundaries. The high flexibility of this mesh generator is characterized by the fact that all three techniques can be combined [12] arbitrarily, also at one cell if necessary. For the FDTD, S -parameters are extracted via the matrix pencil method [87,88,105] which reduces the number of involved timesteps as compared with more standard methods.

2.5. Multilevel Fast Multipole Algorithm (MLFMA) and Adaptive Integral Method (AIM)

Matrix equations for N unknowns resulting from MoM solutions [e.g., Eqs. (16)–(20)] require $O(N^2)$ operations when applying standard MoM solutions by using an iterative solver [6,7]. Hence, for a high number of unknowns arising in large-scale problems, such as slot arrays, it is imperative to apply fast integral equation solvers, such as the multilevel fast multipole algorithm (MLFMA) or the adaptive integral method (AIM). The MLFMA allows matrix vector products to be effected in $O(N \log N)$ operations [3–7,10,89]. Applications of MLFMA have been restricted mainly to scattering problems so far. MLFMA applications to apertures with an electric field integral equation (EFIE) approach have been introduced in Refs. 90 and 91; a combined field integral equation (CFIE) MLFMA solution for coupled apertures was presented more recently [92,93].

Fast integral solvers based on the adaptive integral method (AIM) have proved appropriate for large-scale problems [94–98]. The method retains the advantages of the conjugate-gradient fast Fourier transform (CGFFT) technique allowing matrix vector products to be effected in $O(N \log N)$ operations as well as flexible modeling techniques involving adequate basis functions [97]. Applications of AIM have been restricted mainly to scattering problems and microstrip antennas [94–97]. Initial investigations of the applicability of the AIM method to aperture radiating problems, such as slot arrays, have been presented more recently [98,113].

For application to, for example, the slot array problem (Fig. 6), the formulation is subdivided into three calculation steps. In the first step, the MoM is applied to calculate

the integral equation for the radiating aperture(s) within the corresponding external (horn or slot array) structure geometries. The eigenvectors of rectangular and circular apertures are analytically given or can be calculated for arbitrarily shaped apertures by the FE approach [51,54].

In the second step, the AIM is utilized for the efficient solution of the matrix–vector product. The third step comprises the calculation of the radiation field by taking into account the generalized scattering matrix composed of the complete radiating and feed parts. The computation scheme for the example of slot arrays is shown in Fig. 6.

The solution is based on the magnetic field integral equation (MFIE) setup in the aperture areas of the slot array [113]:

$$\hat{z} \times \mathbf{H}^{\text{inc}} + \hat{z} \times \mathbf{H}_1\{-\mathbf{M}_z\} = \hat{z} \times \mathbf{H}_2\{\mathbf{M}_z\} \quad (23)$$

For the solution of (23), the magnetic surface current density is discretized using the aperture eigenvectors \mathbf{e}_j as basis functions

$$\mathbf{M}_z = -\hat{z} \times \sum_j M_j \mathbf{e}_j \quad (24)$$

Scalar multiplication by weighting function and integration over the apertures yields the matrix equation in the usual form [99]

$$\underline{\mathbf{Z}} \cdot \underline{\mathbf{M}} = \underline{\mathbf{I}} \quad (25)$$

with

$$\begin{aligned} (\underline{\mathbf{Z}})_{ij} &= \iint w_i \cdot \mathbf{H}_2\{\mathbf{M}_z\} dA - \iint w_i \cdot \mathbf{H}_1\{-\mathbf{M}_z\} dA, \\ (\underline{\mathbf{I}})_i &= \iint w_i \cdot \mathbf{H}^{\text{inc}} dA, \\ (\underline{\mathbf{M}})_j &= M_j \end{aligned} \quad (26)$$

and the excitation vector

$$(\underline{\mathbf{I}})_i = -2 \iint \hat{z} \cdot (\mathbf{e}_i \times \mathbf{h}^{\text{inc}}) dA. \quad (27)$$

The matrix elements can be formulated in their mixed-potential form, which alleviates the problem with singularities [100]:

$$\begin{aligned} (\underline{\mathbf{Z}})_{ij} &= - \iint \hat{z} \cdot (\mathbf{e}_i \times \mathbf{h}_j) dA - \frac{2jk}{4\pi Z_F} \iint \mathbf{e}_i \cdot \iint \frac{e^{-jkR}}{R} \mathbf{e}_j' dA' dA \\ &\quad - \frac{2}{jk4\pi Z_F} \iint (\hat{z} \cdot \text{rot}_i \mathbf{e}_i) \\ &\quad \iint \frac{e^{-jkR}}{R} (\hat{z} \cdot \text{rot}_i' \mathbf{e}_j') dA' dA. \end{aligned} \quad (28)$$

The principle of the adaptive integral method [94–98] consists in the representation of distributed sources by an

Schmitt (now European Space Agency (ESA), Noordwijk, The Netherlands).]

Figure 10. Extending the MM/FE and MM/MoM methods to coaxial structures. Typical feed elements for combine filters: direct post, loop, disk, slope, sheetmetal coupling, transformer coupling.

equidistant mesh of point sources. The electric field strength of the j th wave mode is, for instance, given by

$$\begin{aligned} \mathbf{e}_{xj} &= \sum_n \Lambda_{jn}^x \delta(\vec{r} - \vec{r}_n), \\ \mathbf{e}_{yj} &= \sum_n \Lambda_{jn}^y \delta(\vec{r} - \vec{r}_n), \\ \hat{z} \cdot \text{rot}_t \mathbf{e}_j &= \sum_n \Lambda_{jn}^\phi \delta(\vec{r} - \vec{r}_n) \end{aligned} \tag{29}$$

The weights for mesh points are determined by the identity of the moments. For an aperture with a partial grid of $N_x N_y$ points, we obtain by the requirement

$$\begin{aligned} &\sum_{n_x=0}^{N_x-1} \sum_{n_y=0}^{N_y-1} \Lambda_{n_x n_y}^x (x_{n_x} - x_0)^{m_x} (y_{n_y} - y_0)^{m_y} \\ &= \iint_{A_{pj}} e_x (x - x_0)^{m_x} (y - y_0)^{m_y} dA \\ &\forall 0 \leq m_x < N_x \wedge 0 \leq m_y < N_y \end{aligned} \tag{30}$$

a linear equation system for the weights of the x components of the electric field strength in the equivalent source mesh. For \vec{r}_0 the centerpoint of the aperture leads to minimum numerical effort, although other choices are also possible. This equivalent representation is inserted in (28), and one obtains

$$\begin{aligned} (\underline{Z}^{\text{AIM}})_{ij} &= -\frac{2jk}{4\pi Z_F} \sum_n \sum_{n'} \Lambda_{in}^x g(\vec{r}_n - \vec{r}_{n'}) \Lambda_{jn'}^x \\ &\quad - \frac{2jk}{4\pi Z_F} \sum_n \sum_{n'} \Lambda_{in}^y g(\vec{r}_n - \vec{r}_{n'}) \Lambda_{jn'}^y \\ &\quad - \frac{2}{jk 4\pi Z_F} \sum_n \sum_{n'} \Lambda_{in}^\phi g(\vec{r}_n - \vec{r}_{n'}) \Lambda_{jn'}^\phi \end{aligned} \tag{31}$$

For this expression, application of the fast Fourier transformation (FFT) is possible. For the near couplings, the accuracy of the expression has to be improved by taking into account corrections due to the method of moments.

The matrix is not stored explicitly; hence, an iterative solver has to be applied, which is based on a fast matrix

 \end{aligned} \tag{32}$$

3. TYPICAL APPLICATION EXAMPLES

The extremely high CPU speed that can be achieved by applying hybrid methods is demonstrated by a simple example, a rectangular waveguide with a ridge discontinuity (Fig. 7), a structure originally reported in Ref. 101. The hybrid MM/FE method takes less than 2 s for

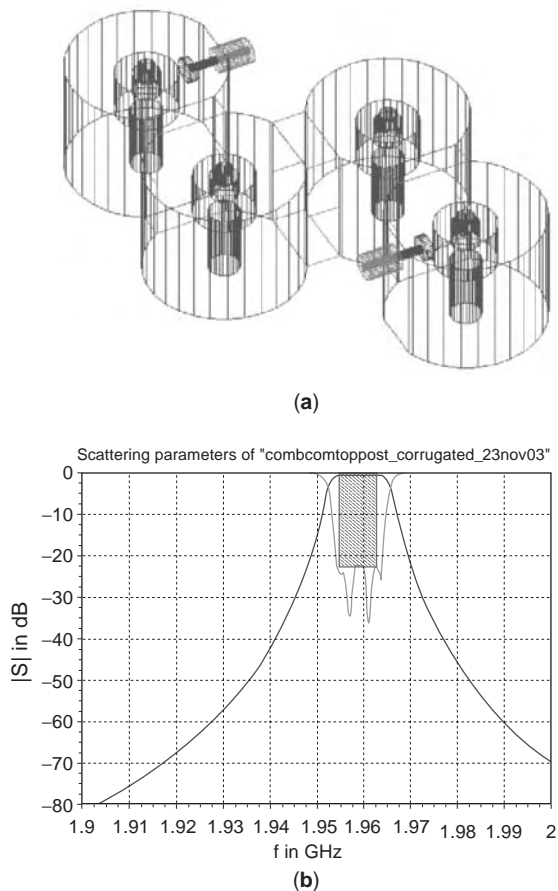

Figure 15. Advanced combline filter with rounded cavities and corrugated reentrant resonators directly optimized toward the goal of -23 dB return loss: (a) structure; (b) S -parameter results. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

500 frequency points (i.e., ~ 4 ms per frequency point, 41 modes, 2-GHz P4 PC), with the time required for the 2D FE eigenvalue solution included.

The excellent accuracy, high dynamic range, and high CPU speed achieved by the MM/FE method are demonstrated by an optimized and measured C-band waffle-iron filter (WR-229) Fig. 8 for space applications. The filter has been fabricated without any tuning screws. The advanced filter utilizing a large gap width for high-power applications has been optimized by applying the evolution strategy [30,54], and has been multipacting tested with >1.5 kW by the European Space Agency (ESA).

The next example, a septum polarizer (Fig. 9), relates to a typical MM/FE application, where the ridge sections (i.e., FE eigenvector sections) are directly connected to each other. Hence—as outlined in Section 2—for the corresponding coupling coefficients, calculations via area integrals are preferred to line integrals in this case. The dimensions are chosen according to Ref. 102, where cross section field-matching has been applied for solution of the eigenvalue problem [103], which is considerably more time-consuming than applying the MM/FE technique because of the search algorithm involved in the MM eigenvalue solution problem.

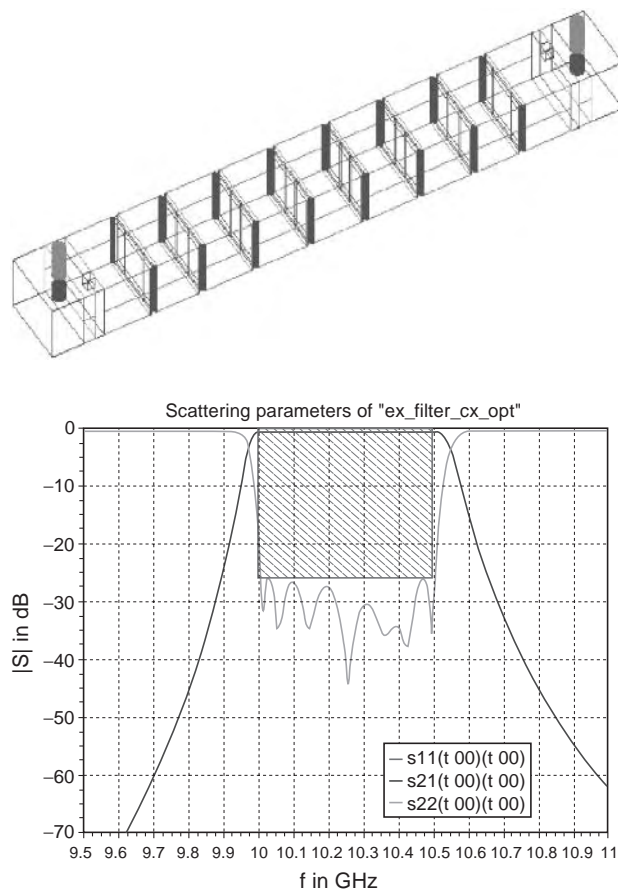

Figure 16. WR-90 H -plane iris seven-resonator filter with rounded corners, fed by topwall SMA connectors. Optimization of the whole filter including the effect of the coax feeds. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

The MM/FE and MM/MoM methods have been extended for inclusion of typical coaxial feed structures in Fig. 10, where TEM mode expressions (Sections 2.1,2,3) have to be taken into account. This achieves the possibility of fast CAD and optimization of combline and interdigital filters/diplexers with rectangular post elements. The rectangular post structure in combline/interdigital filters can be utilized for low-cost fabrication, such as by computer-controlled milling techniques [110,112] directly, or the rectangular structure can be converted into corresponding circular posts by applying well-known formulas, such as those in Ref. 111, of identical characteristic impedances (square/circular rod between two plates). This yields good starting points for further optimizations by applying, for example, the MM/FD or MM/MoM methods for circular posts.

For accuracy and computing speed verification, a simple direct post-fed four-resonator rectangular combline filter for 2.32 GHz midband frequency has been optimized and fabricated by a computer-controlled milling technique without any tuning screws (Fig. 11). Advanced CAD tools based on these hybrid techniques [68], allow the corresponding data file to be directly and conveniently loaded from the graphical output after optimization. Very good

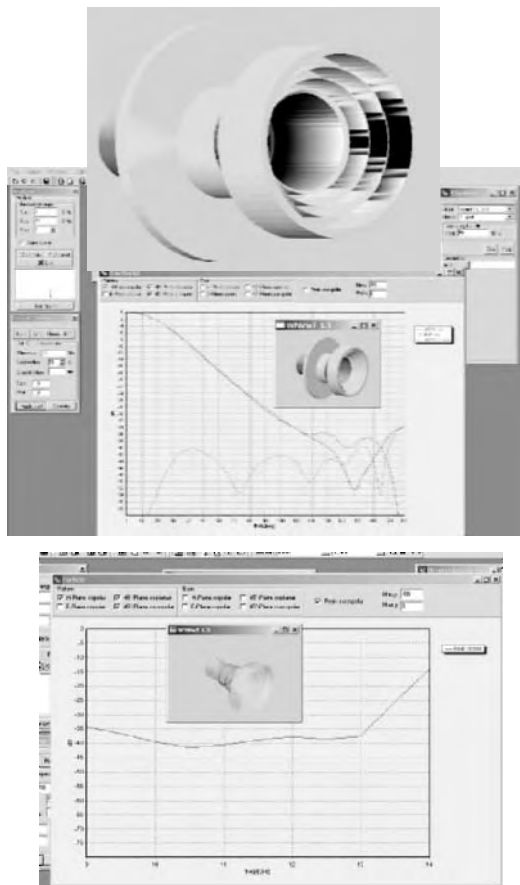

Figure 17. Axially corrugated (“choked”) horn optimized for broadband low cross-polarization. Lower plot shows the peak cross-polarization level as a function of frequency. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

agreement between theory and measurements can be achieved. For the MM/FE calculation, 125 modes have been taken into account; the CPU speed is 0.1s per frequency point on a 2-GHz P4 PC, which underlines, again, the efficiency of the hybrid MM/FE method also for this class of filters, making their optimization a straightforward task.

An application example for the MM/transfinite FE method for planar waveguides with arbitrary contour is the oversized cavity filter shown in Fig. 12. The TE₂₀ mode excited by offset irises can be controlled to achieve a dual-mode behavior with stopband poles [37].

The application of the MM/MoM method for 3D waveguide structures is demonstrated in Fig. 13 with the example of a magic T compensated by a post and an iris. The CPU speed is about 8 s per frequency point on a 2-GHz P4 PC. Good agreement with reference calculations using the FDTD method [59] and the MM/FE generalized scattering matrix separation (GSMS) technique [105] can be achieved. In this way, rather complicated 3D structures, such as waffle-iron filters with round teeth [76] can be modeled.

Figure 14 demonstrates the application of the MM/MoM technique for an advanced broadband taper/branching orthomode transducer (OMT) with a tapered branch-

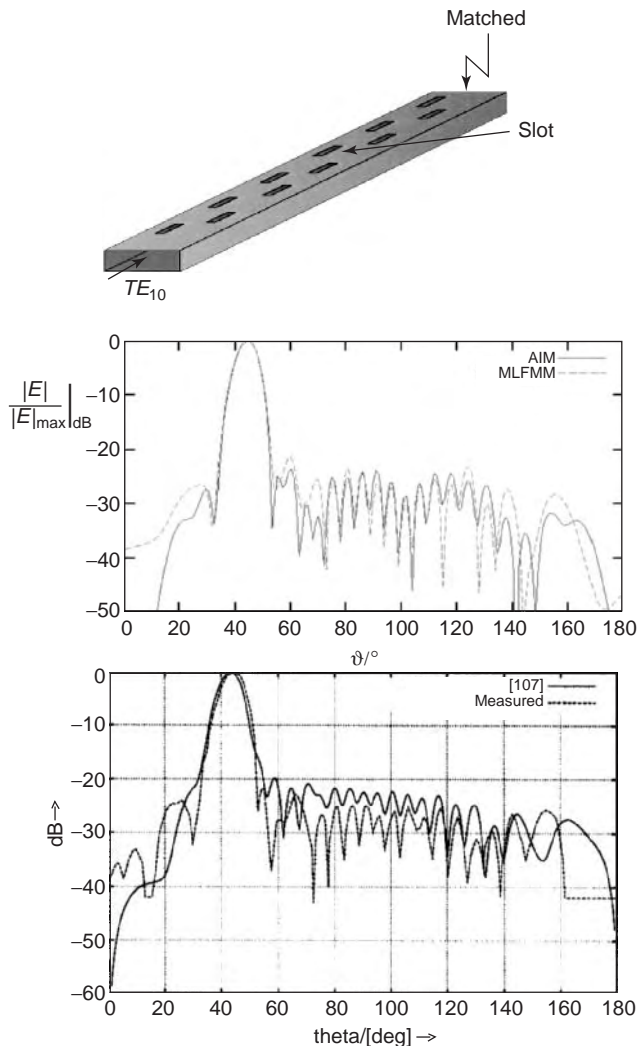

Figure 18. Traveling-wave slot array antenna with 21 slots according to Elliott [107]. Dimensions given in Ref. 102. The author’s own calculation with fast MoM techniques: adaptive integral method (AIM) and multilevel fast multipole method (MLFMM). Comparison with reference calculations [107] and measurements [106]. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

ing section. The ~20% bandwidth achieved compares well with the usual 10% of more standard designs [104].

The MM/MoM technique can also advantageously be applied for more complicated components such as a comb-line filter with rounded cavities and reentrant resonators for convenient tuning (Fig. 15).

An application example for the hybrid MM/transfinite FE/MoM technique with high practical importance is shown in Fig. 16: a WR-90 H-plane iris filter with rounded corners, fed by a coax standard 50 Ω subminiature version A (SMA) connector transition from the topwall. Because of the high CPU speed (1 s per frequency point, 2-GHz P4 PC, 102 modes), the filter can be directly optimized taking the effect of the coax feed rigorously into account.

An antenna application example of the MM/MoM technique is the design of an axially corrugated (“choked”)

horn (Fig. 17). Because of the consequent utilization of the hybrid technique, the CPU speed achieved (~ 5 s per frequency point, 3-GHz P4 PC) allows the convenient direct optimization toward desired broadband low cross-polarization levels.

Figure 18 shows a traveling-wave slot array antenna with 21 slots in the broad waveguide wall [106]. The utilization of the MM/MoM AIM and MLFMM techniques including the internal coupling provides results that agree well with measurements reported in Ref. 106 and with reference calculations using the more standard MoM spectral-domain technique [107].

4. CONCLUSION

Fast EM-based CAD tools yielding accurate, optimized designs within adequately short response times are indispensable for solving challenging optimization tasks of advanced modern microwave and millimeter-wave component applications. This goal is achieved by hybrid CAD techniques, which typically go beyond the possibilities of single methods, by expanding the capabilities and enhancing the efficiency. The hybrid CAD techniques described here combine advantageously the efficiency of the mode-matching (MM) method with the flexibility of finite-element (FE), finite-difference (FD), and method-of-moments (MoM) techniques. Typical application examples demonstrate their versatility and high calculation speed. The accuracy is verified by available measurements and reference calculations.

1. INTRODUCTION

Hybrids and couplers form an indispensable component group in modern MIC technology. With the inventions of planar transmission lines such as stripline, microstrip line, finline, dielectric image line, and their derivatives, hybrid and coupler technology has undergone a substantial change since the mid-1960s as a result of the rapidly growing applications of MICs in the electronic warfare, communications, and radar industries.

Despite the fact that the basic philosophy behind the operation of such couplers remains the same as in couplers designed using conventional transmission lines, their analyses and syntheses are quite involved. This is because most of these lines support hybrid modes due to inhomogeneity in configuration. However, the present-day analysis and synthesis techniques for such hybrids and couplers are believed to have gained maturity.

This article describes the design aspects of planar hybrids and couplers in as self-contained a presentation as possible within a limited space. In what follows in this section, we present the basics of hybrids and couplers and discuss different types of hybrids and couplers and their applications. The next section describes the design of matched hybrid “tees” (Ts), hybrid rings, and 90° hybrids. This is followed by a section on coupled-line couplers, both the TEM and the distributed types, as well as other miscellaneous types of couplers. The final section includes various aspects of coupler design, such as losses and improvement of directivity.

1.1. Basics of Hybrids and Couplers

A hybrid or a directional coupler can in principle be represented as a multiport network. In such a network, the

Figure 1. Four-port network.

port into which the electrical power is fed is called the *incident port*. The ports through which the desired amounts of coupled power are extracted are called *coupled ports*, while the rest of the ports are called *isolated ports*. Although hybrids and couplers having up to six ports find applications in many systems, we will restrict ourselves mostly to discussion of four-port networks without loss of generality.

Consider the four-port network shown in Fig. 1. If P_1 is the power fed into port 1 (which is matched to the generator impedance) and P_2 , P_3 , and P_4 are the powers available at the ports 2, 3, and 4, respectively (while each of the ports is terminated by its image impedance), the coupling coefficient is defined as

$$C = -10 \log \left| \frac{P_n}{P_1} \right| \quad n = 3, 4 \quad (1)$$

If port 3 happens to be the desired coupled port, the coupling coefficient is given by

$$C = -10 \log \left| \frac{P_3}{P_1} \right| \text{ dB} \quad (2)$$

If port 4 is the desired uncoupled port, the desired isolation is given by

$$I = -10 \log \left| \frac{P_4}{P_1} \right| \text{ dB} \quad (3)$$

The transmission to the primary port 2 is given by

$$T = 10 \log \left| \frac{P_2}{P_1} \right| \text{ dB} \quad (4)$$

The measure of directivity between the coupled and the uncoupled ports is given by

$$D = I - C \quad (5)$$

As a general practice, the performance of a hybrid or a directional coupler is specified in terms of its coupling, directivity, and the characteristic impedance at the center frequency of its band of operation. These data enable the circuit designer to calculate the structural parameters of the coupler.

1.2. Types of Hybrids and Couplers

Hybrids use directly connected circuit elements. Couplers can be parallel-coupled or aperture-coupled.

Figure 2a shows the simplest form of a hybrid. This is a branchline coupler, consisting of two mainlines coupled by two $\frac{1}{4}\lambda$ line sections spaced $\frac{1}{4}\lambda$ apart, where λ is the wavelength. Such a branchline hybrid can also be in circular form as shown in Fig. 2b. In either case, the total length of all the lines is one wavelength.

Figure 3 shows a parallel-coupled coupler. It consists of two coupled transmission lines. The lines can have any form depending on the application.

A parallel-coupled line coupler (Fig. 4) can be of two types: the TEM type or the distributed type. In the former, the coupled transmission lines support a pure TEM or a quasi-TEM mode. In the latter, the mode supported by the coupled lines are non-TEM in nature. While all of these types of couplers are realized using planar IC technology, there can be another type of coupler using aperture coupling, through some common ground plane (as used in conventional aperture-coupled waveguide couplers as shown in Fig. 5) with two similar or dissimilar types of planar transmission lines.

Figure 2. (a) Single-section branchline hybrid; (b) circular form of branchline hybrid.

Figure 3. Direct-coupled coupler.

To achieve tighter coupling over a wider bandwidth, multisections of the previously mentioned couplers can be cascaded in tandem (to be discussed in a later section).

1.3. Applications

Virtually all kinds of microwave circuits use hybrids or couplers in one form or another. In general, the areas of application can be divided into two parts:

1. *Passive*—tuners, delay lines, filters, and matching networks (sometimes an array of couplers may be needed for a desired performance of the network).
2. *Active circuits*—used mainly as directional couplers in balanced amplifiers, mixers, attenuators, modulators, discriminators, and phase shifters

Figure 4. Parallel-coupled line coupler.

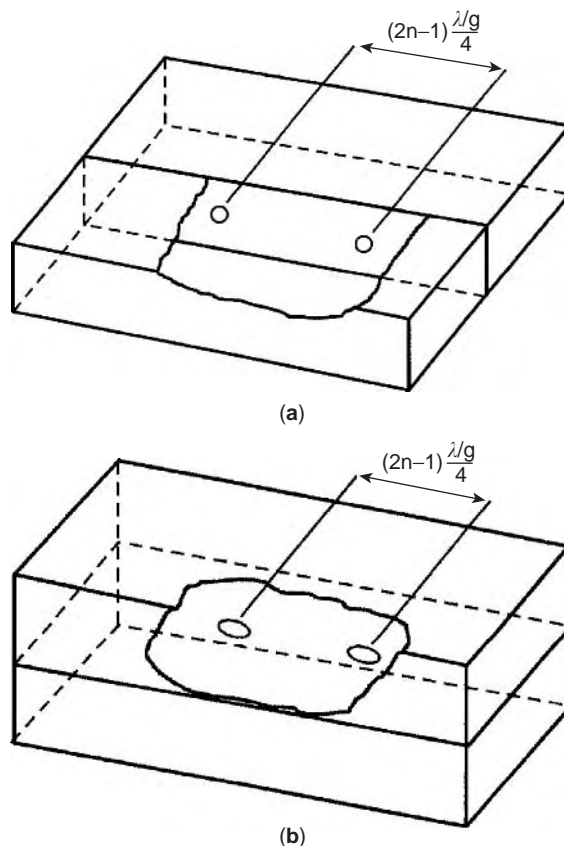

Figure 5. Aperture-coupled couplers: (a) narrow-wall coupling; (b) broad-wall coupling.

2. DESIGN OF HYBRIDS

2.1. 90° Hybrid

The simplest 90° hybrid is the branchline hybrid shown in Fig. 2a. For a certain input power at port 1, under match condition, there will be 90° phase difference between the waves appearing at ports 2 and 3, at the center frequency at which each arm is exactly a quarter-wavelength long. This 90° phase difference varies over ±5° for a 10% change in frequency around the center frequency. The coupling bandwidth is 20%, but its usable bandwidth is limited to 10%, due to an unacceptable change in the isolation over a bandwidth exceeding 10%. Ideally such couplers can be designed for 3–9 dB coupling.

There are three main arm losses in branchline hybrids: losses due to the portion of power coupled to the secondary arm (1) and the power dissipated as a result of dielectric (2) and conductor (3) losses.

Branchline hybrids can be realized using virtually all kinds of planar transmission lines, for example, stripline, microstrip line, slotline, finline, and image line. However, the basic design principle is extremely simple and the same in all cases.

The coupling factor is determined by the ratio of the impedance of the shunt and series arms and is optimized to meet the proper match over the required bandwidth.

For 90° hybrids, the following conditions hold good (see Fig. 2a):

$$\frac{P_2}{P_3} = \left(\frac{Z_0}{Z_p}\right)^2 \quad (6)$$

$$\left(\frac{Z_0}{Z_r}\right)^2 = \left(\frac{Z_0}{Z_p}\right)^2 + 1 \quad (7)$$

Although the two-branch hybrid is the most fundamental structure, it has a very narrow bandwidth. This disadvantage can be overcome by using multisection hybrids, but in most cases, planar transmission lines require too wide a range of impedances for this purpose. These may sometimes be difficult to realize physically. On the other hand, very wide linewidths may require unreasonable aspect ratios at higher frequencies due to shorter wavelengths. The physically unrealizable high-impedance line can be avoided by using a modified hybrid ring [1].

Complete analytical design techniques for such hybrids using Chebyshev and Zolotarev [2,3] functions are available. However, such techniques may sometimes be unsuitable for the design of planar circuits because of the wide impedance range problem, as previously mentioned. Muraguchi et al. [4] presented a computer-aided design technique that is most suitable for an optimum design.

2.2. Ring Form of Branchline Hybrid

This is a circular ring version of the square 90° hybrid described in the previous section. Therefore, the discussion of the previous section is equally valid for hybrid rings. The configuration is shown in Fig. 2b and is particularly advantageous in the realization of microstrip phase detectors and balanced mixers, with all ports matched.

2.3. Matched Hybrid T (Ratrace Hybrid)

A matched hybrid T is a special kind of ring form of the branch-line coupler in which the circumference is an odd multiple of $\frac{3}{2}\lambda$. As a result, the phase response is $0^\circ/180^\circ$. The simplest version of a matched hybrid T is shown in Fig. 6. Ports A–B, B–C, and C–D are separated by 90° , and

Figure 6. Hybrid ring.

ports A and D are three quarter-wavelengths away from each other.

Because of the impedance and the phase relationships shown in the structure, any power fed into port C splits equally into two parts that add up in phase at ports B and D and out of phase of port A. As a result port A is isolated from the input. Similarly, power fed at port A divides equally between ports B and D with 180° phase difference, and port C remains isolated.

The frequency response of a typical $\frac{3}{2}$ wavelength hybrid T is shown in Figs. 7a and 7b. It is observed that it offers around 20% bandwidth in terms of matching, split, and isolation. Moreover, the 180° phase relationship is much more frequency-sensitive than is the 0° phase relationship. Still, such a response is quite adequate for applications in mixers, SSB (single-side band) generators, and other components.

For high-frequency applications, a circumferential length of $\frac{3}{2}$ wavelengths may pose fabrication difficulties due to unrealizable aspect ratios of the transmission lines. This problem is overcome by having a ring of circumferential length of two wavelengths, where ports A and D are located $\frac{5}{4}\lambda$ away on the ring.

The design of a hybrid amounts to realizing the required transmission-line sections with proper phase velocities and characteristic impedances. Direct synthesis equations can be used in cases of stripline [5], microstrip [6], suspended microstrip, and inverted microstrip [7], which support pure TEM or quasi-TEM modes of propagation.

Realizations of the hybrids using non-TEM transmission lines such as slotline, finline, or image line use iterative techniques with the help of accurate analysis equations [7–9] depending on the mode of propagation. However, closed-form design equations are also available.

Microstrip and stripline hybrids have been realized and successfully used in commercially available microwave-balanced mixers and other circuit components. Development of finline and image-line hybrids are still at the experimental stage [10].

3. COUPLED-LINE DIRECTIONAL COUPLERS

The hybrids described in the previous sections are inherently of narrow bandwidth. Broadbanding of microwave couplers is achieved in a number of different ways, depending on the application.

Broadband couplers are either aperture-coupled or parallel-coupled. Aperture coupling is used very successfully in conventional waveguide techniques for realizing directional couplers with large bandwidths. Although aperture coupling is a convenient way of realizing directional couplers using two different planar transmission lines, directional couplers using the same kind of planar transmission lines are realized more efficiently using parallel coupling.

3.1. Directional Couplers Using Aperture-Coupled Lines

Figure 8 shows a simple two-hole directional coupler. Electromagnetic energy is coupled from the primary guide to

Figure 7. (a) Response curves for $\frac{3}{2}$ ratrace magic T (power split and isolation are expressed in decibels); (b) phase response curves for $\frac{3}{2}$ ratrace magic T.

the secondary guide due to the field radiated by the excited electric and magnetic dipoles generated at the holes by the propagating electromagnetic wave in the primary guide. The holes are spaced such that the round-trip phase shift of a wave through them should be 180° . Therefore the backward-traveling waves in the secondary guide will be completely out of phase to cancel each other at port 3. If the coupled lines have the same propagation constant, then the forward-traveling waves in the secondary guide will be of the same phase regardless of hole spacing and are added at port 4.

Figure 8. Schematic of a two-aperture directional coupler.

Such aperture-coupled directional couplers can be realized using various kinds of planar transmission-line combinations, for example (1) microstrip–microstrip, (2) microstrip–image line, (3) image line–image line, (4) image line–trough guide, or (5) trough guide–trough guide. Some possible combinations are shown in Fig. 9.

3.2. TEM Line Directional Couplers

When the center conductors of two coaxial lines supporting a pure TEM mode of propagation are brought into close proximity of each other, electromagnetic energy is coupled from one line to the other. This property has given rise to a class of broadband planar directional couplers. Most such couplers use striplines or microstrip lines that support pure TEM or quasi-TEM modes, respectively.

Planar TEM-line directional couplers can be either edge-coupled or broadside-coupled as shown in Figs. 10a and 10b.

In general, such coupled TEM lines support two modes that interact to give rise to the coupling. These are the even and odd modes. Properties of the coupled lines can be evaluated by suitable linear combinations of even and odd modes.

Figure 9. Possible combinations of various aperture-coupled lines: (a) microstrip-waveguide coupling; (b) microstrip-microstrip line; (c) microstrip-image line; (d) image line-image line; (e) trough line-trough line; (f) dielectric guide-dielectric guide.

TEM-line couplers can be reduced to a two-port network as shown in Fig. 11a. There is a plane of symmetry that becomes a perfect magnetic wall for the incident signals of equal amplitude and same phase at ports 1 and 4.

The plane of symmetry becomes a perfect electric wall for the incident signals of equal amplitude but of exactly opposite phases at the same ports. Therefore each mode corresponds to a two-port network as shown in Figs. 11b and 11c for even and odd modes, respectively. Analysis of the directional coupler is accomplished by analyzing these two networks and superimposing the responses as shown in Fig. 11d.

The S -matrix equation of a Four-port symmetric and reciprocal network can be written as

$$\begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} & S_{13} & S_{14} \\ S_{12} & S_{11} & S_{14} & S_{13} \\ S_{13} & S_{14} & S_{11} & S_{12} \\ S_{14} & S_{13} & S_{12} & S_{11} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ a_3 \\ a_4 \end{bmatrix} \quad (8)$$

where

$$S_{11} = \frac{1}{2}(\Gamma_e + \Gamma_o) \quad (9a)$$

$$S_{12} = \frac{1}{2}(T_e + T_o) \quad (9b)$$

Figure 10. (a) Edge-coupled microstrip lines; (b) broadside-coupled microstrip line.

$$S_{13} = \frac{1}{2}(T_e - T_o) \quad (9c)$$

$$S_{14} = \frac{1}{2}(\Gamma_e - \Gamma_o) \quad (9d)$$

Evaluation of the even- and odd-mode reflection and transmission coefficients is done from the corresponding effective dielectric constants and the characteristic impedances:

$$\Gamma_i = \frac{A_i + B_i/Z_0 - C_i Z_0 - D_i}{A_i + B_i/Z_0 + C_i Z_0 + D_i} \quad (10a)$$

$$T_i = \frac{2}{A_i + B_i/Z_0 - C_i Z_0 + D_i} \quad (10b)$$

where the transmission matrix

$$\begin{bmatrix} A_i & B_i \\ C_i & D_i \end{bmatrix} = \begin{bmatrix} \cos \theta_i & jZ_{0i} \sin \theta_i \\ \frac{j \sin \theta_i}{Z_{0i}} & \cos \theta_i \end{bmatrix} \quad i = e, o \quad (11)$$

Knowing $Z_{0,e}$, θ_e , $Z_{0,o}$, θ_o , and Z_0 and the system characteristic equation, we can calculate the performance of the directional coupler using (9) and (10).

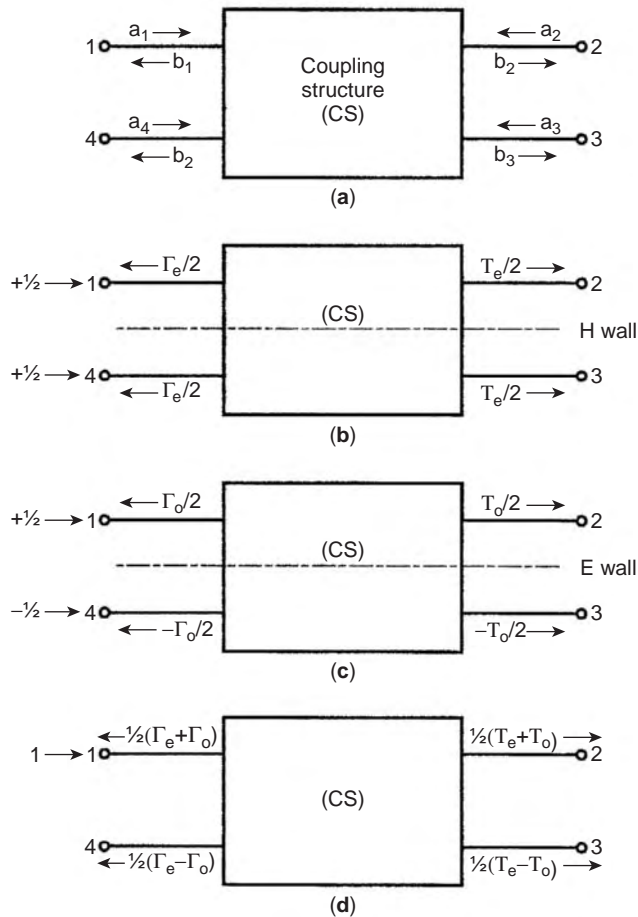

Figure 11. Schematic of directional coupler: (a) wave parameters; (b) even-mode excitation; (c) odd-mode excitation; (d) input excitation.

3.2.1. Coupled TEM Line. For coupling between the purely TEM lines shown in Fig. 12, we have the following special case

$$\theta_e = \theta_o = \theta \tag{12}$$

which means equal, even-, and odd-mode phase velocities, and

$$Z_0 = \sqrt{Z_{0,e}Z_{0,o}} \tag{13}$$

$$\Gamma_e = -\Gamma_o = \frac{j[(Z_{0,e}/Z_{0,o})^{1/2} - (Z_{0,o}/Z_{0,e})^{1/2}] \sin \theta}{\Sigma} \tag{14}$$

where

$$\Sigma = 2 \cos \theta + j \left[\left(\frac{Z_{0,e}}{Z_{0,o}} \right)^{1/2} + \left(\frac{Z_{0,o}}{Z_{0,e}} \right)^{1/2} \right] \sin \theta \tag{15}$$

Substitution of (14) and (15) into (9) gives

$$S_{11} = 0 \tag{16a}$$

$$S_{12} = T_e \tag{16b}$$

$$S_{13} = 0 \tag{16c}$$

$$S_{14} = \Gamma_e \tag{16d}$$

Such couplers, known as *backward-wave couplers*, are in general a quarter-wavelength long at the center frequency or $\theta = \frac{1}{2}\pi$.

From (13) and (14) the coupling coefficient is given by

$$C = -20 \log |S_{14}| = -20 \log \left| \frac{Z_{0,e} - Z_{0,o}}{Z_{0,e} + Z_{0,o}} \right| \text{ dB} \tag{17}$$

Moreover, for a system impedance Z_0 of 50 Ω , the matching condition (condition for a perfect input match) gives

$$Z_0^2 = Z_{0,e}Z_{0,o} \tag{18}$$

Therefore, for a specified coupling C the design equations become

$$Z_{0,e} = Z_0 \left[\frac{1 + 10^{-C/20}}{1 - 10^{-C/20}} \right]^{1/2} \tag{19a}$$

$$Z_{0,o} = Z_0 \left[\frac{1 - 10^{-C/20}}{1 + 10^{-C/20}} \right]^{1/2} \tag{19b}$$

Once $Z_{0,e}$ and $Z_{0,o}$ are known, the physical dimensions of the coupler can be obtained using the equations for coupled TEM transmission lines [6,20].

3.2.2. Coupled Quasi-TEM Line. In coupled quasi-TEM lines, for example, in microstrip, the odd-mode phase velocity is different from the even-mode phase velocity. Therefore, the condition given by (12) does not hold good. However, for weak couplings, (12) can be assumed to be approximately true. Hence the designer may go ahead and determine the initial design using (17)–(19). However, as the coupling gets tighter, the previous equations tend to be less valid. In such a case, the condition for

Figure 12. Coupling between two TEM lines.

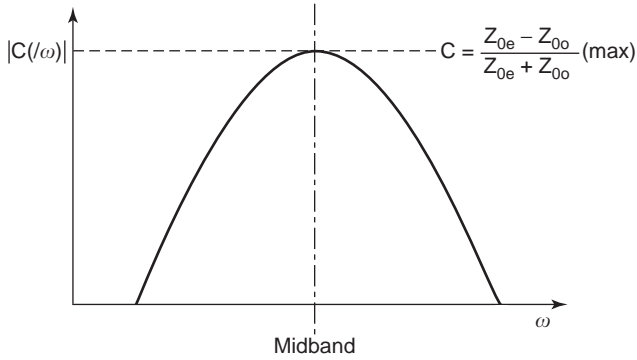

Figure 13. Approximate frequency response of a quasi-TEM line.

input matching becomes

$$Z_0 = \left(\frac{Z_{0,e} \sin \theta_e + Z_{0,o} \sin \theta_o}{Z_{0,e} \sin \theta_o + Z_{0,o} \sin \theta_e} \right)^{1/2} \sqrt{Z_{0,o} Z_{0,e}} \quad (20)$$

and the electrical length at the center frequency is

$$\theta = \frac{1}{2}(\theta_e + \theta_o) = \frac{2\pi}{\lambda_0} \frac{\sqrt{\epsilon_{ee}} + \sqrt{\epsilon_{eo}}}{2} l = 90^\circ \quad (21)$$

where l is the physical length of the coupler.

Single-section quarter-wave parallel-coupled line couplers are used extensively in many applications. They are usually of narrow bandwidth of approximately one octave. To obtain the desired coupling at the band edges, the coupler has to be designed for overcoupling at the center frequency.

3.2.3. Frequency Response of a Single-Section Coupler. Using the analysis equations (9)–(17), it can be shown that the frequency response of the coupling coefficient is given by

Figure 14. Multisection (a) symmetric and (b) asymmetric couplers.

cient is given by

$$C/(\theta) = \frac{jC \sin \theta}{\sqrt{1 - C^2} \cos \theta + j \sin \theta} \quad (22a)$$

where C is the midband coupling for a matched, loosely coupled coupler. The approximate frequency response of a quasi-TEM coupler is shown in Fig. 13. The response follows Eq. (22a) when the coupled lines support TEM mode.

The general expression for the directivity or the undesired coupling is given by [11]

$$D = \left[\frac{\pi \Delta (1 - |\xi|^2)}{4|\xi|} \right]^2 \quad (22b)$$

where

$$\Delta = \frac{\beta_e - \beta_o}{\beta_o}$$

$$\xi = \left(\frac{\rho_e}{1 + \rho_e^2} \right) - \left(\frac{\rho_o}{1 + \rho_o^2} \right)$$

$$\rho_e = \frac{Z_{0,e} - Z_0}{Z_{0,e} + Z_0} \quad \rho_o = \frac{Z_{0,o} - Z_0}{Z_{0,o} + Z_0}$$

and β_e and β_o are the even- and odd-mode propagation constants, respectively, $D = 0$ for $\beta_e = \beta_o$, that is, for a TEM coupler.

3.2.4. Multisection Couplers for Wider Bandwidth. For many applications, the single-section coupler proves to be of inadequate bandwidth. Therefore, the designer should have recourse to a multisection design. A multisection coupler is a cascaded combination of more than one single-section coupler, each a quarter-wavelength long at the center frequency of the band. The number of sections to be used depends on the tolerable insertion loss, bandwidth, and the available physical space.

Multisection couplers can be either symmetric or asymmetric around the center section, as shown in Fig. 14.

3.2.5. Symmetric Coupler. The symmetric coupler gives 90° phase difference between the direct and the coupled output ports under matched conditions. In what follows we present a direct synthesis technique.

Figure 14a shows a multisection symmetric coupler. The coupling factor for an n -section symmetric coupler with weak coupling can be written as [12]

$$C(\theta) = \left| \frac{V_2}{V_1} \right|$$

$$= C_1 \sin(n\theta) + (C_2 - C_1) \sin[(n-2)\theta] + \dots \quad (23)$$

$$+ (C_i - C_{i-1}) \sin[(n-2i+2)\theta]$$

$$+ (C_{[(n+1)/2]} - C_{[(n-1)/2]}) \sin \theta$$

If the desired coupling response is maximally flat, then C_i must satisfy a set of $\frac{1}{2}(n-1)$ linear equations

obtained from

$$\left[\frac{d^r C(\theta)}{d\theta^r} \right]_{\theta=\pi/2} = 0 \quad r=2, 4, 6, \dots, n-1 \quad (24)$$

Note that n is always an odd integer.

The design concept is based on the fact that the backward-coupled wave of a TEM coupler corresponds to the reflected wave of a quarter-wave filter. Therefore the designer of a TEM-wave coupler has to synthesize only a two port in place of a four port with the reflection coefficient response the same as the desired coupling coefficient response of the four-port directional coupler.

In terms of the midband VSWR R of the quarter-wave filter, the coupling coefficient is given by [12]

$$C_0 = \frac{R-1}{R+1} \quad (25)$$

3.3. Multiconductor Couplers

The interdigital coupler, or multiconductor coupler, invented by Lange [13], has always been a popular component in planar circuits. Figure 15 shows a four-element interdigital coupler, although in certain applications the number of elements may be greater than four. The coupler is usually designed for 3 dB coupling and the output phases are in quadrature. Obviously, the best realization is in the microstrip form.

Figure 15. Lange coupler.

An interdigital coupler has advantages because of its small size and relatively large line separation when compared with the two-coupled line device and has a much larger bandwidth when compared with branchline couplers.

Interdigital couplers are used for balanced MIC amplifiers, balanced mixers, and binary power divider trees.

3.3.1. Design of Interdigital Couplers. Kajfez et al. [14] have described a simplified design technique for the interdigital coupler. The proposed technique serves many practical purposes but seems to be inadequate for an accurate design. So far the method due to Presser [15] has been found to be the most accurate and simplest. Moreover, it has the provision for finite stripthickness correction.

Consider the layout shown in Fig. 15. The designer is supplied with the desired coupling coefficient C and the system characteristic impedance Z_0 . The length of the coupled region l has to be a quarter wavelength at the center of the band.

The main design equations for an N element (N even) coupler are written as

$$R = \frac{Z_{0,o}}{Z_{0,e}} \quad (26a)$$

$$C = \frac{(N-1)(1-R^2)}{(N-1)(1+R^2)+2R} \quad (26b)$$

$$Z = \frac{Z_{0,o}}{Z_0} \frac{\sqrt{R[(N-1)+R][(N-1)R+1]}}{1+R} \quad (26c)$$

3.4. Distributed-Type Couplers

Distributed-type coupling takes place between two adjacent transmission lines supporting purely non-TEM modes. For example, distributed-type couplers can be realized using two open dielectric waveguides (or image guides) or finlines.

In general, two distributed-type coupled lines can be represented as shown in Fig. 16. Under the assumption that all four ports are matched and the coupling structure has the length l , the ratio of the fields in the two lines can be shown to be [16]

$$\frac{E_b(l)}{E_a(l)} = \tan\left((\beta_e - \beta_o)\frac{l}{2}\right) \quad (27)$$

where β_e and β_o are the even- and the odd-mode phase constants, respectively.

Therefore for complete transfer of power from line a to line b requires

$$(\beta_e - \beta_o)\frac{L}{2} = \frac{\pi}{2} \quad (28)$$

or

$$L = \frac{\pi}{\beta_e - \beta_o} \quad (29)$$

Figure 16. (a) Schematic of distributed coupler; (b) coupled fin-lines and field distributions; (c) coupled image lines and field distributions.

The scattering coefficients of the structure can be written as a function of l normalized by L as

$$|S_{12}| = \left| \cos \left(\frac{\pi l}{2L} \right) \right| \quad (30a)$$

$$|S_{13}| = \left| \sin \left(\frac{\pi l}{2L} \right) \right| \quad (30b)$$

Equation (30b) shows that the required length for 3 dB coupling is one half of L .

The preceding equations are based on the assumptions that the bent portions of the guides have no effect on coupling. Branch junction effects near the bends are negligible, but the assumed uncoupled lines $z \leq 0$ and $z \geq z_0$ do get coupled. This extra coupling can be taken into consideration by

Figure 17. Single-section Wilkinson coupler.

defining the effective length of the coupler as

$$l_{\text{eff}} = l + \frac{2L}{\pi} \int_{z_0}^{z'} [\beta_e(z) - \beta_o(z)] dz \quad (31)$$

The integration limit z' is chosen to be the point at which the coupling is practically negligible.

From the preceding discussions it appears that the design of any distributed coupler requires a precise knowledge of the even- and the odd-mode phase constants of the coupled lines. Figures 16b and 16c show the cross sections of a coupled finlines and image lines, respectively, as examples of two commonly used distributed couplers.

3.5. Wilkinson Couplers, Power Dividers, and Combiners

A Wilkinson coupler [17,18] is a special case of couplers that do not have isolated ports and offer broad bandwidth and equal phase characteristics at each of its output ports. Figure 17 shows the schematic diagram of a Wilkinson coupler. The output port's isolation is obtained by series terminating the output ports. Each quarter-wave line has the characteristic impedance of $\sqrt{2}Z_0$ and the output is terminated by a resistor of $2Z_0 \Omega$, where Z_0 is the system impedance.

A Wilkinson power divider offers a bandwidth of about one octave. The typical frequency response is shown in Fig. 18. An adequately flat response is obtained over more than one octave band, but at the band edges the isolation is affected by the load impedance.

The performance of a Wilkinson coupler can be further improved, depending on the availability of space, by the addition of a $\frac{1}{4}\lambda$ transformer in front of the power division step. The output VSWR of the uncompensated coupler is better than the output VSWR of the compensated circuit.

3.5.1. Multisection Wilkinson Coupler. The octave bandwidth of a single-section coupler proves to be inadequate in many applications; therefore Cohn [18] proposed the use of multisections for bandwidth expansion. The use of multisections makes it possible to obtain a decade bandwidth.

Figure 18. Frequency response of Wilkinson coupler. (After Howe [5]. Reprinted with permission of Artech House.)

A multisection Wilkinson power divider coupler consists of a number of quarter-wave sections with resistive terminations at the end of every section, as shown schematically in Fig. 19. Larger bandwidth and greater isolation are obtained when a large number of sections are used.

The characteristic impedances of the sections are obtained from the normalized impedances for $\frac{1}{4}\lambda$ transformer sections for a 2–1 transformer. This can be done with the help of charts in Ref. 5, which presents design curves up to four sections. Similar figures are also available for higher numbers of sections. Having obtained the impedance of each section, we can obtain values of the terminating resistors for each section.

For a two-section divider the values of the terminating resistors are given by

$$R_2 = \frac{2Z_1Z_2}{[(Z_1 + Z_2)(Z_2 - Z_1 \cot^2 \phi)]^{1/2}} \quad (32a)$$

$$R_1 = \frac{2R_2(Z_1 + Z_2)}{R_2(Z_1 + Z_2) - 2Z_2} \quad (32b)$$

where

$$\phi = \frac{\pi}{2} \left[1 - 0.707 \left(\frac{f_2 - f_1}{f_2 + f_1} \right) \right] \quad (32c)$$

and f_1, f_2 are the upper and lower band edge frequencies of operation.

Figure 19. Multisection Wilkinson coupler.

3.6. Other Couplers

3.6.1. Tandem Coupler. The design of a multisection coupler with tight coupling over a broad bandwidth requires some of its sections to have tighter coupling than the overall coupling. This invariably leads to the physically unrealizable spacings between the two conductors or severely reduced directivity due to significant mechanical discontinuities in the sections. To solve this problem, in a restricted physical space, various combinations of symmetric and asymmetric couplers are tandemed [5,19]. Since in the majority of applications, the tightest coupling may be 3 dB, two couplers may be connected in tandem to achieve the goal. Figure 20a shows the symmetric tandem of two 8.34-dB couplers, while Fig. 20b shows the symmetric tandem of two asymmetric couplers. When tandemed, each 8.34-dB coupler gives an overall coupling of 3 dB. This configuration offers high power-handling capability and often represents a good choice, provided the particular application does not require maximum bandwidth with very low loss.

Figure 21 shows the configuration of an asymmetric tandem of symmetric couplers. As in the symmetric tandem of symmetric couplers, the quadrature phase shift is maintained between the outputs.

As is apparent from the interconnections, the 90° phase relationship is maintained in the symmetric case, but in the asymmetric case, the phase relation depends on the number of sections.

4. DESIGN CONSIDERATIONS

4.1. Losses in Hybrids

The total loss in hybrids can be estimated from the combined dielectric and conductor losses in the individual lines. These are obtained using closed-form equations for microstrip- and stripline-type transmissions lines [20].

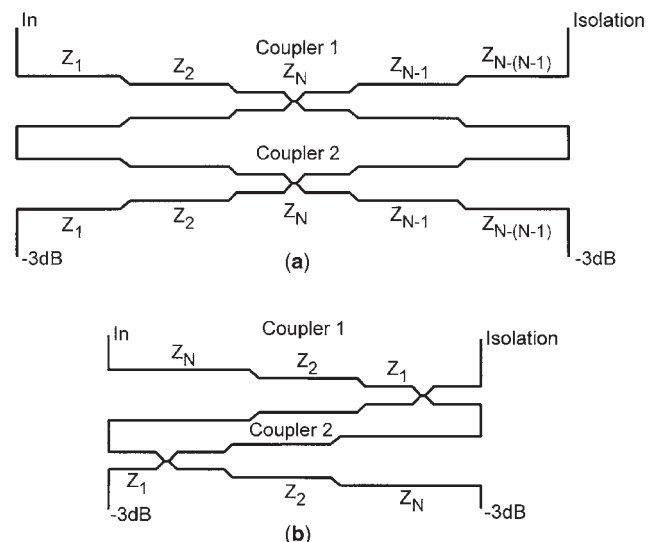

Figure 20. Tandem coupler: (a) Symmetric tandem of symmetric couplers; (b) symmetric tandem of asymmetric couplers.

Figure 21. Asymmetric tandem of symmetric coupler.

For other types of transmission lines, numerical techniques are used [21].

The attenuation due to the even mode α_c^e is always less than that due to the odd mode α_c^o . In coupled lines the loss is given by the average of the losses due to even and odd modes. In almost all planar coupled lines the conductor loss greatly exceeds the dielectric loss [20].

As in striplines and microstrip lines, the primary contributors to losses in dielectric-based planar waveguide couplers are the dielectric loss and the metallic loss. Such losses are always computed numerically from the associated field equations [22].

4.2. Directivity Improvement

Because of the inhomogeneity in dielectric structure, the directivity of microstrip couplers offers a poor bandwidth resulting from different odd- and even-mode phase velocities. There are several ways to equalize the phase velocities, which are described as follows.

4.2.1. Use of a Shield. These structures nearly equalize even- and odd-mode phase velocities. The cross section of the structure is shown in Fig. 22. This configuration essentially redistributes the field with a substantial amount of the field in the air-dielectric medium above the coupled strips. For $d = h$ the phase velocities are exactly equal, and each is equal to

$$v_e = v_o = \frac{c}{\sqrt{(\epsilon_r + 1)/2}} \tag{33}$$

Strictly speaking, improvement in directivity is obtained at the cost of manufacturing difficulties in this case.

4.2.2. Use of Lumped Capacitors. Using lumped capacitors at the ends of the coupled section is the simplest way of achieving equal phase velocities. The structure is shown

Figure 22. Parallel-coupled microstrip with grounded shield.

Figure 23. Lumped-capacitor compensation of microstrip coupler.

in Fig. 23. This effectively increases the odd-mode phase angle by [16]

$$\Delta\theta_o = 2\pi f_0(C_1 + C_2)Z_{0,o} \tag{34}$$

where f_0 is the center frequency of the coupled line.

4.2.3. Use of a Dielectric Overlay. The presence of another dielectric layer of the same permittivity as that of the substrate reduces the odd-mode phase velocity to a large extent without considerably affecting the even-mode phase velocity [23]. Thus, by controlling the thickness and width of the overlay, the even- and the odd-mode phase velocities can be equalized within 1% over quite a broad band. As shown in Fig. 24, the overlay covers the two strips where the main coupling takes place. The overlay is bonded with the help of some kind of epoxy. However, this method is practically cumbersome because of its poor repeatability. To overcome this problem a multilayer structure using different dielectric constants materials has been proposed [23].

Figure 24. Parallel-coupled microstrip with overlay compensation.

IMPATT DIODES AND CIRCUITS

JAMES W. McCLYMONDS
Raytheon Systems Company

IMPATT (impact avalanche transit time) diodes have the highest output power of any solid-state device at millimeter-wave frequencies. Significant advances have been made to power-combine these devices efficiently, and IMPATT diode transmitters can now rival the output power per unit volume of vacuum-tube transmitters. IMPATT transmitters have several advantages over tubes, particularly for missile radar applications, so very high-power transmitters are being developed for several military systems. IMPATT diodes are also suited for low-cost commercial applications that require the power of only a few devices.

This article will explain the basic principles for designing IMPATT diode circuits, beginning with the characteristics of the diodes. General circuit principles will be discussed, and calculations of amplifier circuit performance will be illustrated. The general principles then will be applied to several types of single-diode circuits. Last, an approach for building very high-power transmitters with hundreds of diodes will be shown.

Much of the material in this article is drawn from the author's personal experience in designing IMPATT transmitters at Raytheon Systems Company. Many of the diodes and circuits that will be used for illustrations have military applications, so exact performance levels and design details cannot be revealed. However, this article will provide all the fundamental concepts and guidelines to design IMPATT transmitters for many applications.

1. IMPATT DIODE OVERVIEW

As a two-terminal device, an IMPATT diode generates radiofrequency (RF) power by causing the RF current to be approximately 180° out of phase with the RF voltage [1]. This is accomplished by two current delaying mechanisms, avalanche multiplication and transit-time delay, which are the basis for the acronym IMPATT.

Figure 1 shows the doping profile $N(x)$ and electric field profile $E(x)$ of the most common type of IMPATT diode. The two curves are related by Poisson's equation in one dimension:

$$dE/dx = -qN(x)/\epsilon$$

The integral of the electric field over distance (i.e., the area under the curve) is equal to the applied voltage plus the built-in diode potential.

The thin region in the center of the device is called the "avalanche zone". The field is highest there, and avalanche multiplication occurs when a sufficient bias

Figure 1. Doping versus depth and electric field versus depth of a double-drift IMPATT diode.

voltage is applied. To the right of the avalanche zone is a thin spike of n-type doping, which causes a large drop in the electric field. On the left side of the avalanche zone is a p-type doping spike that causes a similar drop in the electric field. These doping spikes confine the avalanche process to the thin, high-field avalanche zone.

The IMPATT structure in Fig. 1 also has an n-type drift zone on the right side of the avalanche zone and a p-type drift zone to the left. The doping in these regions is chosen to cause the electric field to slope gradually away from the center of the device. The right side of the device is bounded by a heavily doped n-type contact layer, and the left side is bounded by a p-type contact.

Figure 2 explains how this structure accomplishes the necessary phase delay between the RF voltage and the RF current. The upper graph shows a sinusoidal RF voltage (35 GHz is used in this example) superimposed on a DC bias. The second graph shows the current that leaves the avalanche zone in response to the sinusoidal terminal voltage. Notice that the peak of the avalanche current is delayed by 90° from the peak of the terminal voltage. This phase shift occurs because the avalanching process needs many collisions, each with a very short delay, to generate a significant current. There are few electrons and holes at

Figure 2. Simplified theory of an IMPATT diode.

the beginning of the cycle, and most of the positive half of the RF cycle is needed for the current to grow exponentially to a significant level. In the second half of the cycle, the electric field is insufficient to sustain the avalanche, and the current quickly decays until the next cycle.

The pulses of electrons and holes that were generated in the avalanche zone during the positive half of the RF cycle flow with constant velocity through the drift zones during the negative half of the cycle. The motion of the large bunch of electrons toward the n contact on the right and the motion of the holes to the left induce the external current shown in the third graph of Fig. 2. Notice that the terminal current is flowing primarily during the negative half-cycle of the terminal voltage (i.e., the diode behaves as a negative resistance at its operating frequency). This causes the IMPATT diode to deliver energy to the external circuit at the frequency of the voltage excitation. The remainder of the bias power that is not converted to RF energy is dissipated in the diode as heat.

The concept of negative resistance is very useful to the circuit designer, who must tailor the impedance of the IMPATT circuit to the impedance of the IMPATT diode to achieve the desired oscillation or amplification. However, to those readers who are not accustomed to this concept, another way to understand the power generation of an IMPATT diode is to consider the power dissipation in the diode relative to the applied DC power. The DC input power is the average DC voltage multiplied by the average DC current, whereas the power dissipation is the time average of the product of the instantaneous voltage and

instantaneous current. These quantities are illustrated in the top and bottom graphs in Fig. 2. The dissipation is about 80% of the DC input power in this illustration, and the remaining 20% emerges from the device as RF power at the frequency of the RF voltage excitation.

Notice in Fig. 2 that the induced current waveform is not centered at 270° where the minimum RF voltage occurs. The length of the induced current pulse can be adjusted by changing the lengths of the drift zones, and the highest efficiency occurs when the induced current pulse is somewhat shorter than 180°.

It is important for a circuit designer to understand that the impedance of an IMPATT diode is a function of the RF voltage amplitude. Figure 3 illustrates the terminal voltage and induced terminal current at three different voltage amplitudes. The upper graph shows the small-signal waveform conditions where both the current and the voltage are sinusoidal. The amplitude of the RF current is proportional to the RF voltage, causing the device impedance (the ratio of the RF voltage to the RF current) to be insensitive to the voltage amplitude. With the medium voltage amplitude shown in the center graph, the current waveform has become distorted, and additional increases in RF voltage will not result in proportional increases in the RF current. Then, under the large-signal conditions shown in the lower graph, the current waveform is nearly a square wave. Additional increases in the RF voltage amplitude cannot cause additional increases in the amplitude of the induced

Figure 3. Induced current in an IMPATT diode for low-, medium-, and high-voltage amplitudes.

Figure 4. IMPATT diode conductance and susceptance versus RF voltage amplitude.

current because the time average of the current waveform must equal the fixed bias current.

The admittance of the diode at its terminals can be extracted from these waveforms by computing the amplitude of the first harmonic of the current waveform and its phase relative to the RF voltage. Figure 4 shows the conductance and susceptance at the terminals of a 35-GHz IMPATT diode over the range of RF voltages shown in Fig. 3. The susceptance includes the fixed-capacitive susceptance of the diode as well as the portion caused by the currents in Fig. 3.

Several observations about these curves are important to an RF circuit designer. Notice that negative conductance of the diode is considerably lower for high RF voltage amplitudes than for small signals. This will cause gain compression in IMPATT amplifiers. Notice also that the susceptance of the diode is a function of RF voltage amplitude. This will cause the center frequency of an IMPATT amplifier to decrease as the RF signal level increases. It also causes the gain–frequency characteristic of an IMPATT amplifier to drop more rapidly below the center frequency than on the high side of the center frequency. All these observations will be discussed later in this article.

The power P that is generated by an IMPATT diode can be calculated using

$$P = -\frac{1}{2}GV^2$$

where G is the chip conductance (a negative quantity) and V is the RF voltage amplitude.

Figure 4 has tickmarks along the conductance–RF voltage amplitude curve in intervals of 1 W. In this example, the maximum RF power is 12 W at an RF voltage of 16.5 V. At higher RF voltage amplitudes, other physical effects begin to affect the induced current waveform, and the output decreases.

A convenient way for the circuit designer to plot this information is to convert the chip conductance and susceptance data at each tickmark to chip impedance $-Z_C$ as illustrated in Fig. 5. Notice that the negative resistance of an IMPATT diode is relatively low, varying in this case from a small-signal value of -6.4Ω to a large-signal value of -0.8Ω . It is difficult to match low impedance levels like this over a broad frequency range, so IMPATT amplifiers are generally used for systems with fractional bandwidths of 5% or less. Most transmitters require less than 5% bandwidth, so this is not a significant restriction.

The electrical characteristics shown in Figs. 4 and 5 are approximations to the properties of a pulsed Ka-band IMPATT diode. Exact values have not been used because these devices are useful in military systems. The shapes of the curves are qualitatively correct, and they will be used in later sections to explain circuit design principles.

Figure 6 is a cross-sectional drawing of a typical millimeter-wave IMPATT diode package. The chip is thermal-compression-bonded to a diamond heatsink, which gives the best possible heatsinking. The diamond is imbedded in a copper puck to facilitate a good thermal contact to the bottom of the diode package. The chip is surrounded by a ceramic or quartz insulating ring, and beam leads or bonding straps connect the top of the chip to the top of the insulator. A cap is soldered over the top of the ring to provide mechanical protection and an hermetic enclosure.

Figure 7 is a photograph of a Raytheon device in which one-half of the ceramic ring is removed to reveal the internal construction. This type of package can be easily

Figure 5. IMPATT diode resistance and reactance as functions of RF power.

Figure 6. Cross section of an IMPATT diode package.

inserted or removed from an RF circuit, held in place with a copper screw for heat removal. The ring is as small as possible to minimize the electrical transformation through the parasitic inductances and capacitances of the package. Low-cost IMPATT diodes at lower microwave frequencies have a threaded stud in place of the diamond puck.

2. IMPEDANCE MATCHING OF A NEGATIVE-RESISTANCE DEVICE

An IMPATT diode can be used as a stable amplifier, an injection-locked oscillator, or a free-running oscillator. The mode of operation is determined by the load impedance that the RF circuit presents to the IMPATT chip. This section will explain the general principles of IMPATT diode impedance matching to lay a foundation for later discussions of specific circuits.

2.1. Free-Running Oscillator

Figure 8 contains the IMPATT chip impedance curve $-Z_C$ from Fig. 5 (the “device line”) plus a curve of load impe-

Figure 8. IMPATT device line and load line for an oscillator.

dance versus frequency Z_L (the “load line”). In Fig. 8, we will assume that the impedance of this 35-GHz diode does not change appreciably over a frequency range of 2 GHz (a 6% bandwidth). The load line of the circuit Z_L crosses the device line $-Z_C$ at 35 GHz near the highest power point on the device line. At the intersection, the condition for oscillation is met:

$$Z_C + Z_L = 0$$

If the load line is moved vertically, the frequency of intersection will shift, causing the diode to oscillate at a new frequency. If the load line is moved horizontally, the intersection will occur at a different RF output power level. Moving the load line horizontally also changes the frequency slightly as a result of the slope of the device line.

2.2. Injection-Locked Oscillator

Figure 9 is similar to Fig. 8, but the load line is shifted to the right. The point of intersection occurs at 35.25 GHz on the load line and at less than full power on the device line. In the absence of an RF input signal, the diode will oscillate in this circuit at 35.25 GHz with an output power of about 1 W.

If a 35.25 GHz RF input signal is applied, the power P_A that is added by the diode will combine with the RF input signal P_I to produce an RF output signal P_O that is larger than the input signal

$$P_O = P_I + P_A$$

The gain G of the circuit is the ratio of RF output to RF input

$$G = P_O/P_I$$

Figure 7. Photograph of an IMPATT diode package.

Figure 9. IMPATT device line and load line for an injection-locked oscillator.

These two equations can be combined to solve for both P_O or P_I in terms of P_A and G :

$$P_I = P_A / (G - 1) \quad (1)$$

$$P_O = G P_A / (G - 1) \quad (2)$$

Figure 10 illustrates a simple equivalent circuit for an IMPATT amplifier. A more accurate approach to circuit characterization will be discussed later, but the basic principles can be explained more clearly with this simple model. The model is an LC circuit in series with the IMPATT chip Z_C . The coupling between the resonant circuit and the external load Z_O is an ideal transformer with a turns ratio of n .

The input impedance Z at angular frequency ω of the diode and circuit shown in Fig. 10 is

$$Z = n^2 [Z_C + j\omega L + 1/(j\omega C)]$$

This equation can be further simplified by substituting $j\omega X_L = j\omega L + 1/(j\omega C)$, so that

$$Z = n^2 (Z_C + j\omega X_L) \quad (3)$$

The voltage reflection coefficient Γ from an impedance Z in a transmission line with characteristic impedance Z_0 is

$$\Gamma = (Z - Z_0) / (Z + Z_0) \quad (4)$$

Figure 10. Equivalent circuit for a one-diode IMPATT amplifier.

Substituting Eq. (3) into Eq. (4) and making a few algebraic steps, we obtain

$$\begin{aligned} \Gamma &= [n^2(Z_C + j\omega X_L) - Z_0] / [n^2(Z_C + j\omega X_L) + Z_0] \\ &= [(Z_C + j\omega X_L) - Z_0/n^2] / [(Z_C + j\omega X_L) + Z_0/n^2] \quad (5) \\ &= [Z_C - (Z_0/n^2 - j\omega X_L)] / [Z_C + (Z_0/n^2 + j\omega X_L)] \end{aligned}$$

The load impedance seen by the diode is $Z_L = (Z_0/n^2) + j\omega X_L$ and its complex conjugate is $Z_L^* = (Z_0/n^2) - j\omega X_L$. Substituting these quantities into Eq. (5), we have

$$\Gamma = (Z_C - Z_L^*) / (Z_C + Z_L) \quad (6)$$

The gain of the amplifier is the square of the magnitude of the reflection coefficient

$$G = |\Gamma|^2 = |(Z_C - Z_L^*) / (Z_C + Z_L)|^2 \quad (7)$$

Equations (1), (2), and (7) can be used to construct curves of P_O versus P_I from the data in Fig. 9 using the following procedure:

1. Choose a value of $-Z_C$ on the device line (start at the left end of the device line) and note the added power P_A .
2. Note the value of Z_L from the load line at the frequency of operation.
3. Calculate the gain G using Eq. (7).
4. Calculate the RF input power P_I and RF output power P_O using Eqs. (1) and (2).
5. Repeat this calculation for several other values of $-Z_C$ and draw a curve of P_O versus P_I .

As the choice for $-Z_C$ is moved to the right along the device line toward the intersection of the device line and the load line, the gain of the circuit increases, and the calculated input power decreases. When $-Z_C$ is chosen to be the intersection between the device line and the load line, the gain is infinite, and the RF input power is zero, which is the free-running oscillator condition. Values of $-Z_C$ that are to the right of the intersection point will not result in stable operation, and the injection-locked oscillator will “break lock” [2] from the RF input signal and generate a free-running signal.

Figure 11 shows curves of P_O versus P_I at five different frequencies. All the curves were calculated with the same procedure, but with different values of Z_L from the load line for each of the frequencies. Notice that the curves do not pass through the origin because of the free-running oscillation at 35.25 GHz. At frequencies near 35.25 GHz, P_O increases rapidly for small values of P_I because the gain is very high when $-Z_C$ is close to Z_L [see Eq. (7)]. For larger values of P_I , P_O continues to increase but at a slower rate because the gain is steadily decreasing. This effect is called *gain compression*.

The diagonal lines in Fig. 11 are contours of constant added power. At 35.0 GHz, the maximum added power is

Figure 11. RF output power versus RF input power of an injection-locked oscillator.

12 W, which occurs at an input power of 3 W. For maximum efficiency, the circuit should be designed to operate near this point. Notice, however, that the added power of the circuit is relatively constant over a modest range of input powers. This makes IMPATT circuits tolerant to being underdriven or overdriven.

The data in Fig. 11 show how an injection-locked IMPATT circuit behaves as a function of RF input power at several fixed frequencies, and these are called *drive curves*. Data points from this graph can be replotted such that the RF input power is held constant while the frequency is varied. This is illustrated in Fig. 12, and these are the frequency response curves of the IMPATT circuit. There are several interesting observations regarding these curves. First, the curves are not symmetric because the device line is tilted relative to the load line in Fig. 9. As the RF input drive is decreased, the circuit becomes unlocked at the lower edge of the operating frequency range before it becomes unlocked at the high end of the band.

Figure 12. RF output power versus frequency of an injection-locked oscillator.

Another important observation is that the bandwidth of the circuit is greater when the RF input power is higher. When the RF input power is 0.2 W, the gain is high at 35.0 GHz, but it decreases rapidly for other frequencies. When the RF input power is between 3 and 4 W at 35.0 GHz, the circuit adds about 12 W. At 5 W of RF input, the diode is overdriven and only 11 W are added. This saturation behavior causes the output power and gain to be relatively constant over the entire frequency range at the higher drive levels.

2.3. Stable Amplifier

The mode of operation in Figs. 9, 11, and 12 is called *injection-locked*, and the circuit is called an *injection-locked oscillator*. The gain of an injection-locked oscillator as illustrated in Figs. 11 and 12 will increase if the circuit designer moves the device line in Fig. 9 to the left toward the maximum added power point along the device line. This will be accompanied by a corresponding decrease in injection-locking bandwidth. Conversely, the gain will decrease and the bandwidth will increase, if the load line is moved to the right in Fig. 9. If the load line is moved far enough to the right, there is no intersection between the load line and the device line. In this case, the IMPATT circuit will not oscillate if the RF input signal is removed. This type of circuit is called a *stable amplifier*.

Figure 13 illustrates relationship between the device line and the load line for a stable amplifier. The same procedure that was used earlier to calculate the drive curves and frequency response curves can be applied to the stable amplifier case. Figures 14 and 15 illustrate the resulting graphs. Notice that all the curves in Fig. 14 begin at the origin because the output of a stable amplifier is always “locked” to the RF input signal. Both figures show that the gain of the circuit is lower, and Fig. 15 clearly demonstrates an accompanying increase in bandwidth.

The choice of operating mode—oscillator, injection-locked oscillator, or stable amplifier—depends on the

Figure 13. IMPATT device line and load line for a stable amplifier.

Figure 14. RF output power versus RF input power of a stable amplifier.

application. A free-running oscillator is useful for generating a high-power RF signal with a minimum of hardware. For example, a mechanically tuned oscillator is a good source of RF power for laboratory instrumentation.

An injection-locked oscillator is best for most transmitter applications. Gains of 3–10 dB are typical, and multiple stages can be cascaded for higher overall gain. If the bandwidth requirement is small, fewer stages with higher gain per stage can be used. The drive curve of an injection-locked oscillator is very nonlinear (see Fig. 11), and a multiple-stage transmitter will have many decibels of gain compression. Therefore, injection-locked oscillators are used only with frequency-modulated or phase-modulated signals.

An important application for injection-locked IMPATT amplifiers is pulsed radar systems. The bias current to the IMPATT diodes is turned on and off with the same

Figure 15. RF output power versus frequency of a stable amplifier.

waveform as the RF input signal. In this way, the IMPATT amplifier does not generate a free-running signal or noise while the radar receiver is detecting the reflected signal from the target. Pulsing the diode bias also reduces the prime power requirement by the duty cycle of the RF waveform.

Stable amplifiers are used when a free-running oscillation cannot be tolerated. A stable IMPATT amplifier might also be chosen for an amplitude-modulated signal if a modest amount of gain compression is acceptable. The use of constant voltage bias instead of constant current bias can be used to produce more linear drive curves [3], but constant voltage bias can also produce parametric instabilities, which will be discussed in a later section.

2.4. Effect of Load Mismatch

One final note of caution for the circuit designer is to provide a good external load for the IMPATT amplifier circuit. In the preceding examples, a perfect matched load Z_0 was assumed. A load impedance other than Z_0 will perturb the circuit impedance seen by the diode, changing the response of the amplifier. In practice, an amplifier circuit will be connected to a circulator to separate the output and input signals, and circulators have a return loss of about –25 dB over a 5% bandwidth.

A convenient way to estimate the effect of load mismatch is to estimate the amplitude of the wave that is reflected from the mismatch. This signal will combine with the intended RF input signal, resulting in a different amplitude. The maximum combined amplitude will occur when the voltage vectors for the two signals are in phase, and the minimum occurs when they are out of phase. The engineer should estimate the maximum and minimum voltage vectors and then calculate the maximum and minimum RF input power to the amplifier circuit.

For example, if an amplifier circuit has a gain of 5 dB and the load to which the circuit is connected has a return loss of 25 dB, the portion of the amplifier output signal that is reflected from the load will be 20 dB (a factor of 0.01) below the intended or nominal RF input signal. The voltage amplitude of a signal is proportional to the square root of its power, so the voltage amplitude of the signal that is reflected from the load will be approximately 0.10 relative to the voltage amplitude of the nominal RF input signal. The maximum RF input occurs when the nominal input signal and the signal that is reflected from the load are in phase:

$$\max P_I \approx (1 + 0.10)^2 \text{ nominal } P_I = 1.21 \text{ nominal } P_I$$

The minimum RF input occurs when the two signals are out of phase:

$$\min P_I \approx (1 - 0.10)^2 \text{ nominal } P_I = 0.81 \text{ nominal } P_I$$

It can be seen that even a good external load causes a modest uncertainty in the RF drive to an amplifier circuit. Fortunately, the gain compression that is evident in the drive curves in Figs. 11 and 14 causes the added power of a high-power IMPATT amplifier to be insensitive to an input

power range of this size. The early stages of a multiple-stage amplifier will be more sensitive to load mismatch, however, because the gains are usually higher, and there is less gain compression when the diodes are operated at lower power levels.

3. PARAMETRIC OSCILLATION

The preceding sections of this article have explained how an IMPATT diode generates negative resistance at the frequency of operation and how the impedance of the circuit must be tailored to the device impedance. An IMPATT diode is very nonlinear when the RF voltage is high, and parametric effects cause it to develop negative resistance over a wide frequency range. This section will explain the origin of the parametric negative resistance and how to design an IMPATT circuit to prevent unwanted oscillations.

3.1. Bias Circuit Oscillation

One source of instability in IMPATT diodes is caused by the decreased power dissipation that occurs when the RF voltage across the diode is increased and the device generates more RF power. The ionization rates in the avalanche zone are higher if the temperature is reduced, so the DC bias current will increase if the voltage is held constant. A runaway condition can occur in an IMPATT oscillator because an increase in the bias current will cause a further increase in the RF voltage amplitude. This type of instability can cause oscillation in the bias input to an IMPATT amplifier or oscillator at frequencies up to ~ 10 MHz. The effect diminishes at higher frequencies because the thermal time constant of the IMPATT chip and package are too long to allow the junction temperature to respond to the changes in dissipated power.

Preventing this form of bias oscillation requires a high-impedance bias current source. When the RF voltage increases incrementally and the dissipated power decreases, the bias voltage will drop incrementally if the current is held constant. The RF properties of the diode are relatively insensitive to small changes in the operating voltage, so there is not a positive-feedback effect as there is in the case of constant voltage bias. The drop in operating voltage that is caused by an increase in RF voltage amplitude is called the *rectification effect* or *backward-bias effect*.

The simplest way to create a high-impedance DC bias source in the laboratory is to insert a noninductive power resistor between the bias input of the IMPATT circuit and a DC power supply. The minimum value of resistance that is needed for stability will need to be determined experimentally, but $100\ \Omega$ is a good starting value. The resistor should consist of a network of lower power, noninductive resistors rather than a single, high-power, wirewound resistor. The "constant current" mode of a power supply should not be used because the response time of the feedback loop within the supply is much too long to protect the diode from a runaway condition.

The primary disadvantage to using a series resistor to make a high-impedance current source is the amount of

heat that is dissipated in the resistor. A better approach is to design a constant current electronic bias circuit with a low-voltage drop (typically 5 V). If a pnp transistor or a p-channel FET is used for the pass transistor in the bias circuit, the bias output will come from the collector or drain and have a relatively high impedance well beyond 10 MHz. If the IMPATT circuit is to be used in a pulsed radar transmitter, the electronic bias circuit must be designed for both high output impedance and fast switching speed.

Another effect occurs at high RF voltage amplitudes when the current leaving the avalanche zone becomes very low between cycles. In IMPATT diodes that are designed for microwave frequencies such as 10 GHz, the avalanche current waveform may reach the saturation current level. If the RF voltage amplitude is increased further, the avalanche current cannot drop below the saturation current level. During the positive half of the RF voltage cycle, the avalanche current builds up too quickly from this lower bound. This will result in a higher peak avalanche current and a higher DC current if the bias voltage is not reduced. This effect is quite strong in low-frequency devices, and it generates negative resistance to several gigahertz. However, this mechanism does not exist in millimeter-wave diodes because there is insufficient time between RF cycles for the avalanche current to drop to the ionization current level.

An IMPATT bias circuit must have a high impedance to several gigahertz to prevent the last type of parametric oscillation. It is particularly important to have low shunt capacitance in the bias circuit of the IMPATT circuit and in the bias supply. There are several comprehensive articles on this subject from the early years of IMPATT research [4,5]. The principles in these articles can be adapted to other types of IMPATT circuits.

3.2. Subharmonic Oscillation

Another type of parametric effect that is common in IMPATT circuits is subharmonic oscillation [6–9]. Simply stated, the IMPATT diode generates broadband negative resistance as a result of the nonlinear behavior of the avalanche process. One form of subharmonic oscillation is a signal at exactly one-half of the fundamental operating frequency. Subharmonic oscillation can also appear as a pair of signals whose frequencies add up to the fundamental frequency.

Subharmonic oscillation is very difficult to prevent because of the very broad frequency range where it can occur, so it is usually present in IMPATT amplifiers. A general approach to minimize the magnitude of subharmonic oscillation is to load the bias port of the IMPATT circuit with a microwave-absorbing material. This load will absorb some of the RF power at the fundamental, but the circuit designer can find creative ways to minimize the lost power.

If the circuit designer uses a high-impedance bias supply, minimizes the shunt capacitance in the bias circuit of the IMPATT circuit and in the bias supply, and also loads the bias port with a microwave absorber, the IMPATT circuit should behave well.

4. TYPES OF IMPATT CIRCUITS

All the general principles of IMPATT diode operation and the RF circuit requirements have been discussed in the previous section of this article. This section will briefly illustrate several types of IMPATT circuits that meet these general requirements.

An IMPATT circuit must present a load resistance of only a few ohms to an IMPATT chip, so a large transformation is required between the characteristic impedance of the RF port of the IMPATT circuit and the chip. In a coaxial transmission line medium, this can be accomplished with a coaxial matching transformer as illustrated in Fig. 16. The low-impedance transformer is created by reducing the diameter of the outer conductor rather than increasing the diameter of the inner conductor because this results in lower parasitic inductance in the mount. The “puck” style of IMPATT package that was illustrated in Figs. 6 and 7 can be easily installed and removed from this kind of diode mount.

The matching transformer (typically $\frac{1}{8}$ th wavelength long because of the parasitic reactance of the package and the mount) is designed to transform the characteristic impedance of the coaxial line (typically 50Ω) to the desired load impedance. Wider bandwidth can be achieved with a two-section transformer. Bias is applied to the center conductor through a bias tee (not shown), and the RF input and output signals are separated by a coaxial circulator (not shown). The circulator should have wide bandwidth to provide RF loading in the subharmonic frequency range.

The top-hat circuit [15], illustrated in Fig. 17, was used extensively in the early years for oscillator testing of IMPATT diodes. The diode is mounted in the floor of a waveguide cavity (a threaded diode package works well with this type of circuit), and a top hat resonator is placed on top of the diode. The region under the top hat is a radial transmission line that transforms the high impedance of the waveguide to the low impedance of the chip. The frequency of oscillation is set primarily by the diameter of the top hat, and the backshort (backward-traveling short circuit) is adjusted to set the cavity resonant frequency to be equal to the top-hat frequency. The load resistance that is seen by the IMPATT diode is set by the spacing between the top hat and the floor of the waveguide. At millimeter-wave frequencies, the diameter of the top hat might be as small as the diameter of the bias pin. An *E-H* tuner or slide-screw tuner can be connected to the waveguide output for fine-tuning. The bias pin contains an RF absorber for parametric stability.

Figure 16. Coaxial circuit.

Figure 17. Top-hat circuit.

A very common and useful type of IMPATT circuit is the rectangular Kurokawa circuit [10], which is illustrated in Fig. 18. A resonant cavity is formed in a rectangular waveguide between the movable short circuit at the right and

Figure 18. One-diode rectangular Kurokawa circuit.

an iris on the left. A coaxial transmission line passes through the broad walls of the waveguide cavity to which it is magnetically coupled. An IMPATT diode and a matching transformer are located at one end of the coaxial line, and an RF absorber is inserted into the other end. The coaxial transformer is the primary impedance-matching element, and the load resistance and reactance are controlled by the transformer impedance and length, respectively.

The cavity resonance in the rectangular Kurokawa circuit causes a significant perturbation in the diode load impedance near the operating frequency. The movable short circuit is adjusted to make the cavity resonant frequency correspond to the resonant frequency of the diode and matching transformer, and the hole diameter in the iris controls the coupling to the external load. Far from the operating frequency, the cavity has little effect, and the RF absorber helps prevent parametric oscillation.

The Kurokawa circuit is very useful for diode testing because a wide range of load impedances can be achieved with different matching transformers and irises. The RF load in the coaxial line absorbs about 25% of the generated power, but the circuit efficiency can be measured with an automatic network analyzer so that the RF power of the diode can be calculated.

The Kurokawa circuit can be modified to be a power combiner [11] by adding additional coaxial lines as shown in Fig. 19. The pairs of coaxial lines are separated by one-half of a wavelength so that the coupling from the waveguide cavity to each coaxial line is approximately the same.

A variation of this last circuit type is the cylindrical Kurokawa circuit illustrated in Fig. 20. The coaxial lines that contain the diodes are the same as the ones in the

Figure 19. Four-diode rectangular Kurokawa circuit.

Figure 20. Eight-diode cylindrical Kurokawa circuit.

rectangular Kurokawa, but the cavity is now cylindrical instead of rectangular. The RF output port is a coaxial line in the top of the cavity, and the coupling between the cavity and the external load is adjusted by changing the penetration of the electric field probe.

5. IMPATT CIRCUIT CHARACTERIZATION

The discussion of impedance matching a negative-resistance device used a lossless series resonant equivalent circuit. In practice, an IMPATT circuit is not lossless, nor does its impedance vary with frequency as in this simple model. However, this model is qualitatively correct and useful for the purposes of illustration.

It is not practical to measure directly the load impedance that is seen by an IMPATT diode because the load impedance is only a few ohms and the chip location is inaccessible to a network analyzer. However, those IMPATT circuits where the diode is mounted in a coaxial transmission line can be characterized indirectly with a network analyzer. If the diode and its matching transformer are removed, a network analyzer with a coaxial input can be connected to the circuit. After the two-port *S* parameters of the circuit are measured, an equivalent circuit for the matching transformer and the diode package parasitic reactance can be used to calculate the load impedance at the diode chip. Figure 21 illustrates how a network analyzer

Figure 21. Direct characterization of an IMPATT circuit with a coaxial adapter.

would be used to make this two-port measurement of a one-diode rectangular Kurokawa circuit.

There is another measurement technique that requires only one-port network analyzer measurements. Figure 22 shows a rectangular Kurokawa circuit with the diode and its coaxial transformer removed. These components are replaced by a coaxial short (circuit) and an outer conductor spacer to create an offset short. The reflection coefficient Γ_2 of a load that is attached to port 2 is transformed to Γ_1 at port 1 by the S parameters of the circuit according to the equation

$$\Gamma_1 = S_{11} + S_{21}S_{12}\Gamma_2 / (1 - S_{22}\Gamma_2)$$

Figure 22. Characterization of an IMPATT circuit by using offset short circuits.

This equation has three unknowns (S_{11} , S_{22} , and the product $S_{21}S_{12}$) that fully describe the circuit at a single frequency. Different values of Γ_2 are created by three offset shorts, and Γ_1 is measured for each one. This gives three simultaneous equations that can be solved for the three unknowns. More accurate results over a wider range of circuit impedance can be obtained by using more than three (typically five to seven) offset shorts and using numerical methods to find a least-squares best fit for the three unknowns. The procedure to calculate the circuit S parameters over a frequency range of interest is easily programmed into a computer that controls an automatic network analyzer.

Figure 23 illustrates the S_{22} of a one-diode rectangular Kurokawa oscillator circuit. The load impedance at the chip was calculated by referring the S_{22} data through an equivalent circuit for the matching transformer and package parasitic reactance. Notice that the load resistance at the chip is nearly constant and the reactance increases linearly with frequency. This impedance-versus-frequency behavior was the basis for choosing a series-resonant equivalent circuit in the earlier discussion on impedance matching. The oscillator circuit efficiency η is the ratio of the power that emerges from the oscillator divided by the power generated by the diode

$$\eta = |S_{21}S_{12}| / (1 - |S_{22}|^2)$$

This relationship is used during IMPATT diode oscillator testing to calculate the RF output power of the diode.

The offset short method for characterizing a circuit has several advantages and disadvantages compared to a direct two-port network analyzer measurement. The offset method can be used to characterize a multiple diode combiner circuit if all the coaxial ports are electrically identical. To do this, the coaxial lines are loaded with identical offset shorts. Network analyzer measurements are taken for three or more sets of these offset shorts, and the data

Figure 23. Smith chart impedance plot of the S_{22} and chip load impedance of an oscillator circuit.

are analyzed as if the combiner were a one-diode circuit. The offset short method is also preferable for circuits that operate at high millimeter-wave frequencies where coaxial network analyzer measurements are unfeasible or insufficiently accurate. The disadvantage of the offset method is that it works only when there is good coupling between the coaxial line and the RF output port. Therefore, this method cannot be used to characterize most circuits at frequencies where parametric oscillations occur.

6. TRANSMITTERS USING A COMBINER PLATE

This article has explained the basic principles of IMPATT circuit design. As a conclusion, a new power combining technique that uses the IMPATT circuits discussed earlier will be described.

Many millimeter-wave systems require high-power transmitters, especially missile radar seekers, so an efficient means for combining hundreds of IMPATT diodes is needed. In the 1970s and 1980s, cylindrical Kurokawa power combiners were developed with as many as 60 IMPATT diodes [12]. However, these circuits had limited bandwidth, and the failure of one diode would seriously detune the other devices, resulting in poor graceful degradation.

A new transmitter architecture was invented at Raytheon in the late 1980s that has been applied with great success to many frequency ranges and power levels [13–15]. The basic concept of a combiner plate (16) is illustrated in Fig. 24. The IMPATT diodes are mounted in rectangular Kurokawa “modules,” typically with four devices per module. Many of these modules are then power combined passively by the combiner plate.

The combiner plate consists of two plates with square grooves machined on the mating surfaces. The pattern of grooves is the same on both plates, so a network of rectangular waveguides is formed when the plates are mated. The joint is in the middle of the broad wall of the waveguides where no RF current will cross the joint. This results in very low attenuation within the combiner.

Figure 24. Concept drawing of an IMPATT transmitter using a combiner plate.

The transmitter is designed to use a binary number of IMPATT modules in every stage. Magic tee junctions are built into the waveguide network to split the RF input power to the modules in a stage and then recombine their outputs. Exceptionally good port matches (typically -30 dB return loss) can be achieved with magic tees, so the modules can be integrated with the combiner plate without retuning. This is important for achieving the manufacturing cost goals for these transmitters. The magic tees also permit high isolation (typically -30 dB) between module ports, so this architecture also has very good graceful degradation.

The combiner plate is used as the main mechanical structure of the IMPATT transmitter with most components attached to it. The combiner plate is also the thermal heat sink. Water-cooling passages can be machined into the plate or air-cooling fins attached to the bottom. In missile applications, the thermal mass of the transmitter is adequate to maintain a safe temperature for the few seconds of operation that are required.

The combiner plate architecture has been used to develop very powerful solid state transmitters for military applications. The performance characteristics cannot be reported here, but they generate more power in the same volume as a traveling-wave-tube amplifier. Moreover, solid-state transmitters have lower phase noise, better reliability as a result of graceful degradation, and they do not need high-voltage electronics.

7. CONCLUSIONS AND FUTURE DIRECTIONS

IMPATT transmitters are emerging as the best technology for high-power millimeter-wave applications, displacing even traveling-wave-tube amplifiers. This article has given an overview of the characteristics of IMPATT diodes, the operating principles of IMPATT circuits, descriptions of the most common types of circuits, and how they can be power-combined to make a high-power, multistage transmitter.

As this technology enters large-scale production, there will be pressure to reduce the cost to fabricate and assemble these transmitters. Innovations that might result are hybrid microstrip IMPATT circuits or fully integrated MMIC IMPATTs with their matching circuits. These new IMPATT circuits may appear to be radically different from today's technology, but they will use the same operating principles that were described in this article, only they will be applied to another transmission-line medium.

1. INTRODUCTION

Generally speaking, RF and microwave circuits and systems consist of multiple planar and/or nonplanar

transmission-line sections (passive elements) and active devices (e.g., transistors, diodes) that are interconnected in an appropriate manner in order to achieve specific high-frequency signal processing. In some cases, it is also possible to design a complete microwave system with only passive components. At lower frequencies (e.g., 300 MHz–10 GHz), the circuits usually involve lumped elements such as resistor, inductor, and capacitor to keep circuit dimensions small. At higher frequencies, the quality of lumped elements deteriorates rapidly, and mostly distributed elements are used. In any case, the transmission-line technique is the foundation for designing such microwave elements. In a typical microwave circuit or system, the passive part easily makes up 75% or more of the circuit real estate area. Because of different electromagnetic signal processing techniques involved in each component and also specific requirements for component-to-component signal transfer or transmission, impedance transformers, and/or matching networks are always needed.

The purpose of an impedance transformer is to transform a given impedance to a specific value in view of microwave signal transmission. An impedance-matching network may consist of more than one impedance transformer. Its design goal is to match a given impedance to a prescribed value over a frequency range of interest to ensure maximum power transfer from one place to another (e.g., from a source to a load). Impedance transformers and matching networks are perhaps the most important and most widely used microwave circuit components, which are usually passive. There also exist in practice active and electronically tunable impedance transformers and matching networks for special applications such as broadband or multiband systems design. In this case, semiconductor-based monolithic microwave integrated circuits (MMICs) are a choice of preference. Electrical (active) and/or mechanical (passive) impedance tuners, for example, are widely used in RF and microwave measurement setups, such as load-pull nonlinear and noise characterization systems. Nevertheless, most practical matching networks are fixed (passive) with respect to the center frequency, bandwidth of application, and impedance transformation (impedance ratio). Typical applications include optimizing return loss between an antenna and a low-noise amplifier for receiver, realizing low-noise performances in active circuits, providing conjugate complex matching in amplifier design, and usually matching high-contrast impedance values between a laser diode and its microwave driving circuit for optoelectronic applications.

It is imperative to mention that the definition of impedance may vary from one transmission line to another, and it usually depends on the use or operation of guided-wave mode such as transverse electromagnetic (TEM), transverse electric (TE), or transverse magnetic (TM) mode. Unfortunately, the definition of voltage and current is rather ambiguous and mode-dependent at microwave frequencies. As far as single-mode structures are concerned, this problem may be solved easily with specific definition of impedance that should be consistent for the entire circuit design. This becomes a quite complex issue for multimode non-TEM-mode structures, which still poses a challenge even today in the design of impedance

Figure 1. Basic block diagram of a two-port impedance transformer or matching network.

transformer and matching network if the classical network synthesis is used with lumped-element network parameters. This generally requires a full-wave numerical analysis and optimization of the transformer structures. In a practical design, the characteristic impedance of the transformer and matching network depends on the type of transmission line that dictates its achievable impedance range. Further, the type of transmission line used gives preference to either shunt (common voltage) or series (common current) branch connection in the formulation of equivalent circuit or network synthesis. In a microstrip line (MLINE), for example, stubs are best used in shunt-parallel connections.

A basic block diagram of impedance transformers and matching networks is shown in Fig. 1. Various design techniques are available. Techniques based on the Smith chart are popular in connection with the lumped-element network approach. Matching networks may be built from lumped or distributed elements or a combination of both. In the following, we will begin with the description of an impedance-matching network with various techniques of impedance transformers. Practical examples are also shown to highlight application features of those techniques. A comprehensive comparison is made with respect to design parameters and practical specifications. Then, commonly used line-to-line transitions are presented as a special impedance transformer or transition transformer because the impedance matching between two different lines is generally involved in the design. Among such transitions, balun transformers present a special class of microwave passive components that converts the fundamental guided mode from balanced to unbalanced or vice

versa. This is why it is called *balun* (balance-to-unbalance). In this case, the impedance may also be transformed in this line-to-line modal conversion. Usually, a balun structure deals with two different types of transmission-line geometry that are used as input and output of the circuit. A class of balun structures will be described and discussed.

2. IMPEDANCE-MATCHING NETWORK

The purpose of an impedance transformer (commonly called an *impedance-matching network*) is to transform an arbitrary load or a specific value of impedance at one reference plane into a desired value at another reference plane. Usually in the very beginning, the impedance-matching network may be handled in the design as an insert part between two circuits or two components although it is in fact an integrated part of the final circuit. Since the impedance definition may be ambiguous at microwave frequencies for non-TEM-mode transmission lines or high-order modes, the following presentation will be limited to the well-defined impedance cases such as TEM-mode impedance-matching networks. The impedance-matching process allows a circuit of interest to meet a given requirement, such as to minimize the reflection coefficient, minimize the noise, or maximize the output power of an amplifier. The reflection coefficient from a load is given by

$$\Gamma = \frac{Z_L - Z_0}{Z_L + Z_0} \tag{1}$$

where Z_L is the load impedance and Z_0 is the source impedance of the circuit. The circuit is said to be matched when the reflection coefficient is equal to zero, $\Gamma = 0$. To do so, the source and load impedances must be equal, or $Z_L = Z_0$. This condition is the basis for all impedance-matching networks.

Table 1 shows different kinds of impedance-matching networks and their principal characteristics. The element type used, bandwidth, design flexibility, and network complexity are some of the principal aspects that must be considered in the choice of a network topology. Two

Table 1. Lossless Matching Networks and Their Properties

Matching Network	Element Type	Operating Bandwidth	Network Flexibility	Network Complexity	Load Impedance	Design Technique
L network	Lumped	Narrow	Low	Low	Complex	Smith chart or analytical equation
T and Π networks		Medium	Medium	Medium	Complex	Smith chart or analytical equation
Ladder network		Large	High	High	Complex	Synthesis method
Single stub	Distributed	Narrow	Low	Low	Complex	Smith chart
Double stub		Medium	Medium	Medium	Complex	Smith chart
Filter theory		Large	Large	High	Complex	Synthesis method
Quarter-wave transformer		Narrow	None	Low	Real	Analytical equation
Multisection transformer		Large	Medium	High	Real	Synthesis method
Tapered line		Large	Large	High	Real	Analytical equation
Combination	Lumped and distributed	Small to large	Large	Low to High	Complex	Smith chart or Analytical equation

different element types are used in (ideally) lossless matching networks: (1) lumped elements such as inductors and capacitors and (2) distributed elements such as transmission-line sections and open- and short-circuit stubs. Seldom do all the networks provide the same bandwidth. The general rule is that as the number of elements used grows, the bandwidth gets wider up to a maximal value, as will be discussed in Section 2.3. Furthermore, some networks are more flexible than others. When different configurations are available and different element values can be used, much freedom is gained to meet the specifications. On the other hand, this flexibility usually leads to more complex circuits.

Generally, impedance-matching networks can be divided into two different categories: complex load-related matching networks and real load-related matching networks. In the former case, a complex load, $Z_L = R_L + jX_L$, must be transformed into a real load, Z_0 . The latter case is generally used to connect two transmission lines with different impedances, Z_1 and Z_2 . The design of these networks is achieved with different techniques. The Smith chart is still the basic tool for the designer. However, analytical equations are available for some designs, and synthesis methods are applied in the design of multisection matching networks.

2.1. Lumped Elements

With inductors and capacitors, any complex load on the Smith chart can be transformed into real impedance. The special case of a straight reactance cannot be matched with a lossless network. This case will be discussed in Section 2.3. Commercial off-the-shelf lumped elements are popular at low frequencies, up to ~ 3 GHz. Beyond this frequency, parasitic elements are too important to ignore. For MMIC chip circuits, the frequency limit is largely extended and some lumped elements are even designed above 100 GHz.

2.1.1. L Network. The L networks are made up of two reactances, one in series and one in parallel. There are eight different configurations, but none of them can be used to match every load on the Smith chart. However, there is always more than one choice to match a given load. The eight configurations and their matching area on the Smith chart are shown in Fig. 2. The area in gray shows the locations of loads that cannot be matched with the respective network.

The simplest way to design an L network is to use the Smith chart. The method is explained in detail by Gonzalez [1, Chap. 2]. Analytical equations are also available

Figure 2. Eight different configurations for the L network: series-parallel (a–d) and parallel-series (f–i). The areas that cannot be matched for a given configuration are shown in gray. Series-parallel and parallel-series are represented in a more general way by diagrams (e) and (j), where the gray area on the Smith chart is associated with the analytical equation.

for this network [2]. In this case, the Smith chart is first divided in two regions delimited by the circle $1 + jx$. If the normalized load, Z_L/Z_0 , falls inside the circle, the circuit shown in Fig. 2j is used. The reactance values are then given by

$$B = \frac{X_L \pm \sqrt{R_L/Z_0} \sqrt{R_L^2 + X_L^2 - Z_0 R_L}}{R_L^2 + X_L^2} \tag{2}$$

$$X = \frac{1}{B} + \frac{X_L Z_0}{R_L} - \frac{Z_0}{B R_L} \tag{3}$$

Equations (2) and (3) indicate that there are always two different networks available to match a load. These two possible choices are the circuits shown in Figs. 2f and 2g. If the normalized load is outside circle $1 + jx$, the circuit in Fig. 2e is used. The reactance values are then calculated by using the following equation:

$$X = \pm \sqrt{R_L(Z_0 - R_L)} - X_L \tag{4}$$

$$B = \pm \frac{\sqrt{(Z_0 - R_L)/R_L}}{Z_0} \tag{5}$$

Once again, these equations suggest that there are always two possible configurations to match a load, thus giving some flexibility to the designer.

2.1.2. T and Π Networks. The T and Π networks are shown in Fig. 3. These networks are essentially L networks in which one element has been added. There are 16 possible configurations that provide much more freedom than do the L networks. This freedom can be used to obtain the desired element values or to control the operating bandwidth. Kuroda’s identities are used to transform an L network into a T or Π network [3]. Furthermore, a T network can be transformed to a Π network, or vice versa, with the following relations:

$$\begin{aligned} Z_A &= \frac{Z_1 Z_2}{Z_1 + Z_2 + Z_3} & Z_1 &= \frac{Z_A Z_B + Z_B Z_C + Z_A Z_C}{Z_C} \\ Z_B &= \frac{Z_1 Z_3}{Z_1 + Z_2 + Z_3} & Z_2 &= \frac{Z_A Z_B + Z_B Z_C + Z_A Z_C}{Z_B} \\ Z_C &= \frac{Z_2 Z_3}{Z_1 + Z_2 + Z_3} & Z_3 &= \frac{Z_A Z_B + Z_B Z_C + Z_A Z_C}{Z_A} \end{aligned} \tag{6}$$

Matching a load with a T or Π network is usually done with the Smith chart. However, analytical expressions are also available for some T networks [3].

Figure 3. The T and Π matching networks.

2.1.3. Ladder Network. As we have seen, adding an element to the L network increases the degree of freedom in the design. This freedom can be used to improve the bandwidth. As more elements are added, the bandwidth can be increased, but there is a limit, as we will see in Section 2.3. To design a ladder network, synthesis methods should be applied. As in the design of filters, Butterworth or Chebyshev frequency responses can be synthesized for the ladder networks. The technique details are presented in detail in Ref. 4, and are not reproduced in this article.

2.2. Distributed Elements

Most matching networks working at microwave frequencies are designed with distributed elements. Transmission-line sections are easy to fabricate and very flexible, presenting low-loss characteristics. The basic building blocks of distributed matching networks are transmission-line sections, open- and short-circuits stubs. These stubs are theoretically equivalent because a quarter-wavelength line can transform a stub from its open state to its short counterpart and vice versa. In practice, both circuits are quite different from each other. It is not always possible or easy to manufacture a circuit having both stubs with a given technology. With the MLINE technology, for example, an open circuit is easier in the implementation. This is not the case for the rectangular waveguide, where only the short circuit is usable. In all cases, if both stubs are available, the one that requires the shortest physical length should be used in order to minimize the loss and also possibly maximize the bandwidth.

2.2.1. Single-Stub Network. The single-stub network is the most common way to match a load, which has 2 degrees of freedom, namely, the linelength and the stub length. The topology shown in Fig. 4 is a single parallel stub network. The Smith chart is the usual tool in the design of this circuit, and the method has been explained in many references [1,2,4] and will not be repeated here. The network can also be designed with analytical equations. With the parallel stubs, it is easier to work with admittance. The first segment, going from the load to the stub, has admittance equal to Y_0 and an electrical length equal to θ_1 . The admittance looking into the input of the

Figure 4. A single-stub matching network.

transmission-line section is

$$Y_A = G_A + jB_A = Y_0 \frac{Y_L + jY_0 \tan \theta_1}{Y_0 + jY_L \tan \theta_1} \quad (7)$$

The electrical length θ_1 must be chosen so as to match the real part of the admittance: $G_A = Y_0$. Then, a parallel stub of admittance Y_0 and electrical length θ_2 is added to cancel out the reactive part. The admittance looking into the input of this stub, for the open/short-circuit case, is

$$\begin{aligned} \text{Open circuit: } Y_B &= jB_B = jY_0 \tan \theta_2 \\ \text{Short circuit: } Y_B &= jB_B = -jY_0 \cot \theta_2 \end{aligned} \quad (8)$$

The electrical length θ_2 must be selected to cancel out the reactive part; thus $B_B = -B_A$ and yields

$$Y_A + Y_B = Y_0 \quad (9)$$

An analytical solution for θ_1 and θ_2 , given in terms of Z_L and Z_0 , is found in Ref. 2. Parallel stubs are easy to design using MLINE. However, there are some transmission lines such as coupled lines, where a serial stub is easier to design. The design steps to match a load are the same when working with a serial stub as with a parallel one, but Eqs. (7)–(9) are calculated with impedance instead of admittance.

2.2.2. Double-Stub Network. With a single-stub network, the length between the load and the stub is a variable related to the value of the load. In some cases it is better to have the stub at a fixed position, for example, in the case of designing a tunable matching network in which the stub length is easier to change than its position. This can be done by using two stubs. The double-stub matching network is widely used to design tuners. The circuit is shown in Fig. 5 with two parallel stubs. Serial stubs are also used in the same way. This type of network cannot match all the loads on the Smith chart. There is always a blind zone that is impossible to match. To minimize this area, the distance between the two stubs must be kept as short as possible. This distance is, however, limited by the physical size of each stub. Furthermore,

Figure 5. A double-stub matching network.

spacing close to 0, $\lambda/2$, and their multiples are too frequency-sensitive to be of interest. In practice, spacing equal to $\lambda/8$, $3\lambda/8$, or $5\lambda/8$ is usually chosen. The double-matching technique makes use of the Smith chart or analytical equations in finding the length of each stub [2].

2.2.3. Filter Theory for Designing Matching Networks. As can be seen in Section 2.1, increasing the number of elements make it possible to design matching networks with a wider bandwidth. In the same way, multisection distributed-element networks are usually used to improve the bandwidth. Filter synthesis techniques are also applied in the design of such circuits. The reader is referred to Ref. 3 for a complete explanation of the synthesis method.

2.2.4. Quarter-Wave Transformer. All the matching networks presented in the preceding sections can be used to match a complex load. Another class of matching networks is used only to match real loads, presented below. Although those circuits seem limited, they are used largely to connect two transmission lines of different impedances and to design various transitions. The most common network applied to adapt two real impedances is the quarter-wave transformer, as shown in Fig. 6. The impedance looking into the input of the quarter-wave transformer is

$$Z_{\text{IN}} = \frac{Z_m^2}{Z_2} \quad (10)$$

To match both lines, one should have $Z_{\text{IN}} = Z_1$. The quarter-wavelength line impedance must be

$$Z_m = \sqrt{Z_1 Z_2} \quad (11)$$

The bandwidth for this circuit is related to the line impedance at the input and at the output. The closer they are, the wider the bandwidth is. It becomes infinite when the impedances are equal.

2.2.5. Multisection Transformer. With only one section, the bandwidth is limited. As we increase the number of sections, a wider bandwidth is obtained. The multisection transformer can be synthesized with the well-established Butterworth or Chebyshev frequency response. Impedance values for various numbers of sections have already been tabulated [2,4]. The normalized impedance value of each section is available for many Z_2/Z_1 ratios.

2.2.6. Tapered-Line Transformer. If we increase the number of sections to the infinite, a tapered line is formed. However, it has an infinite length, which is not of practical

Figure 6. A quarter-wavelength transformer.

value. The tapered line of finite length is still an excellent matching circuit. The simplest taper is the linear one, and it requires very little calculation, but does not provide a wide bandwidth. Exponential taper increases the bandwidth and is still easy to design. Many other tapers have been proposed, such as in the triangular [2], cosine-squared, and parabolic configurations [5]. With all these tapers available for the design, one may wonder which one is the best. The taper proposed by Klopfenstein [6] is optimum in the sense that it provides the shortest length for a given reflection coefficient. However, the Klopfenstein taper presents a step at both ends. Sometimes, these steps are undesirable because they generate high-order modes and radiation loss. The taper proposed by Hecken then becomes optimum [7]. For a desired reflection coefficient, this profile provides the shortest length for a taper without steps.

Although there are many different tapers, the design technique is fundamentally the same for all of them. Let us begin with a topology shown in Fig. 7. The tapered line design is always done at the lowest frequency of interest. In the first step, the impedance variation as a function of the position $Z(z)$ is formulated. The impedance variations, for the most common tapers, are listed in Table 2. Knowing the impedance, one can evaluate the reflection coefficient as a function of the taper length using the following equation:

$$\Gamma = \frac{1}{2} \int_{z=0}^L e^{-2j\beta z} \frac{d}{dz} \ln \left(\frac{Z(z)}{Z_1} \right) dz \quad (12)$$

Analytical values for the linear [8], the exponential [2], the triangular [2], the Klopfenstein [6], and the Hecken [7] tapers have been obtained and they are available in the literature. If we know the reflection coefficient for an arbitrary length, we can find the minimum length providing a desired reflection coefficient. With this length L and the equations in Table 2, the impedance variation as a function of the position z is then calculated. The impedance taper must then be transformed to a physical taper. Computing the impedance at several points and then finding the physical dimensions from this impedance is the standard method used to generate the dimensions of the taper. The number of points must be large enough to obtain a smooth and continuous taper.

2.3. Fano's Criterion

In Sections 2.1.3 and 2.2.3, a multielement network that was used to improve the bandwidth was described. However, what is the maximum achievable bandwidth? Bode's [9] work and Fano's [10] work have answered this question. For a lossless matching network, the reflection

Table 2. Tapered-line Impedance Z as a Function of Position z (with Taper Length L)

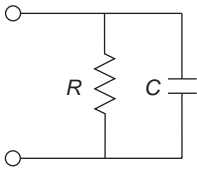

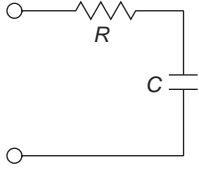

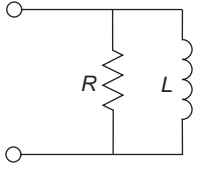

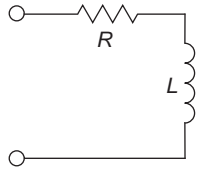

Taper	$Z(z)$
Linear	$Z(z) = Z_1 + \frac{z}{L}(Z_2 - Z_1)$
Exponential	$Z(z) = Z_1 e^{az}$ $a = \frac{1}{L} \ln \left(\frac{Z_2}{Z_1} \right)$
Triangular	$Z(z) = Z_1 e^{2(z/L)^2 \ln(Z_2/Z_1)}$ for $0 \leq z \leq L/2$ $Z(z) = Z_1 e^{(4z/L - 2z^2/L^2 - 1) \ln(Z_2/Z_1)}$ for $L/2 \leq z \leq L$
Cosine-squared	$Z(z) = Z_1 \cos^2 az$ $a = \frac{1}{L} \cos^{-1} \left(\frac{Z_2}{Z_1} \right)$
Parabolic	$Z(z) = (\sqrt{Z_1} + az)^2$ $a = \frac{1}{L} (\sqrt{Z_2} - \sqrt{Z_1})$
Klopfenstein	$\ln(Z(z)) = \frac{1}{2} \ln(Z_1 Z_2) + \frac{\Gamma_0}{\cosh A} A^2 \phi \left(2 \frac{z}{L} - 1, A \right)$ $A = \cosh^{-1} \left(\frac{\Gamma_0}{\Gamma_m} \right), \quad \Gamma_0 = \frac{Z_2 - Z_1}{Z_2 + Z_1}$ $\phi(x, A) = -\phi(-x, A) = \int_0^x \frac{I_1(A\sqrt{1-y^2})}{A\sqrt{1-y^2}} dy$ $I_1(x)$ = first-kind modified Bessel function Γ_m = maximum desired reflection coefficient
Hecken	$\ln(Z(z)) = \frac{1}{2} \ln(Z_1 Z_2) + \frac{1}{2} \ln \left(\frac{Z_1}{Z_2} \right) \psi \left(2 \frac{z}{L} - 1, B \right)$ $B = \sqrt{(\beta L)^2 - 6.523}$ $\psi(x, A) = -\psi(-x, A) = \frac{B}{\sinh B} \int_0^x \frac{I_0(B\sqrt{1-y^2})}{\sqrt{1-y^2}} dy$ $I_0(x)$ = first-kind modified Bessel function β = propagation constant at lowest frequency

coefficient and the bandwidth are related to each other by the following equation

$$\int_0^\infty \ln \frac{1}{|\Gamma(\omega)|} d\omega \leq K \quad (13)$$

where K is a constant related to the load. Equation (13) shows that the area under the reflection coefficient is smaller or equal to a constant K . The value of K for the RC and RL loads is tabulated in Table 3, where ω_0 is the center frequency of the matching bandwidth. Several observations can be made from this equation: (1) a perfect matching, $\Gamma = 0$, can be obtained at only a finite number of frequencies. It is impossible to have a perfect matching over a frequency band; (2) the bandwidth can be increased at the expense of the reflection coefficient—bandwidth and reflection coefficient are exchangeable quantities when matching a load; and (3) if the load is purely resistive, for example, the capacitance is equal to zero in a parallel RC network; the value of K goes to infinity. Thus, multi-section or the tapered-line transformers have an infinite theoretical bandwidth. However, the number of section or the length also increases to infinity. Finally, if the quality factor is infinite, for example, the resistance is infinite in the parallel RC network, the value of K is equal to zero. A reactive load cannot be matched with a lossless network. Incidentally, if the quality factor of the load increases, the maximum area under the reflection curve decreases.

Table 3. K Values for RC and RL Networks

Load Type			
			
$K = \frac{\pi}{RC}$	$K = \pi\omega_0^2 RC$	$K = \frac{\pi\omega_0^2 L}{R}$	$K = \frac{\pi R}{L}$

2.4. Other Types of Impedance Transformer and Matching Networks

There are many other variations of matching networks. A single transmission line can be used as a matching network with proper impedance and length [11]. With this technique, however, only 25% of the Smith chart can be matched. This region can be increased up to 75% if two serial transmission lines instead of a single one are used [12]. Analytical expressions are available for design of the required length and impedance [13]. There are also a broad range of combinations between different matching networks. A quarter-wavelength line can be used with parallel stubs [14]. The respective advantages of lumped and distributed matching networks can also be combined [15]. The coupled line provides the same behavior as does a quarter-wavelength transformer [16]. The hybrid coupler is also a basic building block to design matching networks in a single section [17] or a multiple section [18]. Special impedance-matching networks, some of which have more recently emerged with respect to the development of novel RF and microwave technologies, are described below.

2.4.1. Tunable Matching Networks. The matching networks that we have presented so far are used to match a fixed load. Sometimes, the impedance of the load changes and a tunable matching network becomes necessary. Tunable matching networks can be divided into two categories: adaptative tunable matching networks and selective tunable matching networks. In the former case, the tunable matching network makes it possible to keep a good matching over a variable condition. This variation may come from manufacturing tolerance, temperature change, aging effects, and interaction with the surroundings (detuning effects), to name only a few examples. In the latter case, the matching network is used to select an appropriate value, such as a frequency band in a filter, a particular gain in an amplifier, an operating frequency in an oscillator, or a beaming angle in a scanning beam antenna. Such a tunable matching network is then an effective tool to accomplish critical tasks. The adaptative or selective networks are mostly designed using three categories of elements: varactor diodes, RF microelectromechanical systems (MEMS), and ferrite or ferroelectric materials. Principal characteristics of these elements are

briefly explained as follows. Ferrites have been widely used and are well documented in the literature and thus are not included here.

2.4.1.1. Varactor Diode Techniques. Semiconductor diodes are used to create variable-capacitance components such as varactors. When a reverse voltage is applied to the diode, a depletion region is created whose thickness can be tuned electronically, thus modifying the capacitance. Varactor diodes have been widely used as tuning elements for more than 40 years. This is a very mature technology with a wide range of commercially available components. The principal limitation in a varactor diode is its low quality factor, which suffers from high series resistance of the diode junction.

2.4.1.2. RF MEMS Techniques. RF MEMS technology has generated significant interest [19–21]. Generally, MEMS are made up of two parts: a mechanical part and an electrical part. The mechanical part contains a mobile section that creates the tuning capability controlled by the electrical part. In the design of a tunable matching network, MEMS are used for variable capacitors, which include parallel-plate and interdigital capacitors. Generally, the tuning range is large with a relatively low voltage.

2.4.1.3. Ferroelectric Techniques. The integration of ferroelectric material such as barium strontium titanate (BST) involving the design of tunable microwave devices is relatively new [22]. Different from the techniques described in Sections 2.4.1.1 and 2.4.1.2, a ferroelectric circuit achieves its tuning capability by modifying its dielectric permittivity with respect to an externally applied electric field. In addition, an unusually high dielectric constant of the ferroelectrics can be used to miniaturize the circuits, which are of critical importance for tunable matching networks at lower microwave frequencies such as the emerging software-defined radio. Metal-insulator-metal (MIM) capacitors are the most common variable devices based on this technology. Other solutions are studied, such as double-stub variable matching networks [23].

2.4.2. Active Matching Networks. When a broadband matching network is required, the above-described passive matching networks are not always the best solutions.

The size of the structure may be prohibitively large because of wavelength limitations, which may pose a challenging problem in the design of MMICs in spite of lumped-element techniques. On the other hand, the passive impedance matching may also be loss-limited for some applications. In the design of a RF driving circuitry for multioctave broadband direct modulation with a very-low-impedance laser, it is rather difficult to use a passive matching network. In this case, an active matching network becomes necessary, which may be made of transistors or MMIC chips. FET transistors operating in a common gate provide a good input match over a wide bandwidth, which has been used, for example, to design multioctave amplifiers [24,25]. Details related to the active matching techniques are beyond the scope of this article, and some references may be found in Ref. 26.

3. TRANSMISSION-LINE TRANSITIONS

The above-described matching techniques allow for a high-quality connection between two different impedance circuits or components of the same microwave transmission structure such as MLINE and waveguides. However,

the connection may be required between two circuits or components made of different transmission structures. In this case, the transmission-line transitions should be used, which possibly involve mode conversion and impedance matching. As we discussed earlier, the impedance definition may vary from line to line, suggesting that the design of such transition structures is much more involved. These transitions are essential for a wide range of microwave circuits such as mixer, filter, and antenna feeder. In most practical cases such as the connection of active elements to low-loss/high-quality waveguide components, the transitions play a vital role in maintaining the performance of the whole circuit.

The design of a transition between two different transmission structures depends on the electromagnetic field or modal configuration of each structure [27]. If the electromagnetic fields or modes have similar profiles, an impedance taper can be designed such that the shape of one transmission line is gradually altered so to physically match that of the other transmission line, as detailed in Section 2.2.6. This seems to be the best option in terms of the insertion loss and bandwidth. If those electromagnetic fields or modes are incompatible, an electromagnetic (noncontact) coupling technique between the two structures is preferred.

Figure 8. Transmission structure classification.

Figure 9. Topology of the MLINE-CPW transition proposed in Ref. 30 with its equivalent model: (1) \Rightarrow CPW; (2) \Rightarrow transformer; (3) \Rightarrow MLINE.

In the following, we begin by classifying the principal transmission structures used in the design of RF, microwave, and millimeter-wave circuits. Then, we will show different examples of transitions design illustrating planar-to-planar transitions and planar-to-nonplanar transitions. We will discuss differences among impedance taper transitions, electromagnetic coupling transitions, and special balanced line-unbalanced line (balun) transitions.

3.1. Transmission Structures

To classify the transmission structures (see Fig. 8), three distinct criteria are used in this article; the first is related to the possible TEM mode transmission lines or non-TEM-mode waveguides. The second looks into the structure whether it is planar or nonplanar. The last one is in connection with balanced and unbalanced topologies, which apply only to TEM-mode transmission lines. A balanced transmission line has by definition a transmission line that has equally distributed resistance, capacitance, inductance, and conductance elements between its conductors. Usually this means that the two conductors of a balanced transmission line are of the same size, opposite to an unbalanced transmission line having a small conductor and a wide ground plane. This also implies that a metallic sheet could be placed in the middle of a balanced line without affecting it, which is analog to the electric symmetry plane (electric wall) that exists in some propagating modes in waveguide. A variety of transmission-line structures are used in RF, microwave and millimeter-wave circuits, many of which are simple derivatives of the basic structures shown in Fig. 8.

3.2. Planar-to-Planar Transitions

Planar-to-planar transitions are very useful in the realization of wideband mixers, printed antennas, measurement setups, and multifunction modules (MFMs). Examples presented in the following subsequent sections constitute the most popular ones.

3.2.1. Microstrip Line (MLINE)-CPW Transition. Transitions between MLINE and CPW have been realized in many ways. For MMIC, a transition between MLINE and CPW is necessary for measurement purposes with CPW probes directly in contact with the circuit wafer. A model

for this transition was developed in Ref. 28. For cases where the MLINE and CPW are placed on opposite sides of the dielectric substrate, a broadband transition without via hole was designed by Lin [29]. For cases where both MLINE and CPW are placed on the same side of the dielectric substrate, Houdart and Aury [30] have proposed a transition using the coupling between the ground planes of the MLINE and CPW. The layout of the transition is illustrated in Fig. 9. A design approach based on the quasi-TEM approximation was proposed.

3.2.2. MLINE-to-Twinline Balun. This transition is particularly useful in the realization of printed dipole antenna array [31–33]. Since both transmission lines have a very similar electromagnetic field orientation, a simple impedance taper between both the lines can be used as shown in Fig. 10. The length L is usually equal to a quarter-wavelength in the middle of the band.

3.2.3. Planar Balun Transitions. In the design of a planar mixer or a planar magic tee, the use of printed Marchand and/or double-Y baluns is necessary for wideband operation and high isolation. Trifunovic and Jokanovic [34] provide an overview of these baluns, which are illustrated in Fig. 11. Marchand type baluns offer bandpass frequency

Figure 10. Topology of the MLINE-to-twinline balun.

			CPW - SLOTLINE
			CPW _{Gap} - CPS

Figure 11. Printed balun topologies.

response. Double-Y baluns could provide allpass frequency response. Because of the limitation on the realization of perfect open and short circuits in planar technologies, the allpass response begins at DC and is limited to a certain maximum frequency. This maximum frequency is designed as a function of the length of open and short circuits of the junction, which in turn depend on the gaps used in the realization of CPW, slotline, or CPS. Note that the use of CPW with a slotline or a CPS allows the realization of uniplanar mixer circuits, which is of great importance in MMIC technology.

3.3. Nonplanar-to-Planar Transitions

Generally, the coaxial-line technology is useful up to 65 GHz. Therefore, transitions between a coaxial line and a planar circuit are very important for circuit measurements and module interconnects. At higher frequencies, transitions between rectangular waveguides and planar circuits are more appropriate. Three typical application examples are described below.

3.3.1. Coaxial Line-to-MLINE Transition. The transition between coaxial line and MLINE is of critical importance in the RF industry. Many types of connector layout are now available for RF and microwave circuit designer. We can divide the most commonly used connectors into three basic types: (1) the inline connector, (2) the through-ground connector, and (3) the top connector (see Fig. 12).

Directly applicable design models are not available for these transitions. A resonance measurement method was used to characterize them [35]. The method is accurate and has been applied to many types of coaxial transition.

Figure 12. Cutaway view of the three basic coaxial line-to-MLINE transition topologies: (a) inline transition, (b) through-ground transition; (c) top transition.

Figure 13. Topology of four different transitions between MLINE and RWG: (a) aperture coupling [40]; (b) ridge waveguide approach [41]; (c) quasi-Yagi antenna in the E plane [43]; (d) E -plane probe [47].

For the through-ground transition, an interesting example was illustrated in Ref. 36.

3.3.2. Rectangular Waveguide (RWG)-to-MLINE Transition. Different strategies have been developed for designing MLINE-to-RWG transitions. The first is an aperture coupling placed at the end of the RWG [37–40]. The second is a complex structure consisting of an MLINE-to-RWG transition through an intermediate ridge waveguide [41,42]. Another configuration uses a printed quasi-Yagi antenna placed at the end of the RWG [43]. It seems that the simplest topology is the use of an MLINE E -plane probe inside the RWG [44–49]. All topologies are illustrated in Fig. 13. All these transition geometries provide a great flexibility in the design process.

Aperture coupling generally tends to be narrowband except for the design in Ref. 40, where the use of a waveguide taper considerably increases the bandwidth. The MLINE–Ridge–RWG transition provides low loss and very wide bandwidth. Nevertheless, its construction is difficult and expensive. The quasi-Yagi antenna transition gives a good bandwidth with acceptable performance. The E -plane probe allows a good performance over a wide bandwidth, but a quarter-wavelength backcavity is necessary in this case.

3.3.3. RWG-to-Slotline (Finline) Transition. The transition between RWG and slotline can be made wideband and low-loss [50–52]. Figure 14 illustrates a general topology

of the transition. A simple geometric design approach can be used for the realization of the transition [51]. On the other hand, a sophisticated optimization algorithm can be used for critical applications where the minimum return loss is required [52].

3.4. Nonplanar-to-Nonplanar Transitions

A large number of useful transitions between nonplanar structures have been studied and developed. Impedance

Figure 14. Topology of the RWG-to-slotline transition.

Figure 15. Cutaway view of coaxial line-to-RWG transitions: (a) inline transition using intermediate square coax (1) and ridge waveguide (2) stages; (b) perpendicular wideband transition.

taper can be used effectively when the electromagnetic field orientations (mode profiles) between the two waveguides are similar. Some types of transition make use of a small antenna (loop or monopole), while the others use small-aperture coupling. We illustrate in the following each type of transition with an example.

3.4.1. Coaxial Line-to-RWG Transition. The geometry of the transition between coaxial line and RWG can be designed in two ways, as illustrated in Fig. 15. The first is inline (end-launched) [53,54], meaning that both the coaxial line and the RWG are on the same axis. The second topology places the RWG and the coaxial line perpendicular to each other [55]. The geometry of the transition can be an important criterion of selection in system planning. Usually, the perpendicular type provides the widest bandwidth for the smaller length.

The general topology of inline configuration was described by Chan et al. [53]. This transition can provide wideband operation by using an intermediate ridge waveguide section in the transition. The fabrication cost of this transition limits its application to specific cases.

In the perpendicular configuration using the inner conductor of the coaxial line a quarter-wavelength monopole antenna is contained inside the RWG. It was found [55] that the best topology for the transition was to fix $d = \lambda g/4$ at the average frequency of the RWG and to adjust the

dimensions of the monopole for optimum return loss (see Fig. 15). This provides a $VSWR \leq 1.02$ over the entire useful bandwidth of the RWG.

3.4.2. NRD Guide–RWG Transition. The NRD guide is a special class of low-cost dielectric guide providing superior performance at millimeter-wave frequencies [56]. The hybrid LSM_{10} mode is the preferred mode of operation because of its low-loss characteristics. For the measurement purposes of NRD guide components, a high-performance transition between NRD guide and RWG was developed in Ref. 57. Since the TE_{10} mode of RWG has similar electromagnetic field orientations with reference to the LSM_{10} mode, continuous-impedance tapers [7] are used in the design of the transition as illustrated in Fig. 16. This transition is divided into two sections. The first is a transition between a RWG and a dielectric-filled RWG. The second is between the dielectric-filled RWG and the NRD guide.

INDIUM PHOSPHIDE (InP)

OSAMU WADA
Kobe University
Japan

1. INTRODUCTION

Indium phosphide (InP) and its related ternary and quaternary alloys grown epitaxially on InP substrates form one of the most important III–V compound semiconductor families because of their broad applications in electronic, microwave, optoelectronic, and photonic devices with high performance and high reliability. This is due primarily to the physical properties intrinsic to this material

system such as the high electron mobility, high saturation velocity, high thermal conductivity, wide selectivity of the bandgap energy suitable for optical communication wavelengths, and high threshold of optical catastrophic degradation. Also the development of practical devices for both electronic and optoelectronic systems have pushed the technical frontiers in material preparation, processing, device designs, fabrication, and also integration to extremely high standards. Operation frequency of more recent InP-based microwave devices is in the range of 100–200 GHz, and operation bit rates of state-of-the-art electronic and optoelectronic digital devices and integrated circuits are in the range of 40–100 Gbps. In extension to these technologies, research is underway to generate and detect terahertz (THz) waves and also to process optical pulse signals in the femtosecond time domain. Thus InP-based materials and devices are prerequisite in establishing technical infrastructure for ubiquitous communication and informatics utilizing electronic, microwave, and photonic technologies. In what follows, we review first the basic material properties of InP-related material systems and then current device technologies for both electronic and photonic applications.

2. GENERAL PROPERTIES OF InP-BASED MATERIALS AND HETEROSTRUCTURES

InP has, like many other III–V compound semiconductors, zincblende structure with a lattice constant a of 0.58687 nm. The relationships between the energy gap E_g and the lattice constant a are summarized in Fig. 1 for various binary and ternary III–V material systems. A variety of ternary and quaternary alloy systems possessing lattice parameters the same as that of InP can be grown on lattice-matched InP substrates without introducing misfit dislocations. A very wide range of bandgap energy

Figure 1. Relationship between energy gap E_g and lattice constant a for various III–V semiconductors.

variation in this alloy system is extremely useful for device applications, particularly for optoelectronic devices in the long-wavelength region covering 1.3–1.55 μm [1,2]. Lattice-mismatched heterointerfaces can be classified into (1) coherently strained or pseudomorphic interfaces free of misfit dislocations, in which the thickness of strained layer is smaller than the “critical thickness” determined from the elastic property of the crystal; and (2) relaxed interfaces where strain is partially or fully relaxed with the introduction of misfit dislocations. Quality of heterointerfaces is strongly dependent on the crystallographic nature of the interface as well as the growth conditions in real interface formation process, including growth interruption and regrowth. InP-based materials are grown epitaxially on InP substrates usually with (100)-oriented surfaces using various epitaxial techniques including metal organic chemical vapor deposition (MOCVD) and chemical-beam epitaxy (CBE) and also molecular-beam epitaxy (MBE) for non-P-containing materials [2]. InP substrates used for device fabrication are in the range of 2–3 in. in diameter, whereas 4-in. substrate growth technology is available for future high-volume production.

The choice of alloy system is important not only for the bandgap energy itself but also for the band discontinuity or lineup at the heterointerface. Figure 2 shows the band lineup (type I) for lattice-matched InP/In_{0.53}Ga_{0.47}As and In_{0.52}Al_{0.48}As/In_{0.53}Ga_{0.47}As heterointerfaces, which are used most widely for electronic and optoelectronic devices, whereas the lattice-matched InP/In_{0.52}Al_{0.48}As heterointerface is of type II staggered lineup [2]. For application of InP-based heterostructures to electronic and optoelectronic devices, alloy composition must be designed for optimizing the band discontinuity for tight carrier confinement. In the optoelectronic device applications, the bandgap energy and refractive index must be designed for the operation wavelength and optical confinement within heterostructure devices. The maximum conduction band discontinuity for lattice-matched interfaces is obtained by AlAsSb/InGaAs heterostructure, which can be

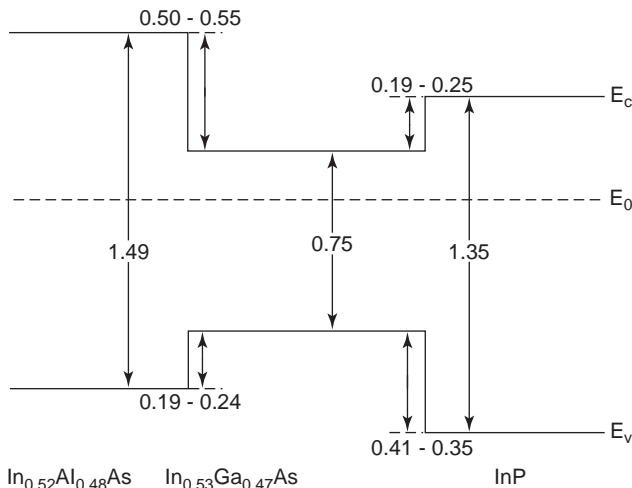

Figure 2. Band lineup for In_{0.52}Al_{0.48}As/In_{0.53}Ga_{0.47}As/InP heterostructure. Units are in eV.

Figure 3. Monte Carlo calculation of velocity–field curves for InP and GaAs. InP has a higher peak velocity and a higher corresponding electric field than does GaAs. (After J. Hayes [3].)

useful for cascade lasers and intersubband transition optical modulators and switches, as will be described later. Another important factor that plays an important role in heterointerface band lineup is strain. For example, uniaxial tensile (compressive) strain is induced to In_xGa_{1-x}As interfacing to InP when x is less (greater) than 0.53, which splits the degenerate valence bands at $k = 0$, which causes the light-hole (heavy-hole) band to lie higher than the heavy-hole (light-hole) band. Such an effect is critical to determine the operation wavelength and polarization properties of optical devices, and also to determine the carrier transit speed and confinement effect in electronic devices.

Figure 3 shows velocity–field characteristics for different semiconductor materials [3]. Low electric field mobility, which is defined by the slope of the velocity–field curve close to the axis, for all III–V compounds exceeds that of Si. Another significant difference in velocity–field characteristics is in that there is a region of negative resistance resulting from the electron dynamics and the band structure. The negative resistance of InP is initiated at a field much higher than that of GaAs, and correspondingly the electron saturation velocity is much higher than in GaAs. This is caused by larger energy separation between Γ and L valleys in InP conduction band [3]. InGaAs ternary alloy shows the highest low-field mobility in excess of 10,000 $\text{cm}^2/\text{V}\cdot\text{s}$ and maximum saturation velocity over 2.4×10^7 cm/s . For a given class of device structures, this can result in lower parasitic resistance, higher current-carrying capacity, and shorter transit time. Unique properties of InP-based materials include a stable surface property, which is well known for lasers under age testing to be much more resistant to facet degradation than for GaAs-based lasers. Low surface recombination velocity and a lower rate of recombination-enhanced defect formation are characteristic to this material system. Such material properties, together with the higher thermal conductivity, InP, and related alloys, may also be suitable for high-power applications.

3. ELECTRONIC DEVICES AND INTEGRATED CIRCUITS

The most important electronic devices based on InP are high-electron-mobility transistors (HEMTs) and hetero-

bipolar transistors (HBTs). Significant improvement is being made in these discrete devices as well as their monolithic microwave integrated circuits (MMICs). In order to indicate RF and microwave performance of these devices, characteristic parameters such as f_t , f_{max} , and noise figure are used. f_t is defined as the frequency where the current amplification gain equals unity, and is basically determined by the intrinsic device speed. f_{max} is defined as the maximum oscillation frequency, and is influenced by parasitic components such as the gate resistance and drain feedback capacitance. Noise figure is defined by the ratio of noise at the input and output represented in decibels (dB).

InP-based HEMTs using the $In_{0.52}Al_{0.48}As/In_{0.53}Ga_{0.47}As$ 2DEG system were first reported in 1985 [4]. Typical device structure is shown in Fig. 4, together with a band diagram of the 2DEG heterostructure [5]. The performance of HEMTs has improved rapidly since then primarily by shrinking the device size, particularly reducing the gate length down to 100 nm and beyond. Pseudomorphic heterostructure in which the In composition $x > 0.53$ provides lower bandgap energy and enhances the electron drift velocity, conduction band discontinuity ΔE_c , and also sheet carrier density, so that extremely high f_t data have been achieved by more recent developments. Figure 5 shows the structure of such a pseudomorphic ($x = 0.7$) HEMT with a gate length of 25 nm [5]. In reducing the gate length, it is important to avoid the short-channel effect by decreasing the gate-channel distance. The gate-channel distance of only 4 nm has been achieved in this case by introducing the etch-stop layer technique together with the electron-beam-processed two-step recess gate technique. Static I-V and current gain-frequency characteristics are shown in Fig. 6, indicating that $f_t = 562$ GHz. A lattice-matched HEMT with the same structure has exhibited a frequency of 500 GHz [6].

Figure 5. Schematic cross-sectional view of InGaAs/InAlAs HEMT (left) and cross-sectional TEM image around the bottom of the 25-nm-long T-shaped gate. (After A. Endoh et al. [6].) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

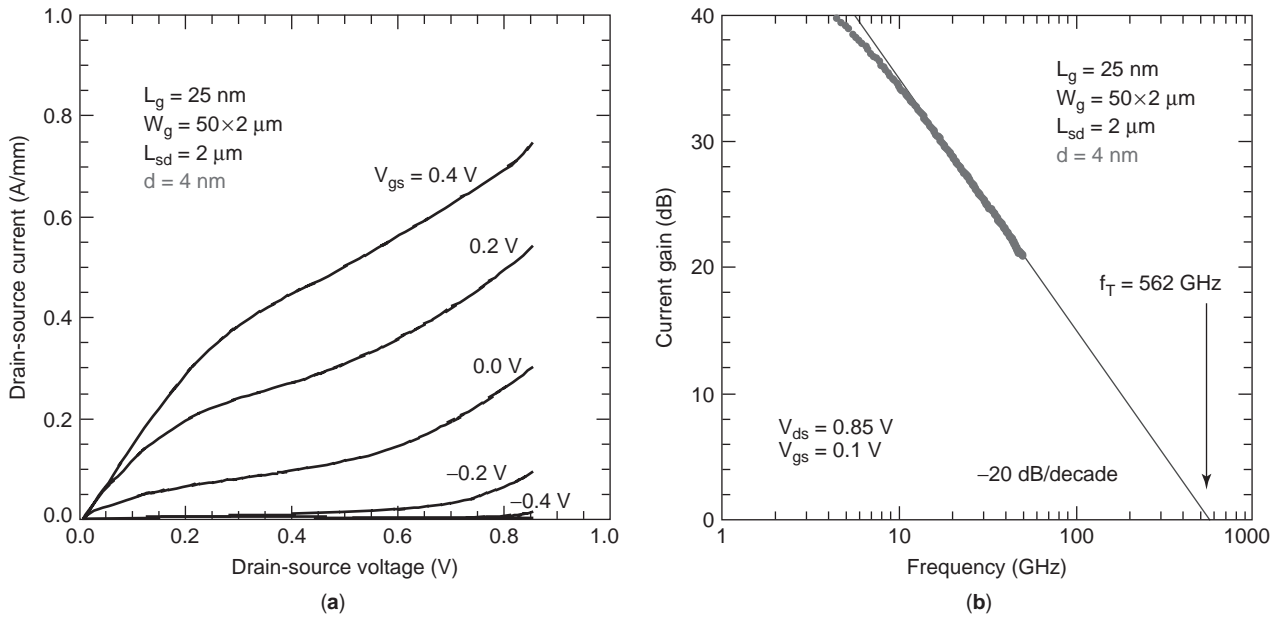

Figure 6. (a) Static current–voltage characteristics and (b) current gain–frequency characteristics of 25-nm-gate pseudomorphic HEMT with gate–channel distance of 4 nm. The maximum DC transconductance is about 1.23 S/mm. The cutoff frequency achieved is 562 GHz. (After A. Endoh et al. [6].) (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Typical application of InP-based HEMT includes millimeter-wave communication and remote sensing instruments for Earth atmosphere, radio astronomy, medical thermography, and target seekers. Millimeter-wave radar for the automotive collision avoidance system is another key application of InP HEMT MMICs.

For the application to low-noise amplifiers (LNAs), InP HEMTs are intrinsically suitable because of their high transconductance, high f_t , and low source resistance. InP HEMT MMIC, which exhibits 25 dB gain and 3.0 dB noise figure at 102 GHz, and 12 dB gain and less than 6 dB noise figure in the range of 170–200 GHz, has been developed [7]. Also a six-stage coplanar waveguide design MMIC has demonstrated 20 dB average gain with a noise figure of < 6 dB over a range of 160–215 GHz [7]. A high breakdown

voltage is achieved through composite InGaAs–InP channel designs, and a single-chip power amplifier has achieved 16 dB gain and 420 mW output power at 95 GHz with a 20% power-added gain efficiency [7].

Digital ICs based on InP-based HEMTs will be indispensable in developing ultrafast optical communication systems. Device structure and fabrication technique adequate to achieve uniform threshold characteristics over the wafer are essential for digital ICs. Chipsets for 40 Gbps (gigabits per second), including multiplexing (MUX) and demultiplexing (DEMUX) circuits, have been developed [8]. An IC structure with 100-nm-long gates fabricated using double-recess and InP-etch stop-layer techniques is shown in Fig. 7, exhibiting $f_t = 175$ GHz, a threshold voltage of -0.58 V, and the standard deviation

of 36 mV. Figure 8 shows the circuit diagram of a channel selector and Fig. 9, an “eye” diagram demonstrating error-free operation at 100 Gbps [9].

Another important class of InP-based electronic devices is heterojunction bipolar transistors (HBTs). The schematic structure and band diagram of InGaAs/InAlAs HBTs are shown in Figs. 10a and 10b, respectively. HBTs have a great advantage in increasing the current gain by limiting the backward injection of holes into the emitter with the introduction of a wide-bandgap emitter as illustrated in Fig. 10b. This allows significant increase in base doping, resulting in lower base resistance and high base current operation at high speed. Although the Si bipolar has remained very competitive in high-speed applications not only with the superaligned technology but also with inclusion of SiGe HBTs, the highest performance has been recorded by InP-based HBTs. Ultrafast HBTs over 200 GHz are key to next generation analog-to-digital converters and other digital and mixed-signal circuits. The schematic cross-sectional structure of superscaled double-

(a)

(b)

Figure 10. (a) Typical device structure for InGaAs/InAlAs HBT; (b) energy band diagram for InGaAs/InAlAs HBT.

heterojunction HBTs (DHBTs) and important factors for high-speed performance are shown in Fig. 11 [10]. InP-based DHBTs have achieved a combined f_t/f_{max} of 300/300 GHz and 21 dB unilateral power gain at 100 GHz [7,10]. More recent InP-based HBTs involving heavily C-doped GaAsSb base layers have also shown outstanding performance with $f_t = 300$ GHz [10]. InP-based HBT MMICs have been developed for a variety of applications, including an X-band direct synthesizer consisting of 3000 InP HBTs [7].

Figure 11. Schematic of a scalable, high-performance, InP HBT for mixed-signal circuits. (After J. C. Zolper [10].)

4. OPTOELECTRONIC DEVICES AND INTEGRATED CIRCUITS

Since the development of low-loss optical fibers at wavelengths $1.3\ \mu\text{m}$ and then $1.55\ \mu\text{m}$, InP-based quaternary alloy systems, particularly the lattice-matched $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{P}_{1-y}$ system, have become indispensable for light source and photodetector devices for optical communications. Development of erbium-doped fiber amplifiers (EDFAs) and the wavelength-division multiplexing (WDM) technique have improved the throughput and functionality of optical network greatly and also enhanced the importance of InP-based optoelectronic devices. Present InP-based device development covers many different directions. Improvement of device performance in WDM systems and high-speed systems with the bit rate greater than 40 Gbps is being tackled. Another important direction is the development of easy-to-use, compact devices at acceptable cost for further widening the application of optical techniques in communication networks and interconnections within systems. A variety of approaches using new type of devices such as coolerless (uncooled) Fabry-Perot (FP) lasers and vertical cavity surface emitting lasers (VCSELs), and integration of devices are being developed using hybrid and monolithic techniques, including photonic and optoelectronic integrated circuits (PICs and OEICs) [2,11,12]. Another direction required toward the next-generation network enabling support of Tbps (terabits per second)-level throughput is the development of ultrafast devices operating at a bit rate exceeding 100 Gbps, where device operation must be all-optical,

since no electron devices would be able to function at that rate. Some of the current developments are reviewed in the following paragraphs.

Figure 12 shows a $1.3\text{-}\mu\text{m}$ -wavelength InGaAlAs/InP multiple-quantum-well (MQW) distributed-feedback (DFB) laser with ridge waveguide structure [13]. The introduction of an InAlAs cladding layer provides a large conduction band discontinuity, and the insertion of a grating layer in the p-type region eliminates the valence band notch at the heterointerface, enabling uncooled operation up to temperatures of 115°C as shown in Fig. 13. Direct modulation at 10 Gbps has confirmed error-free transmission over 30 km with 20 ps/nm dispersion.

Figure 14 shows a InGaAsP/InP electroabsorption modulator (EAM)-integrated DFB laser for 40 Gbps modulation at $1.55\ \mu\text{m}$ [14]. A short-length ($100\text{-}\mu\text{m}$) EAM with ridge waveguide structure with minimized capacitance has been introduced for widening the modulation bandwidth. The EAM quantum-well number, quantum-well thickness, and detuning against the laser emission wavelength have been optimized for improving the extinction ratio. The eye diagram observed at a bit rate of 40 Gbps demonstrates successful transmission with an extinction ratio greater than 12 dB over a 2-km-long conventional single-mode fiber without dispersion compensation fiber using a drive voltage as low as 3.2 V, as shown in Fig. 15 [15]. Also, a clearly open eye diagram has been observed after transmission in 80-km nonzero dispersion-shifted fiber with dispersion compensation [14].

The photonic integration technique is useful for integrating other devices on InP substrates. Multiple-wavelength

Figure 12. Structure of uncooled $1.3\text{-}\mu\text{m}$ InGaAlAs-MQW DFB laser involving a low-resistance (notch-free) grating layer. (After K. Nakamura et al. [13].)

Figure 13. Light output and resistance–current characteristics for uncooled 1.3- μm InGaAlAs-MQW DFB laser. Resistance observed is 30% lower than that of conventional floating-type grating. (After K. Nakamura et al. [13].)

sources, in which distributed Bragg reflector (DBR) lasers with different center wavelengths, an optical coupler, and a semiconductor optical amplifier (SOA) are integrated, and multisection tunable lasers, in which an optical gain, tuning, and phase matching sections are integrated, are typical examples. Figure 16 illustrates the structure of an InGaAsP/InP eight-channel multiwavelength laser exhibiting emission in the 1535–1558 nm wavelength range with high uniformity, high output power (+ 15 dBm), and high single-mode suppression ratio (SMSR > 50 dB) [16].

On the photodetector side, PIN photodiodes (PIN PDs) and avalanche photodiodes (APDs) have been improved in performance by using both the optimization of heterostructure design and the development of integration and packaging techniques. Figure 17 shows the structure of an APD amplifier receiver integrated by using a lensed, flip-chip structure photodiode (PIN PD or APD) and a Si or GaAs preamplifier chip [17]. A monolithic lens formed by the ion etching technique on the InP substrate provides extremely small junction diameter (10–15 μm) but maintaining a very high quantum efficiency, reducing the overall capacitance to improve both the speed and noise performance. High performance of InGaAs/InP APD is represented by a gain–bandwidth product in the range of 30–50 GHz. Using such an APD, the hybrid integrated receiver has shown excellent performance up to 10 Gbps. Monolithic integration of optical receivers has also been developed using mainly PIN PDs and HEMT and HBT amplifier circuits on InP substrates. The more recent PIN/amplifier OEIC receiver bandwidth is in excess of 30 Gbps [18], and is promising for application to not only optical communication systems but also optical interconnections in high-speed electronic systems.

For application to systems at 40 Gbps and beyond, the cutoff frequency of the vertical structure photodiode becomes limited by the carrier transit time, rather than the CR time constant as described in the previous example. Waveguide photodiodes and APDs are being developed for this reason by adopting a structure such as that shown in Fig. 18 [19]. A device with optimized structure (20 μm length) has exhibited a high quantum efficiency (70%) maintaining a speed sufficient to achieve a record gain–bandwidth product of 140 GHz as shown in Fig. 19 [19]. Monolithic OEIC receiver has been developed by integrating a waveguide PIN PD and a 500-nm-gate-length HEMT cascade amplifier, which has exhibited – 22.7 dBm at 40 Gbps [20]. More complicated integrated receivers using OEIC and PIC techniques, including arrayed waveguide grating integrated multichannel photoreceivers,

have been also investigated for application to WDM systems [2].

5. ULTRAFAST ALL-OPTICAL DEVICES

Toward the development of ultrafast optical transmission systems with the bit rate beyond 100 Gbps, an optical time-division multiplexing (OTDM) technique based on stable, compact all-optical devices is a prerequisite. The most basic devices required in OTDM systems are ultrafast light sources and all-optical switches [21]. Figure 20 illustrates the structure of a monolithic colliding pulse-mode-locked (CPM) laser, consisting of a pair of optical gain sections sandwiching a saturable absorber section, all formed on an InP substrate by MOCVD [22]. To ensure an extremely high repetition rate (500 GHz) together with a high extinction ratio, a short (174- μm) cavity design, and an ultrafast saturable absorber with graded-index separate confinement heterostructure (GRIN-SCH)

Figure 20. Structure of monolithic colliding pulse-mode-locked (CPM) laser fabricated on an InGaAsP/InP-based multiple quantum-well wafer. A very short cavity length is used for ultrafast operation. Synchronous optical injection locking technique is applied for stabilizing the repetition rate. (After S. Arahira et al. [22].)

Figure 21. SHG correlation trace of monolithic mode-locked laser, indicating 580 fs half-width pulse generation at 480 GHz repetition rate. (After S. Arahira et al. [22].)

have been adopted. Laser facets have been coated by high-reflectivity (85%) mirrors. Figure 21 shows a second-harmonic generation (SHG) correlation trace of pulses generated by this laser with bias current 78 mA for two sections. Averaged output optical power is 1.6 mW, and the extinction ratio is high, as shown in Fig. 21. Also, low jitter characteristics have been achieved at 480 GHz by applying the synchronous optical injection technique using an external master laser [22].

Ultrafast all-optical switch is another device prerequisite for OTDM systems, and a variety of new materials and devices are being researched currently worldwide. One promising all-optical switch is the InP-based symmetric Mach-Zehnder (SMZ) all-optical switch. The basic structure and operation principle are illustrated in Fig. 22 [23]. The two arms of SMZ switch involve nonlinear waveguides, and they are activated (switched on) by a pair of incoming control light signals with a mutual timeshift of T . When there is no optical phase difference between two arms, no output signal is generated at the output port of the SMZ interferometer. A rectangular pulse can thus be generated at the output port only during the time interval T . Such a device has been fabricated by a hybrid integration technique using two InGaAsP/InP SOAs as nonlinear

elements and a silica-based planar lightwave circuit (PLC), as shown in Fig. 23. Figure 24 depicts SHG waveforms, clearly demonstrating 168 Gbps–10.5 Gbps DEMUX operation at the signal wavelength of 1560 nm (control wavelength: 1545 nm) [24]. The pulsewidth observed is as narrow as 1–2 ps, and the switching energy intrinsically required for control pulses is as low as 50–80 fJ. Error-free DEMUX operation has also been shown at 336 Gbps–10.5 Gbps [25].

Figure 25. Schematic band diagram showing various transitions in a single quantum well. Ultrafast relaxation is expected for the intersubband transition in contrast to the interband transition.

Other approaches for developing all-optical switches include application of the intersubband transition (ISBT) in quantum-well (QW) structure for modulating the absorption and/or refractive index of a waveguide. Referring to the QW band diagram illustrated in Fig. 25, ISBT in the conduction band can exhibit an ultrafast relaxation time unlimited by the carrier lifetime and high oscillator strength. A wide tunability range is obtained by designing the well width. Figure 26 shows the structure of ridge waveguide ISBT switch incorporating 80 periods of AlAsSb/InGaAs-coupled quantum wells grown on an InP substrate [26]. In order to achieve operation at communication wavelengths, an AlAsSb/InGaAs QW, which has a conduction band discontinuity of 1.6–1.7 eV, has been introduced. Figure 27 shows a pump-probe measurement result demonstrating basic DEMUX operation for a series of four input pulses with an equivalent repetition rate of 1 THz. The operation wavelength is 1.55 μm, and the control energy required is 27 pJ. Further reduction of the

switching energy is necessary for practical application and the subject of future research [26].

6. SUMMARY

Technologies of InP and related materials have been developed at very rapid rates since the mid-1980s and have already been applied to a variety of real-world devices covering electronic, microwave, and optical areas. This progress is due primarily to the advantageous properties of these materials, and also a very strong market pull, particularly from continuously increasing demands in optical communication systems in the long-wavelength region. Most of the recorded high performance of transistors, lasers, photodiodes, and electronic and optoelectronic integrated circuits has been demonstrated by InP-based materials. Future development planned for InP-based material and device technology includes improvement in operation speed, bandwidth, throughput, and device functions by exploiting novel material physics and device principles using, for example, quantum dots and photonic crystals. Another significant technical challenge to be targeted is the development of low-cost, reliable, easy-to-use

devices and circuits to provide firm infrastructure for ubiquitous communications and information processing. Further progress of integration technology will play an important role in this direction.

INTEGRAL EQUATIONS

S. M. RAO
G. K. GOTHARD
Auburn University
Auburn, Alabama

Mathematics plays a very important role in all the areas of electrical engineering. Whenever we are asked to develop a system or address a problem, the first thing we need to do is to develop a simple model. This simple model often turns out to be a mathematical model. The mathematical model lets us study many important aspects of the problem thoroughly and in an inexpensive manner.

In this article, we deal with an area of mathematics known as *integral equations*. We define an equation as an integral equation when the unknown quantity, specifically, the quantity to be determined, is under an integral sign. Integral equations are usually formulated when it is required to obtain the driving mechanism (input) of a physical system, given the description of the system along with the response function (output). For electrical engineers, the physical system may be an electrical circuit, an electrical machine, or, sometimes, a complex structure such as a fighter aircraft whose electromagnetic signature is the quantity of interest. Similarly, in many situations in electrical engineering, the response function may, simply, be the voltage at some given terminals or the current flowing in a wire.

Several methods are used to solve integral equations [1] using complex mathematics. However, in many practical situations, these methods are inadequate and, quite often, we need to resort to numerical methods to solve these equations. In the following section, we formally introduce *integral equations* using simple mathematical language. We also introduce standard terminology to describe such equations and describe various types of integral equations. In Section 2, we describe a general numerical method, known as *method of moments*, to solve these equations. In Section 3, we present a new technique that makes the method of moments technique computationally more efficient along with a set of numerical results. Note that, although the topic of *integral equations* is really a mathematical subject, we develop the subject using examples from electrical engineering and, in fact, from electromagnetic theory. It must be clearly understood that this way of treatment of the subject does not necessarily preclude the application of the techniques discussed in this article into other areas of engineering.

1. INTEGRAL EQUATIONS

Mathematically speaking, an equation involving the integral of an unknown function of one or more variables is known as an *integral equation*. One of the most common integral equations encountered in electrical engineering is the *convolution integral* given by

$$\int X(\tau)H(t, \tau)d\tau = Y(t) \tag{1}$$

where we note that the response function $Y(t)$ and the system function $H(t, \tau)$ are known and we need to determine the input $X(\tau)$. Of course, if $X(\tau)$ and $H(t, \tau)$ are known and we need to determine $Y(t)$, then Eq. (1) simply represents a integral relationship that can be performed in a straight forward manner. We further note that $H(t, \tau)$ is also commonly known as *impulse response* if Eq. (1) represents the system response of a linear system. In general, in mathematics and in engineering literature, $H(t, \tau)$ is known as *Green's function* or the *kernel function*. We also acknowledge that, for some other physical systems, $Y(t)$ and $X(t)$ may represent the driving force and response functions, respectively.

Next, we note that Eq. (1) is known as *integral equation of first kind*. We also have another type of integral equation given by

$$C_1X(t) + C_2 \int X(\tau)H(t, \tau)d\tau = Y(t) \tag{2}$$

where C_1 and C_2 are constants.

In Eq. (2), we note that the unknown function $X(t)$ appears both inside and outside the integral sign. Such equation is known as the *integral equation of second kind*. Further, we also see in electrical engineering yet another type of integral equation given by

$$C_1 \int X(\tau)H(t, \tau)d\tau + C_2X(t) + C_3 \frac{dX(t)}{dt} = Y(t) \tag{3}$$

which is known as an *integrodifferential equation*.

It may be noted that for a limited number of kernel and response functions, in Eqs. (1)–(3), it is possible to obtain the solution using analytical methods. Several textbooks have been written to discuss the mathematical aspects of the integral equations from analytical point of view [2–4]. However, for a majority of practical problems, these equations can be solved using numerical methods only. Fortunately, in this day and age, we can obtain very accurate numerical solutions owing to the availability of fast digital computers. In the following section, we discuss a general numerical technique, popularly known as *method of moments*, to solve the integral equations (1)–(3).

2. METHOD-OF-MOMENTS SOLUTION

The method-of-moments (MoM) solution procedure was first applied to electromagnetic scattering problems by

Harrington [5]. Consider a linear operator equation given by

$$AX = Y \tag{4}$$

where A represent the integral operator, Y is the known excitation function, and X is the unknown response function to be determined. Now, let X be represented by a set of known functions, termed *basis functions* or *expansion functions* (p_1, p_2, p_3, \dots), in the domain of A as a linear combination:

$$X = \sum_{i=1}^N \alpha_i p_i \tag{5}$$

where the α_i terms are scalars to be determined. Substituting Eq. (5) into Eq. (4), and using the linearity of A , we have

$$\sum_{i=1}^N \alpha_i A p_i = Y \tag{6}$$

where the equality is usually approximate. Let (q_1, q_2, q_3, \dots) define a set of testing functions in the range of A . Now, multiplying Eq. (6) with each q_j and using the linearity property of the inner product, we obtain

$$\sum_{i=1}^N \alpha_i \langle q_j, A p_i \rangle = \langle q_j, Y \rangle \tag{7}$$

for $j = 1, 2, \dots, N$. The set of linear equations represented by Eq. (7) may be solved using simple matrix methods to obtain the unknown coefficients α_j .

The simplicity of the method lies in choosing the proper set of expansion and testing functions to solve the problem at hand. Further, the method provides a most accurate result if properly applied. However, for the integral equation operators, the method generates a dense matrix that may be expensive in terms of computer storage requirements when complex systems are involved. In the following subsections, we discuss the application of the method of moments to some commonly used integral equations in engineering and science.

2.1. Integral Equations without Derivatives

In this section, we develop simple numerical methods to solve integral equations (both first and second kind) applying the method of moments. Further, we restrict our treatment to integral equations with single independent variables (one-dimensional) only. The extension to multiple variables is straightforward and hence is not considered here. The numerical methods are general methods, and thus applicable to variety of practical problems.

Consider an integral equation given by

$$\int_{x'=-w}^w u(x')g(x, x')dx' = f(x) \quad x \in (-w, w) \tag{8}$$

Figure 1. Match points for the integral equation.

in which $u(x)$ is the unknown function to be determined. For the MoM analysis of such problems, we develop a numerical scheme known as the *collocation method*, *sub-domain method*, or *point-matching method*. For this procedure, we first divide the interval $-w$ to w into N equal segments of width Δ as shown in Fig. 1.

The segment centerpoints are given by

$$x_i = -w + (i - 1)\Delta + 0.5\Delta \quad i = 1, 2, \dots, N \quad (9)$$

Note that while defining Eq. (9), we have divided the interval $-w$ to w into equal segments, although this need not be the case in general.

The next step in the MoM solution procedure is to define a suitable set of basis and testing functions. Our research shows that, for this type of problem, namely, the integral equations with no derivatives, the most convenient and simple set of functions are pulse functions with unit amplitude as basis functions and Dirac delta distributions (functions) as testing functions. In the following, we formally define these functions, as shown in Fig. 2, given by

$$p_i(x) = \begin{cases} 1 & x_i - \frac{\Delta}{2} \leq x \leq x_i + \frac{\Delta}{2} \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

and

$$q_j(x) = \delta(x - x_j) \quad (11)$$

Here, we emphasize that Eqs. (10) and (11) are by no means the only set of functions used in practice. It is quite

Figure 2. Pulse function and delta function.

possible to define a completely different set of functions as long as these functions satisfy a certain set of conditions [6–8]. Further, it is also possible to carry out an entirely different scheme in which the expansion and testing functions are defined over the whole interval without ever dividing the solution region into subsections. Such numerical schemes are known as *entire-domain methods*. Entire domain methods are known to be mathematically unstable [5], which may be overcome by a suitable choice of testing and basis functions and/or a combination of sub-domain/entire-domain functions [9]. However, we will not present the numerical treatment with entire-domain functions in this work since the subject is still in research stage.

First, we shall consider the testing procedure. Here, we multiply the Eq. (8) by the testing function q_j and integrate over the whole interval to obtain a set of equations given by

$$\int_{x'=-w}^w u(x')g(x_j, x') dx' = f(x_j) \quad j = 1, 2, \dots, N. \quad (12)$$

Observe that, while evaluating Eq. (12), we made use of the well-known properties of the delta distribution (function). Also note that Eq. (12) is actually a set of N equations for each j and that x_j represents the value of the independent variable at the center of the j th subdomain. Further, observe that we are matching the LHS and RHS (left- and right-hand sides) of Eq. (12) at points x_j for $j = 1, 2, \dots, N$. Thus, these points are known also as *match points*.

Next we consider the expansion procedure. Using the basis functions defined in Eq. (10), the unknown quantity $u(x)$ may be written as

$$u(x) = \sum_{i=1}^N \alpha_i p_i \quad (13)$$

where the α terms represent the unknown scalar coefficients. Substituting Eq. (13) into Eq. (12), we have

$$\sum_{i=1}^N \alpha_i \int_{x'=x_i-\Delta/2}^{x_i+\Delta/2} g(x_j, x') dx' = f(x_j) \quad j = 1, 2, \dots, N. \quad (14)$$

Note that Eq. (14) may be written as a matrix equation, given by

$$[Z][I] = [V] \quad (15)$$

where

$$Z_{ji} = \int_{x'=x_i-\Delta/2}^{x_i+\Delta/2} g(x_j, x') dx' \quad (16)$$

$$V_j = f(x_j) \quad (17)$$

and the column vector $[I]$ contains unknown coefficients α . Except for certain special cases, the matrix $[Z]$ is a well-conditioned matrix, and hence the solution of Eq. (15) is

Figure 3. Infinite strip raised to 1 Volt potential.

straightforward. Also, the integrations involved in Eq. (16) may be performed either analytically or numerically depending on the exact nature of the kernel function.

Finally, the numerical method described so far is also known as the *pulse expansion* or *point-matching method*. In the following, we present an example problem based on the procedure described so far.

Example 1. Consider an infinitely long conducting strip of width of 0.1m located symmetrically at the origin as shown in Fig. 3. The strip is raised to a potential of 1V. Note that the reference point (i.e., $V=0$) is at $x = 1$ m. Calculate the charge distribution on the strip.

Solution: Following the basic principles of electrostatics, an integral equation may be developed, given by

$$\int_{x'=-0.05}^{0.05} q_s(x') \ln |x - x'| dx' = 2\pi\epsilon_0 \quad x \in (-0.05, 0.05) \quad (18)$$

where $\epsilon_0 = 8.854e - 12$ is the permittivity of the surrounding medium. Following the numerical procedures described so far, we obtain the elements of the $[Z]$ matrix given by

$$\begin{aligned} Z_{ji} &= \int_{x'=x_i-\Delta/2}^{x_i+\Delta/2} \ln |x_j - x'| dx' \\ &= \Delta - \frac{\Delta}{2} \ln \left| (x_j - x_i)^2 - \left(\frac{\Delta}{2}\right)^2 \right| \\ &\quad - (x_j - x_i) \ln \frac{|x_j - x_i + \Delta/2|}{|x_j - x_i - \Delta/2|} \end{aligned} \quad (19)$$

and the elements of the $[V]$ matrix are

$$V_j = 2\pi\epsilon_0 \quad (20)$$

In Fig. 4, we present the charge distribution for N equal to 10, 50, and 100 obtained by solving the integral equation (18).

Figure 4. Charge density distribution on the infinite strip.

2.2. Integral Equations With Derivatives

In this section, we develop simple numerical methods to solve integrodifferential equations, that is, integral equations with derivative operators, applying the method of moments. As before, we restrict our treatment to integral equations with a single independent variable (one-dimensional) only. The extension to multiple variables is straightforward and hence is not considered here. The numerical methods are general methods, and thus applicable to variety of practical problems.

We consider two cases in this section: (1) the first-order integrodifferential equation and (2) the second-order integrodifferential equation. Obviously, higher-order derivatives may be handled in a similar manner.

2.2.1. First-Order Integrodifferential Equation. Consider a first-order integrodifferential equation given by

$$\frac{\partial}{\partial x} \int_{x'=-w}^w u(x')g(x,x')dx' = f(x) \quad x \in (-w, w) \quad (21)$$

subject to

$$\int_{x=-w}^w u(x)dx = 0 \quad (22)$$

Equation (22) is also known as *constraining equation*. In variety of situations, constraining equation can be implicitly enforced by a proper choice of basis and/or testing functions. This necessitates a more elaborate construction of basis/testing functions that, although seeming to be complicated, result in an efficient numerical solution. It is

Figure 5. Match points for Integrodifferential equation.

quite easy to see that a straightforward application of the method discussed in the previous section, namely, pulse expansion and point-matching method, results in a $N \times N$ matrix. However, the application of the constraint equation adds one more column to the $[Z]$ matrix, thus making the problem an overdetermined system. Further, other numerical problems, such as stability and nonuniqueness, set in when MoM is applied blindly. Thus, we develop the following numerical procedure for this case.

As before, the interval $(-w, w)$ is divided into N equal segments. But for this case, the match points are labeled in the following way for mathematical convenience as shown in Fig. 5.

$$x_i = -w + i \times \Delta \quad i = 1, 2, \dots, N - 1 \quad (23)$$

In order to enforce the constraining equation (22), we let the basis function to overlap over two subdomains with positive unit height in the first subdomain and negative unit pulse in the second subdomain as shown in Fig. 6.

Thus, mathematically, we define the basis function as

$$p_i(x) = \begin{cases} 1 & x_{i-1} \leq x \leq x_i \\ -1 & x_i \leq x \leq x_{i+1} \\ 0 & \text{otherwise} \end{cases} \quad (24)$$

and express the unknown quantity $u(x)$ as

$$u(x) = \sum_{i=1}^{N-1} \alpha_i p_i \quad (25)$$

Note that, by defining basis functions as in Eq. (24), Eq. (22) is automatically satisfied, which can be proved as

$$\begin{aligned} \int_{x=-w}^w u(x) dx &= \sum_{i=1}^N \alpha_i \int p_i dx \\ &= \sum_{i=1}^N \alpha_i \left[\int_{x_{i-1}}^{x_i} dx - \int_{x_i}^{x_{i+1}} dx \right] \\ &= 0 \end{aligned} \quad (26)$$

Figure 6. Pulse doublet function.

The functions defined by Eq. (24) are known as *pulse doublet functions*.

Next, we define the testing procedure for this case. Note that we have one derivative on the integral sign. By simple mathematical manipulation, we transform the derivative operator onto the testing function q_j . Using a compact notation

$$\langle f, g \rangle = \int fg dx \quad (27)$$

we can write the integrodifferential equation (21) as

$$\left\langle \frac{\partial v}{\partial x}, q_j \right\rangle = \langle f(x), q_j \rangle \quad (28)$$

where

$$v(x) = \int_{x'=-w}^w u(x')g(x, x')dx' \quad (29)$$

Then, we have

$$\begin{aligned} \left\langle \frac{\partial v}{\partial x}, q_j \right\rangle &= \int \frac{\partial v}{\partial x} q_j dx \\ &= [q_j v] - \int \frac{\partial q_j}{\partial x} v dx \end{aligned} \quad (30)$$

The first term in the Eq. (30) can be set to zero if $q_j = 0$ at the ends of the subdomain.

Keeping this procedure in mind, we select the testing functions in such a way that when the derivative is transformed onto the testing function, the result must be a delta distribution (function). A unit pulse function, as shown in Fig. 7, has this property whose derivative happens to be two delta distributions on either end of the pulse.

Thus, for first-order integrodifferential equations, we choose the testing function q_j as

$$q_j(x) = \begin{cases} 1 & x_j - \frac{\Delta}{2} \leq x \leq x_j + \frac{\Delta}{2} \\ 0 & \text{otherwise} \end{cases} \quad (31)$$

The numerical procedure may be best illustrated by the following example.

Example 2. Consider an infinitely long conducting strip of width 1 m, as shown in Fig. 3, is immersed in a electrostatic field. Calculate the charge distribution on the strip.

Figure 7. Pulse-testing function.

Solution: Following the basic principles of electrostatics, and applying the electric field boundary condition on perfect conducting bodies, an integral equation may be developed, given by

$$\frac{\partial}{\partial x} \int_{x'=-w}^w q_s(x') \ln|x-x'| dx' = 2\pi\epsilon \mathbf{a}_x \cdot \mathbf{E}^i \quad x \in (-w, w) \quad (32)$$

subject to

$$\int_{x=-w}^w q_s(x) dx = 0 \quad (33)$$

where \mathbf{E}^i , q_s , and \mathbf{a}_x are the impressed electric field, charge density, and the x -directed unit vector, respectively. For the numerical solution, we divide the interval $(-w, w)$ into N subdomains of width Δ and label the match points as shown in Fig. 5. Note that when the interval is divided into N divisions, we actually have $N-1$ match points.

Defining the testing functions by Eq. (31), and carrying out the mathematical steps outlined in Eq. (30), we get

$$\int_{x'=-w}^w q_s(x') \ln\left|x_j + \frac{\Delta}{2} - x'\right| dx' - \int_{x'=-w}^w q_s(x') \ln\left|x_j - \frac{\Delta}{2} - x'\right| dx' = 2\pi\epsilon \Delta \mathbf{a}_x \cdot \mathbf{E}^i(x_j) \quad (34)$$

for $j = 1, 2, \dots, N-1$.

Next, we apply the expansion procedure. By selecting the basis functions as described in Eq. (25), the constraining equation (33) is automatically enforced. Thus, applying the method of moments procedure, we obtain $[Z][I] = [V]$, where

$$\begin{aligned} Z_{ji} = & \int_{x_{i-1}}^{x_i} \ln\left|x_j + \frac{\Delta}{2} - x'\right| dx' \\ & - \int_{x_i}^{x_{i+1}} \ln\left|x_j + \frac{\Delta}{2} - x'\right| dx' \\ & - \int_{x_{i-1}}^{x_i} \ln\left|x_j - \frac{\Delta}{2} - x'\right| dx' \\ & + \int_{x_i}^{x_{i+1}} \ln\left|x_j - \frac{\Delta}{2} - x'\right| dx' \end{aligned} \quad (35)$$

and

$$V_j = 2\pi\epsilon \Delta \mathbf{a}_x \cdot \mathbf{E}^i(x_j) \quad (36)$$

In Fig. 8, we present the charge distribution for N equal to 10, 50, and 100 obtained by solving the integrodifferential equation (32). Note that, in this procedure, the dimension of the system matrix is $N-1$.

2.2.2. Second-Order Integrodifferential Equation. In this section, we consider techniques for solving the integrodif-

Figure 8. Charge density distribution on the infinite strip immersed in electric field $\mathbf{E}^i = \mathbf{a}_x$.

ferential equation

$$\frac{\partial^2}{\partial x^2} \int_{x'=-w}^w u(x') g(x, x') dx' = f(x) \quad x \in (-w, w) \quad (37)$$

where the unknown function $u(x)$ must satisfy the boundary conditions $u(w) = u(-w) = 0$.

These types of integral equations usually appear in electromagnetic and acoustic scattering problems; the most common is the dipole antenna problem in antenna engineering. Further, the treatment of the second-order integrodifferential equation, coupled with the treatment of first-order derivatives, provides a solution procedure for handling higher-order derivatives.

We begin our analysis by re-writing the integrodifferential equation (37) in the following form:

$$\frac{\partial}{\partial x} \int_{x'=-w}^w u(x') \frac{\partial g(x, x')}{\partial x} dx' = f(x) \quad x \in (-w, w) \quad (38)$$

For almost all mathematical problems in engineering, there exists a definite relationship between $\partial g/\partial x$ and $\partial g/\partial x'$. In fact, for electromagnetic (EM) and acoustic scattering problems, we have $\partial g/\partial x = -(\partial g/\partial x')$. Using this relationship, we can write Eq. (38), at least for EM and acoustic problems, as

$$\frac{\partial}{\partial x} \int_{x'=-w}^w \frac{\partial u(x')}{\partial x'} g(x, x') dx' = f(x) \quad x \in (-w, w) \quad (39)$$

Now, we have an integrodifferential equation of first order that we already know how to handle. At first, we divide the interval $(-w, w)$ into N segments and label $N-1$ match points as shown in Fig. 5. The definition of testing functions and the testing procedure are identical to those of the first-order integrodifferential equation and hence need not be repeated again. However, we need to look more closely at the basis functions.

Note that, for the case of first-order integrodifferential equations, we defined the “pulse doublet” as the expansion function and obtained the solution for the unknown function. In the present case we can do the same thing, if we define the *antiderivative* of the pulse doublet as the expansion function. Following this logic, we define the basis functions for the solution of second order integrodifferential equation as

$$p_i(x) = \begin{cases} 1 - \frac{x_i - x}{\Delta} & x_{i-1} \leq x \leq x_i \\ 1 + \frac{x_i - x}{\Delta} & x_i \leq x \leq x_{i+1} \\ 0 & \text{otherwise} \end{cases} \quad (40)$$

The functions described in Eq. (40), and shown in Fig. 9, are popularly known as *triangle functions*, which are linear piecewise.

Thus, to solve the second-order integrodifferential equation, we employ triangle function expansion and pulse function testing. We describe the numerical procedure using the following example.

Example 3. Consider a finite-length straight wire with radius $a = 0.001\lambda$ and length $2h = 0.5\lambda$ illuminated by an electromagnetic plane wave (wavelength λ) as shown in Fig. 10. Calculate the current induced on the wire.

Solution: Since the radius a is very small compared to λ and h , we can use the thin-wire theory [10] to formulate the integrodifferential equation. Following the mathematical procedures described by Jones [11], we derive the following integral equation, given by

$$\begin{aligned} & \frac{\partial}{\partial z} \int_{z'=-h}^h \frac{\partial I(z')}{\partial z'} G(z-z') dz' \\ & + k^2 \int_{z'=-h}^h I(z') G(z-z') dz' \\ & = -j \frac{4\pi k}{\eta} E_z^i(z) \quad z \in (-h, h) \end{aligned} \quad (41)$$

Figure 9. Triangle basis function.

Figure 10. Straight wire illuminated by a plane wave.

where

$$G(z-z') = \frac{e^{-jkR}}{R} \quad (42)$$

and

$$R = \sqrt{(z-z')^2 + a^2} \quad (43)$$

In Eqs. (41)–(43), I is the unknown current induced on the wire, $E_z^i(z)$ is the z component of the incident plane wave, $k = 2\pi/\lambda$ is the wavenumber, and η is the wave impedance of the surrounding medium.

First, divide the wire region $(-h, h)$ into N equal segments, labeling $N-1$ match points as shown in Fig. 5. Next, for this problem, we choose the expansion functions p_i defined in Eq. (40) to express the unknown current I and the testing functions q_j defined in Eq. (31).

Thus, we have

$$I = \sum_{i=1}^{N-1} \alpha_i p_i \quad (44)$$

Next, we consider the testing procedure. By following the same procedures of the previous section on the first-order integrodifferential equation, the testing procedure yields

$$\begin{aligned} & \int_{z'=-h}^h \frac{\partial I(z')}{\partial z'} G\left(z_j + \frac{\Delta}{2} - z'\right) dz' \\ & - \int_{z'=-h}^h \frac{\partial I(z')}{\partial z'} G\left(z_j - \frac{\Delta}{2} - z'\right) dz' \\ & + \Delta k^2 \int_{z'=-h}^h I(z') G(z_j - z') dz' \\ & = -j \frac{4\pi k \Delta}{\eta} E_z^i(z_j) \end{aligned} \quad (45)$$

for $j = 1, 2, \dots, N-1$. Note that, in Eq. (45), the integrations on the second term and the right-hand side of the Eq. (41) are approximated by a simple one-point rule.

Substituting the expansion equation (44) into Eq. (45), we obtain the matrix equation $[(1/\Delta)[Z^a] + (k^2\Delta)[Z^b]] [I] = [V]$, where the matrix elements are:

$$Z_{ji}^a = \int_{z_{i-1}}^{z_i} G\left(z_j + \frac{\Delta}{2} - z'\right) dz' - \int_{z_i}^{z_{i+1}} G\left(z_j + \frac{\Delta}{2} - z'\right) dz' - \int_{z_{i-1}}^{z_i} G\left(z_j - \frac{\Delta}{2} - z'\right) dz' + \int_{z_i}^{z_{i+1}} G\left(z_j - \frac{\Delta}{2} - z'\right) dz' \tag{46}$$

$$Z_{ji}^b = \int_{z_{i-1}}^{z_i} \left\{1 - \frac{z_i - z}{\Delta}\right\} G(z_j - z') dz' + \int_{z_i}^{z_{i+1}} \left\{1 + \frac{z_i - z}{\Delta}\right\} G(z_j - z') dz' \tag{47}$$

and

$$v_j = -j \frac{4\pi k \Delta}{\eta} E_z^i(z_j) \tag{48}$$

The integrations involved in Eqs. (46) and (47) may be carried out using the methods discussed in [12].

In Fig. 11, we present the current induced on a half-wave dipole wire scatterer due to a unit-amplitude,

Figure 11. Current induced on the wire scatterer.

normally incident plane wave for N equal to 20 and 50 divisions obtained by using Eqs. (46)–(48).

2.3. Integral Equations with More Variables

In the previous subsection, we discussed numerical methods applying the method of moments to handle integral and integrodifferential equations with one independent variable. Extension to the multivariable case is straightforward and follows the same numerical procedures discussed so far. For example, for the two-variable case, that is, the xy plane, the solution region may be divided into square or rectangular cells, and one can construct the basis and testing functions using the methods discussed in the previous section [13]. For a more general situation, the solution region can be divided into triangular subdomains along with suitable basis and testing functions [14,15]. Efficient solutions have been obtained for very complex problems using these methods in electromagnetics and acoustics [16–19], and it is quite possible that these methods found applications in other areas of engineering. Finally, we discussed primarily only boundary-value problems in this work, but solutions have also been obtained for initial-value problems [20–28] using the same methods. An extensive application of method of moments to electromagnetic scattering problems may be obtained from Miller et al. [29].

3. SPARSE-MATRIX METHODS

One major problem with MoM is the generation of a dense matrix and for complex problems; the dimension of this matrix can be prohibitively large. Usually, for electromagnetic and acoustic scattering problems, it is necessary to divide the solution region into subdomains small enough to yield accurate results. By “small enough,” we mean about 200–300 subdomains per square wavelength. In usual practice, we may typically solve for several thousand unknowns for large, complex problems. This requirement quickly becomes expensive, in terms of computational resources, and may even become impossible to handle. Hence, we look for alternate schemes to reduce the computational resources by generating a sparse matrix instead of a full matrix.

The generation of a sparse matrix in the method of moment solution procedure may be achieved in one of two ways: (1) by defining a special set of basis functions to represent the unknown quantity or (2) by handling the influence of the kernel function in a novel way. The use of well-known wavelet-type basis functions to provide the required sparsity belong to the former category [30], and application of the fast multipole method (FMM) belongs to the latter category [31]. So far, the wavelet-type basis functions have been applied to integral equations with one variable only, and it remains to be seen how these functions can be utilized for two or more variable case. In contrast, in the FMM scheme, the matrix-vector product is carried out in a novel way, and this seem to work well for more complex problems. Unfortunately, the FMM is a complicated scheme, and any reasonable summary of the method is beyond the scope of the present article.

There is also yet another scheme, known as *impedance matrix localization* (IML) scheme, which achieves modest sparsity for simple problems [32]. Note that the kernel function is, in general, a decaying function with respect to the distance between the source and observation points. Thus, with increasing distances, the influence of a given source becomes negligible at a sufficiently distant observation point and may actually be set to zero. The IML scheme cleverly exploits this fact. However, there is a certain degree of arbitrariness in this scheme and seems to work for simple problems only.

A newer method, known as the *generalized sparse-matrix reduction* (GSMR), scheme has been proposed and seems to improve on the IML method. The basic concept utilized in the GSMR technique may be qualitatively illustrated as follows. Following similar procedures of the MoM, a moment matrix is also generated in the GSMR method. However, in contrast to the conventional moment method where interaction is computed from each and every cell on other cells, only the interaction from the self-cell and few neighboring cells is computed in the GSMR technique. In fact, for single-variable problems (wire scatterer and two-dimensional, infinite cylinders) only the self-term and two neighboring terms on either side of the self-cell are generated in this technique. This implies that the moment matrix for the GSMR technique is essentially sparse. Further, the effect of nonself-terms is taken into account by defining a set of linearly independent functions over the entire structure. In mathematical terms, for single variable problems, the procedure may be described as follows:

Let $[Z]$ represent the moment matrix for a given problem generated by using appropriate basis and weighting functions. Note that, for well-defined problems with proper choice of basis and testing functions, the moment matrix is well conditioned and diagonally strong. The j th row of the moment matrix may be written as

$$\sum_{i=1}^N Z_{j,i} I_i = V_j \quad (49)$$

where all the matrix elements $Z_{j,i}$ are nonzero. In the new GSMR technique, the j th row is modified as

$$\sum_{i=j-1}^{j+1} \alpha_{j,i} Z_{j,i} I_i = \Gamma_j V_j \quad (50)$$

where $\alpha_{j,j-1}$, $\alpha_{j,j}$, $\alpha_{j,j+1}$, and Γ_j are the unknown coefficients and the remaining terms in the row are set to zero. Further, dividing by $Z_{j,j}$, Eq. (50) may be rewritten as

$$\sum_{i=j-1}^{j+1} \beta_{j,i} I_i = \gamma_j V_j \quad (51)$$

which may be expressed, using the matrix notation, as

$$[\beta][I] = [V] \quad (52)$$

where $[\beta]$ is a sparse matrix with, at most, three nonzero elements per row.

On a close examination of Eq. (52), it is obvious that one needs to reconstruct the $[\beta]$ matrix. This task may be accomplished by first setting $\gamma_j = 1$ for $j = 1, \dots, N$ in Eq. (51).

Next, define three linearly independent functions, $I^{(1)}$, $I^{(2)}$, and $I^{(3)}$, over the entire domain of the problem. These functions may be regarded as source distributions. For the examples we discuss below, these functions are assumed to be a constant, $\cos(kl)$ and $\sin(kl)$, where $k = (2\pi/\lambda)$ is the wavenumber and l is the parameter measured along the length of the independent variable in the integral equation.

The next step in the GSMR technique is to compute the corresponding response functions, $V^{(1)}$, $V^{(2)}$, and $V^{(3)}$. This task may be easily accomplished by using the assumed source distributions $I^{(1)}$, $I^{(2)}$, and $I^{(3)}$, and utilizing Green's function for the problem.

Once we have $I^{(1)}$, $I^{(2)}$, $I^{(3)}$, $V^{(1)}$, $V^{(2)}$, and $V^{(3)}$, we may construct the $[\beta]$ matrix as follows:

- For any j , sample $I^{(1)}$, $I^{(2)}$, and $I^{(3)}$ at locations $j-1$, j , and $j+1$, $V^{(1)}$, $V^{(2)}$, and $V^{(3)}$ at location j , and write the following system of equations:

$$\begin{aligned} \beta_{j,j-1} I_{j-1}^{(1)} + \beta_{j,j} I_j^{(1)} + \beta_{j,j+1} I_{j+1}^{(1)} &= V_j^{(1)} \\ \beta_{j,j-1} I_{j-1}^{(2)} + \beta_{j,j} I_j^{(2)} + \beta_{j,j+1} I_{j+1}^{(2)} &= V_j^{(2)} \\ \beta_{j,j-1} I_{j-1}^{(3)} + \beta_{j,j} I_j^{(3)} + \beta_{j,j+1} I_{j+1}^{(3)} &= V_j^{(3)} \end{aligned} \quad (53)$$

- Solve Eq. (54) to obtain $\beta_{j,j-1}$, $\beta_{j,j}$, and $\beta_{j,j+1}$ and store in the j th row of the $[\beta]$ matrix.
- Repeat the previous two steps for all values of j .

Further, note that for $j=1$ and $j=N$, we select $\beta_{1,N}$, $\beta_{1,1}$, and $\beta_{1,2}$, and $\beta_{N,N-1}$, $\beta_{N,N}$, and $\beta_{N,1}$, respectively.

Once all the coefficients for each row are computed, we have successfully generated the new matrix representation for the integral equation. Finally, Eq. (52) may be solved efficiently using iterative methods such as the conjugate gradient method [33] or the GMRES [generalized minimal residual (algorithm)] method [34] since we are dealing with sparse matrices.

Example 4. Consider a 10λ straight wire, with 0.001λ radius, illuminated by a normally incident plane wave. The matrix sizes for the MoM and GSMR method are 149×149 and 149×3 , respectively. The results are shown in Fig. 12, and the comparison is excellent.

Example 5. Consider the case of a circular loop located in the $z=0$ plane with center at the origin. The loop is illuminated by an x -polarized plane wave traveling along the z axis. Figure 13 shows the results for $ka=150$, where k and a are the wavenumber and the radius of the loop, respectively. The matrix sizes for the MoM and the GSMR technique are 1800×1800 and 1800×3 , respectively. It is evident from the figure that the results compare very well

Figure 12. Current induced on the 10λ wire scatterer.

with each other. This example clearly illustrates the applicability of the GSMR method for truly large bodies.

Example 6. Finally, we present the case of an infinitely long, conducting strip illuminated by a transverse magnetic (TM) incident electromagnetic plane wave. The derivation of the governing integral equation for this problem may be found in the text by Harrington [5]. Figure 14 shows the current density induced on a 150λ bent strip

Figure 13. Current induced on the circular loop.

Figure 14. Current induced on the conducting bent strip by a TM incident plane wave. The cross section of the strip is shown in the inset.

obtained by applying MoM and GSMR techniques. The comparison between both methods is reasonably accurate for both cases as evident from the figure.

Finally, before closing the discussion on GSMR technique, the existence of $[\beta]$ matrix may be explained in the following way. It may be noted that the moment matrix generated in the conventional MoM solution procedure is a representation of the unique relationship that exists between the source and the response. This relationship is specified in mathematical terms via Green's function along with the boundary conditions. Further, this relationship holds for any source distribution and response function as long as the response function is derived utilizing Green's function satisfying the appropriate boundary conditions. Since the $[\beta]$ matrix is developed using this unique relationship, Eq. (52) must represent a discretized form of the operator equation. Further, it should be noted that, although the operator equation is unique, the matrix representation is *not necessarily* unique. This is quite obvious since different basis and testing functions result in a different matrix representation. Also, one can perform elementary row and column operations on the given system of equations and arrive at another representation of the same operator equation. However, as a word of caution, it may be noted that the GSMR technique is a recent concept and has been tested only on some simple problems. It is obvious that the procedure needs to be validated for more complex geometries. Presently, work is in progress to apply the GSMR technique to some of these cases.

INTEGRATED ANTENNA SYSTEMS

KYOHEI FUJIMOTO
University of Tsukuba
Japan

1. GENERAL

An antenna system is ordinarily designed independently from transmitter or receiver circuitry, to which the antenna is connected by a transmission line (Fig. 1a). Unlike such an ordinary antenna system, an *integrated antenna system* (IAS) incorporates components, either passive, active, or both, into the antenna structure (Fig. 1b) [1]. The term *integration* here implies unification of an antenna and device or circuitry so that the performance of the antenna system is determined by both the antenna and the integrated device or circuitry. By means of integration, one can expect either improvement or modification of the antenna characteristics, or enhancement of antenna performance due to the addition of functions introduced by the integration.

INTEGRATED ANTENNA SYSTEMS

KYOHEI FUJIMOTO
University of Tsukuba
Japan

1. GENERAL

An antenna system is ordinarily designed independently from transmitter or receiver circuitry, to which the antenna is connected by a transmission line (Fig. 1a). Unlike such an ordinary antenna system, an *integrated antenna system* (IAS) incorporates components, either passive, active, or both, into the antenna structure (Fig. 1b) [1]. The term *integration* here implies unification of an antenna and device or circuitry so that the performance of the antenna system is determined by both the antenna and the integrated device or circuitry. By means of integration, one can expect either improvement or modification of the antenna characteristics, or enhancement of antenna performance due to the addition of functions introduced by the integration.

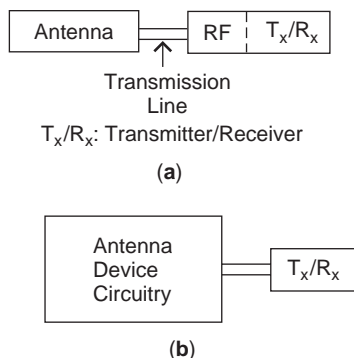

Figure 1. Conventional antenna system and integrated antenna systems.

When an active device or circuitry is integrated, IAS is referred to as *active IAS* (AIAS) and when a passive device or circuitry is integrated, as *passive IAS* (PIAS) (Fig. 2).

The terms *active antenna* (AA) [2,3] and *active integrated antenna* (AIA) [4] are also used interchangeably with IAS. AA has been used since the early 1960s as the most popular term, whereas active integrated antenna has been used mainly for planar AIAS, which is integrated in planar structures such as patches, microstrip substrates, and microwave integrated circuit (MIC) modules [4]. Another term, *integrated active antenna* (IAA) [5], has also been used for AIAS. In Ref. 5, active integration and passive integration are distinguished from each other and termed AIA and *passive integrated antenna* (PIA), respectively [6].

A number of features in the IAS are noted:

1. Compact and low loss structure may be realized by incorporating a circuitry directly into an antenna, thus dispensing with connecting cable between antenna and circuitry, which may be part of the RF front end of a transmitter or receiver.
2. Improvement of the antenna characteristics or enhancement of the antenna performance may be achieved as a consequence of the integration.
3. Realization of an antenna system, which can perform improved or modified functions due to the integrated device or circuitry in addition to the inherent antenna performance, is possible.
4. The inherent antenna characteristics such as linear, reciprocal, and time-invariable, may be changed to nonlinear, nonreciprocal, and time-variable, respectively. Thereby, creation of new antenna systems, which would never be achieved by the conventional concept, may become possible.

Figure 2. Integrated antenna system terminology.

Figure 3. Basic dipole IAS structures: (a) dipole IAS; (b) folded dipole IAS; (c) dipole antenna and the current distribution; (d) current distribution and radiation pattern of dipole IAS.

One can use any type of antenna in order to constitute an IAS. Linear elements such as monopole, dipole, and loop were used mainly in the early stages of IAS development. Use of planar antennas such as printed and microstrip antennas (MSAs) began in the 1980s and application of the microwave monolithic integrated circuit (MMIC) module to IAS technology appeared in the 1990s. Arrays were first used in the early 1960s; however, intensive use began in the mid-1990s when they were applied to power combiners and as phased arrays.

Devices used for integration are also full of variety; various types of solid-state devices such as diodes and transistors are applied to AIAS and impedance components (R , C , and L) and diodes, for PIAS.

The objective of IAS development in the early 1960s was mostly to achieve gain in small antennas and in turn reduction of antenna size by integration of an amplifier into an antenna. Other functional antennas such as frequency conversion, pattern control, and pattern synthesis were studied in addition to the amplifier antennas. Later, the IAS concept was applied to array structures, in which power combiners and phased arrays were particularly significant. The successful application of spatial power combiners in microwave (MW), millimeter-wave (MMW), and

Figure 4. Varactor-diode integrated patch antenna.

sub-millimeter-wave (SMMW) regions was attributed to the incorporation of IAS. IAS was ideally suited for power combiners, which require a number of distributed sources, for which small, compact, low-power-consumption and low-cost devices such as IAS is preferred. IAS is also advantageous since power deficits in solid-state oscillation were overcome by using a number of IAS devices as the distributed array sources, and thus high-efficiency radiation was accomplished. IAS was instrumental in developing a variety of power combiners and phased arrays that brought various types of functional antenna systems, which perform such functions as oscillation, multiplying, mixing, beamscanning, beamsteering, and frequency conversion. Other IASs that have been used in practice so far are receivers, transceivers, and sensors. Some typical integrated antenna systems are illustrated in the following figures.

Figure 3a shows some dipole antennas in which an integrated device is shown by a blackbox, which may be a part of the RF front end of the transmitter (Tx) or the receiver (Rx). As is shown in the figure, no transmission line and conventional matching are used between the dipole and the blackbox. By dispensing with the connection cable between the antenna and the RF front end, loss in the

transmission line can be avoided, noise performance may possibly be improved, input impedance may be varied to have wide frequency band, and the antenna structure can be made compact and/or planar. When an amplifier circuitry is used in the blackbox, IAS works as an amplifier antenna and the gain can be increased.

Figure 3b shows two types of folded-dipole IAS, in which a blackbox depicts an integrated device. The input impedance of the antenna can be varied by varying parameters in the blackbox, enabling one to obtain wideband characteristics. By adjusting the integrated circuit parameters, thus varying the phase of the current distributions on the dipole, radiation patterns can be varied. Unidirectional radiation pattern is an example.

Figure 3c depicts a dipole along with the current distribution and the radiation pattern. Figure 3d shows a dipole IAS, where two impedance components Z_1 and Z_2 are integrated, thereby producing asymmetric current distribution on the antenna element that produces variation in the radiation pattern. This type of IAS has a feature in that neither changing antenna dimensions nor moving the antenna element is necessary for beamshifting, beamscanning, or beamsteering.

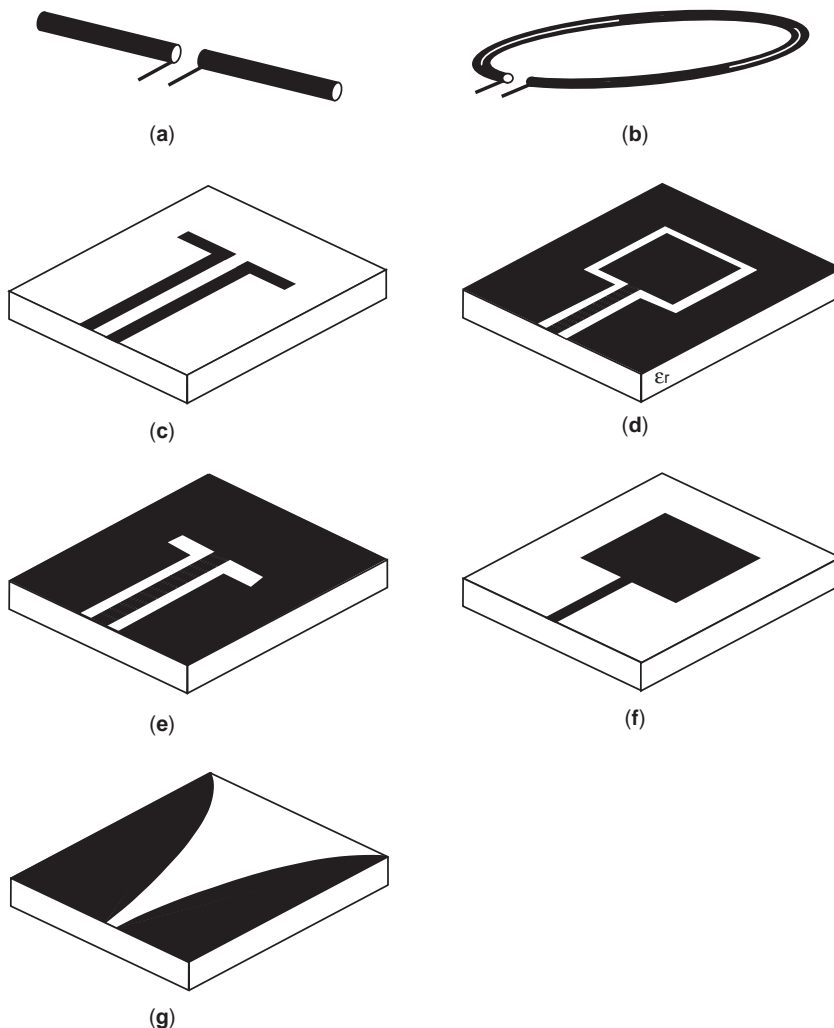

Figure 5. Various antenna structures as the base of IAS: (a) dipole; (b) loop; (c) planar dipole; (d) slot dipole; (e) slot loop; (f) microstrip patch; (g) tapered slot.

In Fig. 4, a patch antenna integrated with a varactor-diode is shown. The resonance frequency can be controlled by varying parameters of the varactor circuit with variation of the bias voltage to the circuit. Change in the resonance frequency results in change in the operating bandwidth and radiation pattern.

By integration of functions such as mixing, oscillation, and phase control, antennas performing such functions as well as radiation can be developed. By integrating an amplifier into a small antenna, the gain can be increased. This in turn suggests the possibility of producing a small antenna while keeping the gain unchanged.

Figure 5 illustrates typical antenna types used as the base of IAS. Practical examples are a bowtie mixer antenna (Fig. 6a), a unidirectional loop IAS (Fig. 6b), an oscillator patch antenna (Fig. 6c), a notch receiver IAS (Fig. 6d), a slot loop mixer IAS (Fig. 6e), a cross-slot IAS for polarization control (Fig. 6f), and a slot array IAS for pattern synthesis (Fig. 6g).

Early power combiners used open-cavity resonators such as that shown in Fig. 7a. However, since IAS was considered ideally suited for the distributed power sources in the power combiners, IAS application to the power combiners was widely current. Figure 7b depicts the basic structure of the power combiner with distributed power sources in an IAS array. Grid oscillators have also been applied to the power combiners as shown in Fig. 7c.

IAS is constituted on not only a simple planar structure but also layered, three-dimensional (3D), or multistage structures. Examples of various IAS structures are shown in Fig. 8.

Design concepts of integrated antenna systems differ from those of the conventional antenna systems. Conventionally, antennas have been designed almost independently from transmitter or receiver, to which the antenna is connected, whereas the IAS is designed en bloc; in the design the integrated devices are combined with the antenna structure, with the result that IAS performance

Figure 6. Practical examples of IAS: (a) bowtie mixer antenna; (b) unidirectional loop IAS; (c) oscillator patch antenna; (d) notch receiver IAS; (e) slot-loop mixer IAS; (f) cross-slot IAS; (g) slot array.

depends on both the antenna and the integrated devices, which may be a part of the transmitter or the receiver.

When IAS is designed, one should ideally have the appropriate knowledge and techniques that are associated with all IAS components: antennas, devices, circuitry, and systems. However, experts in some fields might not be versed in what is outside their own fields. In such cases, cooperative efforts of antenna engineers with engineers outside their fields and vice versa should be necessary.

Although both active and passive integration can be implemented, the active integration may have higher potential for application than passive integration because it may flexibly vary or modify antenna performance so that a variety of functional antenna systems can more easily be realized.

Initial work on IAS began in 1960. Early-stage IAS involved mainly active antennas (AAs), in which transistors and tunnel diodes (Esaki diodes) were used as the integrated devices. Most of that AA effort was focused on increasing the gain in small antennas by integrating the amplifier and in turn realizing small antennas. Other attempts to achieve wideband antennas, frequency conversion antenna, radiation pattern synthesis, and pattern control by electronic means, and so forth, were made from the early 1960s through the mid-1970s.

The concept of IAS, including both passive and active integration in order to implement functions such as beam-shaping and control into an antenna system and performing pattern synthesis, was discussed in 1970. Until the mid-1970s, height reduction of antennas or making an antenna smaller by incorporating active integration was still a major subject; however, pattern shaping, beamsteering, and synthesis using both active and passive integra-

tion have gained ground. In the late 1970s, use of patch antennas, instead of linear elements, for IAS began.

Beginning in the 1980s, IAS has made remarkable progress along with progress in solid-state devices in high-frequency regions, especially microwave (MW) and millimeter-wave (MMW) regions. Up to the early 1980s, there was a limitation in the availability of solid-state devices that could perform with low noise and high power capability in MW and MMW regions. Application of IAS shifted to arrays and promoted development of the power combining technique, in which distributed-array sources using IAS were employed. With the use of a number of IAS sources in the power combiners, efficient radiation was accomplished, as the power deficiency of solid-state devices was overcome. IAS was instrumental in advancing the power combiners. Integrated circuit (IC) structure was well suited as the base of IAS, and MMIC structure was also used to compose IAS in a planar, compact, low-loss, and low-power-consumption structure. These IASs, of two-dimensional (2D) or three-dimensional (3D) structure, had accelerated development of novel small, compact, planar, and yet sophisticated functional IAS, including power combiners.

2. TERMINOLOGY

The “active antenna” (AA) [2,3] has been used to express active IAS (AIAS) since the early 1960s. In early days of IAS, AA was simply considered as an antenna in which the power source or head amplifier was closely associated with the radiating or receiving element. With the advancements of IAS technology, this sort of narrow understanding has gradually disappeared. Two other terms are used

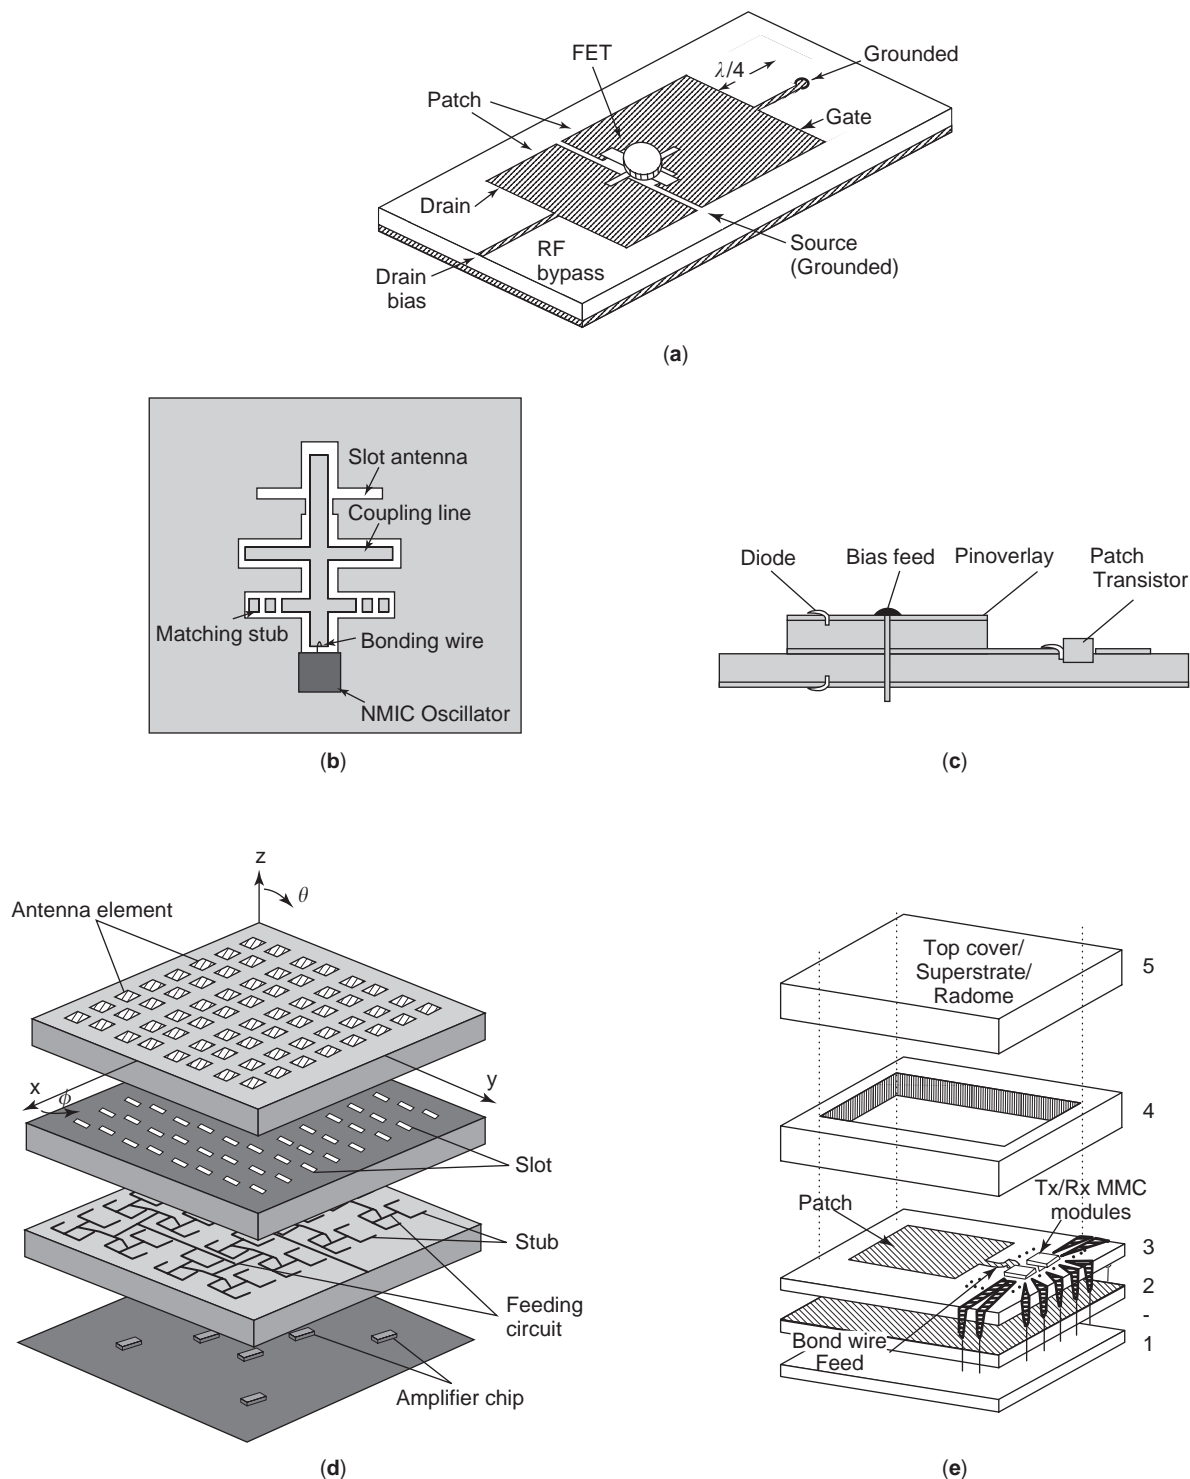

Figure 8. IAS structures: (a) planar structure; (b) MMIC structure; (c) double-layered structure; (d) packaged structure; (e) multistage structure. ((a) from Refs. 5 and 48 with permission from Wiley and IEE; (b) from Ref. 113 with permission from Wiley and IEICE; (d) from Ref. 12 with permission from IEICE; and (e) from Ref. 82 with permission from IEICE, respectively.)

interchangeably with AA: active integrated antennas (AIAs) [4] and integrated active antennas (IAAs) [5]. Both AIA and IAA should be understood to mean AIAS; however, AIA is mainly taken for planar IAS or printed or MIC-based IAS [4]. The term IAA is seldom used by itself,

but with a prefix, in expressions such as diode integrated active antenna and transistor integrated active antenna [5]. For a time “loading” was used instead of “integration”; for example, diode-loaded active antenna. Navarro and Chang [5] define IAS by differentiating active integration

space domain defines relationships between the EM fields E and H and the current distributions J on the antenna system. These relationships are expressed as

$$E = L [J] \tag{1}$$

and

$$J = L^{-1}[E] \tag{2}$$

where L is the operator and L^{-1} is the inverse operator; the overhead bar denotes a vector quantity, and $[]$ denotes matrix.

The immittance domain defines the relationships between the current distributions J and the circuit parameters V and I . These are expressed by using either the impedance matrix $[Z]$ or the admittance matrix $[Y]$ as

$$[V] = [Z][I] \tag{3}$$

or

$$[I] = [Y][V] \tag{4}$$

where the parameters are treated as scalar quantities. This domain is essentially linear, reciprocal, and time-invariable. By integrating devices, either passive, active, or both, into an antenna system, the parameters in the immittance domain are varied, and thus so are the currents J . As a result, the antenna performance is modified, or a new function is implemented into the antenna system.

When an active device is integrated, the immittance domain becomes active in nature, and so does the IAS. If the integrated device is nonlinear, or time-variable, the immittance domain and thus the IAS also become nonlinear or time-variable (Fig. 11). This is one of the most important concepts of the IAS; that is, the fundamental nature of the antenna system may be changed as a consequence of integration, in by which creation of a new antenna system unachievable by conventional antenna technology may become possible.

When functional devices or circuits such as amplifier, oscillator, and mixer, are integrated, the immittance domain and thus an antenna will perform such functions in addition to the performances as a radiator. With addition of the amplifying function, for example, antenna gain can be increased. Increase in the antenna gain without change in the antenna size in turn may be used to decrease the antenna size while keeping the antenna gain unchanged. The bandwidth of a small antenna may be increased by means of integration that can transform the antenna impedance to satisfy the matching requirement for the wide frequency band. Antenna structures having conjugate, complementary, and dual modes may be created by

Figure 11. Physical nature of an antenna.

Figure 12. Synchronization methods: (a) open cavity; (b) external source; (c) external coupling; (d) mutual coupling; (e) rectifier-enhanced coupling. (From Ref. 5 with permission from Wiley.)

integrating either active or passive devices into an antenna system.

An antenna into which an oscillator is integrated, for example, may become a high efficiency transmitting antenna or oscillating antenna, which is useful for application not only to a transmitter but also for power combining

Figure 13. Integration structures of IAS: (a) antenna and circuit in series structure; (b) circuit into antenna structure; (c) antenna into circuit structure (AIA).

and pattern control, beamshaping and so forth, when it is arranged in an array structure. Close implementation of an oscillator into an antenna system reduces the loss in the cable or feedline, which connects the antenna to the transmitter, and thus the efficiency degradation can be mitigated. Integration of mixing function, as another example, will create a mixer antenna, a direct-conversion antenna-receiver system, in which frequency is converted from radiofrequency to the baseband. This direct-conversion antenna-receiver system is useful for small, compact, mobile terminals.

A distinction of IAS from an ordinary antenna system can be clearly recognized in the variation of current distributions on the antenna system due to the integration that will lead to change in the antenna characteristics

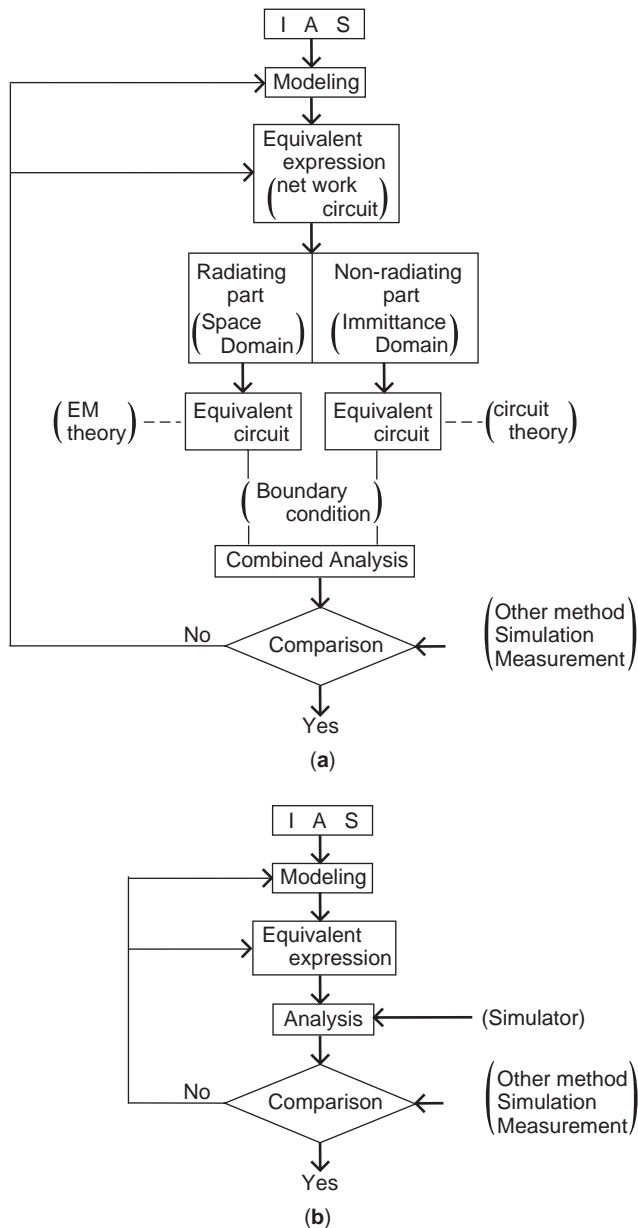

Figure 14. IAS analysis/design procedure for (a) IAS and (b) simple IAS.

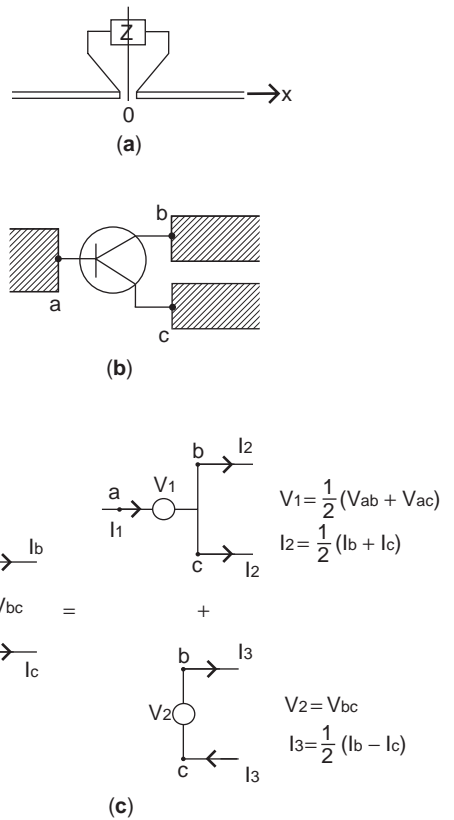

Figure 15. Treatment of integration as loading.

or performance. In general, antenna performance is determined by factors such as the antenna structure, dimensions, and feeding method. When an antenna characteristic—for instance, the impedance—must be changed in order to obtain an appropriate matching condition for a certain bandwidth, the conventional method is to design antenna configuration, dimensions, and so on to accomplish the desired bandwidth. When beamscanning is required, a sharp beam antenna is generally rotated. On the contrary, the antenna impedance can be varied by integrating some components into the antenna structure. This integration attributes the change in impedance to the variation in current distributions in the antenna structure (Fig. 9). In a similar way, radiation patterns can be varied by means of integration, causing variation in current distributions, in turn producing variation in radiation patterns. An example has been shown in Fig. 3d, where current distribution on an antenna element is changed by integration of a device, resulting in shifting of the beam direction. An essential concept of IAS is to vary current distributions on the antenna system by integration so that the desired antenna characteristics or performance levels will be achieved.

In AIA here, which is generally constituted on a MIC substrate, integration is not the main purpose for varying the current distributions on the antenna structure, but rather for implementing MIC functions into either an antenna or vice versa (antenna functions into MIC). Nevertheless, current distributions on the antenna element would in most cases be varied as a result of integration

Figure 16. Dipole antenna integrated with a transistor (DAT).

because of interaction between the antenna and the circuitry or vice versa, which is caused by electromagnetic (EM) coupling between the antenna and the circuitry, due to their close physical proximity. In turn, in some areas on the circuitry, radiation currents might be induced as a result of the EM coupling. These components, which are normally nonradiating, then act as a part of the radiator and assist to either enhance or reduce the radiation. These interactions may result in either modification or degradation of the circuit functions and the radiation performance as well. In designing IAS, very careful considerations of these interactions is necessary.

5. A BRIEF HISTORY

There is a view that the antenna used in Hertz' first experiment in 1888 to verify the existence of EM waves was a type of IAS. The Hertz antenna [8] was a loop that was directly combined with an induction coil to produce a high potential at the loop terminals with the resonance condition. Hence the loop was classified as a type of IAS.

Another antenna, a monopole antenna [9] introduced in 1928, is also considered to be a type of IAS. In this

antenna, an amplifier circuit is directly connected to the antenna terminals so that the antenna is in resonance condition and radiates efficiently.

Although these antennas seem to have IAS characteristics, they were not intentionally designed as IAS. The substantial work on the IAS started in early 1960 with the active IAS. Some initial work had been done by Frost and Pedinof. Frost developed an active cylindrical dipole [10], in which a parametric diode was integrated, and discussed the parametric amplification and radiation pattern control by means of parametric excitation to the dipole antenna. In his antenna, a tunnel diode was integrated into a slot antenna, and some transmission gain was reported [11].

The most notable work was done by researchers at Technische Hochschule Munchen (THM), Germany, and the Ohio State University (OSU; USA) from early 1960. At THM, Lindenmeier, Landstorfer, Flachenecker, and their colleagues, under the direction of Prof. Meinke worked mostly on small antennas by integrating a diode or a transistor into an antenna structure [2,12-14]. Later, Landstorfer discussed noise and bandwidth limitation of AA in MW regions [15], and Lindenmeier extended his work to include improvement of receiver performance by using AA [16].

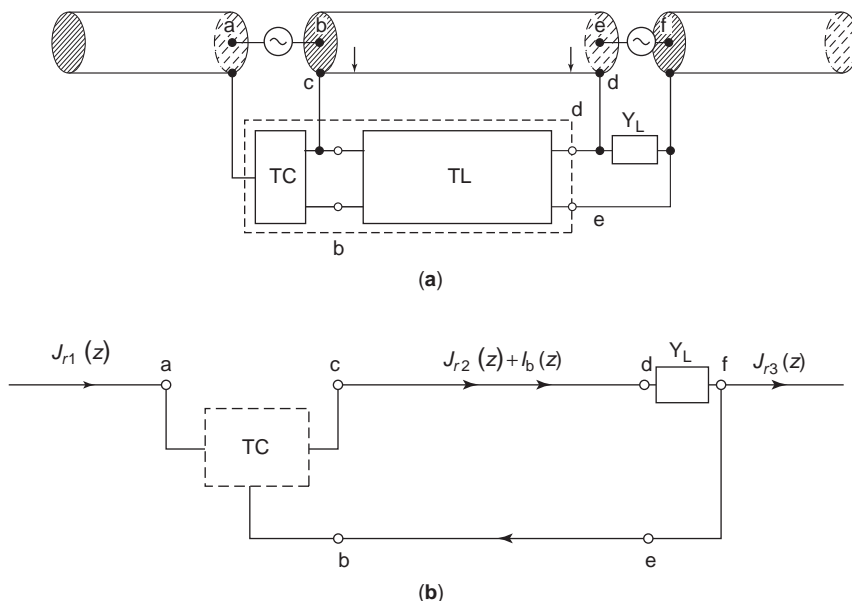

Figure 17. Equivalent expressions of DAT: (a) equivalent model of DAT; (b) equivalent circuit of DAT. (From Refs. 89a and 89b with permission from Research Studies Press and IEICE, respectively.)

Figure 18. Equivalent-circuit expressions of DAT: (a) radiating part (space domain); (b) nonradiating part (immittance domain); (c) radiation patterns (calculated result). (From Ref. 89a with permission from Research Studies Press.)

Meanwhile, researchers at OSU and Copeland, Robertson, and their colleagues under Prof. Walter did pioneering work on various types of AAs with functions such as amplification and mixing, and wideband characteristics [17,18]. They demonstrated several AAs, one of which is referred to as an *antennafer*, where the amplifier function is integrated with an antenna, and another, referred to as an *antennaverter*, where the converter function is integrated. In these IAS designs, tunnel diode (or Esaki diode) and transistors were used as the active devices, while dipole, traveling-wave structure, and conical-spiral configurations were used as the antenna elements. One of their colleagues, Fujimoto, had shown extensive treatment of Esaki diode integrated dipoles [19,20]. More significant work done at OSU was on antenna synthesis by using an antennafer array, which was

Figure 19. Multiport expression of a patch IAS.

demonstrated by Copeland and Robertson both theoretically and experimentally [21].

In an early stage of IAS research and development, integration of an amplifier into an antenna seemed to be main issue, because gain increase in small antennas was taken as the most interesting subject. By integrating an amplifier into the antenna structure, the loss observed between antenna terminals and RF circuitry was compensated by the amplifier gain. This results in increasing the gain of an antenna and also improves the radiation efficiency. However, there was a noise problem at that time in solid-state devices in high-frequency regions that had degraded the SNR (signal-to-noise ratio) performance of IAS, although the output signal power was increased because of the amplifier gain. Thus there were some arguments on

Figure 20. Equivalent expression of edge parameters. (From Ref. 91 with permission from Wiley.)

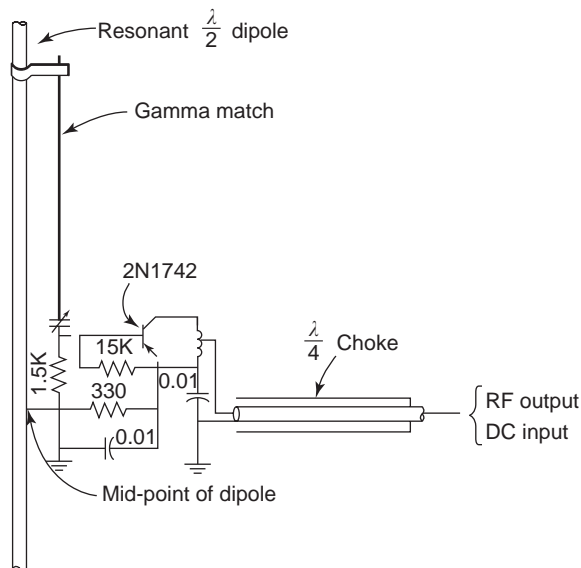

Figure 21. Antennafier (variable gain). (From Ref. 21 with permission from IEEE.)

the significance of AA with the rather narrow understanding that AA was merely an amplifier antenna.

In 1970, treatment of the IAS was discussed [1], clarifying the concept of IAS to extend inclusion of passive integration as well as active integration so that various new antenna systems could be realized as the consequence of either passive or active integration.

From late 1960s to the mid-1970s, numerous studies applying either passive or active integration to modify antenna performance were undertaken to achieve beam-shifting [22], a unidirectional pattern [23], beam control [24], and wideband performance [25]. Antennas with a variety of configurations such as loop [26], dipole [27], monopole [28], inverted L [29], ferrite coil [30], and dipole array [31] were used as the base of the IAS. Meanwhile, the small antenna, to which the IAS concept was applied, was still the main subject of research until the late 1970s. Maclean and Ramsdale analyzed performance of the active loop dipole antenna for both transmitting and receiving [27]. They also worked on the receiving dipole for height reduction [32] and SNR performance [33]. Daniel et al. discussed the wideband performance of a transistor-loaded folded dipole [25]. They also treated mutual coupling in an array using passive/active dipoles [34] and showed its reduction in superdirective arrays [35]. Anderson worked on an array that used transistor-loaded dipoles [36] and discussed the reduction of frequency dependence in an array [37].

Other examples of transistor-integrated small antenna are an indoor TV receiving antenna [38] and an inverted-L antenna for a portable receiver [29]. These active antennas were commercialized and used in practice. One more interesting antenna is a parametric excitation ferrite antenna [30], which achieved 10 dB excess *S/N* gain over a ferrite antenna of the same size. It should be noted that this is a really “active” antenna, as the ferrite element itself as a radiator is made active. In general AIAS function,

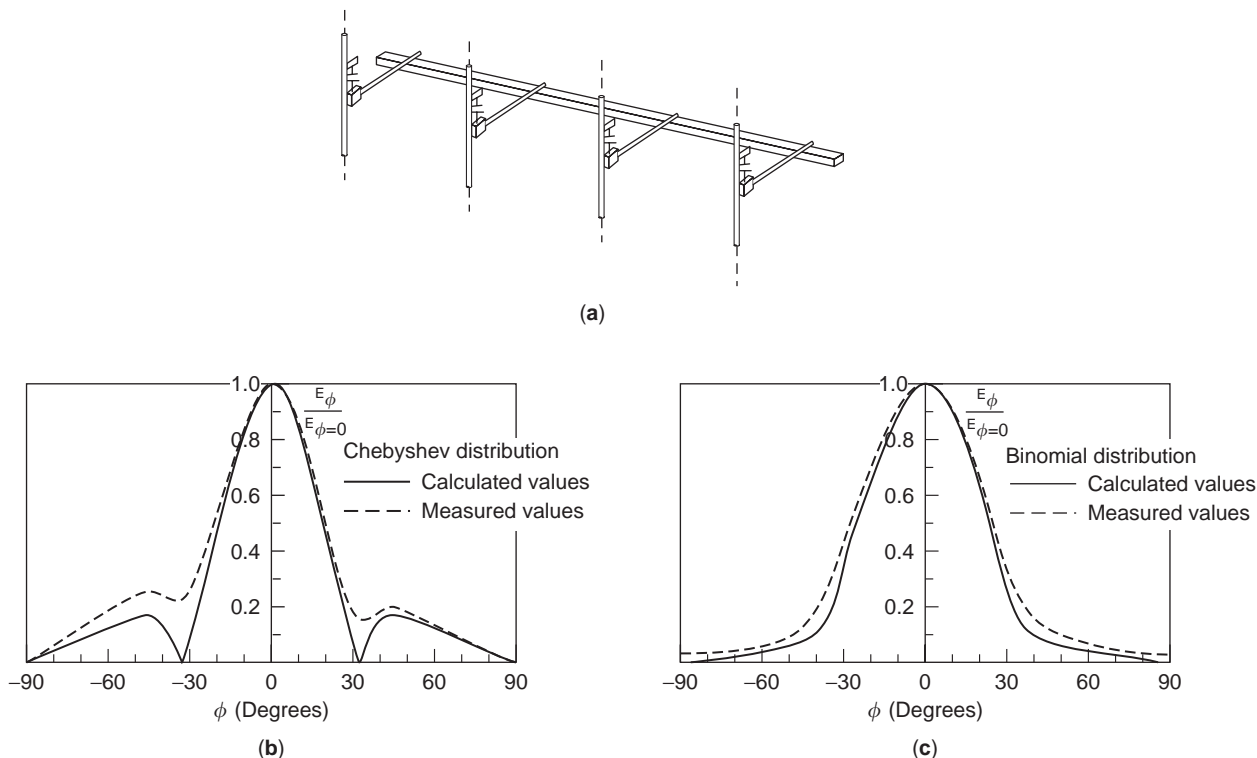

Figure 22. Pattern synthesis with antennafier array: (a) a four-element variable-gain antennafier array; (b) synthesized 15-dB Chebyshev pattern; (c) synthesized binomial pattern. (From Ref. 21 with permission from IEEE.)

the radiator itself is inherently passive, even though it is called as an “active antenna.”

Since the early 1980s, progress in IAS was accelerated by the availability of solid-state devices at higher frequency regions and also by progress in antenna technology. A planar IAS first appeared in 1980, replacing the linear IAS. This was an AA embedded on a microstrip antenna (MSA) in which a barrier injection transit time (BARITT) diode was integrated [39]. Solid-state devices used in those days included the BARITT diode [40], the Gunn diode [41], the impact ionization avalanche transit-time (IMPATT) diode [42], and the field-effect transistor (FET) [43]. These devices gradually became available after the mid-1980s.

Methods of integration in IAS have evolved with the use of integrated circuit (IC) structure and further evolved to the hybrid IC. Later, the microwave monolithic integrated circuit (MMIC) became available. The MMIC technique brought further sophistication in the functional IAS that was eventually embedded in two-dimensional (2D) or 3D MMICs [44].

The trend of using a single IAS shifted to an IAS array in the mid-1980s. In one particular array, reactance components were integrated and pattern synthesis was accomplished [45]. Applications of IAS to power combining and phased array were the main focuses of R&D. The power combining was first proposed by Mink [46], who analyzed the possibility of using arrays of millimeter-wave devices in open resonators for power combining. The spatial power combiners use distributed sources, which radiate power freely in space. These sources are synchronized by means of mutual coupling, an external circuit network, an extra source, or an open cavity. When an open cavity is used, array sources are synchronized through the

open-resonator mode. Hence this technology is called the *quasioptical technique* because of its similarity to Fabry–Perot laser applications in optical frequency.

Young and Stephan applied the quasioptical technique to an array in which open-cavity resonator was replaced by distributed oscillator sources, and demonstrated a beamsteering array [47]. Active IAS was instrumental in the application of power combiners such as those capable of generating the power produced by the array of many solid-state devices and combined in free space, compensating the combination loss limitation and generating efficient radiation. Using IASs as individual sources of array elements, the power deficiency due to inherent low-power solid-state devices in MW and MMW regions was overcome, as the power was enhanced by combining the individual powers of sources in space. The injection locking and phase-locked-loop (PLL) techniques were applied to synchronous operation of free-running oscillators in arrays. Typical phase locking methods are shown schematically in Fig. 12, illustrating

Figure 24. Folded-dipole IAS: (a) antenna integrated with a transistor circuit; (b) frequency characteristics. (From Ref. 25 with permission from IEEE.)

the open-cavity method (a), use of external locking reference source (b), use of mutual coupling using free-space waves (c), mutual coupling by means of surface waves (d), and use of a reflector to enhance coupling (e), thereby increasing output. Various types of power combiners were developed [48,49]. Functional antenna systems that perform beam control, beamsteering, beamscanning, and so forth, have also been achieved by applying IAS to phased arrays.

In power combining, the grid is used as alternative method to AIA. The grid consists of small, planar AA modules. Early grid arrays used diodes, which converted energy into DC power in a microwave wireless link [50]. This type of antenna system is called “rectifying antenna” or “rectenna.” Since the grid structure is suitable for quasi-optical power combining, it was applied to not only power combiners but also quasi-optical oscillators, amplifiers, mixers, multipliers, phase shifters, and switches.

Popovic and Rutledge introduced first a grid oscillator used in quasi-optical power combining [51]. In this oscillator, the Gunn diode was used; however, it was later replaced by the metal–semiconductor field–effect transistor (MESFET) in order to increase efficiency [52]. Since then, many investigators have worked on grid oscillators [53,54]. For instance, Popovic reported analyses of the planar grid oscillator [55], the 3D power combiner [56], the quasi-optical VCO [57], and the multielement grid oscillator [58]. Prior to development of these arrays, beam control by means of a single-dipole IAS had been accomplished [59,60].

From the mid-1980s to 1990, a variety of further advanced active integrated antenna (AIA) designs were developed. The AIA in this era attributed its progress to advances in array antenna technology in addition to MW and MMW solid-state devices and MMIC technologies [61,62]. In an AIA, the antenna is placed on the same substrate of MMIC so that the antenna and circuitry could be directly connected and losses ordinarily existing between them be reduced. In conjunction with the quasi-optical power combining technique, the IAS array could enhance system performance; specifically, power output or SNR could be increased, as a number of solid-state sources contribute to increase the power output and reduce the losses associated with circuitry and transmission lines. MMIC can serve as the base for such individual sources.

Examples of IAS in those days can be seen in amplifier antennas [63,64], mixers [65], beamsteering [66], beam-scanning [67], and other features in microwave antenna systems.

Itoh has investigated and demonstrated a number of IAS arrays [49]. He has shown some practical applications of IAS such as a transceiver [68] and transponder [69]. Chang and Navarro have also shown a variety of IAS designs [48]. Chang first demonstrated the FET integrated active patch [70] and worked on many spatial power combiners [71,72] and other IASs.

Meanwhile, Hall showed analysis and design of circuit antenna modules, in which the microwave or radiofrequency circuit is integrated with a radiator [73]. In addition, he described a detailed treatment of IAS, including

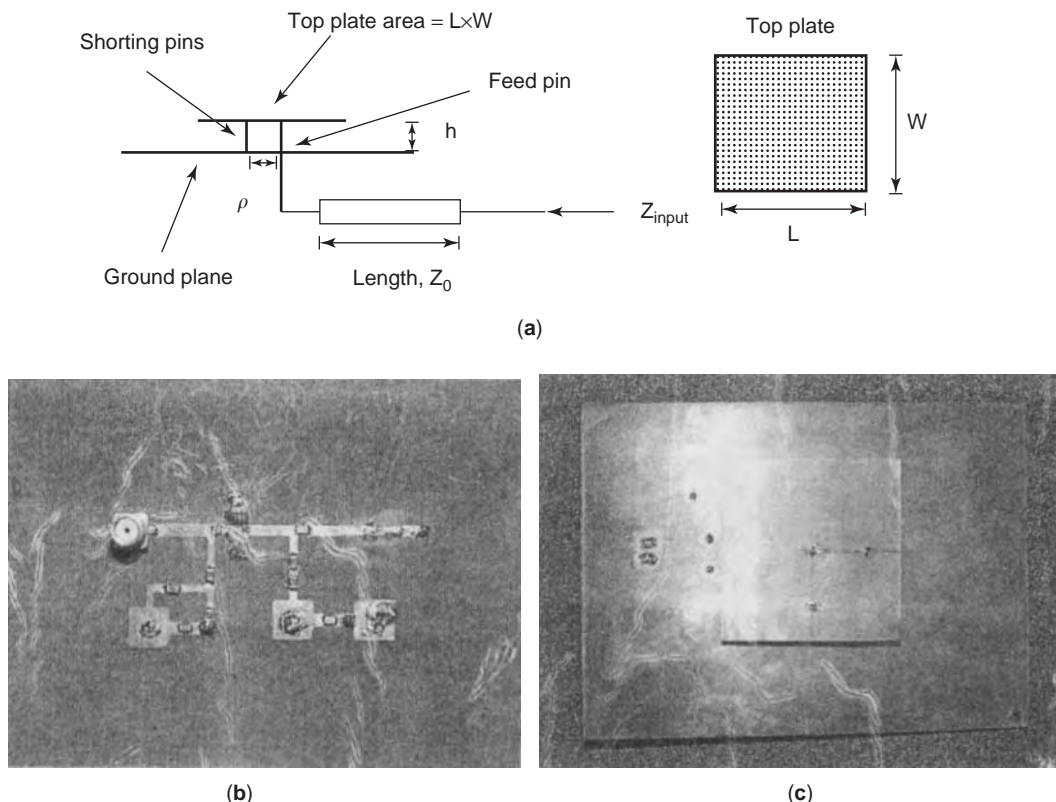

Figure 25. Active PIFA: (a) schematic expression; (b) amplifier circuit (side 1); (c) PIFA (side 2). (From Ref. 88 with permission from IEEE.)

the CAD process, the circuit-simulator based-method, and the multiport network method [73]. He had shown integration techniques with the aid of hybrid IC, MMIC, or other packaging methods. One example was an MMIC-type GaAs oscillating patch for 30 GHz [74] and another was a multilayer-type packaging IAS at 2.45 GHz (Fig. 8d) [75], which did not use MMIC structure, but was fabricated by a hybrid method, mounting a patch on the same substrate with circuits.

In the early stage of AIA arrays, diodes (i.e., two-terminal devices) were most commonly used; however, since diodes generally have disadvantages of low power, low DC-RF efficiency, and inconvenience in integrating into a circuitry, transistors (i.e., three-terminal devices) were gradually regarded as the preferable component to be integrated into IAS. Typical transistors widely used in those days were the HEMT (high-electron-mobility transistor) [76] and the HBT (heterojunction bipolar transistor) [77]. These advantages of transistors over two-terminal diodes include high gain, high DC-to-RF efficiency, low noise, and planar structure that is easily integrated in MMW regions.

HEMT has higher power efficiency and lower noise than does MESFET, while HBT can improve SNR and power efficiency as compared with other diodes such as the PIN diode.

In the current era of (2000 and beyond), much more advanced MMIC technology, higher-frequency solid-state devices, and refined precise processing of circuit structure have become accessible to develop further complicated and sophisticated IAS. Quasioptical and grid array techniques have also been utilized to produce a number of functional antennas. The current trend in IAS development has gradually shifted toward promoting practical applications rather than basic investigation. The direct-conversion antenna [78], circulator antenna [79], polarization-controllable MSA [80], mixer array [81], multistage amplifier array [82], retrodirective array [83], self-oscillating mixer [84], reflectarray [85], transceiver [86], RF tag [87], and active PIFA (planar inverted-F antenna) [88], are typical examples.

6. ANALYSIS AND DESIGN OF IAS

Because of the integrated structure of an antenna with circuitry, analysis of IAS requires special attention beyond that needed for treating the ordinary antenna system. The analysis method depends on the type of IAS; one is for the IAS, in which antenna and circuitry functions interact through the transmission structure connecting them (Fig. 13a), and another is for a different type of IAS (Fig. 13b), in which the circuitry is integrated within the antenna structure in such a way that the IC and the antenna cannot be clearly treated separately in terms of each individual function. The concepts are similar; however, there is yet another type of IAS (Fig. 13c) in which an antenna is integrated into a circuit structure; for example, a MIC structure is the base of the IAS (Fig. 8b). In this type of IAS, integration of antenna system functions is a major design objective (Fig. 9). Almost all AIA design types belong to this type of IAS.

In either case, the analysis must be done in steps starting with modeling of an IAS and representing it with a network or an equivalent circuit, if possible (Fig. 14a). Then the network model or the equivalent-circuit model is divided into two; one part relates to radiation (i.e., the space domain), and another part deals with nonradiation

Figure 26. Slot amplifier array: (a) exploded view; (b) cross-sectional view; (c) radiation patterns. (From Ref. 92 with permission from IEICE.)

(i.e., the immittance domain). This approach is advantageous in representing interaction of the antenna to the circuitry or vice versa, which is caused by the physical interconnection and the EM coupling between the antenna and the circuitry. Such interaction is usually difficult to treat since it cannot be observed explicitly. However, it can be included in the network or equivalent-circuit representation. Depending on how such an interaction is classified, it is included in either the radiation (space-domain) or nonradiation (immittance-domain) part.

EM theory is applied to the space domain in order to obtain the field parameters that correspond to antenna performances such as radiation patterns, and the circuit theory is applied to the immittance domain to identify the parameters that correspond to the antenna characteristics such as impedance and bandwidth. Analysis may be made by directly applying the simulator to the equivalent expression of IAS when the IAS has a simple structure (Fig. 14b).

EM formulation of the space domain depends on the type of antenna. Linear antennas can be treated with the conventional integral equations, by which field parameters are obtained using Green's function weighted with

currents on the antenna structure. The method of moments (MoM) is often used to solve this sort of field problem. Equivalent circuits of the integrated devices, consisting of either two or three terminals, are inserted in the antenna structure. Dimensions of the integrated devices are considered to be small enough to prevent interruption of antenna performance. When MoM is used, the equivalent-circuit components representing the integrated device are treated as a load at the point $z=0$, where the device Z is located (Fig. 15a). When a three-terminal device such as a transistor is used (Fig. 15b), the terminal where the device is located can be divided into two parts as shown in Fig. 15c. Then analysis can be made by using parameters shown in the figure.

Either small- or large-signal representation of the active device is used, depending on the signal level. If the high signal level is taken into consideration, in some cases nonlinear treatment of the system is required.

Planar antennas such as MSA and patch antennas can be represented by a model using the equivalent circuit, the transmission-line, and the cavity concept [73], which is not necessarily applicable to linear structures. The equivalent

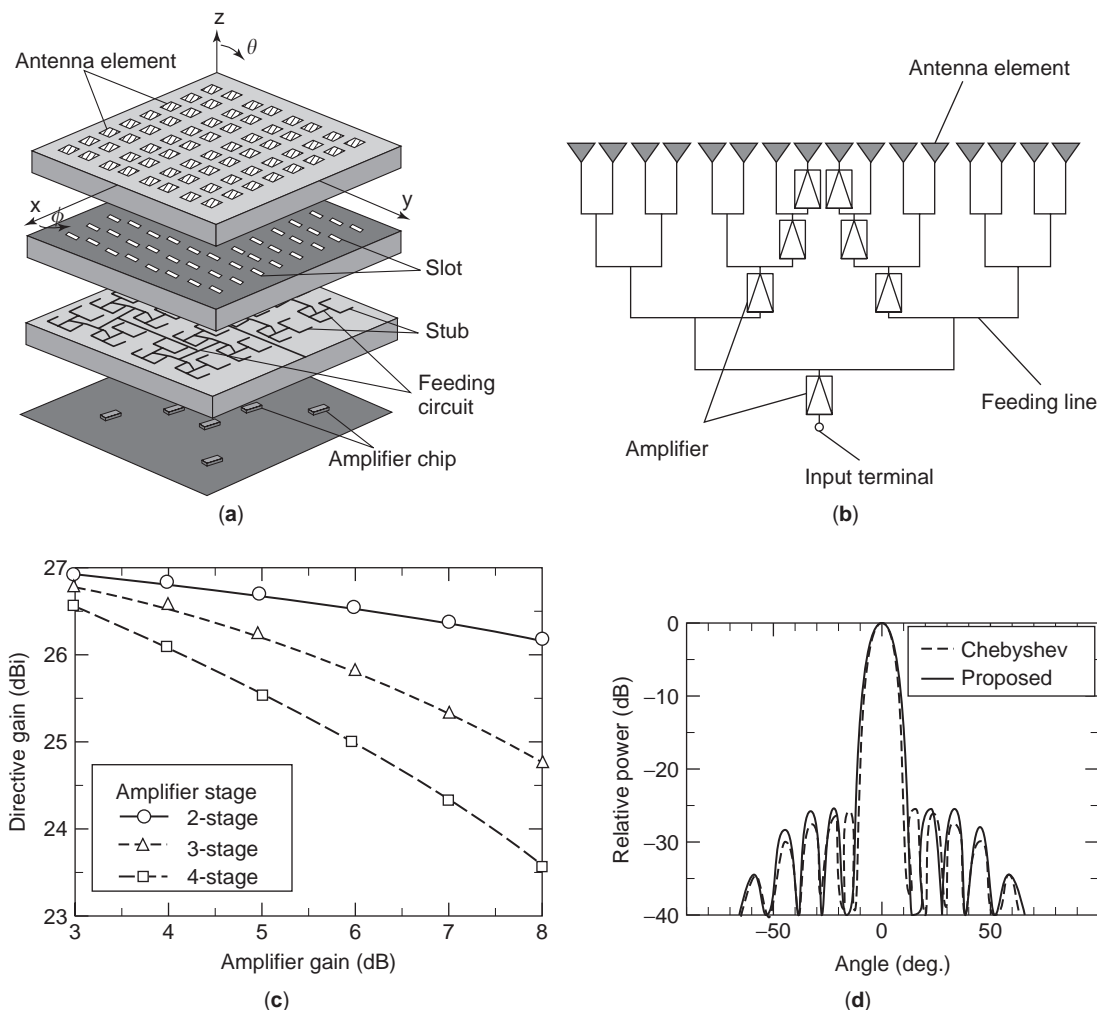

Figure 27. Multistage amplifier IAS: (a) antenna structure; (b) array structure with amplifier; (c) directive gain versus amplifier gain; (d) H -plane radiation patterns. (From Ref. 82 with permission from IEICE.)

Figure 28. Barrier injection transit time (BARITT) diode integrated oscillator patch antenna. (From Refs. 5 and 39 with permission from Wiley and IEEE, respectively.)

circuit of the planar antenna can be constructed by using parameters obtained by either measurement or simulation of the antenna. The circuitry or device to be integrated, which is also modeled with an equivalent circuit, is included in the equivalent antenna model without difficulty. The transmission-line model is convenient for designing patch antennas; however, assumption of uniform field distributions on the patch edge and attention to the direction of current flow on the patch are necessary. On the contrary, the cavity model is more convenient as compared with other modeling such as the equivalent circuit and transmission line. Since a cavity is a resonator and the field inside the cavity can be obtained by rather simple EM formulation and the field at the open edge is found as the source of radiation. Integration of circuitry or device is effected with the parallel combination of the impedance at the site of integration. This provides more accurate results regardless of the geometries of the patch structure as compared with the results obtained using other models.

For the immittance domain, the conventional circuit theory is applied generally to analyze IAS in the lower-frequency regions such as VHF and UHF. The network modeling or equivalent-circuit representation in the MW and MMW regions warrants some special consideration.

Parameters in each domain are combined with boundary conditions at the terminals where they are connected, and the field parameters and the circuit parameters each are obtained as the result of analysis with respect to either antenna performance or characteristics. The results are usually compared with the results obtained by either simulation or experiment. When discrepancies are found between the two methods, the analysis should be repeated from the beginning.

The strategy used to obtain the field and circuit parameters is similar to cases where network modeling is used. EM simulators may be used to obtain the field parameters E and H from the electric/magnetic currents J/M on the antenna structure. Typical EM simulators are MoM, FDTD (finite-difference time-domain method), and IE3D and so forth. When materials other than metal are used for the substrate, HFSS may be applied.

In the case of AIA, where an antenna is integrated onto a planar structure like MIC, integration is not the prime objective for obtaining variation in current distributions

Figure 29. FET-integrated oscillator patch antenna: (a) antenna configuration; (b) radiation pattern (E -plane); (c) radiation pattern (H -plane). (From Refs. 5 and 43 with permission from Wiley and IEE, respectively.)

Figure 30. IMPATT diode integrated oscillator MSA. (From Refs. 5 and 62 with permission from Wiley and IEEE, respectively.)

on the antenna structure, but it does provide the functions, and either modification or enhancement of the antenna performance is obtained thereby. Hence, the AIA may often be modeled by a network in which the radiating part can be represented separately from the nonradiating part relatively easily, so that the space domain and the immittance domain, respectively, can be treated comparatively easily. However, in some cases the radiating and nonradiating parts cannot be clearly differentiated. The degree of distinction depends on the MIC structure and the integration status, particularly in case of 2D or 3D structure. In this case, modeling of the antenna system and hence the analysis is not performed easily.

For instance, an MSA-based IAS, which is fed through an active device without using the transmission line and

hence the functions of the antenna and in which the active circuitry components interact through the transmission structure, network representation can be used for the analysis. The integrated device is formulated by an equivalent circuit consisting of some lumped constants and loaded on the antenna terminals.

In general IAS structure, a concurrent approach is required in which the EM theory and circuit theory are combined because of the blurred distinction between the antenna and the circuitry. There are two approaches: (1) using the network representation and (2) performing simulation, combining the EM simulator with the circuit simulator. In the network approach, the model in most cases is expressed by a multiport network, involving interaction between the antenna and the circuitry, including integrated devices. When an antenna has more than one radiation source, mutual coupling among the components is also expressed by connecting multiport terminals.

Appropriate modeling is essential for the analysis. Even with an appropriate model, in many cases analysis is hardly possible because the model would be so complicated that the solution could be very difficult or impossible to obtain.

Selection of appropriate EM and circuit simulators is essential. When an IAS is represented by an appropriate equivalent model, a simulator may be applied even at the beginning of the analysis. Typical frequency-domain simulators are MoM and IE3D based on MoM, whereas FDTD and TLM (transmission line matrix method) are typical time-domain simulators. Each has its own advantages and disadvantages. Selection of the simulator depends on the antenna structure, application, and objectives. Methods of incorporating certain elements of network analysis in EM simulation algorithms have become available as a useful tool for the analysis of IAS. Both frequency-domain and time-domain simulators can be used. Selection of these depends on not only the IAS structure but also speed, accuracy, and ease of the analysis method.

Design of the IAS is based on the analysis. Appropriate CAD can be used for the design of both antenna and circuitry, if available. Results of the analysis will further assist in optimization of the design. When the IAS is designed, the knowledge and techniques involved in antennas, circuitry, network, devices, including IC, MIC, and MMIC, are necessary. However, since experts

in the field of antennas might not necessarily be expert in components outside of their fields of expertise, cooperative work between engineers in different fields is required.

6.1. Analysis Using Network Model and Equivalent Circuit

6.1.1. Dipole Loaded with Transistor Circuit. Here a dipole on which a transistor circuit (TC) is integrated is taken as an example [89a,89b]. Figure 16 depicts the model in which a coaxial line is used in the middle part of the dipole to supply the bias voltage to the TC. This IAS is

referred to as “DAT” (dipole antenna integrated with a transistor). This DAT is used only for a receiving case, where the receiving pattern is controlled by electronic means. In principle, the receiving patterns are changed by varying the parameters of the TC by changing its bias voltage, which varies the phase and amplitude of the current distributions on the dipole.

Figures 17a and 17b, respectively, illustrate an equivalent model and a circuit expression of the DAT. This model is further decomposed into a radiating part (space domain) and a nonradiating part (immittance domain), as shown in Figs. 18a and 18b, respectively. The coordinate system and parameters to be used in the analysis are also shown in the figure. The current distributions J on the radiating part can be obtained by solving the ordinary integral equation method. An appropriate EM simulator, such as MoM, can be applied to find the current distributions, which will give the receiving patterns. Regarding the nonradiating part, which consists of a coaxial transmission line (TL) and TC, the TL theory is applied and the circuit parameters are obtained. Then the field parameters and the circuit parameters are combined by applying the boundary conditions at the common terminals of the space domain and the immittance domain (nodes a, b, c, and d, e, f, respectively, in Figs. 18a and 18b). Figure 18c depicts calculated results, giving variation of the receiving patterns according to variation in the bias voltage of the TC.

With integration of a TC, other functions such as pattern shaping and beams scanning can be performed electronically without movement of the antenna. The volume occupied by the TC on the antenna structure should be small enough to prevent interference with the radiation.

6.1.2. MSA Integrated with a Diode. Multiport network modeling of MSA is considered as an extension of the cavity modeling. The inner and outer EM fields of the patch are modeled separately and the patch is treated with the 2D planar network having multiports (Fig. 19) [90]. For a rectangular MSA, for example, a multiport Z-matrix characterization, which represents the inner

Figure 34. Grid multiplier: quasioptical grid doubler. (From Refs. 5 and 99 with permission from Wiley and IEEE, respectively.)

field of the patch, can be derived by using Green's function as

$$Z_{ij} = \frac{1}{W_i W_j} \int_{W_i} \int_{W_j} G(X_i, Y_i/X_j, X_j) dX dY \quad (5)$$

where $X_i, Y_i, X_j,$ and Y_j denote the locations of the two ports of widths of W_i and $W_j,$ respectively, and G is the impedance Green function for the rectangular patch. This part corresponds to the immittance domain. The outer field of the patch is modeled by an equivalent network consisting of the parallel combination of the capacitance and inductance, which represent the energy stored inside the patch; and the conductance, which represents the power radiated from the patch and the surface waves. Figure 20 depicts an equivalent expression of edge parameters.

The Z matrix of a rectangular MSA is obtained by performing integration given in Eq. (5) using Green's function. The Green function should be known a priori. For a rectangular MSA of thickness $d,$ the length W_X and the width $W_Y,$ which orient along the x and y axes, respectively, the impedance matrix element Z_{pq} for the two ports W_X and W_Y may be expressed as

$$Z_{pq} = \frac{j\omega\mu d}{W_X W_Y} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \sigma_m \sigma_n \phi_{mn}(X_a, Y_a) \phi_{mn}(X_b, Y_b) / (k_x^2 + k_y^2 - k^2) \quad (6)$$

where, for ports oriented along the y direction

$$\phi_{mn}(x, y) = \cos(k_x X) \cos(k_y Y) \text{sinc} \frac{k_y W}{2} \quad (7)$$

and for ports oriented along the x direction

$$\phi_{mn}(x, y) = \cos(k_x X) \cos(k_y Y) \sin \frac{k_y W}{2} \quad (8)$$

The function $\text{sinc}(z)$ is defined as $(\sin z)/z$ and other parameters are

$$k_x = \frac{m\pi}{W_X}, \quad k_y = \frac{n\pi}{W_Y} \quad (9)$$

$$\sigma_m = \begin{cases} 1, & m = 0 \\ 2, & n \neq 0 \end{cases} \quad (10)$$

$$k^2 = \omega^2 \mu \epsilon_0 \epsilon_r (1 - j\delta) \quad (11)$$

where δ is the loss tangent of the dielectric and X_a, Y_a and $X_b, Y_b,$ respectively, are locations of the a and the b ports.

The edge fields of the MSA, which include the radiation field, the surface-wave field, and the fringing fields at the edge, are modeled by the admittance network, which is located between space and the patch network. Figure 20 depicts a part of the admittance network. The edge admittances are assumed to be distributed uniformly over the edge, as the thickness of the MSA is very thin compared with the wavelength and the fields are constant.

With the knowledge of voltages on the edge, the edge admittance can be evaluated. The edge voltage can be found by modal analysis of the fields inside the patch as a cavity.

When a device is integrated into a patch, the impedance at the port where the device is located is changed. The impedance is found by taking a ratio of voltage and current at the terminals where a device is integrated. Equation (6) can be used after modifying it to match the terminal conditions. The main task is to define the terminal conditions adequately, depending on whether it is two-terminal or three-terminal as shown in Fig. 15. When a varactor diode is used, for example, the resonance frequency of the patch can be adjusted by changing the bias voltage of the varactor. The location of the diode is also one of the parameters used to achieve the designed frequency. When a Gunn diode is integrated, as another example, as the diode exhibits a negative resistance at MW frequency regions and thus the DC supply to the diode can be converted to the RF power, the patch can be designed as a transmitting antenna. The impedance at the location of the diode should have the negative resistance of the Gunn

(a) Conventional receiver

(b) Quasi-optical antenna-mixer

Figure 35. Mixer IAS using a loop slot: (a) principle of quasi-optical mixer; (b) antenna configuration. (From Ref. 81 with permission from IEICE.)

diode. The essential of the design is to determine the patch dimensions and the location of the integration that yields the desired impedance.

6.2. Analysis Using Simulators

Modeling of IAS is the first step, as in the other method of analysis. Whichever model is used, simulators are conveniently applied to perform numerical evaluation, by which the IAS can be designed. Depending on the IAS structure, there are two typical cases: one in which an EM simulator and a circuit simulator are applied separately, and another involving the combined use of these simulators. Usually the EM simulator is applied to the radiating part (the space domain) and the circuit simulator, to the nonradiating part (immittance domain). The results obtained for each part are combined according to the boundary conditions at the interface of the two parts, and the final expressions are obtained. Typically, there are two ways to perform simulation. One is to use lumped circuit elements together with EM formulation, where the circuit element is incorporated into, for instance, the radiating part as additional boundary conditions; another is to combine the EM simulator applied to the passive part of the IAS, including radiating parts, with a network simulator applied to the nonradiating parts, including active devices.

EM simulators such as MoM, FEM (finite-element method), and FDTD are capable of including integrated

devices in the process of simulation as loaded impedances or admittances at the segment of the analysis model, which corresponds to the location of the integration. For this purpose, the integrated devices are represented by the equivalent circuits and incorporated in the simulation model.

Simulation is possible in either the time or frequency domain. In either way, the process involves first modeling the IAS accurately, then selecting appropriate simulators for the problem, and finally combining them with exact boundary conditions. Selection of the simulators depends on speed, complexity, and accuracy of the simulator; ease of incorporating active devices; and the flexibility of treating an arbitrary structure. Table 1 compare some typical simulators [91].

When a complicated IAS structure is treated, particularly the IAS type, in which radiating parts and nonradiating parts cannot be clearly separated, application of a simulator would be very difficult, and analysis often becomes impossible. In many cases simulators cannot be applied because the antenna structure is too complicated to deal with.

7. MAIN APPLICATIONS

7.1. Amplifier IAS

The amplifier IAS was the main subject of R&D in the initial stage of IAS. In those days, linear antenna elements were mostly used. In the 1980s, planar IASs were

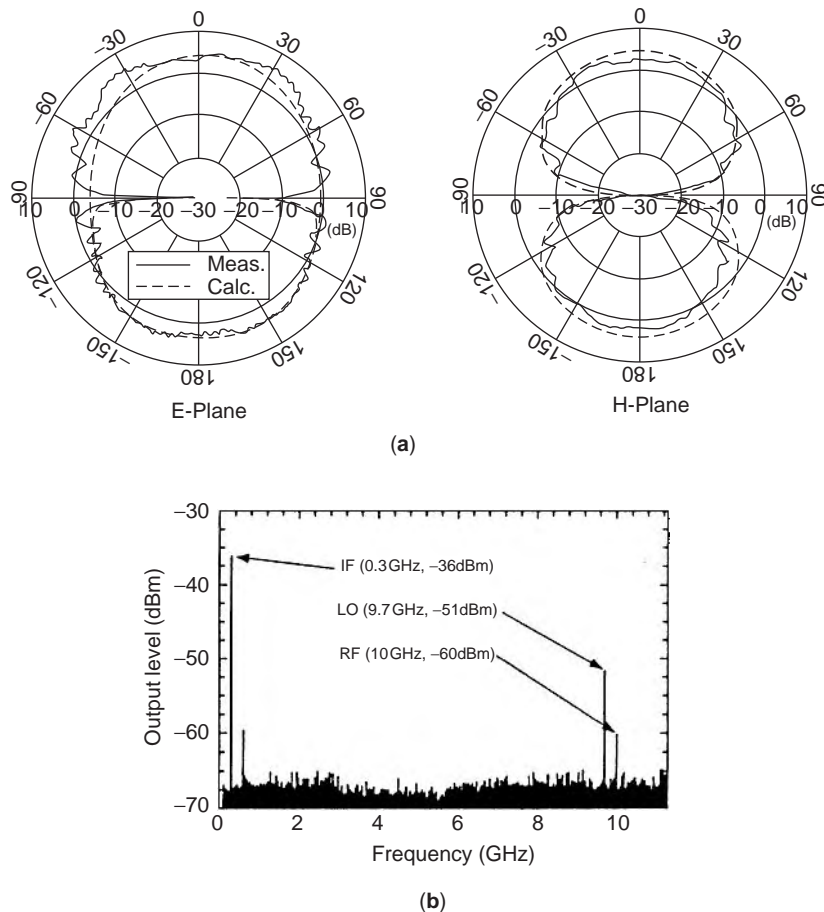

Figure 36. Loop slot mixer IAS performance: (a) radiation patterns; (b) power spectrum showing mixing performance. (From Ref. 81 with permission from IEICE.)

developed; however, the amplifier IASs did not receive much attention as oscillator IASs until their application to the spatial power combiners was recognized as significant. The spatial power combiners require an array of power sources to which small, compact, and low-power-consumption devices are needed. The amplifier IAS was considered to be the most appropriate device to use as the unit of array power source in spatial power combiners.

The first three examples described next are single-amplifier IASs. The remaining IASs are examples applied to power combiners.

7.1.1. Antennafier. Figure 21 illustrates a schematic diagram of an *antennafier* (the combined term for antenna and amplifier) [17], in which a transistor amplifier is

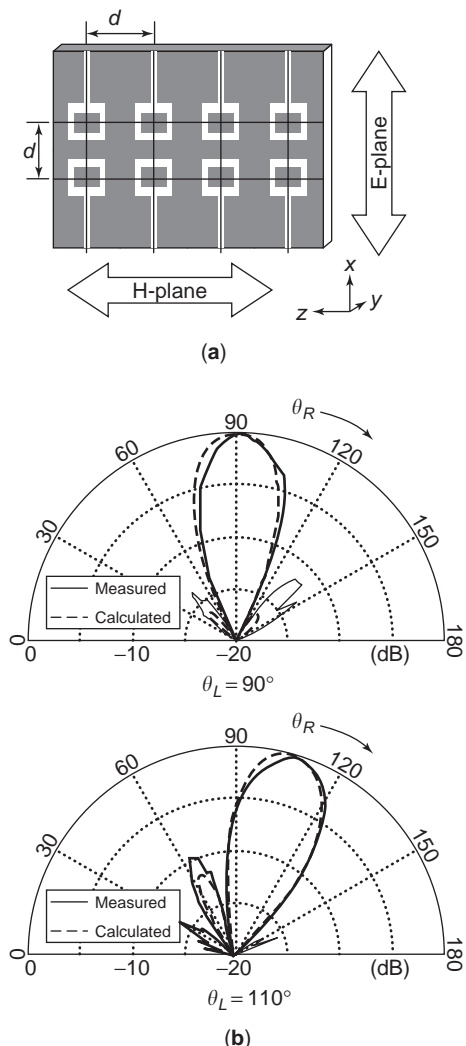

Figure 37. Loop slot mixer IAS array: (a) array structure; (b) beamsteering pattern. (From Ref. 81 with permission from IEICE.)

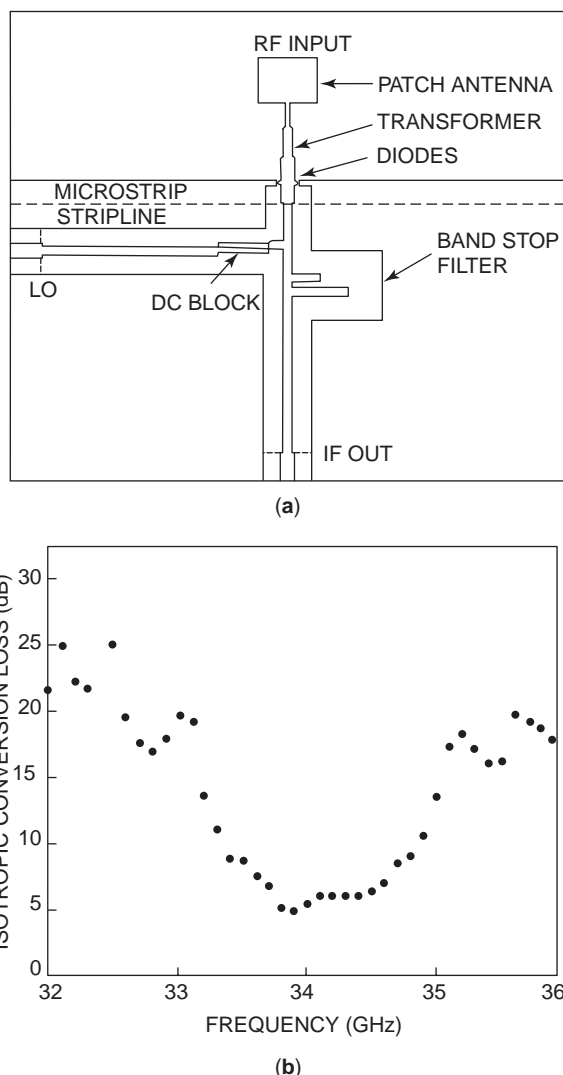

Figure 38. Subharmonic mixer IAS: (a) circuit layout of mixer IAS; (b) conversion loss. (From Refs. 5 and 100 with permission from Wiley and IEEE, respectively.)

Figure 39. Frequency-tunable rectangular MSA: (a) side view of tunnel diode IAS; (b) frequency versus bias voltage. (From Ref. 101 with permission from IEEE.)

integrated into a dipole antenna. This IAS was introduced in 1964 and hence it seems to be a classical example; however, it may have historical significance, as a variety of IASs evolved following the concept demonstrated by this IAS.

This IAS can be viewed as the receiver front end by itself or used as an element of array, by which the receiving pattern is synthesized. Two types of antennafiers were demonstrated: the fixed-gain device, which exhibited a maximum gain of 12.5 dB; and the variable-gain type (Fig. 21), which had a gain ranging from -20 to +12.5 dB.

In a four-element variable-gain antennafier array (Fig. 22a), synthesis of a 15 dB-Chebyshev pattern and a binomial pattern, respectively, was accomplished as

shown in Figs. 22b and 22c. The patterns were controlled by changing the bias voltage to the integrated amplifier circuit, thus varying the phase and amplitude of the array feeding.

7.1.2. Dipole IAS. H-shaped dipoles, into which a tunnel diode was integrated, were analyzed and design parameters discussed [18,20]. Figures 23a and 23b, respectively, illustrate the model and the receiving patterns, which show a gain increase of 6 dB relative to the passive dipole.

A transistor-integrated folded dipole (Fig. 24a) was shown to have accomplished wideband characteristics (Fig. 24b) [25]. The input impedance was adjusted by means of integration so as to achieve the wide bandwidth.

7.1.3. Active PIFA. A power-FET integrated planar inverted-F antenna (PIFA) was shown to have more than 50% power-added efficiency (PAE) at several frequencies between 1 and 2 GHz. This was achieved by designing the antenna system to obtain the optimum power output by using a class F termination as the load to provide optimum power matching for the FET [88]. Figure 25a shows the schematic expression of an active PIFA; Fig. 21b shows an amplifier circuit (side 1), and Fig. 21c illustrates antenna (side 2).

Figure 40. Four-element FET IAS beamscanning array: (a) array configuration; (b) beamscanning performance. (From Refs. 5 and 102 with permission from Wiley and IEEE.)

7.1.4. Slot Amplifier IAS Array. A slot IAS array antenna, to which a MMIC power amplifier is coupled, has been demonstrated [92]. The antenna structure is illustrated in Fig. 26, in an exploded view (a) and a cross-sectional view (b), showing coupling of the amplifier to the array antenna. Analysis was performed first on the slot array on a waveguide using HFSS, and the array performance was experimentally analyzed with a MMIC amplifier coupled to the antenna. Radiation patterns of an eight-element array are shown in Fig. 26c, where a passive slot array pattern is shown for comparison.

7.1.5. Multistage Amplifier IAS. A spatial power combiner based on a multistage structure has been proposed [82]. The antenna system consists of array elements in the first stage, slots in the second stage to couple with antenna elements, and feeding circuitry integrated with amplifiers in the third stage. Figure 27 illustrates the antenna system, showing antenna structure (a) and array structure (b) along with placement of amplifiers. Figure 27c depicts output directive gain versus amplifier gain with the amplifier stage as the parameter, and Fig. 27d shows an *H*-plane radiation pattern.

7.2. Oscillator IAS

Oscillator integrated antenna systems are used either as the front end of a transmitter or a unit of array power

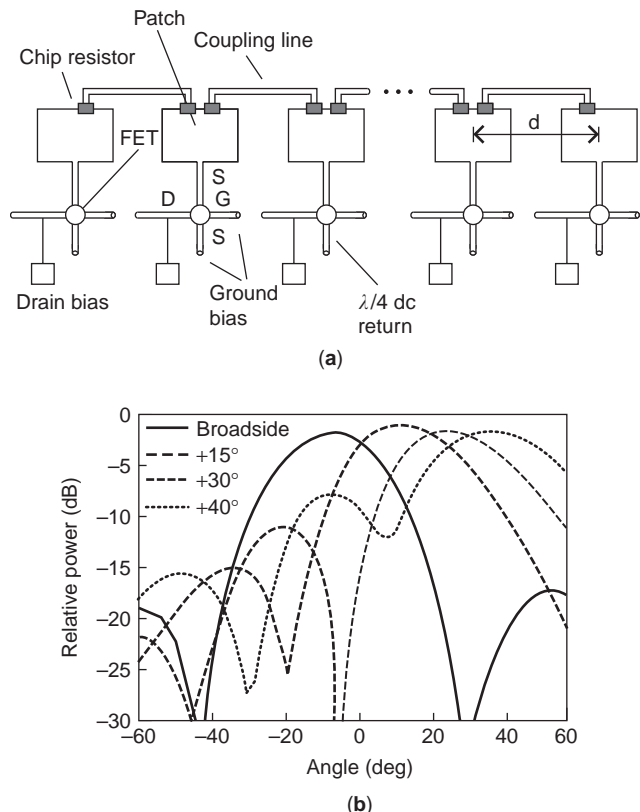

Figure 41. Six-element FET-IAS beamsteering array: (a) array configuration; (b) beamsteering performance. (From Refs. 5 and 113 with permission from Wiley and IEEE, respectively.)

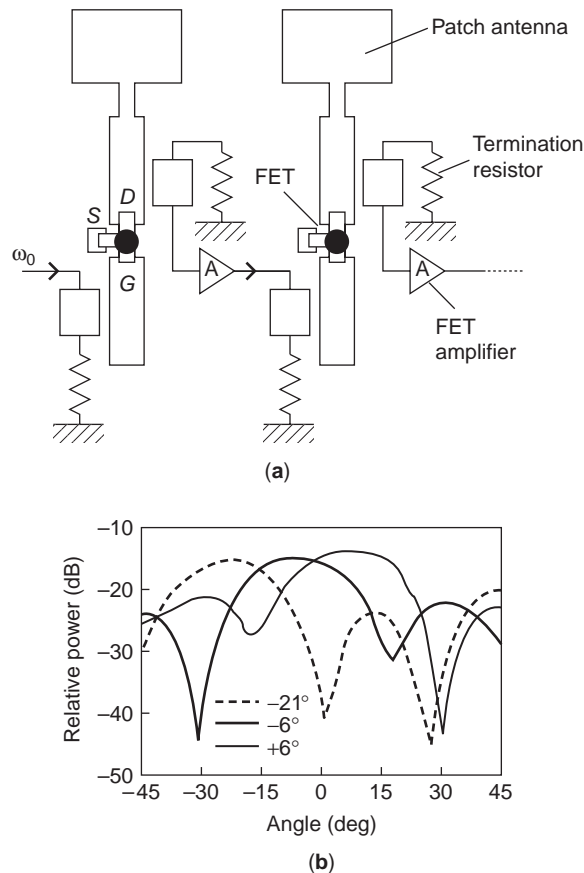

Figure 42. Three-element beamscanning IAS array: (a) part of an array configuration; (b) beamscanning patterns. (From Refs. 5 and 104 with permission from Wiley and IEEE, respectively.)

source in spatial power combiners [93]. Since the spatial power combiners use arrays of distributed power sources in order to achieve efficient and high output radiation in space, small, compact, lightweight, and low-power-consumption devices as the units of array power sources are required. For this purpose, the oscillator IAS is well suited as it meets such requirements.

Two-terminal devices such as IMPATT diodes, Gunn diodes, and tunnel diodes, and also three-terminal devices such as MESFETs, HEMTs, and HBTs, are used for the distributed power source. The two-terminal devices are suitable for high-power applications in MW, MMW, and sub-MMW regions; however, they suffer from relatively low-power DC-RF conversion efficiency. Meanwhile, three-terminal devices provide high gain, high DC-RF conversion efficiency, and low noise figure at MW, MMW, and sub-MMW regions. In addition, they have an advantage in possessing the appropriate structure for integration in a planar structure.

The first oscillating IAS was introduced as a sensor, which consisted of a BARITT diode oscillator and a patch antenna (Fig. 28) [39]. The sensing operation was performed by detecting variation of the operating frequency due to the interaction of its immediate environmental conditions such as temperature and relative motion. This can

be considered as the first application of a patch antenna to the IAS.

Since then, numerous oscillating IASs have been developed [85]. Some examples are described below. Most of them are concerned with the spatial power combiners, and some are constituted in a grid structure.

7.2.1. FET Integrated Oscillator Patch Antenna. The first FET-integrated oscillator patch antenna was demonstrated in 1988 [43]. Figure 29a depicts the IAS in which a patch is shown to be a feedback element for an FET oscillator circuit and a radiator. The IAS operates at 5.7 GHz with a power output of 17 mW. Figures 29b and 29c, respectively, illustrate the *E*-plane and *H*-plane patterns, which also show high cross-polarization levels.

7.2.2. IMPATT Diode Integrated Rectangular MSA. A monolithic IAS was developed as an element of an array of distributed sources in the spatial power combiners [62]. Figure 30 shows an example of two IMPATT diodes that feed the edge of a MSA and have a DC biasing network as well as an open stub for frequency trimming. This IAS operates at 43.3 GHz with an output power of 27 mW at 7.2% DC–RF conversion efficiency.

7.2.3. Gunn Diode Integrated MSA. Figure 31a shows an example of a two-Gunn-diode integrated MSA [94]. Using a MSA designed to resonate at 10 GHz, a Gunn diode oscillator-integrated MSA operates at 10.4 GHz with an output power of 26 mW. Using two Gunn diodes, the

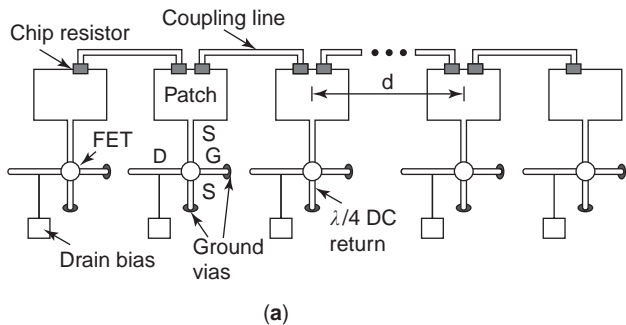

Figure 43. Nonlinear coupled array: (a) array configuration; (b) pattern with reduced sidelobe. (From Ref. 105 with permission from IEEE.)

Figure 44. Beam control by a single-dipole antenna: (a) one-reactance component IAS (ORDA); (b) two-reactance component IAS (TRDA); (c) TRDA beamshifting performance. (From Ref. 106 with permission from Research Studies Press.)

output power was increased about twice the operating frequency of 10.7 GHz and lower cross-polarization patterns were achieved as a consequence of the symmetric configuration as compared with a single-Gunn-diode integrated case. Figure 31b illustrates radiation patterns for both single- and double-Gunn integrated cases.

7.3. Grid and IAS

Use of a large grid array in antenna systems traces back to 1960. Grid formats were applied not only to communication antennas, but also to the rectifier antenna, which converts RF energy to DC power in the microwave wireless link, FSS (frequency-selective surface), which provides different transmission and/or reflection properties as

functions of the frequency, polarization of electromagnetic waves in space, and spatial power combiners. The concept of grid has been applied to not only oscillators in spatial power combining but also to amplifiers, mixers, phase shifters, and switching [95].

7.3.1. Grid Oscillator. The first grid oscillator, introduced in 1988 [51], is shown in Fig. 32, illustrating the front view of a Gunn diode integrated grid (a) and a quasi-optical oscillator configuration (b). Active devices are embedded in a two-dimensionally periodic array on a dielectric substrate. The grid array was placed between a mirror and a partially transparent reflector that constitutes a quasi-optical resonator. The grid oscillator operates at 10 GHz.

The grid oscillator differs from that of other spatial power combiners in that the integrated devices in the grid structure are closely arranged with respect to wavelength,

so that strong coupling and collective interaction among these devices create a quasi-optical component. The grid oscillators demonstrated its substantial usefulness in improving power deficiency and radiation efficiency at that time. Various types of grid oscillators were developed since the first grid oscillator was demonstrated [96].

Another example is a MESFET integrated grid oscillator. The Gunn diode was replaced in order to improve the efficiency. A 10×10 FET grid oscillator has also been demonstrated [97].

7.3.2. Grid Amplifier. Grid structure offers advantages of increasing power-handling capability and eliminating losses associated with feed network. A 50-MESFET grid amplifier demonstrated 11 dB gain at 3.3 GHz [98]. Figure 33 illustrates the grid amplifier structure and the unit cell of the grid amplifier (a); and front (on the left)

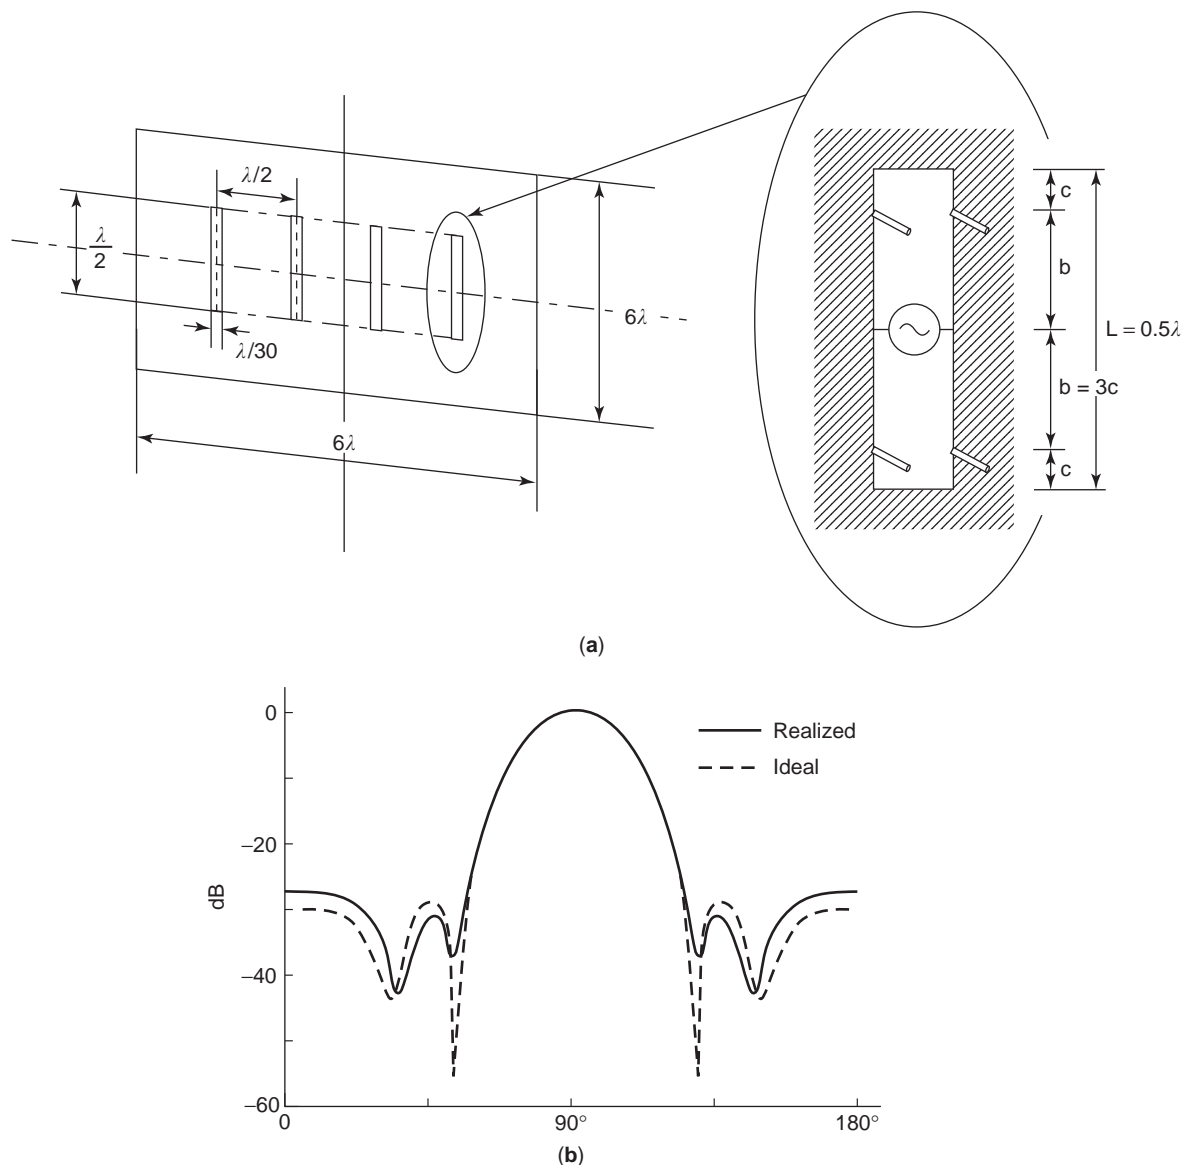

Figure 45. Pattern synthesis by four-slot IAS: (a) array structure; (b) antenna configuration with integrated reactance components (inset); (c) synthesized 30-dB Chebyshev pattern. (From Ref. 45 with permission from IEEE.)

(b) and back (on the right) (c) views. The amplifier accepts a vertically polarized input, amplifies it, and then radiates an asymmetric polarizing output. The unit cell consists of a two-MESFET differential amplifier.

7.3.3. Grid Multiplier. A grid of 1000 Schottky diodes used for frequency doubling [99], producing a power of 0.5 W at 66 GHz with a doubling efficiency of 9.5%, is shown in Fig. 34. The two tuning slabs and two filters were used in order to optimize the fundamental frequency (33 GHz) input to the grid, while similar output filter and tuning slabs were used to match the output.

7.4. Mixer IAS

7.4.1. A Magnetic-Loop Mixer IAS. A mixer IAS, which can perform spatial–optical mixing of RF frequency and a local oscillator within an antenna structure, was proposed by using a loop slot [81]. Figure 35a shows the principle and Fig. 35b, the antenna configuration. The measured antenna parameters are shown in Fig. 36, illustrating radiation patterns at 10 GHz (a) and the power spectrum showing the mixing performance (b). In the measurement, the RF frequency was 10 GHz and the local frequency was 9.7 GHz.

By arraying this IAS unit on a 2D structure (Fig. 37a), beamsteering can be achieved. The basic principle is based on the fact that the direction of an incident RF signal can be shifted by changing either the direction of the local signal or the ratio of the RF frequency and the local frequency. An example beamsteering pattern, measured at the IF frequency, is shown in Fig. 37b.

7.4.2. Subharmonic Mixer IAS. A quasioptical mixer using patch antenna for RF signal, a waveguide for the local signal, and a microstrip for IF is shown in Fig. 38, illustrating the circuit layout (a) and the conversion loss (b) [100]. As the figure shows, the patch antenna, the RF matching network, and the IF output and local oscillator, are integrated on a dielectric substrate. Mixing of 33–36 GHz at RF with 17.6 GHz provides 0–2 GHz IF output. Conversion loss was 5 dB at 34 GHz (Fig. 39b).

7.5. Tunnel Diode Integrated Frequency Tunable MSA

This is an example of a frequency tunable IAS, in which a tunnel diode is integrated and the operating frequency is controlled by the bias voltage in the 51–54 GHz range [101]. Figure 39a depicts the side view of the IAS and Fig. 39b, frequency variation with the bias voltage.

The radiation patterns can also be varied with the bias voltage as the resonance frequency is directly proportional to the bias voltage. The radiation power, beamwidth, and directivity are varied inversely with the increase in bias voltage.

7.6. Beam Control

In a single-antenna system, the radiation pattern can be controlled by the phase control of current distributions on the antenna element. In an array system, a similar concept can be applied to the phase parameters of the array aperture. IAS is useful for this purpose; the current dis-

tributions on an antenna element can be varied by integrating either passive or active devices into the antenna structure so that the radiation patterns can be varied. Similarly, in an array system, phase control of the array feed, and thus radiation pattern control, can be accomplished by integrating either passive or active devices into the array structure. In this case, conventional phase shifters are not necessarily required. The phase control can be performed by other methods such as mutual coupling between array elements, interconnection of array elements by circuitry or external space feeding, and external source excitation (Fig. 12). These phase dynamics can actually be realized in the spatial power combiners, the spatial power combining can serve to not only increase power in space but also provide a method for beam control.

7.6.1. Four-Element FET IAS Array. A four-element beamsteering FET IAS array is shown in Fig. 40, including (a) an array configuration and (b) radiation patterns measured at three different scan angles [102]. A FET using zero-bias gate is integrated into an edge of a patch element to provide oscillation, and the instantaneous phase of each oscillator is varied by the bias voltage, thus producing radiation patterns.

7.6.2. Six-Element FET IAS Array. A six-element beamsteering FET IAS array using a direct-coupling circuit,

Figure 46. Polarization-controllable IAS: (a) antenna structure; (b) principle of operation. (From Ref. 80 with permission from IEICE.)

which adjusts array element phase, is shown in Fig. 41 [103], including (a) an array configuration and (b) measured radiation patterns, showing continuous scanning from broadside to the scan limit of 40° . The array source is composed of the conventional patch fed at the radiation edge of the microstrip oscillator, which is realized by the lumped-element circuit. The radiation edge on the far side of the patch is used to interinjection lock. The combined sources are interinjection locked at the far side of the radiation patch.

7.6.3. Three-Element Beamsanning IAS Array. Figure 42a shows part of an array configuration employing unilateral injection locking using an amplifier to ensure strong coupling between sources [104]. Beamsanning patterns of a three-element active phased array for three different scan angles are shown in Fig. 42b.

7.6.4. Nonlinear Coupled Array. The active antenna array, with which nonlinear dynamics are combined, is discussed by Meaddows et al. [105], who demonstrated interactions between coupled, nonlinear elements to produce a desired far-field pattern such as beamsteering, reduced sidelobe, and beamforming. An example of a nonlinear array structure producing beamsteering is shown in Fig. 43a. The array is composed of a voltage-controlled oscillator (VCO) connected to a patch radiator, which is coupled with a nearest-neighbor element in the array via a stripline. Beamsteering is realized by varying the varactor bias, which adjusts the freerunning frequency of each oscillator. The sidelobe reduction (Fig. 43b) is

accomplished with a nonlinear coupled array, in which amplitude dynamics were employed along with phase dynamics. It should be noted that beamsteering is accomplished with suppressed sidelobes simultaneously.

7.6.5. Beam Control by a Single IAS. Beamshifting or beamsteering realized by a single antenna element has demonstrated [106]. A 0.8λ dipole was used and asymmetric current distributions on the dipole were accomplished by either type I, where one reactance component is integrated as shown in Fig. 44a, or type II, where two different reactance components are used as shown in Fig. 44b. Beamsteering or beamsanning, if required, can be achieved by varying the impedance of the integrated reactance components electronically. Figure 44c shows a beamshifting pattern obtained by using type II.

7.6.6. Pattern Synthesis. The first pattern synthesis using the IAS array was demonstrated in 1964 [21]. A passive integrated dipole array applied to pattern synthesis was later demonstrated in 1985 by using a four-element array [45], into which reactance components were integrated. Figure 45a shows the antenna structure, and Fig. 45b shows an antenna configuration with integrated reactance components, and Fig. 45c shows a synthesized 30-dB Chebyshev pattern. A reactance component was made with a short-circuited two-wire transmission line as shown in the inset in the figure.

7.6.7. Polarization Control Antenna. A polarization-controllable IAS is developed by using a switching diode

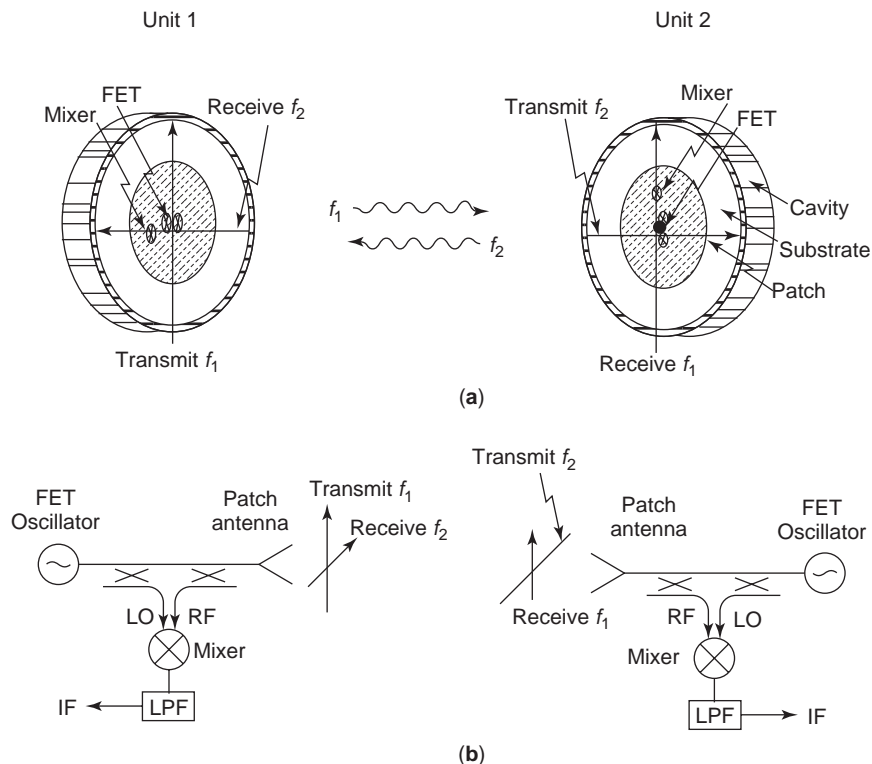

Figure 47. Transceiver: (a) units; (b) operation concept. (From Refs. 5 and 86 with permission from Wiley and IEEE, respectively.)

integrated MSA [80]. Figure 46a shows the antenna structure, which has a cross-slot on the patch surface and Schottky diodes are integrated at the center of these slots. Figure 46b illustrates the principle of operation. Polarization can be varied by changing the current flowing on the patch surface. The antenna operates at two resonance frequencies and produces cross-polarization. The high-frequency current flows in a diagonal direction on the surface, depending on the connection of the diode, while the low-frequency current flows around the cross-slot as shown in Fig. 46b. By changing the bias voltage supplied to the diode, its ON or OFF state can be changed, and thus the direction of the current flow, and thereby polarization of the antenna is changed at each frequency. FDTD is used for the analysis.

7.7. Transmitter–Receiver IAS

IAS can be applied to either transmitter or receiver systems, depending on integration of functions such as oscillation, amplification, mixing, multiplying, and switching. Integrated antenna systems have various advantages in that they can be designed to be small, compact, and lightweight structures, with low power consumption, and to be congruent or compatible with planar and/or MIC structures. An IAS can be constructed as a single structure and is used as an RF front end of either transmitter or receiver. The packaging can take the form of a simple planar structure using a microstrip substrate or 2D or 3D structure consisting of layered substrates or IC, MIC, and MMIC.

Losses associated with interconnection between antenna and RF front end, dielectrics, circuitry, and other properties can be reduced. Noise performance may also be improved as a result of integration. Utilizing IAS technology in this way, a variety of IAS transmitters or receivers have been developed. Typical applications are to transceivers, transponders, and direct-conversion receivers. Some other applications are rectifier antennas, which convert RF energy to DC power; retrodirective antennas, which control radiation patterns to the same direction of the incoming signal; and reflectarray, which produces any desired direction, including the same direction as the incoming wave.

7.7.1. Transceiver. Figure 47a illustrates the units and Fig. 47b, the operation concept [86]. The FET is integrated into a circular patch to oscillate at C band. The oscillator acts as a transmitter and also as a local-oscillator source, which consumes a portion of the oscillation power. Another diode, a Schottky diode, is integrated within the antenna cavity to function as a mixer by receiving the local-oscillator power. This system uses an RF signal of 6 GHz and a local

Figure 51. Notch receiver. (From Refs. 5 and 119 with permission from Wiley and IEEE, respectively.)

frequency of 5.8 GHz, equaling an output signal of 0.2 GHz. The features of the transceiver are low cost, small size, compactness, and light weight, as the mixer and oscillator are configured on the same small patch antenna, avoiding interconnecting lines and circuitry.

7.7.2. Transponder. An antenna integrated with a mixer functions as a receiver front end, to which a local oscillator (LO) can be either integrated on the same substrate or supplied externally by a source in free space. Without using a separate LO, a self-oscillating mixer can be used by utilizing a nonlinear property of an oscillating device itself. In millimeter-wave regions, a LO frequency is achieved by subharmonically pumping up from one-half the value required for a conventional mixer, as the LO frequency with sufficient power to drive the mixer can hardly be obtained.

Such a subharmonically pumped mixer quasioptical mixer practically applied to a noncontact identification transponder has been invented [107]. The transponder has a form of ID card supporting a slot antenna, a bowtie (planar triangular dipole) antenna, and transmitter and receiver circuitry (Fig. 48a). Figure 48b illustrates the operational concept. The transponder receives an interrogation signal at 6 GHz by a dipole antenna as the harmonically pumped LO power and responds with an ASK (amplitude shift keying)-modulated ID code around 12 GHz. Antiparallel Schottky diode pairs are mounted at the terminals of the bowtie antenna. It has the quasioptical mixer structure proposed previously for microwave imaging and telemetry by Stephan and Itoh [108].

7.7.3. Receiver

7.7.3.1. Inverted-L IAS. The inverted-L IAS shown in Fig. 49 [29] was installed inside an 80-MHz small portable receiver, which was used practically in the field. A transistor circuit was integrated into the middle of the inverted-L element and S/N gain of 10 dB over the conventionally used monopole antenna of $\sim \frac{1}{3}\lambda$ was obtained.

7.7.3.2. Ferrite IAS. A parametric excitation integrated ferrite antenna [30], (Fig. 50a) was developed. The frequencies of signal, pump, and output were 1, 3, and 2 MHz, respectively, and an S/N gain of >10 dB over that of the same-size ferrite antenna was obtained as a result of parametric excitation to the ferrite antenna (Fig. 50b).

It should be noted that this IAS is a real “active” antenna, because the part that is involves radiation (receiving) in this antenna is “active.” In general AIAS function, the radiator is not really “active,” but inherently passive, even though it is called an “active antenna.”

7.7.3.3. Notch Receiver. To obtain wideband operation, a notch structure was used for an IAS receiver (Fig. 51) [109]. A notch element is integrated with coupled slotlines to complete an RF front end. A GaAs-FET local oscillator with local resonator slot is used to form a balanced mixer. These components are embedded at the site where the notch element begins to taper out.

7.7.3.4. Direct-Conversion Receiver. Figure 52a illustrates a single integrated I/Q (in-phase/quadrature) direct-conversion converter [110], which is composed of a 40-GHz patch antenna, a quadrature mixer, and a local oscillator, all of which are integrated on a planar substrate. The antenna was designed for a 10 dB bandwidth of 1.64 GHz for wideband operation. The quadrature mixer performs direct downconversion for digitally modulated signals. A pair of antiparallel diodes are used for the mixer, which is LO-pumped subharmonically at half of the RF carrier frequency. Figure 52b is a photo of the receiver.

8. OTHER APPLICATIONS

Applications of IASs other than those described above are rectennas and retrodirective antennas. Rectennas

Figure 52. Direct-conversion receiver: (a) I/Q integrated antenna; (b) photo. (From Ref. 112 with permission from IEICE.)

are antenna systems that convert RF energy into DC power in the wireless transmission link. Either a single antenna element, to which a rectifying device is integrated, or an array of rectennas is used for rectennas. The earliest rectennas were developed by Brown [111], who contributed to microwave power transmission as well as rectenna development. Since then many investigators have developed rectennas [112] applying IAS technology.

Retrodirective antennas are antenna systems that reradiate signals back toward the direction of incoming signals. Retrodirective antennas consist of transmitting and receiving antennas and phase conjugation circuitry.

8.1. Rectenna

A 35-GHz rectenna is shown in Fig. 53a [113], consisting of a patch dipole antenna and a diode integrated at the input terminals of the dipole. The conversion efficiency is shown in Fig. 53b, illustrating formats using either a patch or a dipole.

8.2. Retrodirective antenna

A 6-GHz-band planar active retrodirective antenna, using subharmonic mixing for phase conjugation, has been demonstrated [114]. An incoming signal of 5.79 GHz is subharmonically mixed with the local-oscillator output of 2.9 GHz, thereby producing an IF signal of 10 MHz. Antiparallel diode pairs are used in subharmonic phase

Figure 53. Rectenna: (a) patch rectenna; (b) conversion efficiency. (From Refs. 5 and 111 with permission from Wiley and IEEE, respectively.)

Figure 54. Retrodirective antenna: (a) antenna system; (b) scattering pattern. (From Ref. 113.)

conjugation mixers. The IF frequency is then upconverted with the same local frequency to produce a transmitting frequency of 5.81 GHz. Figure 54a illustrates the antenna system concept, and Fig. 45b shows measured and calculated patterns with an incoming signal on a -20° trajectory. These results verify the advantages of retrodirective performance.

9. PERSPECTIVE

IAS technology and its applications still remain in the process of development. There is no limit to the type of antennas as the base of IAS and also in the integration materials, which include not only solid-state devices but also such components as dielectrics and magnetic materials. The development one may expect in the near future for integrated antenna systems will be integration of metamaterials or left-handed materials into an antenna

system. That would bring small antennas or functional antenna systems, which could never been realized by conventional technology.

IAS technology will promote further advancement of antenna systems in microwave and higher-frequency regions. Integration of materials never used before such as nonreciprocal or nonlinear devices would create new antenna systems with capability beyond the scope of anything available today.

There are various IAS applications. IAS is useful for antenna systems not only in communications but also in other wireless systems such as radar, sensing, control, and broadcasting. In another aspect, application of IAS would offer many advantages in realizing small antennas, including antennas that are functionally as well as electrically small.

INTEGRATED CIRCUITS

N. RANGANATHAN
 RAJU D. VENKATARAMANA
 University of South Florida

The invention of the transistor in 1947 by William Shockley and his colleagues John Bardeen and Walter Brattain at Bell Laboratories, Murray Hill, NJ, launched a new era of integrated circuits (ICs). The transistor concept was based on the discovery that the flow of electric current through a solid semiconductor material like silicon can be controlled by adding impurities appropriately through the implantation processes. The transistor replaced the vacuum tube because of its better reliability, lesser power requirements, and, above all, much smaller size. In the late 1950s, Jack Kilby of Texas Instruments developed the first integrated circuit. The ability to develop flat or planar ICs, which allowed the interconnection of circuits on a single substrate (due to Robert Noyce and Gordon Moore), began the microelectronics revolution. The substrate is the supporting semiconductor material on which the various devices that form the integrated circuit are attached. Researchers developed sophisticated photolithography techniques that helped in the reduction of the minimum feature size, leading to larger circuits being implemented

on a chip. The miniaturization of the transistor led to the development of integrated circuit technology in which several hundreds and thousands of transistors could be integrated on a single silicon die. IC technology led to further developments, such as microprocessors, mainframe computers, and supercomputers.

Since the first integrated circuit was designed following the invention of the transistor, several generations of integrated circuits have come into existence: SSI (small-scale integration) in the early 1960s, MSI (medium-scale integration) in the latter half of the 1960s, and LSI (large-scale integration) in the 1970s. The VLSI (very large scale integration) era began in the 1980s. While the SSI components consisted on the order of 10–100 transistors or devices per integrated circuit package, the MSI chips consisted of anywhere from 100–1000 devices per chip. The LSI components ranged from roughly 1000–20,000 transistors per chip, while the VLSI chips contain on the order of up to 3 million devices. When the chip density increases beyond a few million, the Japanese refer to the technology as ULSI (ultra-large-scale integration), but many in the rest of the world continue to call it VLSI. The driving factor behind integrated circuit technology was the scaling factor, which in turn affected the circuit density within a single packaged chip. In 1965, Gordon Moore predicted that the density of components per integrated circuit would continue to double at regular intervals. Amazingly, this has proved true, with a fair amount of accuracy [1].

Another important factor used in measuring the advances in IC technology is the minimum feature size or the minimum linewidth within an integrated circuit (measured in micrometers). From about $8\mu\text{m}$ in the early 1970s, the minimum feature size has decreased steadily, increasing the chip density or the number of devices that can be packed within a given die size. In the early 1990s, the minimum feature size decreased to about $0.5\mu\text{m}$, and currently 0.3- , 0.25- , and $0.1\text{-}\mu\text{m}$ technologies (also called “deep-submicrometer technologies”) are becoming increasingly common. IC complexity refers, in general, to the increase in chip area (die size), the decrease in minimum feature size, and the increase in chip density. With the increase in IC complexity, the design time and the design automation complexity increase significantly. The advances in IC technology are the result of many factors, such as high-resolution lithography techniques, better processing capabilities, reliability and yield characteristics, sophisticated design automation tools, and accumulated architecture, circuit, and layout design experience.

1. BASIC TECHNOLOGIES

The field of integrated circuits is broad. The various basic technologies commonly known are shown in Fig. 1. The inert substrate processes, further divided as thin and thick film processes, yield devices with good resistive and temperature characteristics. However, they are used mostly in low-volume circuits and in hybrid ICs. The two most popular active substrate materials are silicon and gallium arsenide (GaAs). The silicon processes can be separated into two classes: MOS (the basic device is a metal

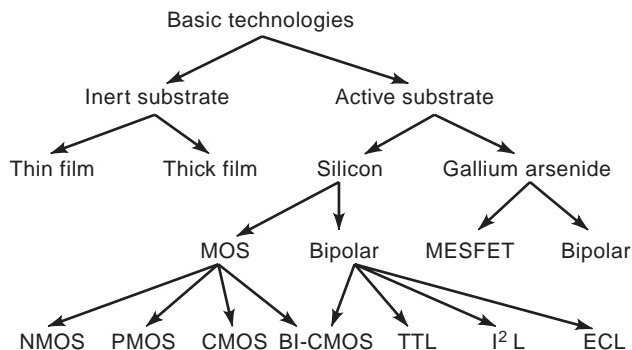

Figure 1. Overview of the basic technologies.

oxide semiconductor field effect transistor) and bipolar (the basic device is bipolar junction transistors). The bipolar process was commonly used in the 1960s and 1970s and yields high-speed circuits with the overhead of high-power dissipation and the disadvantage of low density. The transistor–transistor logic (TTL) family of circuits constitutes the most popular type of bipolar and is still used in many high-volume applications. The emitter-coupled logic (ECL) devices are used for high-speed parts that form the critical path delay of the circuit. The MOS family of processes consists of PMOS, NMOS, CMOS, and BiCMOS. The term *PMOS* refers to a MOS process that uses only p-channel transistors, and *NMOS* refers to a MOS process that uses only n-channel transistors. PMOS is not used much due to its electrical characteristics, which are not as good as the n-channel field-effect transistor (FET), primarily since the mobility of the n-channel material is almost twice compared to the mobility of the p-channel material. Also, the NMOS devices are smaller than the PMOS devices, and thus PMOS do not give good packing density.

CMOS was introduced in the early 1960s; however, it was used only in limited applications, such as watches and calculators. This was primarily due to the fact that CMOS had slower speed, less packing density, and latchup problems although it had a high noise margin and lower power requirements. Thus, NMOS was preferred over CMOS, in general, until the p-channel devices developed began to have similar-characteristics as the nMOS and both the p-channel and n-channel transistors started delivering close to equal amounts of currents with similar transistor sizes. In the 1980s and the 1990s, the need for lower power consumption was the driving factor, and thus CMOS emerged as the leading IC technology [2]. The BiCMOS technology combines both bipolar and CMOS devices in a single process. While CMOS is preferred for logic circuits, BiCMOS is preferred for input/output (I/O) and driver circuits due to its low input impedance and high current driving capability.

Since the 1980s, efforts have been directed toward designing digital ICs using GaAs devices. In many high-resolution radar systems, space systems, high-speed communication circuits, and microwave circuits, the integrated circuits need to operate at speeds beyond several gigahertz (GHz). In silicon technology, it is possible to obtain speeds on the order of up to 10 GHz using ECL

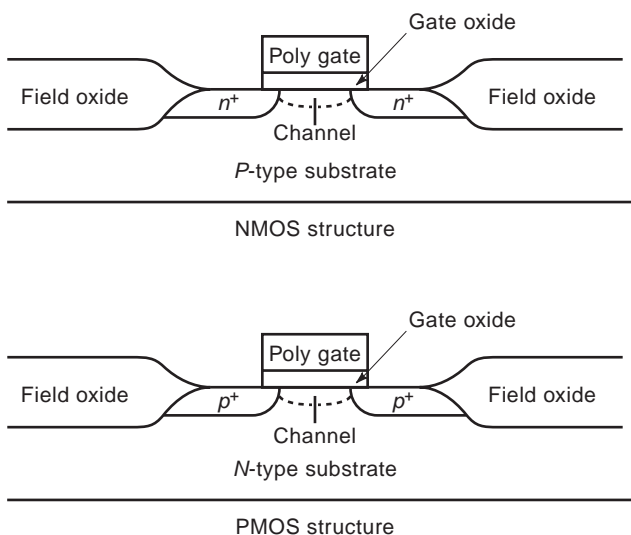

circuits, which is almost pushing the limits of the silicon technology. In GaAs technology, the basic device is the metal semiconductor (Schottky gate) field-effect transistor, called the GaAs MESFET. Given similar conditions, the electrons in n-type GaAs material travel twice faster than in silicon. Thus, the GaAs circuits could function at twice the speed than the silicon ECL circuits for the same minimum feature size. The GaAs material has a larger bandgap and does not need gate oxide material, as in silicon, which makes it immune to radiation effects. Also, the GaAs material has very high resistivity at room temperatures and lower parasitic capacitances, yielding high-quality transistor devices. However, the cost of fabricating large GaAs circuits is significantly high because of its low reliability and yield characteristics (due primarily to the presence of more defects in the material compared to silicon). The fabrication process is complex, expensive, and does not aid scaling. Also, the hole mobility is the same as in silicon, which means that GaAs is not preferable for complementary circuits. Thus, the GaAs technology has not been as successful as initially promised. Since CMOS has been the most dominant technology for integrated circuits, we examine the MOS transistor and its characteristics as a switch in the next section.

2. THE MOS SWITCH

The MOSFET is the basic building block of contemporary CMOS circuits, such as microprocessors and memories. A MOSFET is an unipolar device; that is, current is transported by means of only one type of polarity (electrons in an n type and holes in a p type). In this section, we describe the basic structure of MOSFETS and their operation and provide examples of gates built using MOS devices.

2.1. Structure

The basic structure of a MOSFET (both n and p types) is shown in Fig. 2. We describe the structure of an n-type

NMOS symbol

PMOS symbol

MOSFET (3), (4). It consists of four terminals with a p-type substrate into which two n^+ regions are implanted. The substrate is a silicon wafer that provides stability and support. The region between the two n^+ regions is covered by an insulator, typically polysilicon and a metal contact. This contact forms the gate of the transistor. The insulating layer is required to prevent the flow of current between the semiconductor and the gate. The two n^+ regions form the source and the drain. Due to the symmetry of the structure, the source and the drain are equivalent. The gate input controls the operation of the MOSFET. A bias voltage on the gate causes the formation of a channel between the n^+ regions. This channel causes a connection between the source and drain and is responsible for the flow of the current. The MOSFET is surrounded by a thick oxide, called the “field oxide,” which isolates it from neighboring devices. Reversal of n and p types in the discussion will result in a p-type MOSFET. Typical circuit symbols for n-type and p-type MOSFETS are also shown in Fig. 2.

2.2. Operation

When no gate bias is applied, the drain and the source behave as two pn junctions connected in series in the opposite direction. The only current that flows is the reverse leakage current from the source to the drain. When a positive voltage is applied to the gate, the electrons are attracted and the holes are repelled. This causes the formation of an inversion layer or a channel region. The source and the drain are connected by a conducting n channel through which the current can flow. This voltage-induced channel is formed only when the applied voltage is greater than the threshold voltage V_t . MOS devices that do not conduct when no gate bias is applied are called *enhancement mode* or normally OFF transistors. In nMOS enhancement mode devices, a gate voltage greater than V_t should be applied for channel formation. In pMOS enhancement-mode devices, a negative gate voltage whose magnitude is greater than V_t must be applied. MOS devices that conduct at zero gate bias are called normally ON

Figure 2. Structure of n- and p-type MOSFETS.

or depletion-mode devices. A gate voltage of appropriate polarity depletes the channel of majority carriers and hence turns it off.

Considering an enhancement-mode n-channel transistor, when the bias voltage is above the predefined threshold voltage, the gate acts as a closed switch between the source and drain, the terminals of which become electrically connected. When the gate voltage is cut off, the channel becomes absent, the transistor stops conducting, and the source and the drain channels get electrically disconnected. Similarly, the p-channel transistor conducts when the gate voltage is beneath the threshold voltage and stops conducting when the bias voltage is increased above the threshold. The behavior of the MOS transistor as a switch forms the fundamental basis for implementing digital Boolean circuits using MOS devices.

2.3. Output Characteristics

We describe the basis output characteristics [5,6] of a MOS device in this subsection. There are three regions of operation for a MOS device:

1. Cutoff region
2. Linear region
3. Saturation region

In the cutoff region, no current flows and the device is said to be off. When a bias V_{gs} is applied to the gate such that $V_g > V_t$, the channel is formed. If a small drain voltage V_{ds} is applied, drain current I_{ds} flows from source to drain through the conducting channel. The channel acts like a resistance, and the drain current is proportional to the drain voltage. This is the linear region of operation. As the value of V_{ds} is increased, the channel charge near the drain decreases. The channel is pinched off when $V_{ds} = V_{gs} - V_t$. An increase in V_{ds} beyond the pinchoff value causes little change in the drain current. This is the saturation region of operation of the MOS device. The output characteristics of n- and p-type devices is shown in Fig. 3. The equations that describe the regions of operation can be summarized as follows:

$$0 \text{ if } V_{gs} \leq V_t \text{ (cutoff)}$$

$$I_{ds} = k/2[2(V_{gs} - V_t)V_{ds} - V_{ds}^2]$$

$$\text{If } V_g > V_t, V_{ds} \leq (V_{gs} - V_t) \text{ (linear)}$$

$$k/2(V_{gs} - V_t)^2 \text{ If } V_g > V_t, V_{ds} > (V_{gs} - V_t) \text{ (saturation)}$$

where k is the transconductance parameter of the transistor. A detailed analysis of the structure and operation of MOS devices is described in Refs. 3, 5, 7 and 8.

2.4. CMOS inverter

The basic structure of an inverter is shown in Fig. 4, and the process cross section is shown in Fig. 5. The gates of both the NMOS and the PMOS transistors are connected. The PMOS transistor is connected to the supply voltage V_{dd} , and the NMOS transistor is connected to G_{nd} . When a

Figure 3. Output characteristics of a MOS transistor.

logical 0 is applied at the input V_{in} , then the PMOS device is on and the output is pulled to V_{dd} . Hence the output is a logical 1. On the other hand, when a logical 1 is applied at the input, then the NMOS transistor is on and the output is pulled to the ground. Hence we have a logical 0. The operating regions of the transistor are shown in Fig. 6. In region I, the n device is off and the p device operates in the linear region. Hence the output is pulled to V_{dd} . In region II, the n and p devices operate in the linear and saturation region depending on the input voltage. In region III, the p device is cut off and the n device is operating in the linear region. The output is pulled to the ground. In region II, when both the transistors are on simultaneously, a short circuit is produced between V_{dd} and G_{nd} . This accounts for the short-circuit power dissipation in CMOS logic.

2.5. Transmission Gate

Consider the device shown in Fig. 7, which represents an NMOS or a PMOS device. By suitably controlling the gate bias, the device can be made to turn on or off. It behaves as an electrical switch that either connects or disconnects the points s and d . An NMOS device is a good switch when it passes a logical 0, and a PMOS is a good switch when it passes a logical 1. In CMOS logic, both the NMOS and PMOS devices operate together. In general, the NMOS transistor pulls down the output node to logical 0, and the PMOS device pulls up a node to logical 1. A transmission gate is obtained by connecting the two in parallel, as shown in Fig. 8. The control signal (say, g) applied to the n-type device is complemented and applied to the p-type device. When g is high, both the transistors are on and

Figure 4. Circuit schematic of an inverter.

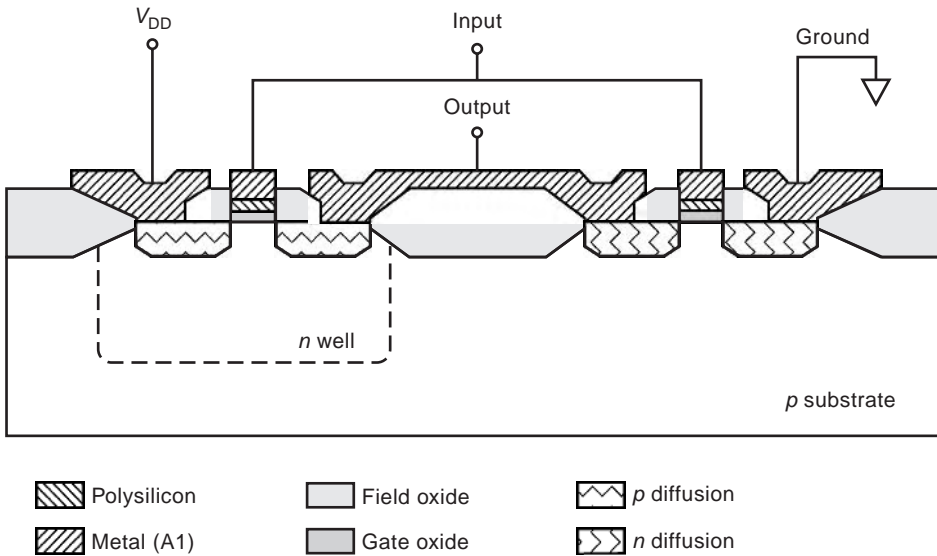

Figure 5. Process cross section of an n-well inverter.

hence a good 1 or a 0 is passed. When g is low, both the devices are off. This is also called a complementary switch, or a C SWITCH [5].

2.6. NAND and NOR Gates

CMOS combinational gates are constructed by connecting the PMOS and NMOS devices in either series or parallel to generate different logical functions. The structures for a two-input NAND and NOR gate are shown in Fig. 9.

2.6.1. NAND Gate. The p devices are connected in parallel, and the n devices are connected in series. When either of the inputs A or B is a logical 0, the output is pulled high to V_{dd} . When both A and B are high, then the output is pulled to the ground. Hence this structure implements the operation $f = (A \cdot B)'$.

2.6.2. NOR Gate. Similarly, in the NOR gate, the p devices are connected in series and the n devices are connected in parallel. When either of the inputs A or B is a logical 1, then the output is pulled to the ground. When

both A and B are low, then the output is pulled to V_{dd} . Hence this structure implements the operation $f = (A + B)'$. The p structure is the logical dual of the n structure. An n input NAND and NOR gate can be constructed in a similar fashion.

3. IC DESIGN METHODOLOGY

To design and realize VLSI circuits, several factors play key roles. The goal of an IC designer is to design a circuit that meets the given specifications and requirements while spending minimum design and development time avoiding design errors. The designed circuit should function correctly and meet the performance requirements, such as delay, timing, power, and size. A robust design methodology has been established over the years, and the design of complex integrated circuits has been made possible essentially because of advances in VLSI design automation. The various stages in the design flow are shown in Fig. 10. The design cycle ranges from the system-level specification and requirements to the end product of a fabricated, packaged, and tested integrated circuit. The basic design methodology is briefly described here, and the various stages are discussed in detail in the following sections using simple examples.

The first step is to determine the system-level specifications, such as the overall functionality, size, power, performance, cost, application environment, IC fabrication process, technology, and chip-level and board-level

Figure 6. Operating regions of the transistor.

Figure 7. A MOS device as a switch.

Figure 8. Transmission gate.

interfaces required. There are several tradeoffs to be considered. The next step is the functional design and description, in which the system is partitioned into functional modules and the functionality of the different modules and their interfaces to each other are considered. The issues to be considered are regularity and modularity of structures, subsystem design, data flow organization, hierarchical design approach, cell types, geometric placements, and communication between the different blocks.

Once the functionality of the various modules is determined, the architectural design of the modules is pursued. Many design alternatives are considered toward optimization. This stage also includes the design of any hardware algorithms to be mapped onto architectures. A behavior-level description of the architecture is obtained and verified using extensive simulations, often with an iterative process. This stage is critical in obtaining an efficient circuit in the end and for simplifying the steps in some of the following stages. In the logic design stage, the architectural blocks are converted into corresponding gate-level logic designs, Boolean minimization is performed, and logic simulation is used to verify the design at this level. In some design flows, the circuit could be synthesized from the logic level by using gate-level libraries (this is referred to as *logic synthesis*). The logic

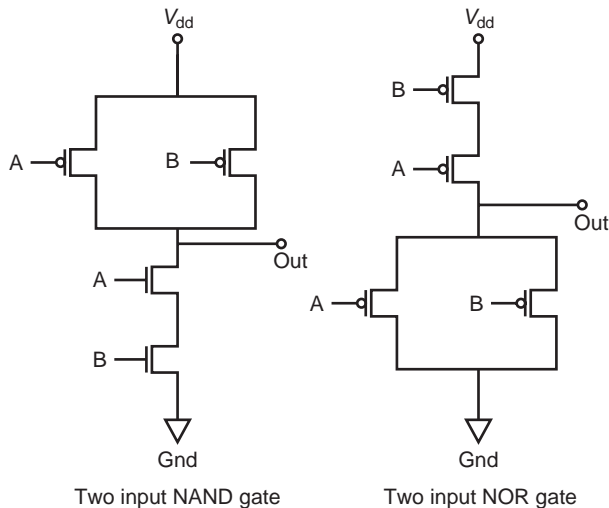

Figure 9. Two-input NAND and NOR gates.

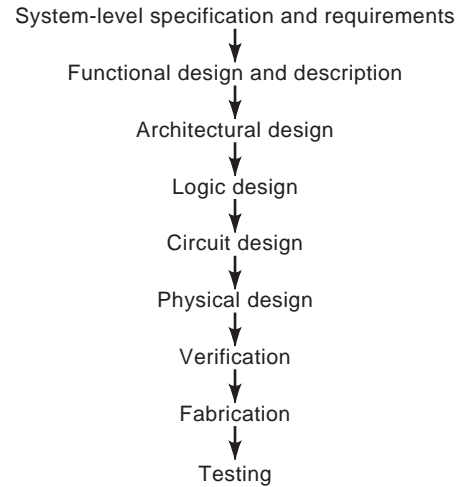

Figure 10. IC design methodology.

design usually includes a conventional logic design approach and a nontraditional design, such as precharge logic. At this stage, gate delays are considered and timing diagrams are derived to verify the synchronization of the various logic modules. The next step is the circuit design stage, which essentially involves converting the logic design modules into a circuit representation. At this stage, the essential factors considered are clocking, switching speeds or delays, switching activity and power requirements, and other electrical characteristics (e.g., resistance, capacitance).

The most complex step in VLSI design automation is the physical design, which includes floorplanning, partitioning, placement, routing, layout, and compaction. This process converts the given circuit design or description into a physical layout that is a geometric representation of the entire circuit. Each step of the physical design by itself is complex and takes significant amounts of iterations and time. The various types of transistors, the interconnecting wires, and contacts between different wires and transistors are represented as different geometric patterns consisting of many layers placed according to several design rules that govern a given fabrication technology and process. The floorplanning step involves higher-level planning of the various components on the layout. The partitioning step converts the overall circuit into smaller blocks to facilitate the other steps. It is usually impractical to synthesize the entire circuit in one step. Thus, logic partitioning is used to divide the given circuit into a smaller number of blocks, which can be individually synthesized and compacted. This step considers the size of the blocks, the number of blocks, and the interconnections between the blocks and yields a netlist for each block that can be used in the further design steps.

During the next step, which is the placement of the blocks on the chip layout, the various blocks are placed such that the routing can be completed effectively and the blocks use minimum overall area, avoiding any white spaces. The placement task is iterative in that an initial placement is obtained first and evaluated for area minimization and effective routing possibility, and alternate

arrangements are investigated until a good placement is obtained. The routing task completes the routing of the various interconnections, as specified by the netlists of the different blocks. The goal is to minimize the routing wirelengths and minimize the overall area needed for routing. The routing areas between the various blocks are referred to as *channels* or *switchboxes*. Initially, a global routing is performed in which a channel assignment is determined on the basis of routing requirements, and then a detailed routing step completes the actual point-to-point routing.

The last step in the physical design is the compaction step, which tries to compact the layout in all directions to minimize the layout area. A compact layout leads to less wirelengths, lower capacitances, and more chip density since the chip area is used effectively. The compaction step is usually an interactive and iterative process in which the user can specify certain parameters and check if the compaction can be achieved. The goal of compaction, in general, is to achieve minimum layout area. The entire physical design process is iterative and is performed several times until an efficient layout for the given circuit is obtained.

Once the layout is obtained, design verification needs to be done to ensure that the layout produced functions correctly and meets the specifications and requirements. In this stage, design rule checking is performed on the layout to make sure that the geometric placement and routing rules and the rules regarding the separation of the various layers, the dimensions of the transistors, and the width of the wires are followed correctly. Any design rule violations that occurred during the physical design steps are detected and removed. Then circuit extraction is performed to complete the functional verification of the layout. This step verifies the correctness of the layout produced by the physical design process. After layout verification, the circuit layout is ready to be submitted for fabrication, packaging, and testing. Usually, several dies are produced on a single wafer and the wafer is tested for faulty dies. The correct ones are diced out and packaged in the form of a pin grid array (PGA), dual in-line package (DIP), or any other packaging technology. The packaged chip is tested extensively for functionality, electrical and thermal characteristics, and performance. The process of designing and building an integrated circuit [9] that meets the performance requirements and functions perfectly depends on the efficiency of the design automation tools.

4. CIRCUIT DESIGN

To create performance optimized designs, two areas have to be addressed to achieve a prescribed behavior: (1) circuit or structural design and (2) layout or physical design. While the layout design is discussed in a later section, this section focuses on the former.

A logic circuit must function correctly and meet the timing requirements. There are several factors that can result in the incorrect functioning of a CMOS logic gate: (1) incorrect or insufficient power supplies, (2) noise on gate inputs, (3) faulty transistors, (4) faulty connections to transistors, (5) incorrect ratios in ratioed logic, and (6)

charge sharing or incorrect clocking in dynamic gates. In any design, there are a certain paths, called *critical paths*, that require attention to timing details since they determine the overall functional frequency. The critical paths are recognized and analyzed using timing analyzer tools and can be dealt with at four levels:

1. Architecture
2. RTL/logic level
3. Circuit level
4. Layout level

Designing an efficient overall functional architecture helps to achieve good performance. To design an efficient architecture, it is important to understand the characteristics of the algorithm being implemented as the architecture. At the register transfer logic (RTL)/logic level, pipelining, the type of gates, and the fanin and the fanout of the gates are to be considered. Fanin is the number of inputs to a logic gate, and fanout is the number of gate inputs that the output of a logic gate drives. Logic synthesis tools can be used to achieve the transformation of the RTL level. From the logic level, the circuit level can be designed to optimize a critical speed path. This is achieved by using different styles of CMOS logic, as explained later in this section. Finally, the speed of a set of logic can be affected by rearranging the physical layout. The following techniques can be used for specific design constraints.

The various CMOS logic structures that can be used to implement circuit designs are as follows:

1. *CMOS Complementary Logic*. The CMOS complementary logic gates are designed as ratioless circuits. In these circuits, the output voltage is not a fraction of the V_{dd} (supply) and the gates are sized to meet the required electrical characteristics of the circuits. The gate consists of two blocks, an n block and a p block, that determine the function of the gate. The p block is a dual of the n block. Thus, an n-input gate will consist of 2^n transistors.
2. *Pseudo-NMOS Logic*. In this logic, the load device is a single p transistor with the gate connected to V_{dd} [5,10]. This is equivalent to replacing the depletion NMOS load in a conventional NMOS gate by a p device. The design of this style of gate [11,12] involves ratioed transistor sizes to ensure proper operation and is shown in Fig. 11. The static power dissipation that occurs whenever the pulldown chain is turned on is a major drawback of this logic style.
3. *Dynamic CMOS Logic*. In the dynamic CMOS logic style, an n-transistor logic structure's output node is precharged to V_{dd} by a p transistor and conditionally discharged by an n transistor connected to V_{ss} [5]. The input capacitance of the gate is the same as the pseudo-NMOS gate. Here, the pullup time is improved by virtue of the active switch, but the pulldown time is increased due to the ground. The disadvantage of this logic structure is that the inputs can only change during the precharge phase

Figure 11. Pseudo-NMOS logic.

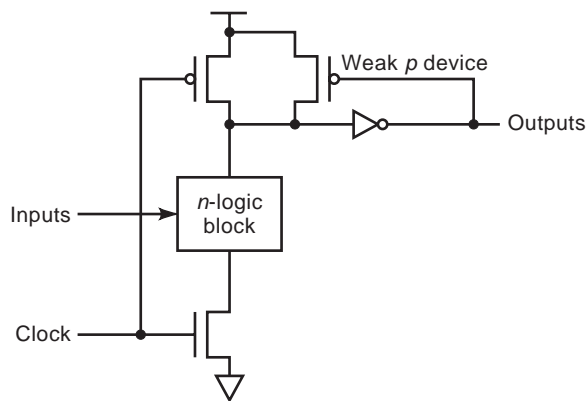

Figure 13. CMOS domino logic.

and must be stable during the evaluate portion of the cycle. Figure 12 depicts this logic style.

4. *Clocked CMOS Logic.* To build CMOS logic gates with low power dissipation [13], this logic structure was proposed. The reduced dynamic power dissipation is realized because of the metal gate CMOS layout considerations. The gates have larger rise and fall times because of the series clocking transistors, but the capacitance is similar to the CMOS complementary gates. This is a recommended strategy for “hot electron” effects, because it places an additional n transistor in series with the logic transistors [14].
5. *CMOS Domino Logic.* This is a modification of the clocked CMOS logic, in which a single clock is used to precharge and evaluate a cascaded set of dynamic logic blocks. This involves incorporating a static CMOS inverter into each logic gate [15], as shown in Fig. 13. During precharge, the output node is charged high, and hence the output of the buffer is low. The transistors in the subsequent logic blocks will be turned off since they are fed by the buffer. When the gate is evaluated, the output will conditionally go low (1–0), causing the buffer to conditionally go high (0–1). Hence, in a cascaded set of logic blocks, each state evaluates and causes the next stage to evaluate, provided the entire sequence can be evaluated in one clock cycle. Therefore, a single clock is used to precharge and evaluate all logic

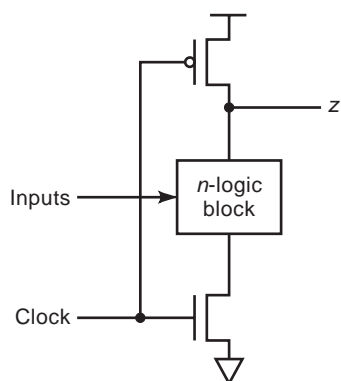

Figure 12. Dynamic CMOS logic.

gates in a block. The disadvantages of this logic are that (1) every gate needs to be buffered, and (2) only noninverting structures can be used.

6. *NP Domino Logic (Zipper CMOS).* This is a further refinement of the domino CMOS [16–18]. Here, the domino buffer is removed, and the cascading of logic blocks is achieved by alternately composed p and n blocks, as is shown in Fig. 14. When the clock is low, all the n-block stages are precharged high while all the p-block stages are precharged low. Some of the advantages of the dynamic logic styles include (1) smaller area than fully static gates, (2) smaller parasitic capacitances, and (3) glitch-free operation if designed carefully.
7. *Cascade Voltage Switch Logic (CVSL).* The CVSL is a differential style of logic requiring both true and complement signals to be routed to gates [19]. Two complementary NMOS structures are constructed and then connected to a pair of cross-coupled p pull-up transistors. The gates here function similarly to the domino logic, but the advantage of this style is the ability to generate any logic expression involving both inverting and noninverting structures. Figure 15 gives a sketch of the CVSL logic style.
8. *Pass Transistor Logic.* Pass transistor logic is popular in NMOS-rich circuits. Formal methods for deriving pass transistor logic for NMOS are presented

Figure 14. NP domino logic.

Figure 15. Cascade voltage switch logic.

in Ref. 20. Here, a set of control signals and a set of pass signals are applied to the gates and sources of the n transistor, correspondingly. From these signals, the truth table for any logic equation can be realized.

9. *Source Follower Pullup Logic (SFPL)*. This is similar to the pseudo-NMOS gate except that the pullup is controlled by the inputs [21]. In turn, this leads to the use of smaller pulldown circuits. The SFPL gate style reduces the self-loading of the output and improves the speed of the gate. Therefore, it shows a marked advantage in high-fanin gates.

Using the various design styles, any circuit design can be built in a hierarchical fashion. The basic gates are first built, from which functional blocks like a multiplexer or an adder circuit can be realized. From these basic blocks, more complex circuits can be constructed. Once a design for a specific application has been designed, the functionality of the circuit needs to be verified. Also, other constraints, such as the timing and electrical characteristics, have to be studied before the design can be manufactured. The techniques and tools to achieve this are the subject of the next section.

5. SIMULATION

Simulation is required to verify if a design works the way it should. Simulation can be performed at various levels of abstraction. A circuit can be simulated at the logic level, the switch level, or with reference to the timing. Simulation is a critical procedure before committing the design to silicon. The simulators themselves are available in a wide variety of types [22].

5.1. Logic-Level Simulation

Logic-level simulation occurs at the highest level of abstraction. It uses primitive models of NOT, OR, AND, NOR, and NAND gates. Virtually all digital logic simulators are

event-driven (i.e., a component is evaluated based on when an event occurs on its inputs). Logic simulators are categorized according to the way the delays are modeled in the circuit: (1) unit delay simulators, in which each component is assumed to have a delay of one time unit; and (2) variable-delay simulators, which allow components to have arbitrary delays. While the former helps in simulating the functionality of the circuit the latter allows for more accurate modeling of the fast-changing nodes.

The timing is normally specified in terms of an inertial delay and a load-dependent delay, as follows

$$T_{\text{gate}} = T_{\text{intrinsic}} + C_{\text{load}} \times T_{\text{load}}$$

where

$$T_{\text{gate}} = \text{delay of the gate}$$

$$T_{\text{intrinsic}} = \text{intrinsic gate delay}$$

$$C_{\text{load}} = \text{actual load in some units (pF)}$$

$$T_{\text{load}} = \text{delay per load in some units (ns/pF)}$$

Earlier logic simulators used preprogrammed models for the gates, which forced the user to describe the system in terms of these models. In modern simulators, programming primitives are provided that allow the user to write models for the components. The two most popular digital simulation systems in use today are VHDL and Verilog.

5.2. Circuit-Level Simulation

The most detailed and accurate simulation technique is referred to as *circuit analysis*. Circuit analysis simulators operate at the circuit level. Simulation programs typically solve a complex set of matrix equations that relate the circuit voltages, currents, and resistances. They provide accurate results but require long simulation times. If N is the number of nonlinear devices in the circuit, then the simulation time is typically proportional to N^m , where m is between 1 and 2. Simulation programs are useful in verifying small circuits in detail but are unrealistic for verifying complex VLSI designs. They are based on transistor models and hence should not be assumed to accurately predict the performance of designs. The basic sources of error include (1) inaccuracies in the MOS model parameters, (2) an inappropriate MOS model, and (3) inaccuracies in parasitic capacitances and resistances. The circuit analysis programs widely used are the SPICE program, developed at the University of California at Berkeley [23], and the ASTAP program from IBM [24]. HSPICE [25] is the commercial variant of these programs. The SPICE program provides various levels of modeling. The simple models are optimized for speed, while the complex ones are used to get accurate solutions. As the feature size of the processes is reduced, the models used for the transistors are no longer valid and hence the simulators cannot predict the performance accurately unless new models are used.

5.3. Switch-Level Simulation

Switch-level simulation is simulation performed at the lowest level of abstraction. These simulators model transistors as switches to merge the logic-level and circuit-level simulation techniques. Although logic-level simulators also model transistors as switches, the unidirectional logic gate model cannot model charge sharing, which is a result of the bidirectionality of the MOS transistor. Hence, we assume that all wires have capacitance, since we need to locate charge-sharing bugs. RSIM [26] is an example of a switch-level simulator with timing. In RSIM, CMOS gates are modeled as either pullup or pulldown structures, for which the program calculates a resistance to power or ground. The output capacitance of the gate is used with the resistance to predict the risetime and the falltime of a gate.

5.4. Timing Simulators

Timing simulators allow simple nonmatrix calculations to be employed to solve for circuit behavior. This involves making approximations about the circuit, and hence accuracy is less than that of simulators like SPICE. The advantage is the execution time, which is over two orders of magnitude less than for SPICE. Timing simulator implementations typically use MOS-model equations or table lookup methods. Examples of these simulators are given in Ref. 27.

5.5. Mixed-Mode Simulators

Mixed-mode simulators are available commercially today and merge the aforementioned different simulation techniques. Each circuit block can be simulated in the appropriate mode.

The results of the simulation analysis are fed back to the design stage, where the design is tuned to incorporate the deviations. Once the circuit is perfected and the simulation results are satisfactory, the design can be fabricated. To do this, we need to generate a geometric layout of the transistors and the electrical connections between them. This has been a subject of intense research over the last decade and continues to be so. The following section introduces this problem and presents some of the well-known techniques for solving it.

6. LAYOUT

The layout design is considered a prescription for preparing the photomasks used in the fabrication of ICs [5]. There is a set of rules, called the *design rules*, used for the layout; these serve as the link between the circuit and the process engineer. The physical design engineer, in addition to knowledge of the components and the rules of the layout, needs strategies to fit the layouts together with other circuits and provide good electrical properties. The main objective is to obtain circuits with optimum yield in as small an area as possible without sacrificing reliability.

The starting point for the layout is a circuit schematic. Figure 2 depicts the schematic symbols for n-type and p-type transistors. The circuit schematic is treated as a

Figure 16. Stick diagram of the inverter.

specification for which we must implement the transistors and connections between them in the layout. The circuit schematic of an inverter is shown in Fig. 4. We need to generate the exact layout of the transistors of this schematic, which can then be used to build the photomask for the fabrication of the inverter. Generating a complete layout in terms of rectangles for a complex system can be overwhelming, although at some point we need to generate it. Hence designers use an abstraction between the traditional transistor schematic and the full layout to help organize the layout for complex systems. This abstraction is called a *stick diagram*. Figure 16 shows the stick diagram for the inverter schematic. As can be seen, the stick diagram represents the rectangles in the layout as lines, which represent wires and component symbols. Stick diagrams are not exact models of the layouts but let us evaluate a candidate design with relatively little effort. Area and aspect ratio are difficult to estimate from stick diagrams.

6.1. Design Rules

Design rules for a layout [28] specify to the designer certain geometric constraints on the layout artwork so that the patterns on the processed wafer will preserve the topology and geometry of the designs. These help to prevent separate, isolated features from accidentally short-circuiting, or thin features from opening, or contacts from slipping outside the area to be contacted. They represent a tolerance that ensures very high probability of correct fabrication and subsequent operation of the IC. The design rules address primarily two issues.

1. The geometric reproduction of features that can be reproduced by the maskmaking and lithographical process
2. The interaction among the different layers

Several approaches can be used to describe the design rules. These include the micron rules, stated at some micrometer resolution, and the lambda (λ)-based rules. The former are given as a list of minimum feature sizes and spacings for all masks in a process, which is the usual style for the industry. Mead and Conway [29] popularized the λ -based approach, where λ is process-dependent and is defined as the maximum distance by which a geometric feature on any one layer can stray from another feature. The advantage of the λ -based approach is that by defining λ properly the design itself can be made independent of both the process and fabrication house, and the design can be rescaled. The goal is to devise rules that are simple, constant in time, applicable to many processes,

Figure 17. Transistor layout of the inverter.

standardized among many institutions, and have a small number of exceptions for specific processes. Figure 17 gives the layout of the inverter, with the design rules specified.

To design and verify layouts, different computer-aided design (CAD) tools can be used. The most important of these are the layout editors [30], design rule checkers, and circuit extractors. The editor is an interactive graphic program that allows us to create and delete layout elements. Most editors work on hierarchical layouts, but some editors, like Berekely's Magic tool [31], work on a symbolic layout. The latter include somewhat more detail than the stick diagram but are still more abstract than the pure layout. The design rule checker, or DRC, programs look for design rule violations in the layouts. Magic has an online design rule checking. The circuit extractor is an extension of the DRC programs. While the DRC must identify transistors and vias to ensure proper checks, the circuit extractor performs a complete job of component and wire extraction. It produces a netlist, which lists the transistors in the layouts and the electric nets that connect their terminals.

6.2. Physical Design

From the circuit design of a certain application and the design rules of a specific process, the physical design problem is to generate a geometric layout of the transistors of the circuit design conforming to the specified design rules. From this layout, photomasks can be generated that will be used in the fabrication process. To achieve this, the different modules of the design need to be placed first and then electrical connections between them realized through the metal layers. For instance, a two-layer metallization would allow the designer to lay out metal both vertically and horizontally on the floorplan. Whenever the wire

changes direction, a via can be used to connect the two metal layers. Due to the complexity of this problem, most authors treat module placement and the routing between modules as two separate problems, although they are related critically. Also, in former days, when designs were less complex, design was done by hand. Now we require sophisticated tools for this process.

6.2.1. Placement. Placement is the task of placing modules adjacent to each other to minimize area or cycle time. The literature consists of a number of different placement algorithms that have been proposed [32–35]. Most algorithms partition the problem into smaller parts and then combine them, or start with a random placement solution and then refine it to reach the optimal. The modules are usually considered as rectangular boxes with specified dimensions. The algorithms then use different approaches to fit these boxes in a minimal area or to optimize them to certain other constraints. For instance, consider a certain number of modules with specific dimensions and a given area in which to fit them. This is similar to the bin-packing algorithm. After the placement step, the different modules are placed in an optimal fashion and the electrical connections between them need to be realized.

6.2.2. Routing. Once the modules have been placed, we need to create space for the electrical connections between them. To keep the area of the floorplan minimal, the first consideration is to determine the shortest path between nodes, although a cost-based approach may also be used. The cost is defined to include an estimate of the congestion, number of available wire tracks in a local area, individual or overall wirelength, and so on. Since the problem is a complex one, the strategy is to split the problem into global or loose routing and local or detailed routing. Global routing is a preliminary step, in which each net is assigned to a particular routing area, and the goal is to make 100% assignment of nets to routing regions while minimizing the total wirelength. Detailed routing then determines the exact route for each net within the global route. There are a number of approaches to both of these problems.

6.2.2.1. Global Routing. Global routing [36] is performed using a wirelength criterion, because all timing critical nets must be routed with minimum wirelength. The routing area itself can be divided into disjoint rectangular areas, which can be classified by their topology. A two-sided channel is a rectangular routing area with no obstruction inside and with pins on two parallel sides. A switch box is a rectangular routing area with no obstructions and signals entering and leaving through all four sides [37]. The focus in this problem is only to create space between the modules for all the nets and not to determine the exact route. The algorithms proceed by routing one net at a time, choosing the shortest possible path. Since there is a lot of dependency among the nets, different heuristics are used to generate the least possible routing space in which to route the nets. Once space is created for all the nets, the exact route of each net can be determined.

6.2.2.2. Detailed Routing. Detailed routing is usually done by either a maze search or a line search algorithm. The maze-running algorithm [38,39] proposed by Lee and Moore finds the shortest path between any two points. For this, the layout is divided into a grid of nodes, in which each node is weighted by its distance from the source of the wire to be routed. The route that requires the smallest number of squares is then chosen. If a solution exists, this algorithm will find it, but an excessive amount of memory is required to achieve this. In the line search algorithm, vertical and horizontal lines are drawn from the source and the target, followed by horizontal or vertical lines that intersect the original lines. This is repeated until the source and target meet. There are also a number of other heuristic algorithms that exploit different characteristics of the design to generate optimal routing solutions. Genetic algorithms and simulated annealing approaches to this problem have gained importance in recent years.

An introduction to the various algorithms that have been proposed for layouts can be found in Ref. 40. Once the layout has been determined and the photomasks made, the circuit can go to the fabrication plant for processing.

7. FABRICATION

The section describes the approach used in building integrated circuits on monolithic pieces of silicon. The process involves the fabrication of successive layers of insulating, conducting, and semiconducting materials, which have to be patterned to perform specific functions. The fabrication therefore must be executed in a specific sequence, which constitutes an IC process flow. The manufacturing process itself is a complex interrelationship of chemistry, physics, material science, thermodynamics, and statistics.

Semiconducting materials, as the name suggests, are neither good conductors nor good insulators. While there are many semiconducting elements, silicon is chosen primarily for manufacturing ICs because it exhibits few useful properties. Silicon devices can be built with a maximum operating temperature of about 150°C, due to the smaller leakage currents as a result of the large bandgap of silicon (1.1 eV). IC planar processing requires the capability to fabricate a passivation layer on the semiconductor surface. The oxide of silicon, SiO₂, which could act as such a layer, is easy to form and is chemically stable. The controlled addition of specific impurities makes it possible to alter the characteristics of silicon. For these reasons, silicon is almost exclusively used for fabricating microelectronic components.

7.1. Silicon Material Technology

Beach sand is first refined to obtain semiconductor-grade silicon. This is then reduced to obtain electronic-grade polysilicon in the form of long, slender rods. Single-crystal silicon is grown from this by the Czochralski (CZ) or float-zone (FZ) methods. In CZ growth, single crystal ingots are pulled from molten silicon contained in a crucible. For VLSI applications, CZ silicon is preferred because it can better withstand thermal stresses (41) and offers an in-

ternal gettering mechanism than can remove unwanted impurities from the device structures on wafer surfaces (42). FZ crystals are grown without any contact to a container or crucible and hence can attain higher purity and resistivity than CZ silicon. Most high-voltage, high-power devices are fabricated on FZ silicon. The single crystal ingot is then subjected to a complex sequence of shaping and polishing, known as *wafering*, to produce starting material suitable for fabricating semiconductor devices. This involves the following steps:

1. The single-crystal ingot undergoes routine evaluation of resistivity, impurity content, crystal perfection size, and weight.
2. Since ingots are not perfectly round, they are shaped to the desired form and dimension.
3. The ingots are then sawed to produce silicon slices. The operation defines the surface orientation, thickness, taper, and bow of the slice.
4. To bring all the slices to within the specified thickness tolerance, lapping and grinding steps are employed.
5. The edges of the slices are then rounded to reduce substantially the incidence of chipping during normal wafer handling.
6. A chemico-mechanical polishing [43] step is then used to produce the highly reflective and scratch- and damage-free surface on one side of the wafer.
7. Most VLSI process technologies also require an epitaxial layer, which is grown by a chemical vapor deposition process.

The most obvious trend in silicon material technology is the increasing size of the silicon wafers. The use of these larger-diameter wafers presents major challenges to semiconductor manufacturers. Several procedures have been investigated to increase axial impurity uniformity. These include the use of double crucibles, continuous-liquid-feed (CLF) systems [44], magnetic Czochralski growth (MCZG) [44,45], and controlled evaporation from the melt.

7.2. Epitaxial Layer

The epitaxial growth process is a means of depositing a single-crystal film with the same crystal orientation as the underlying substrate. This can be achieved from the vapor phase, liquid phase, or solid phase. Vapor-phase epitaxy has the widest acceptance in silicon processing, since excellent control of the impurity concentration and crystalline perfection can be achieved. Epitaxial processes are used for the fabrication of advanced CMOS VLSI circuits, because epitaxial processes minimize latchup effects. Also in the epitaxial layer, doping concentration can be accurately controlled, and the layer can be made oxygen/carbon-free. Epitaxial deposition is a chemical vapor deposition process [46]. The four major chemical sources of silicon used commercially for this deposition are (1) silicon tetrachloride (SiCl₄), (2) trichlorosilane (SiHCl₃), (3) dichlorosilane (SiH₂Cl₂), and (4) silane (SiH₄). Depending

on particular deposition conditions and film requirements, one of these sources can be used.

7.3. Doping silicon

The active circuit elements of the IC are formed within the silicon substrate. To construct these elements, we need to create localized n-type and p-type regions by adding the appropriate dopant atoms. The process of introducing controlled amounts of impurities into the lattice of the monocrystalline silicon is known as *doping*. Dopants can be introduced selectively into the silicon using two techniques: diffusion and ion implantation.

7.3.1. Diffusion. The process by which a species moves as a result of the presence of a chemical gradient is referred to as *diffusion*. Diffusion is a time- and temperature-dependent process. To achieve maximum control, most diffusions are performed in two steps. The first step is predeposition [47], which takes place at a furnace temperature and controls the amount of impurity that is introduced. The second step, the drive-in step [47], controls the desired depth of diffusion.

7.3.1.1. Predeposition. In predisposition, the impurity atoms are made available at the surface of the wafer. The atoms of the desired element in the form of a solution of controlled viscosity can be spun on the wafer, in the same manner as the photoresist. For these spinon dopants, the viscosity and the spin rate are used to control the desired dopant film thickness. The wafer is then subjected to a selected high temperature to complete the predeposition diffusion. The impurity atoms can also be made available by employing a low-temperature chemical vapor deposition process in which the dopant is introduced as a gaseous compound—usually in the presence of nitrogen as a diluent. The oxygen concentration must be carefully controlled in this operation to prevent oxidation of the silicon surface of the wafer.

7.3.1.2. Drive-in. After predeposition the dopant wafer is subjected to an elevated temperature. During this step, the atoms further diffuse into the silicon crystal lattice. The rate of diffusion is controlled by the temperature employed. The concentration of the dopant atoms is maximum at the wafer surface and reduces as the silicon substrate is penetrated further. As the atoms migrate during the diffusion, this concentration changes. Hence a specific dopant profile can be achieved by controlling the diffusion process. The dopant drive-in is usually performed in an oxidizing temperature to grow a protective layer of SiO_2 over the newly diffused area.

7.3.2. Ion Implantation. Ion implantation is a process in which energetic, charged atoms or molecules are directly introduced into the substrate. Ion implantation [48,49] is superior to the chemical doping methods discussed previously. The most important advantage of this process is its ability to control more precisely the number of implanted dopant atoms into substrates. Using this method, the lateral diffusion is reduced considerably compared to the

chemical doping methods. Ion implantation is a low-temperature process, and the parameters that control the ion implantation are amenable to automatic control. After this process the wafer is subjected to annealing to activate the dopant electrically. There are some limitations to this process. Since the wafer is bombarded with dopant atoms, the material structure of the target is damaged. The throughput is typically lower than in the diffusion doping process. Additionally, the equipment used causes safety hazards to operating personnel.

7.4. Photolithography

Photolithography is the most critical step in the fabrication sequence. It determines the minimum feature size that can be realized on silicon and is a photoengraving process that accurately transfers the circuit patterns to the wafer. Lithography [50,51] involves the patterning of metals, dielectrics, and semiconductors. The photoresist material is first spin-coated on the wafer substrate. It performs two important functions: (1) precise pattern formation and (2) protection of the substrate during etch. The most important property of the photoresist is that its solubility in certain solvents is greatly affected by exposure to ultraviolet radiation. The resist layer is then exposed to ultraviolet light. Patterns can be transferred to the wafer using either positive or negative masking techniques. The required pattern is formed when the wafer undergoes the development step. After development, the undesired material is removed by wet or dry etching.

Resolution of the lithography process is important to this process step. It specifies the ability to print minimum size images consistently under conditions of reasonable manufacturing variation. Therefore, lithographic processes with submicrometer resolution must be available to build devices with submicrometer features. The resolution is limited by a number of factors, including (1) hardware, (2) optical properties of the resist material, and (3) process characteristics [52].

Most IC processes require 5–10 patterns. Each one of them needs to be aligned precisely with those already on the wafer. Typically, the alignment distance between two patterns is less than $0.2\ \mu\text{m}$ across the entire area of the wafer. The initial alignment is made with respect to the crystal lattice structure of the wafer, and subsequent patterns are aligned with the existing ones. Earlier, mask alignment was done using *contact printing* [53,54], in which the mask is held just off the wafer and visually aligned. The mask is then pressed into contact with the wafer and impinged with ultraviolet light. There is a variation of this technique called *proximity printing*, in which the mask is held slightly above the wafer during exposure. Hard contact printing was preferred because it reduced the diffraction of light, but it led to a number of yield and production problems. So the projection alignment and exposure system was developed, in which the mask and wafer never touch and an optical system projects and aligns the mask onto the wafer. Since there is no damage to the mask or photoresist, the mask life is virtually unlimited. VLSI devices use projection alignment as the standard production method.

7.5. Junction Isolation

When fabricating silicon ICs, it must be possible to isolate the devices from one another. These devices can then be connected through specific electrical paths to obtain the desired circuit configuration. From this perspective, the isolation technology is one of the critical aspects of IC fabrication. For different IC types, like NMOS, CMOS, and bipolar, a variety of techniques have been developed for device isolation. The most important technique developed was termed LOCoS, for *local oxidation of silicon*. This involves the formation of semirecessed oxide in the nonactive or field areas of the substrate. With the advent of submicron-size device geometries, alternative approaches for isolation were needed. Modified LOCoS processes, trench isolation, and selective epitaxial isolation were among the newer approaches adopted.

7.5.1. LOCoS. To isolate MOS transistors, it is necessary to prevent the formation of channels in the field regions. This implies that a large value of V_T is required in the field region, in practice about 3–4 V above the supply voltage. Two ways to increase the field voltage are to increase the field oxide thickness and raise the doping beneath the field oxide. Thicker field oxide regions cause high enough threshold voltages but unfortunately lead to step coverage problems, and hence thinner field oxide regions are preferred. Therefore, the doping under the field oxide region is increased to realize higher threshold voltages. Nevertheless, the field oxide is made 7–10 times thicker than the gate oxide. Following this, in the channel-stop implant step, ion implantation is used to increase the doping under the field oxide. Until about 1970, the thick field oxide was grown using the *grow-oxide-and-etch* approach, in which the oxide is grown over the entire wafer and then etched over the active regions. Two disadvantages of this approach prevented it from being used for VLSI applications: (1) field oxide steps have sharp upper corners, which poses a problem to the subsequent metallization steps; and (2) channel-stop implant must be performed before the oxide is grown. In another approach, the oxide is selectively grown over the desired field regions. This process was introduced by Appels and Kooi in 1970 [55] and is widely used in the industry. This process is performed by preventing the oxidation of the active regions by covering them with a thin layer of silicon nitride. After etching the silicon nitride layer, the channel-stop dopant can be implanted selectively. The process, has a number of limitations for submicrometer devices. The most important of these is the formation of the “bird’s beak,” which is a lateral extension of the field oxide into the active areas of the device. The LOCoS bird’s beak creates other problems as junctions become shallower in CMOS ICs. The LOCoS process was therefore modified in several ways to overcome these limitations: (1) etched-back LOCoS, (2) polybuffered LOCoS, and (3) sealed-interface local oxidation (SILO) [56].

7.5.2. Non-LOCoS Isolation Technologies. There have been non-LOCoS isolation technologies for VLSI and ultra-large-scale integration (ULSI) applications. The

most prominent of these is *trench* isolation technology. Trench technologies are classified into three categories: (1) shallow trenches ($<1\mu\text{m}$), (2) moderate depth trenches ($1\text{--}3\mu\text{m}$), and (3) deep, narrow trenches ($>3\mu\text{m}$ deep, $<2\mu\text{m}$ wide). Shallow trenches are used primarily for isolated devices of the same type and hence are considered a replacement to LOCoS. The buried oxide (BOX) [57] isolation technology uses shallow trenches refilled with a silicon dioxide layer, which is etched back to yield a planar surface. This technique eliminates the bird’s beak of LOCoS. The basic BOX technique has certain drawbacks for which the technique is modified.

7.6. Metallization

This subsection describes the contact technology to realize the connections between devices, and how the different metal layers are connected to realize the circuit structure.

7.6.1. Contact Technology. Isolated active-device regions in the single-crystal substrate are connected through high-conductivity, thin-film structures that are fabricated over the silicon dioxide that covers the surface. An opening in the SiO_2 must be provided to allow *contacts* between the conductor film and the Si substrate. The technology involved in etching these contacts is referred to as *contact technology*. These contacts affect the circuit behavior because of the parasitic resistances that exist in the path between the metal to Si substrate and the region where the actual transistor action begins. Conventional contact fabrication involves the fabrication of a contact to silicon at locations where the silicon dioxide has been etched to form a window. It involves the following steps:

1. In regions where contacts are to be made, the silicon substrate is heavily doped.
2. A window or *contact hole* is etched in the oxide that passivates the silicon surface.
3. The silicon surface is cleaned to remove the thin native-oxide layer that is formed rapidly when the surface is exposed to an oxygen-containing ambient.
4. The metal film is deposited on the wafer and makes contact with silicon wherever contact holes were created. Aluminum is the most commonly used metal film.
5. After depositing the metal, the contact structure is subjected to a thermal cycle known as *sintering* or *annealing*. This helps in bringing the Si and metal into intimate contact.

Al is desired as an interconnect material because its resistivity, $2.7\mu\Omega\cdot\text{cm}$, is very low, and it offers excellent compatibility with SiO_2 . Al reacts with SiO_2 to form Al_2O_3 , through which the Al can diffuse to reach the Si, forming an intimate AlOSi contact. But using pure Al has certain disadvantages. Since Al is polycrystalline in nature, its grain boundaries offer very fast diffusion paths for the Si at temperatures above 400°C . Hence, if a large volume of Al is available, a significant quantity of the Si can diffuse into Al. As a result, the Al from the film moves rapidly to

fill in the voids created by the migrating Si, which leads to large leakage currents or electrically shorting the circuit. This effect is referred to as *junction spiking* [58]. To prevent junction spiking, different techniques are used:

1. Add approximately 1% of Si to Al.
2. Add a diffusion barrier to prevent Si from diffusing into Al.
3. Decrease sintering temperature, but this increases contact resistance.
4. Add a “barrier” metal to the contact hole [59].

Of these techniques, the most commonly used is the barrier metal. The idea is to block or hinder Al from intermixing with Si. There are three main types of contact barrier metallurgies: (1) sacrificial barrier, (2) passive barrier, and (3) stuffed barrier.

The use of Al has its own problems; the most important is its high resistivity and electromigration. There is also the problem with “hillock” formation. Hillocks are formed as a result of the thermal expansion mismatch among Al, SiO₂, and Si. As the wafer is cooled, thermal expansion mismatch forms stresses (usually compressive), which forms these hillocks. Therefore, copper metallization has been gaining importance. Copper is preferred over Al because it has a low resistivity (1.2 μΩ · cm) and is resistant to electromigration. In fact, copper is added in small quantities to Al to reduce the electromigration problem of Al. However, there are some real problems with copper that need to be addressed before it can replace Al:

1. Cu is a terrible contaminant in Si. It has a very high diffusivity in Si and causes junction leakage, which degrades the gate oxide integrity (GOI).
2. Cu diffuses and drifts easily through SiO₂. Hence, Cu needs to be encapsulated for use in metallization.
3. Cu oxidizes to CuO easily.
4. The etch chemistry for Cu is highly contaminated, and the wafers need to be held at higher temperatures.

Typical process steps involved in the fabrication of a 0.8-μm LOCoS n-well inverter are as follows:

1. Wafer: 1×10^{15} to 1×10^{16} CZ(p) with (100) crystal orientation. Epitaxial layer required because of latchup. The thickness is 2–16 μm with 5×10^{15} .
2. Grown screen oxide layer, with the thickness in the range 400–1000.
3. Expose the n-well photo on the wafer.
4. n-well ion implant. Use $1 \times 10^{13}/\text{cm}^2$ phosphorous. The voltage used is 60 keV–2 MeV.
5. n-well drive-in. This step is carried out at 1050–1100°C for 2–6 h. This activates the dopant atoms. The drive-in depth is around 1–10 μm.
6. Perform LOCoS process.
 - a. Strip wafer.
 - b. Pad oxide. Thickness is 100–400.
 - c. Pad nitride. Thickness is 1000–2000. LPCVD silicon nitride is used.
 - d. Expose the diffusion photo on the wafer.
 - e. Etch the nitride layer.
 - f. Expose the block field (BF) photo. This is the inverse of the n-well photo and prevents the formation of the parasitic transistors between adjacent transistors.
 - g. Field ion implantation. $1 \times 10^{13}/\text{cm}^2$ boron at 60 keV.
 - h. Strip the BF and the resist layer.
 - i. Grow the field oxide. The thickness is about 4000–6000 of SiO₂. The process used is a pyro process at 900–1050°C for 3–6 h.
 - j. Strip the pad nitride layer by dipping the wafer in H₃PO₄.
 - k. Strip the pad oxide layer by dipping the wafer in 50 : 1 HF.
7. Grow a sacrificial oxide layer and strip it. The thickness is about 600–1000. The sacrificial oxide layer eats into the bare silicon, thus exposing fresh silicon area on which the device can be grown.
8. Grow a sacrificial gate oxide layer. Here the thickness is about 80–130. This layer protects the gate when the V_T implant is done.
9. V_T implant. Two masks, one for the n region and one for the p region, are used. The concentration is 1×10^{11} to $1 \times 10^{12}/\text{cm}^2$ at 5–30 keV.
10. Strip the sacrificial gate oxide layer using a 50 : 1 HF solution.
11. Grow the gate oxide layer. Typical thickness is 80–130. The gate oxide layer is grown at 800–900°C for 20 min.
12. Polysilicon is deposited all over the wafer. LPCVD silane is used at 620°C for a blanket deposition. The typical thickness is 2500–4000.
13. Polysilicon doping is done by ion implantation using 5×10^{15} phosphorous.
14. The polysilicon etch is a very critical photo/etch process.
 - l. Polysilicon photo is exposed on the wafer.
 - m. Reactive-ion etch (RIE) is used to etch the polysilicon.
 - n. The resist is stripped.
15. Diffusion processing
 - o. Mask the p regions.
 - p. Perform n⁺ source/drain ion implantation using $5 \times 10^{15}/\text{cm}^2$ As⁷⁵ at 40 keV. As is used because it is slow and does not diffuse deep into the silicon substrate.
 - q. Perform n⁺ anneal at 900°C for 15 min to activate the dopant.
 - r. Strip the resist.
 - s. Mask the n⁺ regions.
 - t. Perform p⁺ source/drain ion implantation using $1 \times 10^{15}/\text{cm}^2$ BF₂/B¹¹ at 5–20 keV.
 - u. Source/drain anneal at 900°C for 30 min in an oxidizing atmosphere. This is a rapid thermal process.
 - v. Strip the resist off.

16. Interlevel dielectric. Borophosphosilicon glass (BPSG) is used because it flows well. Typical thickness is 5000–8000. A 900°C reflow anneal is also performed.
17. The contact photo is exposed on the wafer. This is critical to the layout density.
18. The contacts are etched using RIE.
19. After etching, the contact resist is stripped off.
20. Metallization. Ti barrier metallurgy is used. The actual contact is made with an alloy of Al/Cu/Si with percentages 98%, 1%, and 1%, respectively. The Al alloy is sputtered onto the wafer. The typical thickness is about 1.2 μm.
21. The metal 1 layer photo is exposed.
22. Metal 1 etch.
23. Strip resist.
24. Foaming gas anneal is performed to improve the mobility of the electrons and relieve stress on the wafer.

The inverter is finally fabricated. Figure 5 describes the process cross section of this inverter after the various steps have been performed.

8. TESTING

Testing is a critical factor in the design of circuits. The purpose of testing is to verify conformance to the product definition. To understand the complexity of this problem, consider a combinational circuit with n inputs. A sequence of 2^n inputs must be applied and observed to test the circuit exhaustively. Since the number of inputs are high for VLSI circuits, testing the chip exhaustively is impossible. Hence, this becomes an area of importance to circuit design. There are three main areas that need to be addressed to solve this problem:

1. Test generation
2. Test verification
3. Design for testability

Test generation corresponds to the problem of generating a minimum number of tests to verify the behavior of a circuit. The problem of test verification, which is commonly gauged by performing fault simulations, involves evaluating measures of the effectiveness of a given set of test vectors. Circuits can also be designed for testability.

8.1. Test Generation

Test generation [60] involves the search for a sequence of input vectors that allow faults to be detected at the primary device outputs. VLSI circuits are typically characterized by buried flip-flops, asynchronous circuits, indeterminate states, complex clock conditions, multiple switching of inputs simultaneously, and nonfunctional inputs. Due to these factors, an intimate knowledge of the internal circuit details is essential to develop efficient test strategies. The goal of a test generation strategy [61,62] is

multifold: (1) chip design verification in conjunction with the designer, (2) incorporation of the customer's specification and patterns into the manufacturing test program, and (3) fault detection by fault simulation methods.

8.2. Test Verification

Test verification [63] involves calculating measures for how efficient the test vectors for a given circuit are. This is often accomplished by using fault models [64]. Fault simulation requires a good circuit simulator to be efficient and is hence closely related to logic simulation and timing analysis. While the logic simulator verifies the functionality of a design and ensures that the timing constraints are met, the fault simulator tells the designer if enough analysis has been performed to justify committing the design to silicon. In fault simulation, the true value of a circuit and its behavior under possible faults is simulated. The fault model is a hypothesis based on an abstract model of the circuit, conformed to some precise real physical defects. To begin with, the simulator generates a fault list that identifies all the faults to be modeled. Then a set of test vectors is simulated against the fault-free and faulty models. Those faults that cause an erroneous signal at an output pin are considered as detected faults. Now the fault coverage of the test vector set can be computed as the number of faults detected over the total number of faults modeled.

The most widely used fault model is the single stuck-at fault model. This model assumes that all faults occur because of the shorting of a signal node with the power rail. A number of faults can be detected by this model, but a major disadvantage of this model is its assumption that all faults appear as stuck-at faults. The limitations of this model have led to the increased use of other models, like the stuck-open [65] and bridging fault models [66]. The former can occur in a CMOS transistor or at the connection to a transistor. The bridging faults are short circuits that occur between signal lines. These represent a frequent source of failure in CMOS ICs. A majority of the random defects are manifested as timing delay faults in static CMOS ICs. These are faults in which the increased propagation delay causes gates to exceed their rated specifications. The statically designed circuits have a transient power supply that peaks when the gates are switching and then settles to a low current value in the quiescent state. The quiescent power supply current [67], known as I_{DDQ} , can be used as an effective test to detect leakage paths due to defects in the processing. The measured I_{DDQ} of a defect-free CMOS IC is approximately 20 nA. Most physical defects will elevate I_{DDQ} by one to five orders of magnitude. Thus the I_{DDQ} testing approach can be used to detect short circuits not detectable by the single stuck-at fault model.

There are several other ways of applying logic and fault simulation to testing:

1. *Toggle Testing*. This is the cheapest, simplest, and least time-consuming method of applying simulation to testing. Toggle testing provides a testability measure by tracking the activity of circuit nodes. From a

set of vectors, the method identifies those parts of the network that exhibit no activity. Since the test vectors do not affect these nodes, faults occurring here cannot be detected by the fault simulator.

2. *Fault Simulation of Functional Tests.* The outputs of the functional simulator can be used in the design process as an effective design analysis tool. The lists of detectable and undetectable faults generated by the simulator can be used to locate problems in the design and correct them. This results in substantial savings in development and manufacturing.
3. *Fault Simulation after New Test Vector Generation.* High-quality testing in a reasonable time-frame would require an efficient test pattern generation system and a fault simulator. Test vectors are first generated to detect specific faults, and the fault simulator determines the quality of the vector set. In this scenario, it becomes important to fault simulate after every new test vector is generated in order to catch multiple faults. Accelerated fault simulation is faster than test pattern generation.

8.3. Design for Testability

Design for testability commonly refers to those design techniques that produce designs for which tests can be generated by known methods. The advantage of these techniques are (1) reduced test generation cost, (2) reduced testing cost, (3) high-quality product, and (4) effective use of computer-aided design tools. The key to designing circuits that are testable are two concepts, controllability and observability. *Controllability* is defined as the ability to set and reset every node that is internal to the circuit. *Observability* is defined as the ability to observe either directly or indirectly the state of any node in the circuit. There are programs like SCOAP [68] that, given a circuit structure, can calculate the ability to control or observe internal circuit nodes. The concepts involved in design for testability can be categorized as follows: (1) ad hoc testing, (2) scan-based test techniques, and (3) built-in self-test (BIST).

8.3.1. Ad Hoc Testing. Ad hoc testing comprises techniques that reduce the combinational explosion of testing. Common techniques partition the circuit structure and add test points. A long counter is an example of a circuit that can be partitioned and tested with fewer test vectors. Another technique is the use of a bus in a bus-oriented system for testing. The common approaches can be classified as (1) partitioning techniques, (2) adding test points, (3) using multiplexers, and (4) providing for easy state reset.

8.3.2. Scan-Based Test Techniques. Scan-based approaches stem from the basic tenets of controllability and observability. The most popular approach is the level-sensitive scan design, or LSSD, approach, introduced by IBM [69]. This technique is illustrated in Fig. 18. Circuits designed on the basis of this approach operate in two

Figure 18. Level-sensitive scan design.

modes: normal mode and test mode. In the normal mode of operation, the shift register latches act as regular storage latches. In the test mode, these latches are connected sequentially and data can be shifted in or out of the circuit. Thus, a known sequence of data (controllability) can be input to the circuit, and the results can be shifted out of the circuit using the registers (observability). The primary disadvantage of this approach is the increased complexity of the circuit design and the increased external pin count. The serial scan approach is similar to the LSSD, but the design of the shift register latch is simplified to obtain faster circuits. For most circuit designs, only the input and output register need be made scannable. This technique makes the designer responsible for deciding which registers need to be scanned and is called the *partial serial scan technique* [70]. The *parallel scan* [71] approach is an extension of the serial scan in which the registers are arranged in a sort of a grid, where on a particular column all the registers have a common read/write signal. The registers that fall on a particular row have common data lines. Therefore, the output of a register can be observed by enabling the corresponding column and providing the appropriate address. Data can also be written into these registers in a similar fashion.

8.3.3. Built-in Self-Test. Signature analysis [72] or cyclic redundancy checking can be used to incorporate a built-in self-test module in a circuit. This involves the use of a linear feedback shift register, as depicted in Fig. 19. The value in the register will be a function of the value and number of latch inputs and the counting function of the signature analyzer. The good part of the circuit will have a particular number or signature in the register, while the faulty portion will have a different number. The signature analysis approach can be merged with the level-sensitive scan design approach to create a structure called a built-in logic block observation, or BILBO [73]. Yet

Figure 19. Linear feedback shift register.

another approach to the built-in test is the design for autonomous test, in which the circuit is partitioned into smaller structures that are tested exhaustively. The partitioning method involves the use of multiplexers. The syndrome testing method, in which all possible inputs are applied and the number of 1s at the outputs is counted, is also a test method that requires exhaustive testing. The resultant value is compared to that of a known good machine.

8.4. Other Tests

So far we have discussed techniques for testing logic structures and gates. But we need testing approaches at the chip level and the system level also. Most approaches for testing chips rely on the aforementioned techniques. Memories, for instance, can use the built-in self-test techniques effectively. Random logic is usually tested by full serial scan or parallel scan methods. At the system level, traditionally the "bed of nails" testers have been used to probe points of interest. But with the increasing complexity of designs, system designers require a standard to test chips at the board level. This standard is the IEEE 1149 boundary scan [74] architecture. ICs that are designed on the basis of this standard enable complete testing of the board. The following types of tests can be performed in a unified framework: (1) connectivity test between components, (2) sampling and setting chip I/Os, and (3) distribution and collection of built-in self-test results.

INTEGRO-DIFFERENTIAL EQUATIONS

MANUEL GARCIA

Laboratory
Livermore, California

1. INTRODUCTION

This article focuses on methods of solution. The aim is to show how a student or engineer can manipulate an integrodifferential problem into a form that is simple to calculate. Few of these equations yield analytical solutions. The direct numerical approach of using finite differences for derivatives and sums for integrals relies on the capability of the computer and on the stability of the numerical algorithm. The methods described in this article aim to improve the stability of the eventual calculation by removing derivatives, and to minimize repetitive calculations (nested loops). These techniques make it possible to solve realistic problems with modest personal computers.

An integrodifferential equation describes the influence of an accumulation of points on the value and dynamics of each individual member of the collection. These equations are a balance between a quantity, its derivatives, and its integrals. The most significant applications of integrodifferential equations are in modeling the impact of heredity and the dynamics of systems out of equilibrium. Heredity problems in engineering include analyzing fluid and heat flow, mechanical stress, and the accumulation of residual charge for materials with memory. The study of nonequilibrium systems is based on kinetic theory, where the properties of a gas are calculated as the average of individual molecular collisions. Integrodifferential equations are applied in biology and economics as well as in physics and engineering.

A differential equation describes the dynamics of a quantity. It is a balance between the values of the quantity and its various rates of change *at a given moment*. One such balance is between the acceleration of a particle and

the action of external forces, classical Newtonian mechanics. Basic examples are the one-dimensional mass–spring–damper equation and its electrical analog, the resistor–inductor–capacitor (*RLC*) circuit equation. These specific differential models each conserve a global quantity; for the mechanical example it is momentum, for the electrical example it is current. The implicit assumption in the differential description is that the future state of a system does not depend on its history. Erosion, fatigue, wear, failure, experience, heredity, evolution, karma—all these words express some observation about the impact of past dynamics on future dynamics. One example is the failure of mechanical components subjected to repetitive stress. Engineers routinely calculate the amount of twist of a metal bar subjected to a specific torque. If we assume this phenomenon to be purely differential, then the same amount of torque will always produce the same amount of twist. In reality, metal subjected to repeated strain experiences fatigue. Eventually the application of the same torque produces a different twist, perhaps a catastrophic event. The metal inherits a degradation of its elasticity, an integral of the history of deflections. This effect caused the breakup of two de Havilland Comet jet airliners during flight in 1954. The engineers of the day were unaware that the aluminum fuselage would experience metal fatigue as a result of the frequent cycles of cabin pressurization.

An integral equation describes the influence of all points in a field upon the value of any particular point. Integral equations express an equilibrium. The points can be spatial for a field of stress in a surface or rod, or they can be instants of time in an orbital trajectory, or they can be individual molecules in a gas in which the field is a statistical distribution of molecular velocities. When external conditions change suddenly so that the system is out of balance, energy or information must flow within the system to rearrange it into a new equilibrium. Describing this nonequilibrium process requires differential terms in addition to the original integral equation. Instantaneous equilibration is often assumed in engineering applications, for instance, in thermodynamics, and integrodifferential equations are avoided. However, the sharpening of technology into much smaller space and timescales has required more exacting physical models that account for nonequilibrium dynamics. This technological trend drives the continuing interest in solving integrodifferential equations.

A method is described for transforming integrodifferential equations with linear derivatives into purely integral forms, which are then solved by iteration. Knowledge of an approximate solution speeds the convergence of iteration. One method of developing such approximate solutions is described in the section that follows. By the very nature of approximation, such methods depend on the specifics of the particular integrodifferential equation. It is best to view the development of the approximate solutions in the sample analysis as an example of the attitude and reasoning that may prove useful in other problems. After the discussion of linear equations a nonlinear system with hereditary effects is described. This nonlinear system describes the conflict between populations of predators and prey. This system is reduced to a single nonlinear integral equation for which an iterated

solution is found. However, a much easier calculation of the solution is possible with an approximate equation developed from the nonlinear integral. This approximation recognizes the effect of the hereditary integral and casts the problem as a type of recursion formula $\{x(t) = f[x(t - \Delta t), t]\}$, eliminating the need for any iteration. A discussion of physical applications of integrodifferential equations concludes the article.

2. A SAMPLE ANALYSIS

Consider the following linear, first-order, homogeneous integrodifferential equation for unknown function $y(x)$:

$$\frac{dy(x)}{dx} = - \int_{x-\alpha}^{x+\beta} \frac{p(\xi)}{a(x)} y(\xi) d\xi \tag{1}$$

We will use this equation to demonstrate how a solution may be attempted. Both α and β are positive constants. This particular equation has a separable kernel

$$K(\xi, x) = \frac{p(\xi)}{a(x)} \tag{2}$$

and we suppose that $a(x)$ is not zero in the domain of interest. Can Eq. (1) be cast as a purely differential, or purely integral equation? If so, it may be possible to transform it to a standard form and solve it by established techniques. In this section we will look first at the effect of differentiating Eq. (1), then we will seek an approximate solution directly from the integrodifferential form, then we will transform Eq. (1) into a purely integral form, and finally we will show specific examples.

Differentiating Eq. (1) results in

$$a(x)y''(x) + a'(x)y'(x) = p(x - \alpha)y(x - \alpha) - p(x + \beta)y(x + \beta) \tag{3}$$

where primes refer to differentiation with respect to x . In Eq. (3) derivatives of y at x depend on values of y at positions to either side of x . This form is a differential-difference equation. References 1 and 2 describe this type of equation. From Eq. (3), $y(x - \alpha)$ can be cast as depending on itself at higher x

$$y(x - \alpha) = \frac{a(x)y''(x) + a'(x)y'(x) + p(x + \beta)y(x + \beta)}{p(x - \alpha)} \tag{4}$$

This form of the equation is the basis of a numerical solution in cases where it is known that $y(x)$ decays exponentially with respect to positive x . Above a given coordinate, say x_2 , y is assumed to be small and its derivatives are assumed to be zero. A solution is constructed for $x < x_2$ using Eq. (4). In a range $x < x_1$, where $x_1 < x_2$, the function $y(x)$ is exponentially larger than the starting value assumed, and $y(x)$ is considered an accurate solution. Care must be taken in the numerical treatment of the derivatives, and this is most directly accomplished by using closely spaced points and higher-order differences. If the kernel is not separable, then differentiation will not

remove the integral. It will now contain the derivative of the kernel with respect to x , $K'(\xi, x)$.

Let us assume that $y(x)$ is a positive function that decays exponentially with respect to positive x . In this case both $a(x)$ and $p(x)$ are positive over the range of interest, $x_0 \leq x < \infty$. Let us seek a solution in the form

$$y(x) = \exp \left[- \int_{x_0}^x B(\eta) d\eta \right] \tag{5}$$

where x_0 is a reference coordinate where $y = 1$, an initial condition. Note that $-y'/y = B$. Divide Eq. (1) by $y(x)$ and use Eq. (5):

$$a(x)B(x) = \int_{x-\alpha}^{x+\beta} p(\xi) \exp \left[- \int_x^\xi B(\eta) d\eta \right] d\xi \tag{6}$$

Note that in Eq. (6) it is the ratio $y(\xi)/y(x)$ that appears in the integral with $p(\xi)$, and this ratio is given by the exponential involving $B(\eta)$. Given an estimate of function B , call it B_0 , Eq. (6) can be used to find a possibly more accurate estimate B_1 by the method of successive approximations. This method, also known as the *method of Picard*, uses a prior iterant within the integral (B_0) to find a next iterant (B_1) from the equation. References 3 and 4 describe the validity and use of this method.

If the method of successive approximations converges to a solution, then the exact nature of the initial iterant B_0 is unimportant. However, the more accurately B_0 portrays the actual solution $B(x)$, the fewer iterants need to be calculated. We now seek an initial iterant from Eq. (6) by making whatever assumptions simplify this problem, while at the same time being mindful to avoid a trivial result by being too hasty. For the moment we will assume that $p(x)$ is weakly dependent on x within any band $(x - \alpha, x + \beta)$, and that $B(\xi)$ remains of the same order of magnitude for $(x - \alpha \leq \xi \leq x + \beta)$. The following approximations cascade from Eq. (6) by using these assumptions:

$$\begin{aligned} a(x)B_0(x) &\approx \int_{x-\alpha}^{x+\beta} p(\xi) e^{-B_0(x)(\xi-x)} d\xi \approx p(x) \int_{x-\alpha}^{x+\beta} e^{-B_0(x)(\xi-x)} d\xi \\ &\approx \frac{p(x)}{-B_0(x)} \int_{x-\alpha}^{x+\beta} e^{-B_0(x)(\xi-x)} [-B_0(x)] d\xi \\ &\approx \frac{p(x)}{B_0(x)} [e^{2B_0(x)} - e^{-\beta B_0(x)}] \end{aligned} \tag{7}$$

$$B_0(x) = \sqrt{\frac{p(x)}{a(x)} e^{2B_0(x)} [1 - e^{-(\alpha+\beta)B_0(x)}]} \tag{8}$$

For a small $B_0(x)$ such that both $B_0(x)(\alpha + \beta) < 1$ and $B_0(x)\alpha < 1$, then

$$B_0(x) = \frac{p(x)}{a(x)} (\alpha + \beta) \tag{8a}$$

which is found by expanding the exponentials in Eq. (8). Note that to be consistent, $p(x)/a(x)$ must be less than

$(\alpha + \beta)^{-2}$. For $B_0(x)$ such that $B_0(x)(\alpha + \beta) > 1$ while $B_0(x)\alpha < 1$, which implies $\beta \gg \alpha$, then

$$B_0(x) = \sqrt{\frac{p(x)}{a(x)}} \tag{8b}$$

This case is consistent with $1/(\alpha + \beta) < \sqrt{p(x)/a(x)} < 1/\alpha$. Finally, for $B_0(x)$ such that both $B_0(x)(\alpha + \beta) > 1$ and $B_0(x)\alpha > 1$, then $B_0(x)$ is the root of a transcendental equation

$$B_0(x) = \sqrt{\frac{p(x)}{a(x)} e^{2B_0(x)}} \tag{8c}$$

If none of Eqs. (8a)–(8c) are applicable, then $B_0(x)$ must be found as a root of Eq. (8). The corresponding initial iterant $y_0(x)$ for Eq. (1) is given by using the appropriate result from Eqs. (8) or (8a)–(8c) in definition (5). The example shown below uses the simplest case, Eq. (8a):

$$y_0(x) = \exp \left[-(\alpha + \beta) \int_{x_0}^x \frac{p(\eta)}{a(\eta)} d\eta \right] \tag{9}$$

It is very important to capture the functional nature of $p(x)$ within the integral of Eq. (7). In the preceding, $p(x)$ was assumed to be very weakly dependent on x over the interval $(x - \alpha, x + \beta)$ in a manner similar to a constant or $\log(x)$. If instead, $p(x) = p_0(x)x$, where $p_0(x)$ is a weak function of x as used here, then the results in place of Eq. (8) are as follows:

$$B_0(x) = \sqrt[3]{\frac{p_0(x)}{a(x)} e^{2B_0(x)} \{1 + B_0(x)(x - \alpha) - [1 + B_0(x)(x + \beta)]e^{-(\alpha + \beta)B_0(x)}\}} \tag{10}$$

The case of small $B_0(x)$ corresponding to Eq. (8a) is now

$$B_0(x) = \frac{p_0(x)}{a(x)} (\alpha + \beta) \left(x + \frac{\beta^2 - \alpha^2}{(\alpha + \beta)} \right) \tag{10a}$$

Note the additional linear factor in comparison to Eq. (8a). It is essential to retain that factor of $p(x)$ with significant variation within the integral of Eq. (7). We will only use the simplest B_0 and y_0 , derived as Eqs. (8a) and (9), respectively, to illustrate a first iterant with Eq. (11)

$$a(x)B_1(x) = \int_{x-\alpha}^{x+\beta} p(\xi) \exp \left[-(\alpha + \beta) \int_x^\xi \frac{p(\eta)}{a(\eta)} d\eta \right] d\xi \tag{11}$$

and a $y_1(x)$ can be constructed from the $B_1(x)$ of Eq. (11). A $y_1(x)$ can also be written explicitly from the integral of Eq. (1) by using $y_0(x)$

$$y_1(x) = y(x_0) - \int_{x_0}^x \int_{\xi-\alpha}^{\xi+\beta} \frac{p(\eta)}{a(\xi)} y_0(\eta) d\eta d\xi \tag{12}$$

Recall that $y(x_0) = 1$ in this particular case. Whether the first iterant sought is B_1 from Eq. (11) or y_1 from Eq. (12), a

double integration is required after the zeroth iterants B_0 and y_0 are calculated. It would be very discouraging to do all this work and then find that our iteration was diverging. An effort to reduce repetitive integration follows.

Equation (12) is a purely integral form of Eq. (1) when the subscripts on y are removed and $y(x_0)$ is arbitrary. By reversing the order of integration it is possible to reformulate this equation as a single integration over the unknown $y(\eta)$ with a new kernel

$$\begin{aligned} y(x) - y(x_0) &= - \int_{x_0}^x \int_{\xi-\alpha}^{\xi+\beta} \frac{p(\eta)}{a(\xi)} y(\eta) d\eta d\xi \\ &= - \int_{x_0-\alpha}^{x+\beta} p(\eta) M(\eta, x) y(\eta) d\eta \end{aligned} \tag{13}$$

The new kernel factor $M(\eta, x)$ is given below for this example. The method of reversing the order of integration and generating kernels of this type will be described in Section 3:

$$\begin{aligned} M(\eta, x) &= \left\{ \int_{x_0}^{\eta+\alpha} \frac{d\xi}{a(\xi)}; [x_0 - \alpha] \leq \eta \right. \\ &\quad \left. < [\min(x_0 + \beta, \min(x_0 + \alpha + \beta, x) - \alpha)] \right\} \\ &\quad + \left\{ \int_{x_0}^x \frac{d\xi}{a(\xi)}; \min[x_0 + \beta, \min(x_0 + \alpha + \beta, x) - \alpha] \right. \\ &\quad \left. \leq \eta < [x_0 + \beta] \right\} \\ &\quad + \left\{ \int_{\eta-\beta}^{\min(\eta+\alpha, x)} \frac{d\xi}{a(\xi)}; [x_0 + \beta] \leq \eta \leq [x + \beta] \right\} \end{aligned} \tag{14}$$

The function $\min(a, b, \dots)$, used in $M(\eta, x)$, selects the minimum of its arguments. $M(\eta, x)$ is the sum of three terms, each defined over a different range of η , and these ranges are functions of x . The new kernel $K(\eta, x) = p(\eta)M(\eta, x)$ can be calculated once from known functions $a(x)$ and $p(x)$, and by the explicit operations of Eq. (14). The derivation of Eqs. (13) and (14) proceeds directly from Eq. (1), without requiring any specialized assumptions, as were used in the development of B_0 . Now the original integrodifferential equation has been transformed into a purely integral form, a Volterra equation (variable upper limit) of the second kind [inhomogeneous if $y(x_0) \neq 0$]. The method of successive approximations applied to Eq. (13) proceeds more quickly because each iterant of $y(x)$ is now the result of a single integration.

Two specific numerical examples follow. In both cases $a(x) = a_0x$, and $p(x) = p_0x$, where a_0 and p_0 are constants. Solutions are sought in the range $[(x_0 = 1) \leq x \leq (x_1 = 3)]$, although calculations must consider the wider range $(1 - \alpha, 3 + \beta)$. In these cases $y(1) = 1$. $B_0(x)$ is found as the root of Eq. (10), and a $y_0(x)$ is calculated from Eq. (5). The kernel $K(\eta, x) = p(\eta)M(\eta, x)$ is calculated on the basis of Eq. (14). Two iterants, y_1 and y_2 , are then found by the method of successive approximations from Eq. (13). Figure 1 shows y_0, y_1 , and y_2 for $a_0 = 1, p_0 = 8, \alpha = 0$, and $\beta = 1.45$. Iterants y_0 and y_1 are quite smooth; with y_2 the

Figure 1. Three iterants for the $y(x)$ of Eq. (1) when $a(x)=x$, $p(x)=8x$, $\alpha=0$, and $\beta=1.45$. The zeroth iterant $y_0(x)$ is found by an approximation to its logarithmic derivative $B_0 = -\{d\ln[y_0(x)]/dx\}$ that is given by Eq. (10). The iteration is applied to Eq. (13), which is a single integral form of Eq. (1) with a new kernel $p(\eta)M(\eta,x)$ that is described by Eq. (14). Convergence is rapid. This function decays by two orders of magnitude for $1 \leq x \leq 3$. The relative error is comparable to $y(x)$ at low amplitude. This error diminishes as more points are used (point locations shown for y_2).

point-to-point numerical noise becomes noticeable (point locations are shown for y_2). This noise diminishes as more closely spaced points are used. In this case $y(x)$ has a rapid exponential decay. A second case has $a_0=1$, $p_0=0.08$, $\alpha=0.55$, and $\beta=1.45$. Figure 2 shows the three iterants of y , which decay gently with x . In both cases y_0 and y_1 bracket y_2 . Figures 3 and 4 show the kernel $K(\eta, x)$ for the first case (both appear similar). Two views are given to help visualize this surface over the full range of the calculation.

Figure 2. Three iterants for the $y(x)$ of Eq. (1) when $a(x)=x$, $p(x)=0.08x$, $\alpha=0.55$, and $\beta=1.45$. Another case similar to that of Fig. 1. Here the function decays very gently, and the relative error is small.

Figure 3. A surface plot of $K(\eta,x)=p(\eta)M(\eta,x)$, the kernel used in the example of Fig. 1. The kernel for the second example has the same shape but is of different magnitude. This view extends over the full area of the calculation in the (η,x) plane. The problem has been converted to an integral equation with single integration and a known kernel.

3. LINEAR EQUATIONS

Casting a linear, first-order integrodifferential equation into a simple integral form is very useful because then it can be solved by the method of successive approximations. This transformation involves switching the order of integration of a double integral, an operation mentioned without explanation in Section 2. This transformation will be illustrated for the following equation:

$$\frac{dy(x)}{dx} + b(x)y(x) + c(x) = \int_{x-\alpha}^{x+\beta} K_1(\xi,x)y(\xi)d\xi + \int_{x_0}^x K_2(\xi,x)y(\xi)d\xi \tag{15}$$

We assume that over the domain of interest, $x_0 \leq x \leq x_1$, none of b, c, K_1 , and K_2 become infinite. Also, α and β are positive constants. The labels $V_1(x)$ and $V_2(x)$ will be used to represent the integrals over K_1 and K_2 , respectively.

Figure 4. A surface plot of $K(\eta,x)=p(\eta)M(\eta,x)$ seen from a different orientation. This view shows features of the surface that are hidden in Fig. 3. This example shows that integral equations can have smooth solutions even with discontinuous kernels.

Now Eq. (15) is seen as a linear, first-order differential equation with an inhomogeneous term $V_1(x) + V_2(x) - c(x)$. This is formally integrated to

$$y(x) = e^{-\int_{x_0}^x b(\gamma)d\gamma} \left\{ y(x_0) + \int_{x_0}^x [V_1(\xi) + V_2(\xi) - c(\xi)] e^{\int_{x_0}^{\xi} b(\gamma)d\gamma} d\xi \right\} \tag{16}$$

$$y(x) = y(x_0) e^{-\int_{x_0}^x b(\gamma)d\gamma} - \int_{x_0}^x c(\xi) e^{-\int_{\xi}^x b(\gamma)d\gamma} d\xi + \int_{x_0}^x \int_{\xi-\alpha}^{\xi+\beta} e^{-\int_{\xi}^x b(\gamma)d\gamma} K_1(\eta, \xi) y(\eta) d\eta d\xi + \int_{x_0}^x \int_{x_0}^{\xi} e^{-\int_{\xi}^x b(\gamma)d\gamma} K_2(\eta, \xi) y(\eta) d\eta d\xi \tag{17}$$

The order of double integration will now be reversed. This is done to achieve single integral forms $\int M(\eta, x) y(\eta) d\eta$ with kernels $M(\eta, x)$ that are integrals of known functions. The K_1 and K_2 integrations of Eq. (17) occur over specific areas of the (η, ξ) plane determined by the limits. Figure 5 is a schematic of the area of integration for K_1 . Figure 6 is a similar schematic for K_2 . In Figs. 5 and 6 these integrations would be visualized as progressing horizontally through the respective areas (see arrows). To reverse the order of integration is to progress vertically through the integral areas (see vertical hatching). The original double integrals could each become sums of several “reversed”

Figure 5. The area where double integration with the K_1 kernel is reversed. Horizontal arrows show the original direction of integration across the area. Reversed integration is shown by vertical hatching. As x moves up the ξ axis from x_0 to x_1 , the horizontal arrow from $\eta = x - \alpha$ to $\eta = x + \beta$ moves vertically through the integration area. Reversed integration is done below this rising arrow. Here vertical integration proceeds in sections as η moves from limits $x_0 - \alpha$ to $x_1 + \beta$ (the new outer integral). ξ is integrated successively from: x_0 to the $\eta + \alpha$ boundary line, x_0 to x , the $\eta - \beta$ boundary line to the $\eta + \alpha$ boundary line, and the $\eta - \beta$ boundary line to x (the new inner integral). The limits are conditional statements because the transitions between vertical sections depend on the slant and width of the area.

Figure 6. The area where double integration with the K_2 kernel is reversed. The original integration of $x_0 \leq \xi \leq x$ and $x_0 \leq \eta \leq \xi$ is reversed to $x_0 \leq \eta \leq x$ and $\eta \leq \xi \leq x$.

terms. Each of the new, reversed double integrals would account for a portion of the original (η, ξ) area. The limits of the reversed integrals could be conditional statements that depend on the shape of the area boundary. The result here is shown as Eqs. (18) through (22):

$$y(x) = y(x_0) e^{-\int_{x_0}^x b(\gamma)d\gamma} - \int_{x_0}^x c(\xi) e^{-\int_{\xi}^x b(\gamma)d\gamma} d\xi + I_1(x) + I_2(x) \tag{18}$$

$$I_1(x) = \int_{x_0-\alpha}^{\min[x^*-\alpha, x_0+\beta]} \int_{x_0}^{\eta+\alpha} \dots d\xi d\eta + \int_{\min[x^*-\alpha, x_0+\beta]}^{x_0+\beta} \int_{x_0}^x \dots d\xi d\eta + \int_{x_0+\beta}^{x+\beta} \int_{\eta-\beta}^{\min[\eta+\alpha, x]} \dots d\xi d\eta \tag{19}$$

where the integrands are

$$e^{-\int_{\xi}^{x^*} b(\gamma)d\gamma} K_1(\eta, \xi) y(\eta)$$

for the first term of I_1 , and

$$e^{-\int_{\xi}^x b(\gamma)d\gamma} K_1(\eta, \xi) y(\eta) \tag{20}$$

for the last two terms of I_1 . The function x^* is defined as

$$x^* = \min[x, (x_0 + \alpha + \beta)] \tag{21}$$

Finally, for I_2 , we obtain

$$I_2(x) = \int_{x_0}^x y(\eta) \left\{ \int_{\eta}^x e^{-\int_{\xi}^x b(\gamma)d\gamma} K_2(\eta, \xi) d\xi \right\} d\eta \tag{22}$$

The original equation is now in a purely integral form with single integrations. New kernels, $M_1(\eta, x)$ (three terms)

and $M_2(\eta, x)$, are defined as integrals of the products of an integrating factor and original kernels $K_1(\eta, \zeta)$ and $K_2(\eta, \zeta)$, respectively. The sample analysis describes solving a particular equation from this point.

Linear integrodifferential equations with second-order derivatives can be transformed into a Volterra form in a manner similar to first-order equations. Consider the following second-order equation with the same integrals V_1 and V_2 as in Eq. (16):

$$\frac{d^2y(x)}{dx^2} + b(x)\frac{dy(x)}{dx} + c(x)y(x) + d(x) = V_1(x) + V_2(x) \quad (23)$$

Define the function $p(x) = dy(x)/dx$. Now Eq. (23) becomes a linear, first-order equation for $p(x)$ with inhomogeneous term $V_1(x) + V_2(x) - d(x) - c(x)y(x)$. This is integrated once for $p(x)$ by using an integrating factor $\exp[\int b(x)dx]$, and specifying an initial condition $p(x_0)$. The result for $p(x)$ is integrated from x_0 to x , yielding $y(x) - y(x_0)$

$$\begin{aligned} y(x) = & y(x_0) + p(x_0) \int_{x_0}^x e^{-\int_{x_0}^{\eta} b(\gamma)d\gamma} d\zeta \\ & - \int_{x_0}^x \int_{x_0}^{\zeta} d(\eta) e^{-\int_{\eta}^{\zeta} b(\gamma)d\gamma} d\eta d\zeta \\ & + \int_{x_0}^x \int_{x_0}^{\zeta} [V_1(\eta) + V_2(\eta) - c(\eta)y(\eta)] e^{-\int_{\eta}^{\zeta} b(\gamma)d\gamma} d\eta d\zeta \end{aligned} \quad (24)$$

The first three terms after the equal sign in Eq. (24) are all known, the fourth term contains $y(x)$ within double and triple integrals. Let $f(x, x_0)$ represent the sum of the three known terms in Eq. (24) and $H(x, \eta)$ represent the integral factor

$$H(x, \eta) = \int_{\eta}^x e^{-\int_{\eta}^{\zeta} b(\gamma)d\gamma} d\zeta \quad (25)$$

Using these definitions, and Eq. (21) for x^* , the form of Eq. (24) with only single integrals is

$$\begin{aligned} y(x) = & f(x, x_0) + \int_{x_0-\alpha}^{\min[(x^*-\alpha), (x_0+\beta)]} \\ & y(\zeta) \left\{ \int_{x_0}^{\zeta+\alpha} H(x^*, \eta) K_1(\zeta, \eta) d\eta \right\} d\zeta \\ & + \int_{\min[(x^*-\alpha), (x_0+\beta)]}^{x_0+\beta} y(\zeta) \left\{ \int_{x_0}^x H(x, \eta) K_1(\zeta, \eta) d\eta \right\} d\zeta \\ & + \int_{x_0+\beta}^{x+\beta} y(\zeta) \left\{ \int_{\zeta-\beta}^{\min[(\zeta+\alpha), x]} H(x, \eta) K_1(\zeta, \eta) d\eta \right\} d\zeta \\ & + \int_{x_0}^x y(\zeta) \left\{ \int_{\zeta}^x H(x, \eta) K_2(\zeta, \eta) d\eta \right\} d\zeta \\ & - \int_{x_0}^x y(\zeta) c(\zeta) H(x, \zeta) d\zeta \end{aligned} \quad (26)$$

The five integrals shown for Eq. (26) can be combined into a single integration from $(x_0 - \alpha)$ to $(x + \beta)$ by multiplying each kernel with a difference of Heaviside unit step functions to define limits. This was done to calculate examples from Eq. (14) in the sample analysis.

The linear equations discussed in the preceding have all described initial value problems. If boundary values are placed on $y(x)$ or its first derivative at two points (x_0, x_1) , then the solution of a second-order equation is based on the characteristic functions, or eigenfunctions, of the differential part of the equation. A solution of the form $y(x) = C_0y_0(x) + C_1y_1(x) + C_2y_2(x) + \dots$ is assumed, where the y_i are eigenfunctions corresponding to the eigenvalues λ_i . The coefficients C_i are found in exactly the same way as in boundary value problems involving nonhomogeneous differential equations. The three steps to the solution are (1) substitute the eigenfunction expansion into Eq. (23), (2) multiply by a particular eigenfunction y_i to solve for its coefficient C_i , and (3) integrate over the interval (x_0, x_1) . In purely differential problems the result is a series of equations, one for each of the coefficients C_i . For integrodifferential equations the result is a series of equations linking each coefficient to a weighted sum of coefficients, $C_i = \sum w_n C_n$. The weights w_n result from integration and may be difficult to calculate. This matrix relationship among the coefficients reflects the nature of the original equation. The magnitude C_i of each mode $y_i(x)$ is linked to the magnitudes of the other modes in solution $y(x)$ by the integrals involving K_1 and K_2 .

4. VOLTERRA ANIMALS

Volterra introduced the following system of coupled, non-linear, first-order, integrodifferential equations to describe the dynamics of survival for a population of predators $y(t)$ and a population of prey $x(t)$:

$$\begin{aligned} \left[\frac{1}{x(t)} \right] \frac{dx(t)}{dt} = & a(t) - b(t)y(t) - \int_c^t K_y(t, s)y(s)ds \\ \left[\frac{1}{y(t)} \right] \frac{dy(t)}{dt} = & -\alpha(t) + \beta(t)x(t) + \int_c^t K_x(t, s)x(s)ds \end{aligned} \quad (27)$$

These equations show rates of population growth that are dependent on three factors: herd size or predator density, encounters between species, and hereditary influences. Prey $x(t)$ are adversely affected by encounters with predators, $-b(t)x(t)y(t)$, and by evolutionary improvements in these predators, $-x(t)\int K_y(t, s)y(s)ds$. Predators are adversely affected by too high a population of their own kind, $-\alpha(t)y(t)$. Reference 4 discusses this system in detail. The hereditary integral is described for heredity coefficients (K_x and K_y) of the form $K(t - s)$ under various names; it is the “renewal equation” in Ref. 2, “convolution” in Ref. 3, the “superposition integral” in Ref. 5, and an integral with a “displacement kernel” in Ref. 6. We will describe an approximate method of solution for Eq. (27) that makes few assumptions about the coefficients a, b, α , and β , or the kernels K_x and K_y .

Figure 7. Population histories of predators $y(t)$ and prey $x(t)$ from the Volterra model of Eq. (27) with $a = b = 2$, $\alpha = \beta = 1$, $K_x = K_y = -0.05$, $c = 0$, $y(c) = 2$, and $x(c) = 1$. In this example heredity causes the populations to increase, diverge, and cycle more often.

Figure 7 is a particular example of Eqs. (27) for $0 \leq t \leq 20$, $c = 0$ (“the creation”), $a = b = 2$, $\alpha = \beta = 1$, $K_x = K_y = -0.05$, and initial conditions $x(0) = 1$ and $y(0) = 2$. Figure 8 is a phase diagram for this case where the initial conditions and the direction of time’s arrow are indicated. Without hereditary influences ($K_x = K_y = 0$), the nonlinear, purely differential system has a periodic trajectory that is a noncircular closed path on the xy phase plane (a “vortex cycle”). In general, neither $x(t)$ nor $y(t)$ can be expressed in terms of elementary functions. The effect of the hereditary integrals is to cause a “drift” in the solutions, seen as a rising trend for this example. Additional long-term effects for this case are a diminishing impact of predators (y) on prey (x) and a shortening of the time between cycles.

Figure 8. Phase diagram for the Volterra model example of Fig. 7. If heredity coefficients K_x and K_y are zero, then this curve is a closed noncircular path called a *vortex cycle*. The initial point and the direction of time’s arrow are shown. Heredity causes a drift in the cyclic action.

Converging or diverging populations that either grow or diminish can clearly be simulated by changing the magnitudes and the signs of the coefficients and kernels. More interesting effects arise when these factors are time dependent.

Equations (27) are integrated once

$$\begin{aligned} \ln \left[\frac{x(t)}{x_c} \right] &= \int_c^t a(s) ds \\ &\quad - \int_c^t b(s)y(s) ds - \int_c^t \int_c^s K_y(s,u)y(u) du ds \\ \ln \left[\frac{y(t)}{y_c} \right] &= - \int_c^t \alpha(s) ds + \int_c^t \beta(s)x(s) ds \\ &\quad + \int_c^t \int_c^s K_x(s,u)x(u) du ds \end{aligned} \tag{28}$$

The order of double integration is reversed, and then the following functions are defined:

$$\begin{aligned} A(t) &= \int_c^t a(s) ds \\ \Lambda(t) &= \int_c^t \alpha(s) ds \\ M_x(t,u) &= \int_u^t K_x(s,u) ds \\ M_y(t,u) &= \int_u^t K_y(s,u) ds \end{aligned} \tag{29}$$

Now the equations are

$$\begin{aligned} \ln \left[\frac{x(t)}{x_c} \right] &= A(t) - \int_c^t [b(u) + M_y(t,u)]y(u) du \\ \ln \left[\frac{y(t)}{y_c} \right] &= -\Lambda(t) + \int_c^t [\beta(u) + M_x(t,u)]x(u) du \end{aligned} \tag{30}$$

The equation for $y(t)$ is substituted into the equation for $x(t)$, yielding

$$\begin{aligned} \ln \left[\frac{x(t)}{x_c} \right] &= A(t) - y_c \int_c^t [b(u) + M_y(t,u)] \\ &\quad \times e^{-\Lambda(u) + \int_c^u [\beta(w) + M_x(u,w)]x(w) dw} du \end{aligned} \tag{31}$$

The nonlinear equation for $x(t)$ would appear to be an excellent form on which to apply the method of successive approximations. Figure 9 is a display of 23 successive approximations to Eq. (31) for the specific example described in Figs. 7 and 8; 41 points are used in this calculation, and the range is restricted to $0 \leq t \leq 10$. The zeroth iterant is $x_c = 1$ for the entire range, and calculated values of $x(t)$ larger than $6x_c$ are reset to x_c . The solution is seen to chip its way into the unknown like a pickax repeatedly driven

Figure 9. A sequence of successive approximations to Eq. (31) for the case shown in Figs. 7 and 8. Equation (31) is a nonlinear integral form of the Volterra predator and prey model. Each iterant builds up the solution sequentially, even though iteration occurs over the full time interval ($0 \leq t \leq 10$ in these calculations of 23 iterants). This is because the derivative of the solution at the present moment depends on the integral of its history. The iteration had an upper limit of 6 times the initial condition; any point calculated above this limit was reset to the initial condition. A better method of calculation is based only on prior events.

into concrete. This is because the derivative of the solution at its leading edge depends on the integral of its history, so each iterant only advances the solution a small amount in time. It would be more efficient to calculate a solution by advancing forward in time rather than iterating over the entire time domain. The calculation of $x(t)$ requires iteration because $x(t)$ appears on both sides of Eq. (31). If $x(t)$ could be shown to depend only on its history, and not also on its present value, then the solution would be a recursion formula and calculations would be speedier. A solution of this type is achieved by assuming that $x(t) \approx x(t - \Delta t)$ for Δt sufficiently small. The integral in Eq. (31) is split into two terms, the first with limits $c \leq u \leq t - \Delta t$, and the second with limits $t - \Delta t \leq u \leq t$. The second integral is now approximated by a two-point trapezoid rule [$2 \times \text{integral}/\Delta t = \text{integrand}(t) + \text{integrand}(t - \Delta t)$]. The trapezoid rule integrand at t has the form

$$L_y(t, t)e^{-\Lambda(t) + \int_c^t L_x(t, w)x(w)dw} \tag{32}$$

where $L_y(t, u) = b(u) + M_y(t, u)$ and $L_x(t, u) = \beta(u) + M_x(t, u)$. The two-point trapezoid approximation is used again for the integral in Eq. (32), which now has the form

$$\begin{aligned} & \{L_y(t, t)e^{-\Lambda(t) + \int_c^{t-\Delta t} L_x(t, w)x(w)dw}\} e^{\int_{t-\Delta t}^t L_x(t, w)x(w)dw} \\ & \approx \{ \dots \} e^{(\Delta t/2)[L_x(t, t)x(t) + L_x(t, t-\Delta t)x(t-\Delta t)]} \\ & \approx \{ \dots \} e^{(\Delta t/2)[L_x(t, t) + L_x(t, t-\Delta t)]x(t-\Delta t)} \end{aligned} \tag{33}$$

The resulting approximation in place of Eq. (31) is

$$\begin{aligned} \ln \left[\frac{x(t)}{x_c} \right] = & A(t) - y_c \int_c^{t-\Delta t} L_y(t, u)e^{-\Lambda(u) + \int_c^u L_x(u, w)x(w)dw} du \\ & - \frac{y_c \Delta t}{2} L_y(t, t - \Delta t)e^{-\Lambda(t-\Delta t) + \int_c^{t-\Delta t} L_x(t-\Delta t, w)x(w)dw} \\ & - \left\{ \frac{y_c \Delta t}{2} L_y(t, t)e^{-\Lambda(t) + \int_c^{t-\Delta t} L_x(t, w)x(w)dw} \right\} \\ & \times e^{(\Delta t/2)[L_x(t, t) + L_x(t, t-\Delta t)]x(t-\Delta t)} \end{aligned} \tag{34}$$

Note that for $\Delta t = 0$ we recover the original equation. Here the calculation is an explicit operation moving forward in time. This result makes it much easier to calculate the example shown in Figs. 7 and 8 than by iteration (161 points span the range $0 \leq t \leq 20$).

5. APPLICATIONS

Equation (1) in the sample analysis section is a form of the Boltzmann equation for the drift of a cloud of electrons along a constant electric field through a uniform molecular gas. Physical quantities are as follows: x is electron kinetic energy in units of eV, $y(x)$ is the distribution function of electron kinetic energy in units of $\text{eV}^{-3/2}$, $a(x) = a_0 x = (1/3)(E/N)^2(x/Q)$, E is the electric field in V/cm, N is the particle density of the gas in cm^{-3} , Q is the electron-molecule elastic collision cross section in cm^2 , $p(x) = p_0 x = Sx$, S is the electron-molecule inelastic collision cross section in cm^2 , $\alpha = 0$, $B_0(x)$ is an approximation for the logarithmic derivative of $y(x)$, β is large so $\beta B_0(x) > 1$, and $x B_0(x) > 1$ (this model of electron kinetics is for energies x above the range of thermal motion, $x \gg 0.03 \text{ eV}$). Both Q and S are assumed to be only mildly dependent on x . $B_0(x)$ is given by Eq. (10) and then $y_0(x)$ is

$$y_0(x) = \exp \left\{ - \int_0^x \frac{\sqrt{3Q(\xi)S(\xi)}}{E/N} d\xi \right\} \tag{35}$$

Typical parameters in experiments might be $Q = 10^{-15}$, $S = 3 \times 10^{-16}$, $E = 1000$, and $N = 10^{18}$. Good approximations for distribution functions of electron energy in nitrogen mixtures have been calculated from this result by using cross-section data. Literature on the Boltzmann equation is vast. The pervasive approximation is that the system is never far from thermal equilibrium $f_0(x)$ ("Maxwellian" distribution), so that the nonequilibrium solution $f(x)$ is a perturbation given by an expansion $f(x) = f_0(x)(1 + \phi_1(x) + \phi_2(x) + \dots)$, where succeeding terms are of smaller magnitude. The full development of this Chapman-Enskog method is quite involved (see Ref. 7). The electron energy distribution may be far from thermal equilibrium with the gas molecules in an electric discharge because of the high electric fields. A Chapman-Enskog expansion for electrons might require the calculation of many terms. The alternative is to expand the electron distribution function in a series of spherical harmonics

defined by an axis aligned with the electric field. This creates a sequence of linked equations. Once the zeroth-order equation is solved for the leading term of the expansion, then the first-order term can be solved, and so on. The zeroth term describes the average energy of an isotropic cloud of electrons, and the first term describes the drift of this cloud along the field, a current. The result given by Eq. (35) is an approximation to the isotropic part of the electron distribution. References 8–10 describe kinetic theory and the mathematics of the Boltzmann equation. References 11–13 describe the theory for electrons in a gas.

The mechanical constitutive equation of a material relates the stress tensor to the deformation tensor for a solid, and to the rate of strain tensor for a fluid. Many engineering materials are characterized by linear isotropic constitutive relations: the generalized Hooke’s law for solids; and the Newtonian fluid. Technology is rapidly increasing the application of nonlinear “engineered” solids and plastic “rheological” fluids. These materials can have stress dependent on the deformation and rate of strain in a nonlinear way, on higher velocity derivatives, on anisotropies of their internal structure, and on the history of their deformation and motion. In the most general case the constitutive relation is an integrodifferential equation that relates stress to the entire history of the material. One example follows:

$$m \frac{d^2u(t)}{dt^2} + au(t) + \int_0^t K(t-s) \frac{du(s)}{ds} ds = q(t) \quad (36)$$

This is a mass–spring–damper equation with heredity in the damping term. Here u is distance, t is time, m is mass, a is the spring constant, K is a renewal kernel, and q is a forcing term. References 14 and 15 describe this equation. Reference 2 shows how to solve linear, constant-coefficient renewal equations with Laplace transforms. The solution of Eq. (36) by the methods of this article is

$$\begin{aligned} mu(t) = & u(0) \left[m + \int_0^t \int_0^s K(x) dx ds \right] \\ & + mp(0)t + \int_0^t (t-s)q(s)ds \\ & - \int_0^t u(s) \left\{ a(t-s) + \int_0^{t-s} K(x) dx \right\} ds \end{aligned} \quad (37)$$

where $u(0)$ and $p(0)$ are the initial conditions of the displacement u and its first derivative $p = du/dt$. Note that the kernel is a function of one variable. For $K = q = 0$ the problem collapses to a harmonic oscillator, and it is easy to show that $\sin(\sqrt{a/m}t)$ is a solution of the reduced form of Eq. (37). Volterra had shown that kernels of the type $K(t-s)$ produce periodic solutions [4,16,17]. In general we can expect heredity to alter the frequency of oscillations, to introduce a damping, and to shift the mean position, all during the course of time.

An integrodifferential equation for heat transfer occurs when the constitutive relation between heat flux and temperature gradient in the material is a hereditary integral.

In a similar way, an integrodifferential equation describes the evolution of an electric field in the vicinity of a non-conducting material dielectric with a memory of its charging history (a “Maxwell–Hopkinson dielectric”). These and other applications are described in Ref. 18, a mathematician’s treatise on integrodifferential equations.

The technological application of mechanics with heredity and of nonequilibrium kinetics is likely to drive future efforts to improve the solution of integrodifferential problems. These problems arise in the development of non-equilibrium processes, such as plasma–chemical reactors for modifying material surfaces, and in the development of synthetic materials with engineered physical properties. Another thrust to solving these equations is the desire to improve our understanding of natural phenomena and materials. It is not hard to imagine that natural flows like lava or glaciers, and natural cycles like climate and weather, can have a hereditary factor. It would be interesting to have a method for easily estimating a distant cycle time average of a quantity influenced by heredity, be it metal fatigue or species extinction.

INTERMEDIATE-FREQUENCY AMPLIFIERS

H. R. WALKER
Pegasus Data Systems, Inc.
Edison, New Jersey

The intermediate-frequency (IF) amplifier is the circuitry used to process the information bearing signal between the first converter, or mixer, and the decision making circuit, or detector. It can consist of a very few or a great many component parts. Generally, it consists of an amplifying stage or device to provide gain, plus a bandpass filter, or filters, to limit the frequency band to be passed. The signal to be processed can be audio, video, digital, or pulsed, using amplitude modulation, frequency modulation, phase modulation, or combinations thereof. Several examples are shown in Figs. 13–19.

Bandpass IF amplifiers are also used in radio transmitters to limit the occupied bandwidth of the transmitted signal. Certain modulation methods create a very broad frequency spectrum, which can interfere with adjacent channels. Regulatory agencies, such as the FCC (Federal Communications Commission), require that these out-of-band signals be reduced below a certain permissible level, so they must undergo processing through a bandwidth-limiting filter and amplifier at the transmitter.

For each application there are certain design restrictions or rules that must be followed to achieve optimum results.

1. GENERAL IF AMPLIFIER FUNCTIONS AND RESTRICTIONS

The five basic IF amplifier functions and requirements are as follows:

1. *Image Rejection.* The mixer stages in a superhetrodyne receiver can convert any frequency below or above the local oscillator frequency to an intermediate frequency. Only one of these frequencies is desired. The intermediate frequency must be chosen so that undesirable frequencies or images are removed by the RF amplifier filter (prefiltering) and are rejected by the mixer. This may mean that two or three different intermediate frequencies must be used within the same receiver. The intermediate frequencies in common use range from 0 Hz to approximately 2.0 GHz.

2. *Selectivity.* Selectivity is required to reject as much as possible of any adjacent channel interfering signal. Generally this means attempting to obtain a bandpass

filter characteristic as close to that of the ideal filter as possible that will pass the necessary *Nyquist bandwidth* (the baseband bandwidth from 0 Hz to the highest frequency to be passed) without introducing harmful amplitude or phase distortion.

3. *Gain.* Gain is required to amplify a weak signal to a useful level for the decisionmaking circuit. This gain must be provided by means of a stable amplifier that introduces a minimum of noise, so as not to degrade the receiver *noise figure*. All circuit input and output impedances should be properly matched for optimum power transfer and circuit stability.

4. *Automatic Gain Control.* The amplifier gain must vary automatically with signal strength so that the decisionmaking circuit receives a signal of as nearly constant level as possible. The stages of the IF amplifier must not be overdriven, or go into limiting, until after the last bandpass filter, to prevent “splattering,” or broadening and distortion of the signal.

5. *Linearity.* The amplifier should be linear in phase or amplitude to prevent distortion of the recovered information. AM receivers should be linear in amplitude, while FM or PM receivers should be linear in phase. Some modulation methods can tolerate more linearity distortion than others.

2. SELECTING THE INTERMEDIATE FREQUENCY

Image rejection and signal selectivity are the primary reasons for selecting an intermediate frequency. Most currently manufactured bandpass filters of the crystal, or resonator type, have become standardized so that the designer can obtain off-the-shelf components at reasonable cost for these standard frequencies. The standard AM broadcast receiver utilizes a 455-MHz IF filter because extensive experience has shown that this will reject all but the strongest images. Assume the desired signal is at 600 kHz. A local oscillator operating at 1055 kHz will have an image frequency at 1510 kHz, which the RF input filter can easily reject. Similarly, an FM receiver operating at 90.1 MHz with an intermediate frequency of 10.7 MHz will have an image at 111.5 MHz, which will be rejected by the RF amplifier. In both of these cases, a single intermediate frequency can be used.

A receiver operating at 450 MHz will require two Intermediate frequencies obtained by using first and second mixers, as in Fig. 16. The first IF amplifier may consist of a relatively broadband filter operating at 10.7 or 21.4 MHz, followed by a second converter and IF stage operating at 455 kHz. The first IF filter is narrow enough to reject any 455-kHz images, and the second IF filter is a narrowband filter that passes only the desired signal bandwidth. If the 455-kHz filter had been used as the first IF filter, the 450-MHz RF filter, which is relatively broad, would not have eliminated the image frequency, which is 455 kHz above or below the local oscillator (LO) frequency.

Television receivers use a video intermediate frequency of approximately 45 MHz, since this permits a relatively broad RF filter to pass the broadband TV signal, while still

This may mean that two or three different intermediate frequencies must be used within the same receiver. The intermediate frequencies in common use range from 0 Hz to approximately 2.0 GHz.

2. *Selectivity.* Selectivity is required to reject as much as possible of any adjacent channel interfering signal. Generally this means attempting to obtain a bandpass

filter characteristic as close to that of the ideal filter as possible that will pass the necessary *Nyquist bandwidth* (the baseband bandwidth from 0 Hz to the highest frequency to be passed) without introducing harmful amplitude or phase distortion.

3. *Gain.* Gain is required to amplify a weak signal to a useful level for the decisionmaking circuit. This gain must be provided by means of a stable amplifier that introduces a minimum of noise, so as not to degrade the receiver *noise figure*. All circuit input and output impedances should be properly matched for optimum power transfer and circuit stability.

4. *Automatic Gain Control.* The amplifier gain must vary automatically with signal strength so that the decisionmaking circuit receives a signal of as nearly constant level as possible. The stages of the IF amplifier must not be overdriven, or go into limiting, until after the last bandpass filter, to prevent “splattering,” or broadening and distortion of the signal.

5. *Linearity.* The amplifier should be linear in phase or amplitude to prevent distortion of the recovered information. AM receivers should be linear in amplitude, while FM or PM receivers should be linear in phase. Some modulation methods can tolerate more linearity distortion than others.

2. SELECTING THE INTERMEDIATE FREQUENCY

Image rejection and signal selectivity are the primary reasons for selecting an intermediate frequency. Most currently manufactured bandpass filters of the crystal, or resonator type, have become standardized so that the designer can obtain off-the-shelf components at reasonable cost for these standard frequencies. The standard AM broadcast receiver utilizes a 455-MHz IF filter because extensive experience has shown that this will reject all but the strongest images. Assume the desired signal is at 600 kHz. A local oscillator operating at 1055 kHz will have an image frequency at 1510 kHz, which the RF input filter can easily reject. Similarly, an FM receiver operating at 90.1 MHz with an intermediate frequency of 10.7 MHz will have an image at 111.5 MHz, which will be rejected by the RF amplifier. In both of these cases, a single intermediate frequency can be used.

A receiver operating at 450 MHz will require two Intermediate frequencies obtained by using first and second mixers, as in Fig. 16. The first IF amplifier may consist of a relatively broadband filter operating at 10.7 or 21.4 MHz, followed by a second converter and IF stage operating at 455 kHz. The first IF filter is narrow enough to reject any 455-kHz images, and the second IF filter is a narrowband filter that passes only the desired signal bandwidth. If the 455-kHz filter had been used as the first IF filter, the 450-MHz RF filter, which is relatively broad, would not have eliminated the image frequency, which is 455 kHz above or below the local oscillator (LO) frequency.

Television receivers use a video intermediate frequency of approximately 45 MHz, since this permits a relatively broad RF filter to pass the broadband TV signal, while still

rejecting the images. The video signal from the IF amplifier is AM, with an FM sound carrier riding on it. Television sound is generally obtained from a beat, or difference frequency between the video and sound carriers, which is at 4.5 MHz.

Satellite receivers use a broadband first intermediate frequency covering a frequency block from 900 MHz to 2.1 GHz. This is done by means of a *low-noise block* (LNB) converter. The second mixer is made tunable so that any frequency in the block can be converted to the second intermediate frequency, which is usually fixed at 70 or 140 MHz. The second intermediate frequency, which drives the detector, has a narrower bandwidth to reduce noise and reject adjacent channel interference.

Crystal, ceramic resonator, and SAW filters are massed produced at relatively low cost for the frequencies mentioned above, so that most consumer products employ one or more of the abovementioned standard frequencies and standard mass-produced filters.

3. SELECTIVITY

Carson’s rule, and the Nyquist sampling theorem on which it is based, state that a certain bandwidth is required to transmit a signal undistorted. The necessary bandwidth for an AM signal is given as follows:

$$BW = 2f_m \tag{1}$$

Thus an AM broadcast receiver will require 10 kHz of bandwidth to pass a 5 kHz = f_m audio tone. (f_m = Frequency of modulation.) In data transmission systems, the frequency f_m corresponding to the data rate f_b , is $f_m = \frac{1}{2} f_b$. The data clock frequency is twice the frequency of the data in ones and zeros. This means that a baud rate f_b of 9,600 bits per second (bps) will require a bandwidth of 9.6 kHz.

For FM, the necessary bandwidth required for transmission is

$$BW = 2(f_m + \Delta f) \tag{2}$$

A 15-kHz audio tone (= f_m) and an FM transmitter being deviated with a modulation index of 5 will require 2 (15 + (15 × 5)) = 180 kHz of bandwidth. Δf is (5 × 15) and f_m is 15 kHz. Narrowband FM, or phase modulation (PM) (with a modulation index of < 0.7), is somewhat different in that the bandwidth actually required is the same as that for AM. This is due to the fact the higher J_n Bessel products are missing [Eq. (1) applies].

These values are for *double-sideband transmission*. Single-sideband transmission will require half as much bandwidth. The required baseband bandwidth is the same as the value for f_m . This is also known as the *Nyquist bandwidth*, or the minimum bandwidth that can carry the signal undistorted at baseband.

Ideally, the IF filter, or the equivalent baseband filter, need pass only this bandwidth and no more. This requires the use of an “ideal” bandpass or lowpass filter, which does not exist in practice, but can be approached by various means. The filter must be as narrow as conditions permit

to reduce the noise bandwidth and any adjacent channel interference, since noise power rises linearly with increasing filter bandwidth [14]:

$$\frac{S_o}{N_o} = \beta^2 \frac{\text{bit rate}}{\text{filter BW}} \frac{S_i}{N_i} \tag{3a}$$

$$\frac{S_o}{N_o} = \text{modulation} \times \frac{\text{gain}}{\text{loss}} \times \text{processing gain} \frac{S_i}{N_i} \tag{3b}$$

These two equations show a generalized relationship between the signal-to-noise ratio (SNR) at the receiver input and the SNR at the receiver output. The term β^2 represents a gain, or loss, in power due to the modulation method. In FM or PM it is the modulation angle. The term [(bit rate)/(filter bandwidth)] is generally known as *processing gain*. Narrowing the bandwidth improves the S_o/N_o ratio, but this improvement is not always available, depending on the modulation method. The Nyquist bandwidth rules state that it should be (symbol rate)/BW = 1.

Pulse modulation, as in radar (radio detection and ranging), generally requires a much broader filter bandwidth than the other modulation methods. A condition called *envelope delay* or *group delay* must also be observed. This is discussed later along with the transfer functions of the filters. For optimum results, the filter bandwidth (Δf) must be equal to [1/(pulsewidth)]. If the filter bandwidth is too narrow, the amplitude detected is reduced and the SNR is adversely affected. In this case, the processing gain is ideally = 1 [14].

$$\begin{aligned} \frac{S_o}{N_o} &= (\text{processing gain}) \frac{S_i}{N_i} \\ &= \frac{E_b}{N_o} \end{aligned} \tag{4}$$

4. GAIN

The IF amplifier must provide sufficient gain to raise a weak signal at the RF input to the level required, or desired, by the decisionmaking circuit or detector. This receiver gain can vary from 0 up to 130 dB, most of which is usually provided by the IF amplifier. The RF amplifier and mixer circuits preceding the IF amplifier usually provide ≥ 20 dB of gain so that the IF amplifier generally contributes little to the receiver noise figure. (See NOISE FIGURE article elsewhere in this encyclopedia.) Amplifiers with very high gain have a tendency to oscillate; hence two different intermediate frequencies may be used to reduce the gain on any one frequency, or more of the gain may be obtained from the RF section.

Gain is provided by an amplifying device, such as a transistor, or vacuum tube (in older equipment). These devices have input and output impedances of a complex nature that must be matched to the filtering circuits for best power transfer, stability, and lowest noise. Current practice is often to use a “gain stage,” which consists of multiple amplifying devices in an integrated circuit

package. These packages often contain the mixer stages and detectors as well.

5. AUTOMATIC GAIN CONTROL

Receivers must respond to a wide range of input levels while maintaining a nearly constant level at the detector or decisionmaking circuit. The user or operator does not wish to manually adjust the gain to obtain a constant sound or picture level when changing stations. This function is performed by detecting the output level of the IF amplifier and correcting it by means of a feedback circuit that adjusts the gain to keep the level as constant as possible. Since this detected level can vary rapidly, it is passed through a lowpass filter [usually an RC (resistance × capacitance) pair] to integrate or slow down the changes, then amplified by a DC (direct-current) amplifier and applied to an IF amplifier circuit or gain stage that has variable gain characteristics. Some receivers, such as those used in an automobile, require relatively rapid acting AGC circuits, while fixed receivers can use a much slower AGC time constant. Dual-gate field-effect transistors use the second gate to control the gain. Bipolar or single-gate field-effect transistors vary the gain by means of a bias voltage or current applied to the input terminal along with the signal. Special integrated circuit gain stages for IF amplification are available, such as the Motorola MC1350, which both amplify and provide a variable gain control function.

6. FILTERS FOR IF AMPLIFIERS

Except for block conversions, which convert wide frequency bandwidths, such as those used on satellite receivers, IF amplifiers in general use a narrow bandpass, or a low-pass filter, to limit the bandwidth to the Nyquist bandwidth. Block conversion, on the other hand, can use a highpass-lowpass filter pair, where the bandwidth to be passed lies between the high and low cutoff frequencies.

The traditional bandpass filter requires one or more resonant elements. Although the actual resonator may be a coil and capacitor, ceramic resonator, or SAW filter, the principles are basically the same. Digital filters, which do not use resonators, have been employed more recently. These will be discussed later in brief. They are discussed in more detail elsewhere in this encyclopedia.

The inductance/capacitance resonator was the first used, and is still a comparison standard. Figures 1a and 1b show series resonant circuits, and Fig. 1c shows a parallel resonant circuit. These circuits will pass a signal at the resonant peak and reject a signal off resonance. Resistances R_s and R_p are naturally occurring losses that reduce the circuit efficiency. Figure 2 shows the universal resonance curve, which is applicable to both series and parallel resonant circuits. It is important to note that the signal rejection never goes to a zero level in the area of interest, but reaches an asymptotic value between 0.1 and 0.2 or about -17 dB. If it is necessary to reject a signal on the shoulders of this curve by 60 dB, then four cascaded stages of this filter must be used to obtain the necessary

Figure 1. Series (a,b) and parallel (c) resonant circuits.

rejection. Note also that there is a nonlinear phase shift that reaches a maximum in the area of interest, then changes to $\pm 70^\circ$. When stages are cascaded, this phase shift is multiplied by the number of stages. A nonlinear phase shift can cause distortion in FM receivers. The phase shift curve plotted is for a parallel resonant circuit. The phase reverses for a series circuit. The phase at any point on the curve is obtained by plotting horizontally from the vertical amplitude/phase scale: $\alpha = Q$ (cycles off resonance/resonant frequency).

A frequency f_0 at which the response of a parallel resonant LC filter is a maximum, that is, the point at which the parallel impedance is a maximum, is defined as a pole. A frequency at which the impedance is a minimum, as in the series LC circuit, is defined as a zero. Thus the assumed four cascaded stages above would constitute a four-pole filter, since it contains four resonant poles. The frequency of resonance is given by Eq. (5); this is the frequency at which $[X_c = 1/-j\omega C]$ and $[X_L = j\omega L]$ are equal:

$$f_0 = \frac{1}{2\pi(LC)^{1/2}} \tag{5}$$

The bandwidth that an analog LC filter can pass is altered by the circuit efficiency, or circuit Q, given in Eqs. (6).

Figure 2. Universal resonance curve (BT = bandwidth × bit period).

Generally the bandwidth is specified as the bandwidth between the -3 dB points, where the phase shift is $\pm 45^\circ$.

$$Q = \frac{X_c}{R_s} \text{ for a series circuit} \tag{6a}$$

$$Q = \frac{R_p}{X_c} \text{ for a parallel circuit} \tag{6b}$$

$$Q = \frac{f_0}{3 \text{ dB BW}} \tag{6c}$$

For simplicity in analyzing the following circuits, the Q determining R will be assumed to be a parallel resistance R_p across the inductance.

Figure 3 shows a typical IF amplifier stage as used in earlier transistor radios [1,2]. In this circuit R_p (the total shunting resistive load) is actually three resistances in parallel; one is the equivalent R_p of the coil itself (representing the coil losses), another is the input resistance of the following stage, as reflected, and the third is the output resistance of the driving transistor as reflected. It cannot be assumed that the resulting coil Q , and hence the selectivity of the circuit, is that of the unloaded coil and capacitor alone. Dual-gate field effect transistors have the highest shunting resistance values, bipolar transistors the lowest. The gain can be varied by increasing or decreasing the bias voltage V_b applied to the input terminal.

Manufacturers of amplifying devices often provide the impedances, or admittances of their products on their data sheets. Formerly this was done in the form of h parameters. The more common practice today is to provide the information in the form of S parameters. These values can be converted to impedances and admittances, but the manual process is rather complicated. An easier method is to use the various software programs (see Available

Figure 3. Typical IF amplifier stage.

(a)

(b)

Figure 4. Equivalent circuit of transistor as seen by tuned LC.

Software section at end of this article) to make the conversion. Matrix algebra, h and S parameters are discussed elsewhere in this encyclopedia and also in the Refs. 3 and 4 in this article. Unfortunately, S parameters for bandpass filters are rarely available.

Figure 4a shows the equivalent circuit of the transistor as the tuned LC “sees” it. The transistor amplifies a current, which is passed through a relatively low driving resistance R_s , to the outside. At the same time, the attached LC sees an equivalent shunting resistance R_c and capacitance C_c , which must be added in parallel to R_p , L , and C . The input to the following stage, assumed to be an identical transistor, will have a relatively low shunting resistance R_i , and capacitance C_i , which must be added. Unless the added capacitances are large compared to the resonant C , they merely add to it without greatly detuning the circuit. When tuned, the total C plus L will determine the frequency and the resulting total R_p will determine the Q of the LC circuit, and hence the bandwidth. Thus the complex components can be tuned out and the remaining design problem consists of matching the real or resistive part of the input and output impedances to the best advantage.

The desired end result is to couple the output of the driving stage to the input of the following stage with the least loss by matching the differing impedances. An additional desired result is to narrow the band of frequencies passed by means of a filter. These objectives are accomplished by transforming the input and output impedances to a higher or lower shunting impedance that maintains the desired bandpass characteristic of the filter. A low driving or load impedance can be stepped up to become a very high impedance, which maintains the circuit Q at the desired value.

Impedance matching enables the designer to change the actual impedance to a different apparent value, which

Figure 5. Impedance matching by transformer action.

is optimum for the circuit. Figure 5 shows how impedances are matched by transformer action. A transformer with a 3:1 turns ratio is shown as an example. The output impedance relative to the input impedance is given by Eq. (7), where N_i and N_o are the input and output numbers of turns on the winding.

$$\frac{Z_i}{Z_o} = \sqrt{\frac{N_i}{N_o}} \tag{7}$$

Thus 90 Ω at the input is seen as 10 Ω at the output with a 3:1 stepdown turns ratio. The automatic transformer (tapped coil in Fig. 5) has the same relationship.

When all the reactances and resistances from the tuned circuit and the transistor input and output as modified by the stepup/stepdown process of the impedance-matching networks are added, the network in Fig. 4b results. Calculation of the resonant frequency and circuit Q from these reactances and resistances in parallel is complicated unless they are converted to admittances. Software is available at reasonable cost to perform these calculations (see Available Software section at end of this article).

Stock, or mass-produced IF transformers, which are used to provide bandpass filtering as well as impedance matching, seldom have the desired turns ratio to match the impedances properly. An additional Z -matched circuit using capacitors enables the available transformers to match almost any impedance while preserving the circuit Q . This capacitor divider circuit is often used instead of a tapped coil or transformer as shown in Fig. 6.

The formulas used to calculate the matching conditions using capacitors are more complex than those used for transformer coupling, since there are more variables. In this circuit R_i is assumed to be lower than R_p . Although R_p

Figure 6. Lowering of total shunting by transformer action.

is the equivalent parallel resistance of the LC circuit in Fig. 6, it could also be the reduced resistance or reflected R_{p2} at a transformer tap. N in these equations is equal to the loaded resonator Q , or to a lower arbitrary value if total shunting R_p is lowered by transformer action as in Fig. 6, or if the component ratios become unwieldy [12]:

$$X_{C2} = \frac{R_i}{\left[\frac{R_i(N^2 + 1)}{R_p - 1} \right]^{1/2}} \tag{8}$$

$$X_{C1} = \frac{R_p N}{N^2 + 1} \left(1 - \frac{R_i}{NX_{C2}} \right) \tag{9}$$

$$X_{C2} \approx \sqrt{\frac{R_i R_p}{Q}} \tag{10}$$

$$X_{C1} \approx \frac{R_p}{Q} = X_L \tag{11}$$

Equations (8) and (9) calculate the reactances of the two capacitors. Note that NX_L is the same as QX_L . Starting with a value of $N = Q$, find X_{C1} , then X_{C2} .

If N is large in Eq. (8), the equations reduce to the approximate values in Eqs. (10) and (11). Unless Q is less than 10, these approximate equations are accurate enough for general use. As an example, let $R_i = 100 \Omega$ and $R_p = 10,000 \Omega$ with $Q = 100$. Then, using Eq. (11), X_{C2} becomes 10Ω and X_{C1} becomes 100Ω . C_2 is approximately 10 times larger than C_1 . Note the similarity of this ratio to Eq. (7). If a transformer is involved, N becomes much smaller and the full formulas (8) and (9) should be used.

Equations (8)–(10) apply for $R_i < R_p$ and $N > (R_p/R_i - 1)^{1/2}$.

7. DOUBLE-TUNED CIRCUITS

When two identical LC circuits are coupled together as shown in Fig. 7, a number of responses are possible as shown in Fig. 8. The amplitude response depends on the coupling coefficient K . Undercoupling results in a two-pole filter with the sharpest selectivity. Critical coupling results in the narrowest bandwidth with the highest gain. Transitional coupling is slightly greater than critical coupling and results in a flat-topped response with a wider

Figure 7. Coupling of identical LC circuits.

Figure 8. Results of *LC* circuit coupling: critical (curve A); transitional (curve B); overcoupled (curve C); undercoupled (curve D).

bandwidth. Overcoupling results in a double-humped response with sharper skirts and broad bandwidth. The coupling coefficient can be calculated using Eqs. (12). Equation (12a) applies to mutual inductive coupling and (12b)–(12d), to capacitive coupling.

$$K = \frac{M}{\sqrt{L_1 L_2}} \tag{12a}$$

$$K_c = \frac{1}{\sqrt{Q_1 Q_2}} \tag{12b}$$

$$K = \sqrt{\frac{C_c}{C_c + C_1}} \tag{12c}$$

$$K = \sqrt{\frac{C_1}{C_c + C_1}} \tag{12d}$$

Equation (12a) calculates the coupling coefficient for two identical *LC* tuned circuits that are coupled together by leakage inductance (Fig. 7a), often obtained by using shielded coils with holes in the sides of the shield cans to allow the magnetic fields to interact. The size of the hole determines the value of the mutual inductance *M*. Since this is difficult to control, a coupling capacitor is often used as shown in Figs. 7b and 7c. The critical coupling value is

given by Eq. (12b). The coupling coefficients for Figs. 7b and 7c are given in Eqs. (12c) and (12d).

The amplitude response curves in Fig. 8 do not yield any information as to the phase shifts that take place through the filter. In AM circuits, phase is generally of little concern, with most attention paid to the amplitude ripple and linearity. In FM circuits, nonlinear phase shift or a related term, *differential group delay*, becomes more of a problem and efforts are made to keep the phase shift as linear as possible. In data transmission circuits using phase modulation, or amplitude modulation, any nonlinearity must be avoided. For these reasons, the coupling coefficients are carefully adjusted and cascaded IF amplifier stages are used to get the desired transfer function for the IF amplifier.

8. CASCADING IF AMPLIFIER STAGES AND FILTERS

All filtering actions that take place between the RF input of the receiver and the decisionmaking circuit are parts of the IF amplifier bandpass filter. Since the final decision-making circuit is at baseband, or 0 Hz, all filtering prior to the decisionmaking circuit is part of the IF bandpass filtering, which should be treated as a whole.

A single *LC* circuit seldom has the desired bandpass characteristic for an IF amplifier. Cascading IF amplifier stages with differing coupling and *Q* values enables the designer to obtain the desired transfer response. One combination of *LC* filters uses an overcoupled double-tuned stage followed by a single-tuned stage with a lower *Q*. The result is a three-pole filter with relatively steep skirt slopes. Cascading these stages results in filters with responses resembling Butterworth, Chebyshev, elliptical, or equal-ripple filters, which are noted for their rejection of adjacent channel interference (see Figs. 9 and 10).

When additional filtering is required at baseband, simple *RC* filters, lowpass *LC* filters, or digital finite impulse response (FIR) filters are used. These and other filters are discussed in greater detail elsewhere in this encyclopedia.

9. CRYSTAL AND CERAMIC FILTERS

Figure 10a shows the equivalent circuit of a crystal or a ceramic resonator. These devices have both a pole and a

Figure 9. Curves resulting from cascading IF amplifier stages.

Figure 10. Equivalent circuit of a crystal or ceramic resonator.

zero that are located relatively close to each other in frequency. Quartz crystals have Q values ranging from 2000 to 10,000 depending on the mechanical loading of the crystal. Ceramic resonators usually have Q values between 100 and 2000. The higher the Q , the narrower the filter bandpass. When two of these devices are connected as shown in Fig. 10b, the result is a bandpass filter with steep skirts as shown in Figure 11. These resonators are used in pairs to create a two-pole filter, which can then be combined in a single container with other pairs, to create a filter with as many as eight or more poles. They usually have excellent adjacent-channel rejection characteristics.

When using these devices, care must be taken to carefully match the specified impedance. Any impedance mismatch can seriously alter the response curve of the filter. The impedance-matching techniques discussed previously will enable the designer to obtain a very close match, which will optimize the circuit performance. Typical input and output impedances range from 50 to 4000 Ω . Crystal filter manufacturers often build in transformer or other tuned matching circuits so that the user does not need to provide a matching circuit outside the crystal filter.

SAW (surface acoustic wave) filters utilize a crystal oscillating in a longitudinal mode with many fingers or taps placed along the surface. They can be made with very broad bandpass characteristics, which makes them well suited for TV IF amplifiers, spread-spectrum IF filters, and other uses requiring a wide RF bandwidth. They have losses, which are typically about 8–20 dB, so they must

Figure 11. Steep-skirted bandpass filter.

have amplifiers with adequate gain ahead of them if the receiver noise figure is not to be degraded. They are not suitable for use in ultranarrowband or low-frequency applications. The group delay quoted in the specifications is usually the *differential group delay* and not the actual group delay, which is much higher.

10. BASEBAND IF FILTERING

IF bandpass filters with specific response characteristics are sometimes very difficult to obtain, whereas the desired characteristic is easily and inexpensively obtainable at baseband. This concept is often applied to transmitters where a sharp-baseband-cutoff filter can be obtained using simple components, such as the switched filter. An 8-pole equivalent at baseband becomes a 16-pole filter at the modulation intermediate frequency. For example, a sharp-cutoff filter for voice with a 4-kHz audio cutoff results in a bandpass filter 8 kHz wide at RF after modulation, with the same sharp cutoff. The same cutoff characteristics at RF would be almost impossible to obtain in a crystal filter, which would also be very costly and beyond the manufacturing budget for a low-cost transmitter such as a cordless telephone. By using baseband filtering, a poor-quality RF filter that only rejects the opposite image can be used. Similarly, a wideband, or poor-quality IF filter, can be used ahead of a detector, if the undesired signal components can be filtered off after detection at baseband, by using a sharp-cutoff filter.

Switched-capacitor filters are available as packaged integrated circuits that can be used at baseband and some lower intermediate frequencies. They have internal operational amplifiers with a switched feedback capacitor, the combinations of which determine the filter characteristics. Since they are dependent on the speed of the operational amplifiers and the values of the feedback capacitors, they seldom function much above 100 kHz. They can be configured as Bessel, equal-ripple, and Butterworth filters. Typical of this type of filter are the LTC1060 family manufactured by Linear Technology Corporation (a) and the MAX274 from Maxim (b) [see items (a) and (b) in Available Software list at end of this article].¹ As Bessel filters they perform well out to about 0.7 times the cutoff bandwidth, after which the phase changes rapidly and the Bessel characteristic is lost.

Digital signal processing (DSP) at baseband is widely used to reduce the component count and size of the baseband filters in very small radio receivers, such as cordless and cellular telephones. Almost any desired filter response can be obtained from DSP and FIR filters without using inductors and capacitors, which would require factory tuning (c,d).

Separate FIR filters have a flat group delay response and are the best choice for FM or PM filtering, or filters at baseband. Commercially available software design

¹In the remainder of this article, all lowercase letters in parentheses refer to entries in the Available Software list following the Bibliography. Numbers in brackets refer to Bibliography entries (references) as usual.

packages permit the design of trial circuits to investigate phase shift and group delay (e,f).

Unfortunately, digital filtering of any type is frequency-limited. The filter must use a sampling rate that is much higher than the frequency to be passed. To use a digital filter, such as a FIR filter, or DSP as a bandpass filter at 10.7 MHz, requires an analog-to-digital converter (ADC) operating at 160 MHz or higher. Filtering at baseband means the sampling rate can be much lower.

11. AMPLIFYING DEVICES FOR IF AMPLIFIERS

Transistors in one form or another have become the standard for IF amplifiers. The single bipolar or field-effect transistor used as an individual component, was formerly the preferred device. For very-high-Q circuits, the dual-gate FET performs best, since it is the most stable and offers the lowest shunt resistance. Single-gate FET devices often have too much drain to gate capacitance for good stability. Modern bipolar transistors usually have good stability, but lower shunt resistances than dual-gate FETs. Stability is discussed later in this section.

Monolithic amplifiers [MMIC (monolithic microwave integrated circuit) devices] are stable and have good gain, but the shunt load impedance is too low for most bandpass filters other than a crystal or SAW filter matched to 50Ω.

The most recent practice for IF amplifiers is to use integrated circuit blocks containing more than one transistor in a gain stage. These are then packaged together in an integrated circuit with other circuit components to form an almost complete radio. Integrated circuits of this type are shown below.

12. TYPICAL CONSUMER IF AMPLIFIERS

Consumer radio and TV equipment is mass-produced for the lowest possible cost consistent with reasonable quality. Manufacturers of integrated circuits now produce single-chip IF amplifiers that can be combined with mass-produced stock filters to produce a uniform product with a minimum of adjustment and tuning on the assembly line. In the examples that follow, some circuit components inside and outside the IC have been omitted to emphasize the IF amplifier sections.

Figure 12 shows a single-chip AM receiver that uses the Philips TDA1072 [7] integrated circuit and ceramic IF filters at 455 kHz. The input impedance of the ceramic filter is too low to match the output impedance of the mixer, so a tuned matching transformer is used to both reduce the passed bandwidth (prefilter) and match the impedances. The input impedance of the IF amplifier was designed to match the average impedance of the ceramic filters available. This integrated circuit has a built in automatic gain control that keeps the received audio output level relatively constant at 250 mV as long as the input signal level to the chip exceeds 30 μV.

Figure 13 shows a single-chip FM radio based on the Phillips NE605 integrated circuit (g) that uses ceramic IF filters at 10.7 MHz. The input and output impedance of the

Figure 12. Layout of a single-chip AM receiver.

IF amplifier sections is approximately 1500Ω, to match the ceramic filter impedance, so no matching transformer is required. The audio output is maintained level at 175 mV for all signal levels at the input level from -110 to 0 dBm. An automatic frequency control (AFC) voltage can be obtained from the quadrature detector output. This circuit can also be used for narrow-angle phase modulation if a crystal discriminator is used for a phase reference at the quadrature input.

AGC is available from all FM integrated circuits so that the gain of the mixer and RF stages can be controlled at a level that does not allow these stages to be saturated by a strong incoming signal. Saturation, or nonlinearity before filtering, results in undesirable signal spreading. The NE605 has a “received-signal strength indicator” (RSSI) output that can be amplified and inverted if necessary to provide an AGC voltage, or current, for the RF amplifier and mixer.

Figure 14 shows a TV IF amplifier using the Motorola MC44301/2 video IF integrated circuit (h) with a SAW filter at 45 MHz. The SAW filter bandpass is made

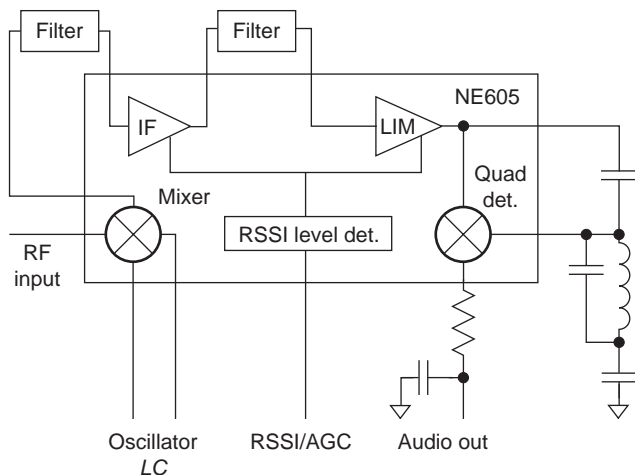

Figure 13. Configuration of a single-chip FM radio.

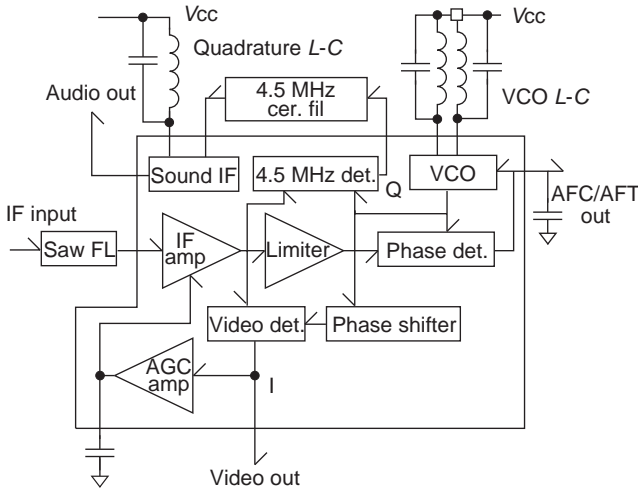

Figure 14. Layout of a television IF amplifier.

approximately 6 MHz wide to pass the video and sound. The circuit has both automatic frequency control (AFC) and automatic gain control (AGC) features built in. Unlike the IF amplifiers used for AM and FM audio broadcast applications, the TV IF amplifier includes a phase-locked loop (PLL) and synchronous detector that locks the frequency of an internal oscillator to the intermediate frequency. This locked, or synchronous, oscillator output is then mixed with the information-bearing portion of the signal to create a baseband signal.

The system shown in Fig. 14 is one of a family of 0-Hz IF amplifiers, are becoming more popular in wireless designs, since they permit most or additional signal processing at baseband. In Fig. 14, the video and sound carriers are both passed by the SAW filter. They beat together at 4.5 MHz in the detector, providing a second IF stage with the sound information. This 4.5-MHz IF information is then filtered by a ceramic bandpass filter approximately 50 kHz wide to remove any video components, limited and detected as a standard FM signal to provide the TV sound. The video portion, consisting of signals from 15 kHz to approximately 4.25 MHz, is then further processed to separate the color information at 3.58 MHz from the black-and-white information. The video output level is detected to provide the AGC voltage.

The phase-locked oscillator, operating at the intermediate frequency, can also be used to provide automatic frequency control to the first mixer stage local oscillator.

Figure 15 shows a dual-conversion receiver in a single integrated circuit for communications use, utilizing the Motorola MC13135 integrated circuit (h). When the receiver is operated at 450 or 850 MHz, as was mentioned above, single-conversion IF stages do not offer the necessary image rejection. This receiver is for narrow-band FM as opposed to wideband FM for entertainment purposes. The first IF filter is a low-cost ceramic filter at 10.7 MHz. The second filter is a multipole crystal or ceramic filter with a bandpass just wide enough to pass the signal with a small FM deviation ratio. Receivers of this type can be used with 12.5 and 25 kHz of channel separation for voice-quality audio. Analog cellular

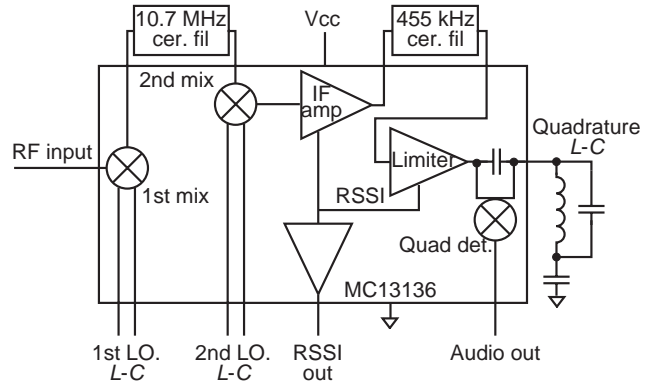

Figure 15. Configuration of a dual-conversion receiver in a single IC.

telephones, aircraft, marine, police, and taxicab radios are typical examples.

13. DIRECT CONVERSION AND OSCILLATING FILTERS

Direct conversion converts the RF frequency directly to baseband by using a local oscillator at the RF carrier frequency. The TV IF amplifier with the detector circuit given in Fig. 14 illustrates some of the reasons. Conversion to baseband can occur at the intermediate frequency or directly from the RF frequency.

There is a noticeable trend in integrated circuit design to utilize synchronous detection [5] with the carrier restored by means of a phase-locked loop, as shown in Fig. 14, or by means of regenerative IF amplifiers [6], to accomplish several desirable features that cannot be obtained from the classical circuits with square-law detectors.

In the case of direct RF-to-baseband conversion, there is no IF stage in the usual sense, and all filtering occurs at baseband. For this reason direct-conversion receivers are referred to as *zero-hertz (0-Hz) IF radios*. Integrated circuits for direct RF conversion are available that operate well above 2.1 GHz at the RF input. The Maxim 2820 (b) and the AMD1771 (i) are examples. DSP and FIR filters are the preferred lowpass filters at baseband, where they are referred to as “windows”.

It was discovered in the 1940s that the performance of a TV receiver could be improved by using a reconstructed synchronous or exalted carrier, as occurs in the TV IF amplifier depicted in Fig. 14. The carrier is reduced by vestigial sideband filtering at the transmitter and contains undesirable AM and PM signal components. By causing an oscillator to be locked to, or to be synchronized with the carrier, and then to be used by the detector, a significant improvement in the received signal can be achieved. Prior to using circuits of this type, the intercarrier sound at 4.5 MHz in earlier TV sets had a characteristic 60 Hz buzz due to the AM and PM on the carrier. By substituting the recovered synchronous carrier instead, this buzz was removed. Figure 14 illustrates an example.

The earliest direct-conversion receivers using locked oscillators or synchronous detectors were built in the

1920s, when they were known as *synchrodyne* or *homodyne* receivers. The theory is relatively simple. A signal from the RF amplifier is coupled to an oscillator, causing a beat or difference frequency. As the frequencies of the two sources come closer together, the oscillator is pulled to match the incoming signal and locks to it. The lock range depends on the strength of the incoming signal. The two signals are then mixed to provide a signal at baseband, which can be further filtered by means of a lowpass filter. In this way, a relatively broad RF filter can be used, while the resulting AM signal bandwidth after detection and baseband filtering can be very narrow. The Q of the oscillator tank circuit rises dramatically with oscillation so that Q values of 6000–10,000 are not unusual and selectivity is greatly improved. AGC can be obtained from the audio signal to maintain an input signal level that is constant to ensure a good lock range. An undesirable characteristic is the whistle or squeal that occurs between stations. Later receivers used a squelch circuit to make the signal audible only after locking has occurred. High-quality receivers for entertainment and communications use were produced in the 1990s using this principle. They offer higher sensitivity, better fidelity, and more controlled response. Integrated circuits for receivers of this type (direct conversion) are now being produced for paging, wi-fi (wireless fidelity), direct-broadcast TV, and cellular and cordless telephones. The Maxim 2820 (b) and the AMD 1771 (i) are examples.

Oscillating filters and phase-locked loops are similar in principle. An intermediate frequency is applied to a phase/frequency detector that compares the intermediate frequency with the oscillator frequency. An error voltage is created that changes the oscillator frequency to match, or become coherent with, that of the incoming IF carrier frequency. In some cases the phase-locked loop signal is 90° out of phase with the carrier, so a phase shifter is used to restore the phase and make the signal from the oscillator coherent in phase with the incoming signal. (See Figs. 14 and 18, where phase-locked loops and phase shifters are employed.)

Synchronous oscillators and phase-locked loops not only extend the lower signal-to-noise ratio but also have a bandwidth filtering effect. The noise bandwidth of the PLL filter is the loop bandwidth, while the actual signal filter bandwidth is the lock range of the PLL, which is much greater. Figure 16 shows the amplitude and linear phase response of a synchronous oscillator. The PLL is not always the optimum circuit for this use because its frequency/phase-tracking response is that of the loop filter.

The locked oscillator [6] performs much better than the PLL since it has a loop bandwidth equal to the lock range without sacrificing noise bandwidth, although with some phase distortion. Some authors hold that the synchronous oscillator and locked oscillator are variations of the PLL in which the phase detection occurs in the nonlinear region of the oscillating device and the voltage-controlled oscillator (VCO) frequency change characteristic comes from the biasing of the oscillator.

Both the PLL and the locked oscillator can introduce phase distortion in the detected signal if the feedback loop is nonlinear. A later circuit shown in Fig. 17 has two

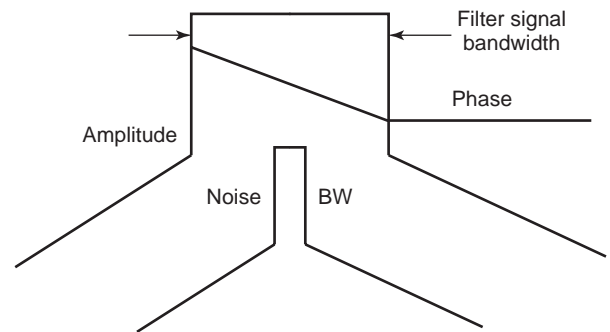

Figure 16. Amplitude and linear phase response of a synchronous oscillator.

feedback loops and is considered to be nearly free of phase distortion [5]. This circuit has the amplitude/phase response given in Fig. 16.

Phase-locked loops have been used for many years for FM filtering, amplification, and detection. They are in common use with satellite communications links for audio and video reception. A 74HC4046 phase-locked loop integrated circuit operating at 10.7 MHz (the FM intermediate frequency) can be used to make an FM receiver for broadcast use [7]. The phase-locked loop extends the lower signal-to-noise limit of the FM receiver by several decibels while simultaneously limiting bandwidth selectivity to the lock range of the PLL. The detected audio signal is taken from the loop filter.

14. AM STEREO (C-QUAM)

AM stereo radio is another application of the phase-locked oscillator at the intermediate frequency. AM stereo radio is dependent on two programs being transmitted at the same time at the same frequency. They arrive at the receiver detector circuitry through a common IF amplifier

Figure 17. Circuit with same amplitude and phase response as in Fig. 16 but with two feedback loops and markedly decreased phase distortion.

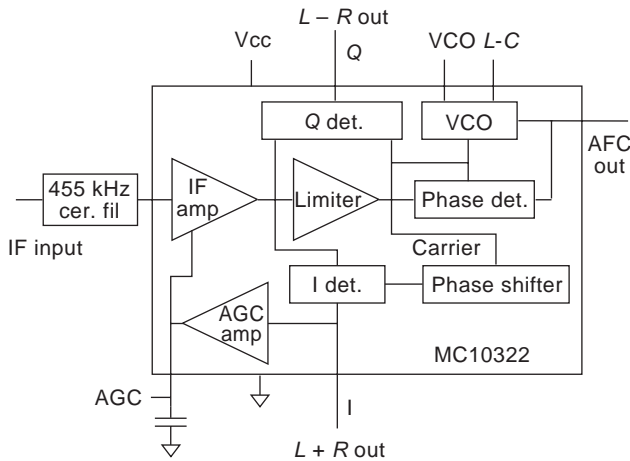

Figure 18. Simplified block diagram of the C-QUAM receiver.

operating at 455 kHz. The normal program heard by all listeners is the $L+R$ program. The stereo information ($L-R$) is transmitted at the same frequency, but in quadrature phase to the $L+R$ program. Quadrature, or orthogonal transmission, is used because the orthogonal channels do not interfere with one another.

Each program section requires a reference carrier, that is coherent with its own sideband data. The $L+R$ program, which has a carrier, may use an ordinary square-law detector or a synchronous detector. This is the program heard over monaural radios. To obtain the $L-R$ program that is transmitted without a carrier, a phase-locked loop is used at the intermediate frequency to lock a voltage controlled oscillator to the carrier of the $L+R$ program. This carrier is then shifted 90° in phase and becomes the reference carrier for the $L-R$ segment. The output of the PLL has the proper phase for the $L-R$ detector, so no phase shifting is necessary. The $L-R$ detector is a coherent or synchronous detector that ignores the orthogonal $L+R$ information. By adding, then inverting and adding, the left and right channels are separated. Figure 18 shows a simplified block diagram of the C-QUAM receiver.

The Motorola MC1032X (h) series of integrated circuits are designed for AM stereo use. The MC10322 and MC10325 have most of the components required, including the IF amplifiers, for a complete AM stereo receiver in two integrated circuit packages.

15. SUBCARRIERS

Subcarriers are used to carry two or more signals on the same carrier. They differ from the orthogonal signals used with C-QUAM in that they are carried as separate signals superimposed over the main carrier information, as in the video sound carrier shown in Fig. 14. In Fig. 14, a frequency-modulated subcarrier at 4.5 MHz is carried on top of the main video signal information, which extends from 0 to 4.25 MHz. This is an example of an AM/FM subcarrier. Nondigital satellites utilize a frequency-modulated video carrier with as many as 12 subcarriers at frequen-

cies ranging from 4.5 to 8.0 MHz. Normal FM stereo broadcasting utilizes a FM/AM subcarrier at 38 kHz to carry the $L-R$ portion of the stereo program. FM stations frequently carry additional subcarriers at 67 and 92 kHz. These FM/FM subcarriers are used to carry background music, ethnic audio programs, and digital data.

To detect a subcarrier, the signal is first reduced to baseband, then a bandpass filter is used that separates only the subcarrier frequencies. The subcarrier frequencies are then passed to a second detector, which must be of the type appropriate for the subcarrier modulation. This can be seen in Fig. 14, where a 4.5-MHz filter is used. This is followed by a limiter and quadrature detector, which is appropriate for the FM signal. In the case of a 67-kHz FM/FM subcarrier, the filter is 15 kHz wide at 67 kHz. Detection can be accomplished by a discriminator, quadrature detector, or PLL.

16. CELLULAR AND CORDLESS TELEPHONES

Analog cellular telephones employ the circuits shown in Figs. 13 and 15. Digital telephones utilizing Gaussian minimum shift keying (GMSK) also use these circuits. Digital telephones using quadrature amplitude modulation (QAM) or phase shift keying (PSK) employ circuits similar to that used for C-QUAM with digital filtering and signal processing instead of audio filtering at baseband. The PLL used for digital receivers is a more complex circuit known as the *Costas loop*, which is necessary to restore a coherent carrier for digital data recovery. Some cellular phones are dual-mode; that is, they can transmit and receive analog voice or digital GMSK modulation using circuits similar to those shown in Figs. 13 and 15.

17. NEUTRALIZATION, FEEDBACK, AND AMPLIFIER STABILITY

Earlier transistors and triode vacuum tubes had considerable capacitance between the output element (collector or plate) and the input side of the device (see Fig. 4). Feedback due to this capacitance is multiplied by the gain of the stage so that enough signal from the output was often coupled back to the input to cause the stage to oscillate unintentionally, as opposed to the planned oscillation of the locked oscillator, synchronous oscillator, or PLL. To prevent this, feedback of an opposite phase was deliberately introduced to cancel the undesired feed back. A neutralized IF amplifier is shown in Fig. 19. Transistors and integrated circuits made since 1985 are rarely unstable and generally do not require neutralization unless seriously mismatched. A better solution than neutralization is usually to improve the matching of the components and the circuit layout.

By carefully controlling the feedback, a regenerative IF amplifier can be constructed that operates on the verge of oscillation. This greatly increases the Q of the tuned circuit, thus narrowing the IF bandwidth. Circuits of this type were once used in communication receivers for

Figure 19. Configuration of a neutralized IF amplifier.

commercial and amateur use, where they were referred to as “ Q multipliers.”

The maximum stable gain (MSG) that can be achieved from a potentially unstable amplifier stage without neutralization is obtainable from the S parameters and can be calculated from Eq. (13). This equation assumes that the input and output impedances are matched and there is little or no scattering reflection at either the input or output. The stability factor K , usually given with the S parameters, must be > 1 . A failure to match the impedances can result in an unstable amplifier, but does not necessarily do so. A higher gain can be obtained, but at the risk of instability.

$$K = \text{MSG} = \frac{S_{21}}{S_{12}} \quad (13)$$

In addition to impedance mismatch, the most frequent cause of amplifier instability, or oscillation, is poor circuit-board layout or inadequate grounding and shielding, not the device parameters. The wiring, whether printed or handwired, forms inductive or capacitive coupling loops between the input and output terminals of the amplifying device. This is particularly noticeable when high-gain ICs such as the NE605 are used. These integrated circuits have IF gains of > 100 dB and require very careful board layouts for best results. Undesirable feedback can greatly decrease the usable gain of the circuit.

18. SOFTWARE RADIO

Digital radios, or radios based on digital signal processing (DSP), offer some technical advantages over their analog predecessors. Digital radios can be used not only for digital modulation but also for AM and FM. One receiver can simultaneously detect both digital and analog modulation; thus they can be used for cellular telephones in environments where multiple modulation standards are used. As a class, they belong to the 0-Hz intermediate-frequency group.

The typical receiver consists of a conventional RF front end and a mixer stage that converts the signal to a lower frequency, as in the dual conversion radios discussed above (Fig. 16). The signal at this stage is broadband in

nature, but not broadband enough to include the image frequencies. The signal is then fed to an analog-to-digital converter (ADC), which is sampled at several times f_m . This converts the portion of interest of the signal to baseband (or 0 Hz) instead of a higher intermediate frequency. The actual filtering to remove unwanted interfering signals then takes place at baseband, using digital filtering. Digital signal processing and decimation are covered elsewhere in this work. The ADC (c) performs the same functions as do the oscillating detectors shown above.

Noise figure, amplification, and AGC considerations of the first IF amplifier are the same as those for a conventional receiver. The ADC and the DSP filters function best with a constant signal input level.

The term “software radio” has been adopted because the tuning function is done in software by changing the sampling frequency at the ADC. The sampling frequency is obtained from a digitally controlled frequency synthesizer instead of tuned LC circuits.

19. SPREAD-SPECTRUM RADIOS

The spread-spectrum receiver also uses a conventional front end with a wideband first IF stage. The same conditions apply as to software radios and dual-conversion receivers. The first IF stage must have the necessary bandwidth to accommodate the spread bandwidth, amplify it with minimum added noise, and match the output to the despreading circuitry. Spread-spectrum technology is covered elsewhere in this encyclopedia. While usually associated with digital reception, spread-spectrum technology can also be used for analog audio.

20. ORTHOGONAL FREQUENCY-DIVISION MULTIPLEXING (OFDM) AND CODED OFDM (COFDM)

These modulation methods could be considered similar to spread-spectrum techniques, or to methods requiring dual conversion, in that they use a very broad spectrum as a first level, followed by a narrowband filter to extract an individual channel. SAW filters are generally used at RF, while second-stage processing can use digital filtering, as in the software radio, or be done at baseband.

21. TRANSFER FUNCTIONS

The amplitude response, plotted relative to frequency of a filter, is usually given in terms of the transfer function $H(f)$. Some typical transfer functions are as follows. For the LC filter of Fig. 2

$$H_{LC}(f) = \exp - \frac{Q\omega t}{2} \quad (14)$$

The LaPlace transform equivalent is

$$H(s) = \frac{K}{s^2 + Bs + \omega_0^2} \quad (15)$$

A similar curve obtainable with digital filters is the Gaussian filter:

$$H_{\text{Gauss}}(f) = \exp -1.38 \left[\frac{1}{(BT)^2} \right] \quad (16)$$

A generalized Nyquist IF filter bandpass spectrum is seen in Fig. 20.

In Fig. 20 the centerline represents either the carrier frequency, or 0 Hz. The portion of the spectrum to the right of the centerline is the baseband response, while both extremes represent the RF double-sideband response with the carrier at the center. The B region is the baseband response of an “ideal” filter, which does not exist in practice. Practical filters have a rolloff, or excess bandwidth, shown in α . Outside the desired bandpass, there is a “comeback” in region C . The “ideal” filter has no rolloff and no comeback. The region B is the required Nyquist bandwidth.

Multilevel digital modulation methods such as quadrature amplitude modulation (QAM) and multiple phase shift keying (MPSK) require filters that are free of amplitude and phase distortion within the Nyquist bandwidth, then having a rolloff α as abrupt as reasonably possible outside that distortion-free bandwidth. The optimum filter for this is considered to be the *raised-cosine filter*, so called because the region after the uniform response is half-cycle of a cosine wave squared (cosine raised to second power). The transfer function for the raised-cosine filter is as follows. In the central bandpass region B , we obtain

$$H(f) = 1 \quad \text{for} \quad |f| > -f_m(1 - \alpha), \quad (17)$$

$$\text{or} \quad < f_m(1 + \alpha) \quad (\text{or } \pm f_m)$$

When $\alpha = 0$, the filter is said to be the “ideal” filter. In the transition region α ; since $\cos 2A = \cos^2 A - 1$ or $1 + \cos 2A = \cos^2 A = 0$ elsewhere, we obtain the following forms of Eq. (17):

1. $H(f) = \cos^2[(\pi|f|T)/2\alpha] - \pi(1 - \alpha)/4\alpha$, for $-f_m(1 - \alpha) < |f| < f_m(1 + \alpha)$
2. $H(f) = \frac{1}{2} \{1 + \cos [(\pi|f|T)/\alpha] - \pi(1 - \alpha)/2\alpha\}$

In practice, there is always some comeback as seen in region C .

Figure 20 shows the double-sided RF bandwidth when the center reference is the carrier. The right-hand side is

Figure 20. A simplified Nyquist filter bandpass spectrum (from Sklar [13] and Feher [14]).

the baseband bandwidth with the reference at 0 Hz. When used as a lowpass filter at baseband, the filter is referred to as a “window.” There are many rolloff curves associated with windows, which are realizable with DSPs or field-programmable gated arrays (FPGAs) used as FIR filters. Designing an RF bandpass filter with these rolloff curves is very difficult; therefore, the preferred practice is to do the filtering at baseband where numerous windowing curves are available.

Some popular rolloff curves for FIR filters used as “windows” are the Bartlett, Blackman, Hamming, Hanning, Elexix, Truncated Sinc/x, and Kaiser. These are usually realized by changing the multipliers in the 2 of Eq. (17) [above; after text following Eq. (17)] form of the raised-cosine equation. For example, using this form of Eq. (17), the Hamming window has the equation $H(f) = \{0.54 + 0.46\cos[(\pi|f|T)/\alpha] - \pi(1 - \alpha)/2\alpha\}$. The “ideal” filter shape ($\alpha = 0$) at baseband is called a “rectangular” window.

22. GROUP DELAY, ENVELOPE DELAY, AND RISE TIME

The group delay for conventional filters is traditionally calculated to be [11]:

$$T_g = \frac{\Delta\Phi}{2\pi\Delta f} \quad (18)$$

For LC or Gaussian filters (Fig. 2), this is

$$T_g = \frac{1}{(4\Delta f)} \quad \text{and} \quad T_g = \frac{Q\Delta\Phi}{\omega} \quad (19)$$

Obviously, a very narrow bandwidth filter $[\Delta f]$ has a very large group delay, which will adversely affect pulse modulation.

There is an associated equation for the risetime of the conventional filter: $T_r = 0.7/B$, where B is the 3-dB bandwidth $[\Delta f]$ of the filter. This is the time interval from 10% to 90% on the RC curve. Bandwidth, risetime, and sampling rate are mathematically linked.

A radar system with a narrow pulse must have a RC risetime that allows the pulse to pass. This necessarily means a very broad filter bandwidth and an accompanying high noise level.

Two-level modulation methods, such as BPSK, QPSK, GMSK, NBFS, and NBPM (binary, quadrature, Gaussian minimum shift keying and narrowband frequency and phase modulation), can use a narrower-than-usual bandpass filter. The bandpass can be as low as $0.2[\Delta f]$ in Eqs. (18) and (19).

Refer to Fig. 2 and Eq. (4), which demonstrate a reduction of the output level of the high-frequency portion of the signal (sidebands) that pass through the filter and a simultaneously reduction of the noise power bandwidth. The result is an overall S_o/N_o improvement. The notation BT is used for this concept $B = \text{bandwidth}$ and $T = \text{bit period} = 1/f_b$. The value of T is fixed, but B can be altered. The effect is to raise the processing gain in Eq. (4) by $1/BT$.

Certain newer modulation concepts (ultranarrowband) require a filter that does not conform to the group delay

Figure 21. Circuit of a half-lattice (bridge-type) filter with near-zero group delay to a single-pulsed frequency (from Chen [12]).

equation [Eq. (18)]. These so called *zero-group-delay filters* have a very narrow bandwidth with almost instantaneous pulse response at a single frequency. Figure 21 shows the circuit of a half-lattice, or bridge-type, filter, that has near-zero group delay to a single-pulsed frequency. At the parallel resonant frequency of the crystal, the crystal appears to have a very high resistance and the signal passes via the phasing capacitor in the opposite bridge arm. This circuit has a frequency response similar to that of the universal curve (Fig. 2) with shoulders that extend from 0 Hz to infinity. Therefore, it must be used together with pre-filters to narrow the total noise bandwidth. A small capacitor or inductor can be used at z to extend the tuning range of the crystal [11].

23. COMPUTER-AIDED DESIGN AND ENGINEERING

Digital filters are easily designed using commercially available software packages and information provided by the IC manufacturers (d-g, l).

For IF filter design using discrete components, the admittances rather than the impedances are easiest to use, since most components are in parallel as shown in the equivalent circuit of Fig. 4b. Unfortunately, most available data are in the form of S parameters, which are very difficult to convert manually to impedances or admittances. Parameters for the filters are rarely available, so calculated values based on assumed input and output impedances must be used unless test equipment capable of measuring return losses or standing waves is available, in which case the S parameters can be measured or calculated.

Smith and Linville charts have been used by some authors to design IF amplifiers, but these methods are not totally satisfactory for IF amplifier design, since a high- Q circuit has its plot near the outer edge of the circle and changes are difficult to observe. The network admittance values shown in Fig. 4 would be used.

Computer-aided programs for linear or analog designs, such as the various "SPICE" programs are readily available (j). Other programs which concentrate specifically on

filter design (f, k-m) can simplify the filter design. They have outputs that then interface with the SPICE programs if desired. Most semiconductor manufacturers provide scattering parameters (S parameters) or SPICE input data on disk for use with these programs. Some design software sources are listed below (after the Bibliography). Some of the IF amplifier integrated circuit manufacturers also provide software specific to their products.

INTERMODULATION

JOSÉ CARLOS PEDRO
University of Aveiro
Portugal

1. INTRODUCTION

1.1. What Is Intermodulation Distortion?

Although the term *intermodulation* is used by some authors to describe a specific manifestation of nonlinear distortion, in this text we will adopt the wide-sense meaning of intermodulation as any form of nonlinear distortion, unless otherwise explicitly stated. So, it is convenient to start an introduction to intermodulation by saying a few words about distortion.

In the field of telecommunication systems, distortion is understood as any form of signal impairment. In this way, distortion takes the broad sense of all differences between the received and the transmitted information signals, specifically, those added or signal-dependent perturbations.

In the first set of added, or signal-independent, perturbations, we should include random noise and deterministic interferences. Typical examples of the former are the always present thermal noise or shot noise of electronic circuits. The second could be illustrated by some man-made (synthetic) repetitive impulsive noise or simply another telecommunications channel that shares the

same transmission medium but that does not carry any useful information.

The set of signal-dependent perturbations can also be divided into two major parts—linear distortion and nonlinear distortion—according to whether what distinguishes the received signal from its transmitted version is due to a linear or a nonlinear process. The reason for this organization stands in the easiness with which we correct linear distortion and the difficulty we have in dealing with nonlinearity. In fact, since linear distortion describes all differences in time-domain waveform, or frequency-domain spectrum, as the ones caused by any usual filter or dispersive transmission medium, it can be corrected by another inverse filter, with a methodology usually known as *pre- or postequalization*. On the other hand, nonlinear distortion cannot be corrected this way, remaining nowadays as a very tough engineering problem.

So, from a purely theoretical point of view, what distinguishes linear distortion from nonlinear distortion is simply the essence of the mapping corresponding to the telecommunication system, from the signal source to the detected signal. If that mapping responds to scaled versions of two different signals with two scaled versions of the responses to these two signals, when they are processed individually, we say that our transmission system obeys superposition, and is thus linear [1]. In any other case, we say that the system is a source of nonlinear distortion. Nonlinear distortion can, therefore, manifest itself in many different forms that range from the obvious signal clipping of saturated amplifiers, to the almost unnoticeable total harmonic distortion present in our high-fidelity audio amplifiers.

Because nonlinear distortion is a property not shared by our more familiar linear systems, we could think of it as something visible only in some special-purpose systems or poorly designed circuits. Unfortunately, that is not the case. To a greater or lesser extent, nonlinear distortion is present in the vast majority of electronic systems. Because nonlinear distortion is associated with PN and PIN diodes or varactors [2], it is found in many control devices such as solid-state switches, controlled attenuators, phase shifters, or tunable filters—and, because of the recognized nonlinearity of magnetic-core inductors, it can also arise from other passive filters and duplexers. However, probably more surprising, is the fact that it can even arise from devices usually assumed as linear.

One example is the nonlinear distortion produced by some RF MEM (radiofrequency micromachined electro-mechanical) switches [3]. Another is *passive intermodulation* (PIM), which is frequently observed when loose connections, or junctions made of different metals or of similar but oxidized metals are subject to high power levels [4]. So, PIM is generated in many RF connectors, antennas, antenna pylons, wire fences, and other components. Finally, intermodulation can even arise from our supposedly linear electronic circuits as it is inherent to the operation of all electronic active transducers. To understand this, let us take the example of the general amplifier described in Fig. 1.

Because our amplifier is a physical system, it must obey energy conservation, which implies that the sum of all

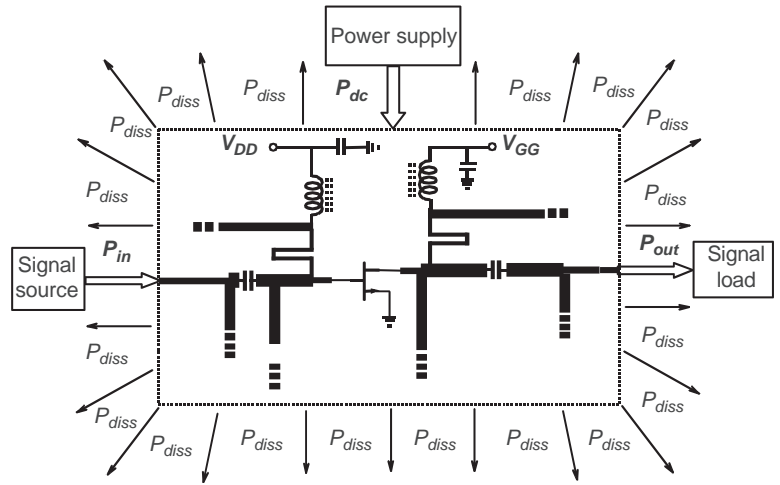

Figure 1. Conceptual amplifier showing input/output power relations.

forms of input power—either signal power P_{in} or DC supply power P_{DC} —must equal the sum of all forms of output power, whether it is signal power delivered to the load P_{out} or dissipated power P_{diss} such as heat or harmonic distortion:

$$P_{in} + P_{DC} = P_{out} + P_{diss} \tag{1}$$

On the other hand, we know that output signal power should be a scaled replica of the input signal power, defining, in this way, a certain amplifier power gain:

$$G_P \equiv \frac{P_{out}}{P_{in}} \tag{2}$$

However, (1) also implies that

$$G_P = 1 + \frac{P_{DC} - P_{diss}}{P_{in}} \tag{3}$$

which shows that no amplifier that relies on a real supply of finite power can keep its gain constant for any increasing input signal level. Sooner or later, it will have to show gain compression, presenting, therefore, nonlinearity.

1.2. Characterizing Intermodulation Distortion

After this brief introduction to the concept of intermodulation distortion, let us now see in more detail which forms of distortion it describes. For that, we will assume a simple system represented by the following cubic model:

$$y(t) = a_1x(t - \tau_1) + a_2x(t - \tau_2)^2 + a_3x(t - \tau_3)^3 + \dots \tag{4}$$

in which the input $x(t)$ is nonlinearly transformed into an output $y(t)$. Note that this system not only shows nonlinearity as it also has memory, since it does not respond instantaneously to the input, but to certain past versions of it. This dynamic behavior is due to the presence of the delays τ_1 , τ_2 , and τ_3 .

1.2.1. Single-Tone Distortion Characterization. Supposing the input is initially composed of one amplitude $A(t)$

and phase $\theta(t)$ modulated RF carrier of frequency ω_c

$$x(t) = A(t) \cos[\omega_c t + \theta(t)] \tag{5}$$

the output will be composed of three sets of terms, say, $y_1(t)$, $y_2(t)$, and $y_3(t)$, each one corresponding to a certain polynomial degree. Illustrations of the time-domain waveforms and frequency-domain spectra of the input $x(t)$ and output $y(t)$ are depicted in Figs. 2a and 2b and in Fig. 3a and 3b, respectively.

The first term of the output is given by

$$y_1(t) = a_1A(t - \tau_1) \cos[\omega_c t + \theta(t - \tau_1) - \phi_1] \tag{6}$$

(where $\phi_1 = \omega_c \tau_1$) and corresponds to the expected linear response. Note that it includes exactly the same frequency components already present at the input.

The second term

$$y_2(t) = \frac{1}{2}a_2A(t - \tau_2)^2 + \frac{1}{2}a_2A(t - \tau_2)^2 \cos[2\omega_c t + 2\theta(t - \tau_2) - 2\phi_2] \tag{7}$$

(where $\phi_2 = \omega_c \tau_2$) involves baseband products whose frequency falls near DC and some other products whose frequencies are located around the second harmonic, $2\omega_c$. The first ones consist of second-order intermodulation products of the form $\omega_x = \omega_1 - \omega_2$ (in which ω_x is the resulting frequency, while ω_1 and ω_2 are any two distinct frequencies already present at the input), and describe the demodulation generally provided by even-order nonlinearities. When $\omega_1 = \omega_2$, then $\omega_x = 0$, and the terms fall exactly at DC. So, they also describe the circuit's DC bias shift. Because they are what is sought in AC to DC converters, in amplifiers they model the variation of the $y(t)$ mean value from the quiescent point, to the mean value shown in presence of a significant RF excitation—the large-signal bias point. The second type of even-order products is again second-order intermodulation distortion whose frequency now falls at $\omega_x = \omega_1 + \omega_2$. For $\omega_1 = \omega_2$,

(a)

(b)

Figure 2. (a) Time-domain waveform of the input signal $x(t)$; (b) corresponding frequency-domain spectrum.

(a)

(b)

Figure 3. (a) Time-domain waveform of the output signal $y(t)$; (b) corresponding frequency-domain spectrum.

then $\omega_x = 2\omega_1$, and the products are known as second-order harmonic distortion.

Finally, the third term is

$$y_3(t) = \frac{3}{4}a_3A(t - \tau_3)^3 \cos[\omega_c t + \theta(t - \tau_3) - \phi_3] + \frac{1}{4}a_3A(t - \tau_3)^3 \cos[3\omega_c t + 3\theta(t - \tau_3) - 3\phi_3] \quad (8)$$

(where $\phi_3 = \omega_c \tau_3$) and also involves two different sets of products located near the input frequency band (or fundamental band) ω_c and the third harmonic $3\omega_c$.

As are the even-order products, the third-order products falling near the third harmonic $3\omega_c$ are classified as out-of-band products. Appearing at $\omega_x = \omega_1 + \omega_2 + \omega_3$, that is, out of the fundamental signal band in RF systems of narrow bandpass characteristics, these products seldom constitute a major source of nonlinear signal impairment as they can be easily filtered out. Note, however, that they may also constitute in-band products in ultra-wide-band systems such as cable television (CATV).

Third-order products falling exactly over, or in the vicinity of ω_c , in which the resulting frequencies can be either $\omega_x = \omega_1 + \omega_2 - \omega_3$, $\omega_x = 2\omega_1 - \omega_2$, or even $\omega_x = \omega_1$ (whether they arise from the combination of three distinct, two equal and one different, or three equal input frequencies, respectively), are obviously called *in-band products*. Contrary to the products treated above, they cannot be eliminated by linear filtering, constituting the principal object of intermodulation distortion studies in microwave and wireless systems. In fact, some authors even reserve the term *intermodulation distortion* for this particular form of nonlinear signal perturbation.

To analyze these in-band distortion products in more detail, we will now consider two different situations of system memory. In the first case, it is assumed that the time delays of (4) are due only to the active device's reactive components or to the input and output matching networks. In this way, they may be comparable to the RF carrier period, but negligible when compared to the much slower modulation timescale. Therefore, the in-band products can be approximated by

$$\frac{3}{4}a_3A(t)^3 \cos[\omega_c t + \theta(t) - \phi_3] \quad (9)$$

which shows that, although the system kept its dynamic behavior to the RF carrier, it became memoryless (i.e., responds instantaneously) to the modulation envelope. Since general amplitude and phase modulations have frequency components that start at DC, we have already seen that these products include spectral lines falling exactly over the ones already present at the input, and some other new components named as spectral regrowth.

The third-order signal components that are coincident with the input are given by $\omega_x = \omega_1 + \omega_1 - \omega_1 = \omega_1 + (\omega_1 - \omega_1) = \omega_1$ and can be understood as being generated by mixing second-order products at DC with first-order (or linear) ones. Except for their associated gain, which is no longer a_1 , but $\frac{3}{4}a_3$ multiplied by the input amplitude-averaged power A^2 , these products are indistinguishable from the linear components of (6). They carry the same information content, and are, therefore, termed *signal-correlated products*. Although, in a strict sense, they should be considered as nonlinear distortion products (as their signal power rises at a slope of 3 dB/dB against the 1 dB/dB that characterizes truly linear components), from an information content viewpoint, they may also be considered as linear products. In fact, since, for a constant-input-averaged power, they cannot be distinguished from the first-order components, it all happens as if the amplifier had remained linear but with a gain that changed from its small-signal value of $G = a_1 \exp(-j\phi_1)$ to an amplitude-dependent large-signal gain of $G(A) = a_1 \exp(-j\phi_1) + (3/4)A^2 a_3 \exp(-j\phi_3)$. So, input amplitude signal variations [or amplitude modulation (AM)] produce different output amplitude variations, according to the so-called amplifier AM-AM conversion. But, since the gain is also characterized by a certain phase, it is obvious that input amplitude signal variations will also generate output phase variations. In conclusion, and as illustrated in Figs. 4a and 4b, the amplifier will show not only AM-AM but also AM-PM conversion.

Figure 5 depicts a possible block diagram of a laboratory setup intended to measure these static AM-AM and AM-PM characteristics [6]. As shown, it relies on a usual microwave vector network analyzer whose signal source is swept in power.

As a curious aside from this analysis, we should point out that, although our nonlinearity manifests a signal amplitude-dependent gain, it is completely insensitive to

Figure 4. (a) Amplifier's AM-AM conversion; (b) AM-PM conversion.

Figure 5. AM-AM and AM-PM characterization setup based on a microwave vector network analyzer.

the input signal phase. In fact, as can be concluded from (9), the bandpass characteristics of our amplifier would be completely transparent to a phase-modulated signal of constant amplitude, in the sense that the phase information present at the output would be exactly equal to the phase information present at its input.

In the second case, it is supposed that, beyond the usual time constants of the order of the RF carrier period, our system may even present time delays, τ_1' , τ_2' , and τ_3' , comparable to the modulation period (e.g., determined by the bias circuitry, active-device charge carrier traps, self-heating). Such time constants are no longer irrelevant for the envelope evolution with time, and the system is said to present long-term or envelope memory effects. The

in-band output distortion becomes

$$\frac{3}{4} a_3 A (t - \tau_3')^3 \cos[\omega_c t + \theta(t - \tau_3') - \phi_3'] \quad (10)$$

and the output envelope will show a phase shift that is dynamically dependent on the rate of amplitude variations. In this case, the output AM-AM or AM-PM is no longer static, and dynamic (or hysteretic) AM-AM and AM-PM conversions are observed, as shown in Figs. 6a and 6b.

This shows that, if our nonlinear system only presents short-term memory effects, and thus is memoryless for the envelope, it may be characterized by a set of gain and

Figure 6. Typical hysteretic AM-AM (a) and AM-PM (b) characteristics shown by nonlinear dynamic amplifiers suffering from both short-term and long-term memory effects.

phase shift tests made with a sinusoidal, or CW (continuous-wave), excitation with swept amplitude and, eventually, with varying frequency. However, if the system is also dynamic to the envelope, then the observed AM-AM/AM-PM varies with the speed of the input amplitude sweep, and such a test becomes questionable. Since each of the tested CW signals can be seen as a carrier modulated by a constant (DC) envelope, it becomes obvious that we cannot fully characterize a dynamic system using only these simple DC excitations.

Moreover, it is clear that testing in-band intermodulation products with a CW signal will never be an easy task, as the output will only have signal-correlated components where $\omega_x = \omega_c$, which all overlap onto the usually much higher linear output. Obviously, in-band intermodulation characterization requires more complex stimuli.

1.2.2. Two-Tone Distortion Characterization. One way to increase the complexity of our test signal is to use a two-tone excitation:

$$x(t) = A_1 \cos(\omega_1 t) + A_2 \cos(\omega_2 t) \tag{11}$$

The in-band output components of (4) when subject to this new stimulus will be

$$\begin{aligned} & a_1 A_1 \cos[\omega_1 t - \phi_{110}] + a_1 A_2 \cos(\omega_2 t - \phi_{101}) \\ & + \frac{3}{4} a_3 A_1^2 A_2 \cos[(2\omega_1 - \omega_2)t - \phi_{32-1}] \\ & + \left[\frac{3}{4} a_3 A_1^3 + \frac{6}{4} a_3 A_1 A_2^2 \right] \cos[\omega_1 t - \phi_{310}] \\ & + \left[\frac{6}{4} a_3 A_1^2 A_2 + \frac{3}{4} a_3 A_2^3 \right] \cos(\omega_2 t - \phi_{301}) \\ & + \frac{3}{4} a_3 A_1 A_2^2 \cos[(2\omega_2 - \omega_1)t - \phi_{3-12}] \end{aligned} \tag{12}$$

Beyond the expected linear components arising at ω_1 and ω_2 , (12) is also composed of other third-order products at ω_1 , ω_2 , $2\omega_1 - \omega_2$, and $2\omega_2 - \omega_1$. They constitute again the signal-correlated (ω_1 and ω_2) and signal-uncorrelated ($2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$) components. The terms at ω_1 (ω_2) that are dependent only on A_1 (A_2) constitute the AM-AM/AM-PM conversion discussed above. But now there are some new terms at ω_1 (ω_2) whose amplitude is also controlled by A_2 (A_1). They model two different, but obviously related, nonlinear effects. One is cross-modulation, a nonlinear effect in which amplitude modulation of one RF carrier is converted into amplitude modulation of the other; the other is known as *desensitization*, the loss of receiver sensitivity to one signal when in presence of an incoming strong perturbation (e.g., a jammer).

The terms at $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$ are spectral regrowth components that appear as sidebands located side by side to the fundamentals at a distance equal to their frequency separation $\omega_2 - \omega_1$. These in-band intermodulation distortion (IMD) sidebands rise at a constant slope of 3 dB per dB of input level rise, until higher-order components (in the case of our polynomial model, output con-

Figure 7. Typical fundamental and third-order intermodulation power versus input power plots. Note the definition of the extrapolated third-order intercept point IP_3 .

tributions due to higher-degree terms) show up. Since first-order components rise at a slope of only 1 dB per dB, we could conceive of an extrapolated (never reached in practice) output power where the output IMD and fundamentals would take the same value. As illustrated in Fig. 7, this is the so-called third-order intercept point IP_3 .

Although meaningful only for small-signal regimes, where the fundamental and IMD components follow their idealized straight-line characteristics, IP_3 is still the most widely used (some times erroneously) intermodulation distortion figure of merit.

Figure 8 shows a block diagram of the most popular laboratory setup used for two-tone intermodulation tests. It relies on a two-tone generator of high-spectral purity, and a high-dynamic range microwave spectrum analyzer.

Although, for many years, two-tone intermodulation characterization has been restricted to these amplitude measurements, more recently we have seen an increasing interest to also identify the IMD components' phase. The reason for this can be traced to the efforts devoted to extract behavioral models capable of representing the device's IMD characteristics and to the design of amplifier linearizers that must be effective even when the main nonlinear device presents long-term memory effects. In fact, since most of the linearizers can be understood as auxiliary circuits capable of generating IMD components that will cancel the ones arising from the main amplifier, it is obvious that those linearizing circuits must be designed to meet both IMD amplitude and phase requirements.

Unfortunately, the first problem that arises when trying to measure the IMD components' phase is that, despite phase is a relative entity, we have no phase reference for IMD. Contrary to what happens to the output fundamentals in which we can refer their phases to the phases at the input (usually arbitrarily assumed zero), the problem is that now there are no input components at the IMD frequencies. So, we first need to create a reference signal at that IMD frequency. That is usually done with a

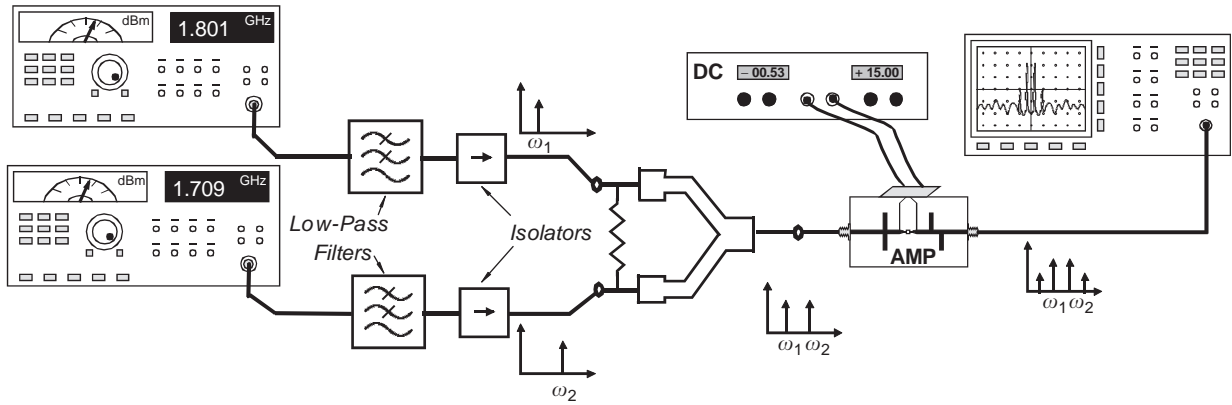

Figure 8. The most popular laboratory setup used for two-tone intermodulation tests.

reference nonlinearity; thus IMD phase measurement results become relative to the reference nonlinearity used in the setup. For example, in the setup depicted in Fig. 9, the reference nonlinearity is based in the nonlinear characteristic of broadband Schottky diodes, and the phase value is acquired from the variable phase shift necessary to balance the device under test (DUT) and reference arms.

1.2.3. Multitone Distortion Characterization. For completeness, let us now briefly introduce intermodulation characterization under multitone excitations. A detailed analysis of this important and up-to-date subject can be found in various references [e.g. 5,6].

First, we will assume that our stimulus can be described as a sum of Q sinusoids of different frequencies:

$$x(t) = \sum_{q=1}^Q A_q \cos(\omega_q t) = \frac{1}{2} \sum_{q=-Q}^Q A_q e^{j\omega_q t} \quad (13)$$

The output of a general power series such as (4) to the excitation of (13) will be

$$y(t) = \sum_{n=1}^N y_n(t) \quad (14a)$$

where each of the orders can be expressed as

$$y_n(t) = \frac{1}{2^n} a_n \left[\sum_{q=-Q}^Q A_q e^{j\omega_q t} \right]^n$$

$$= \frac{1}{2^n} a_n \sum_{q_1=-Q}^Q \cdots \sum_{q_n=-Q}^Q A_{q_1} \cdots A_{q_n} e^{j(\omega_{q_1} + \cdots + \omega_{q_n})t} \quad (14b)$$

which contains various frequencies at $\omega_x = \omega_{q_1} + \cdots + \omega_{q_n}$, originating from many different mixing products.

Since there is, in general, more than one mixing product—that is, more than one combination of input frequencies—falling at the same frequency, the calculation of their output amplitude requires that first we are able to determine the number of those different combinations. One systematic way to do this is to recognize that their frequencies must obey [7]

$$\omega_{n,v} = \omega_{q_1} + \cdots + \omega_{q_n} = m_{-Q}\omega_{-Q} + \cdots + m_{-1}\omega_{-1} + m_1\omega_1 + \cdots + m_Q\omega_Q \quad (15)$$

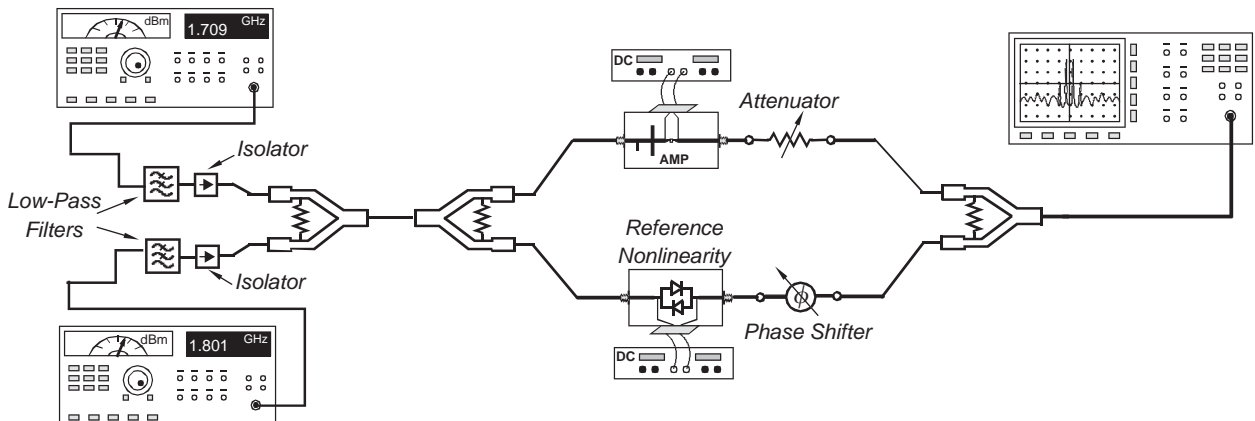

Figure 9. Possible IMD phase measurement setup based on a reference nonlinearity, a spectrum analyzer, and an IMD cancellation loop.

Figure 10. Ratio of two-tone IMR to NPR, M-IMR and ACPR versus the number of tones Q for a memoryless cubic polynomial.

where

$$\sum_{q=-Q}^Q m_q = m_{-Q} + \dots + m_{-1} + m_1 + \dots + m_Q = n \quad (16)$$

defining the following mixing vector:

$$\mathbf{v} = [m_{-Q} \dots m_{-1} m_1 \dots m_Q] \quad (17)$$

Then, the number of different ways of generating the same mixing vector is given by the multinomial coefficient [7]:

$$t_{n,v} = \frac{n!}{m_{-Q}! \dots m_{-1}! m_1! \dots m_Q!} \quad (18)$$

These Q -tone distortion components allow a generalization of the two-tone signal-to-intermodulation distortion ratio [IMR; sometimes also known as carrier-to-IMD ratio (C/I)] to various multitone distortion figures of merit. One of these is defined as the ratio between the constant-amplitude output fundamental signals and the highest sideband IMD component (M -IMR).

Another measure is the ratio between integrated fundamental output power and integrated upper or lower sideband distortion. As this sideband spectral regrowth falls exactly over the location of a potentially present adjacent channel, it is called the *adjacent-channel power ratio* (ACPR).

Finally, a measure of the ratio of the fundamentals to the signal-uncorrelated distortion components that fall exactly among the fundamental components is given by the so-called noise-power-ratio (NPR). The reason for this denomination comes from the fact that, although that figure of merit is being introduced in this text for a multitone excitation, it was traditionally measured with a bandlimited white-noise stimulus—a generalized multi-tone excitation with an infinite number of tones.

Besides all these figures are measures of nonlinear effects that share a common physical origin, and it has not been easy to relate them, except for very particular situations. First, we [5] presented relations between various multitone distortion figures and IMR, obtained for a third-degree polynomial memoryless model. Then,

Boulejfen et al. [8] extended those results for a fifth-degree polynomial. As a summary of these results, Fig. 10 presents the ratio of IMR to the above-defined multi-tone distortion figures versus the number of tones Q for a memoryless cubic polynomial.

A laboratory setup for multitone distortion tests is similar to the one already shown for two-tone tests, except, obviously, with respect to the signal generator [6]. However, since a NPR test focuses on the distortion that falls exactly over the output fundamentals, something must be done to separate the desired distortion components from the much higher fundamental signals. The usual way to solve that problem consists in creating a very narrow measurement window within the input signal bandwidth. This is accomplished by either shutting down a few input tones—when a multitone signal generator is used—or introducing a notch filter between the bandlimited white-noise generator and the nonlinear device under test [6].

2. CAD TOOLS FOR INTERMODULATION DISTORTION PREDICTION

Because intermodulation distortion is a nonlinear effect, any attempt to predict its behavior by hand for even the most simple practical circuits or devices becomes extremely difficult, if not impossible. So, intermodulation distortion prediction relies heavily on good device models and appropriate computer simulation algorithms. Unfortunately, these subjects are so vast that we have to restrict this text to a first guiding overview. So, we will concentrate our discussion on a set of criteria for model quality (for this specific purpose) and give some hints concerning usual simulation tools.

2.1. Nonlinear Device Modeling for Distortion Analysis: General Considerations

Starting with nonlinear device models, we can divide them into four general groups: (1) physical and empirical models and (2) global and local models.

Physical models are mathematical descriptions of the internal device operation that are drawn from the knowledge of the device’s geometric and physical structure, and

from the application of a certain set of basic physics laws. Although relying on extremely complex formulations that require an enormous number of parameters and are computationally expensive to evaluate, they can provide much better accuracy than the empirical models as they necessarily mimic the basic device operation. On the other hand, empirical models do not require any information about the internal structure of the device, relying completely on input–output behavioral observations. Hence, they are also known as blackbox models or behavioral models.

Typical examples of physical models are the Schottky diode equation and the device models described by a set of coupled partial-differential equations of electric potential, charge, and charge carrier mobility. Examples of purely behavioral models are the linear scattering matrix, table-based device models, or even the abovementioned AM–AM/AM–PM models.

Local models can be distinguished from global models for their approximation range. Because they are behavioral in nature, they constitute two different compromises between the domain of fitting and the level of accuracy. While local models are very good in representing mild nonlinear behavior in the vicinity of some quiescent point, global models are conceived as valid for any possible operation regime, but at the expense of an increased error. It is therefore natural that they are also known as *small-signal* or *large-signal models*, respectively. The Gummel–Poon model of BJTs, the quadratic model of FETs, or an AM–AM/AM–PM representation are examples of global models, while the poor extrapolation capability usually associated with polynomial approximators tends to grant them a distinct local behavior. For example, the cubic polynomial that could be extracted from the third-order intercept point is necessarily a local model valid only for small-signal excitation levels.

The polynomial example given above is not accidental as it plays a fundamental role in all nonlinear distortion analysis. In fact, for some unique reason we began this article using exactly the same polynomial of expression (4). As we then concluded, if the model is a polynomial, we have a direct and easy way to calculate the various intermodulation products to any signal that can be described as a sum of sinusoids. Furthermore, by simply selecting its coefficients, we can tailor the polynomial for very different approximation goals. To understand that, let us use an illustration example. Figures 11 and 12 depict the approximation of one typical transfer function characteristic by two different polynomials: a Taylor series and a Chebyshev polynomial series, both of 10th degree.

As seen from Figs. 11a and 11b, the coefficients of the Chebyshev polynomial were selected so that the polynomial could produce an optimum approximation to the response of our original nonlinearity to a sinusoid of 1.5 V peak amplitude, centered at a quiescent point of 0 V (something close to what is found in typical class AB power amplification regimes).

On the other hand, the coefficients of the Taylor series were taken as the appropriately scaled derivatives of the nonlinearity at the same quiescent voltage of 0 V. It constitutes, therefore, the optimum polynomial approxi-

Figure 11. (a) Nonlinear memoryless transfer function, $f(x)$ (---) and its 10th-order Taylor series approximation around $x = 0$ V (---) and Chebyshev polynomial optimized for a sinusoidal input amplitude of $A = 1.5$ V (—); (b) time-domain waveform of the output of the transfer function $f[x(t)]$ (---) and of its 10th-order Taylor series approximation (---) and Chebyshev polynomial (—), when excited by a CW input of amplitude $A = 1.5$ V.

mation to the nonlinear response to any signal of infinitesimal input amplitude (see Fig. 11a).

When excited by sinusoids of variable amplitude, the output DC component (Fig. 12a), the fundamental component (Fig. 12b), and the second- and third-harmonic distortion components (Figs. 12c and 12d, respectively) reveal that these two polynomial approximators present, indeed, very distinct properties.

The Taylor series is clearly a local approximator that produces optimum results in the vicinity of the quiescent point, but then suffers from a catastrophic degradation when the excitation exceeds ~ 0.3 V of amplitude. On the

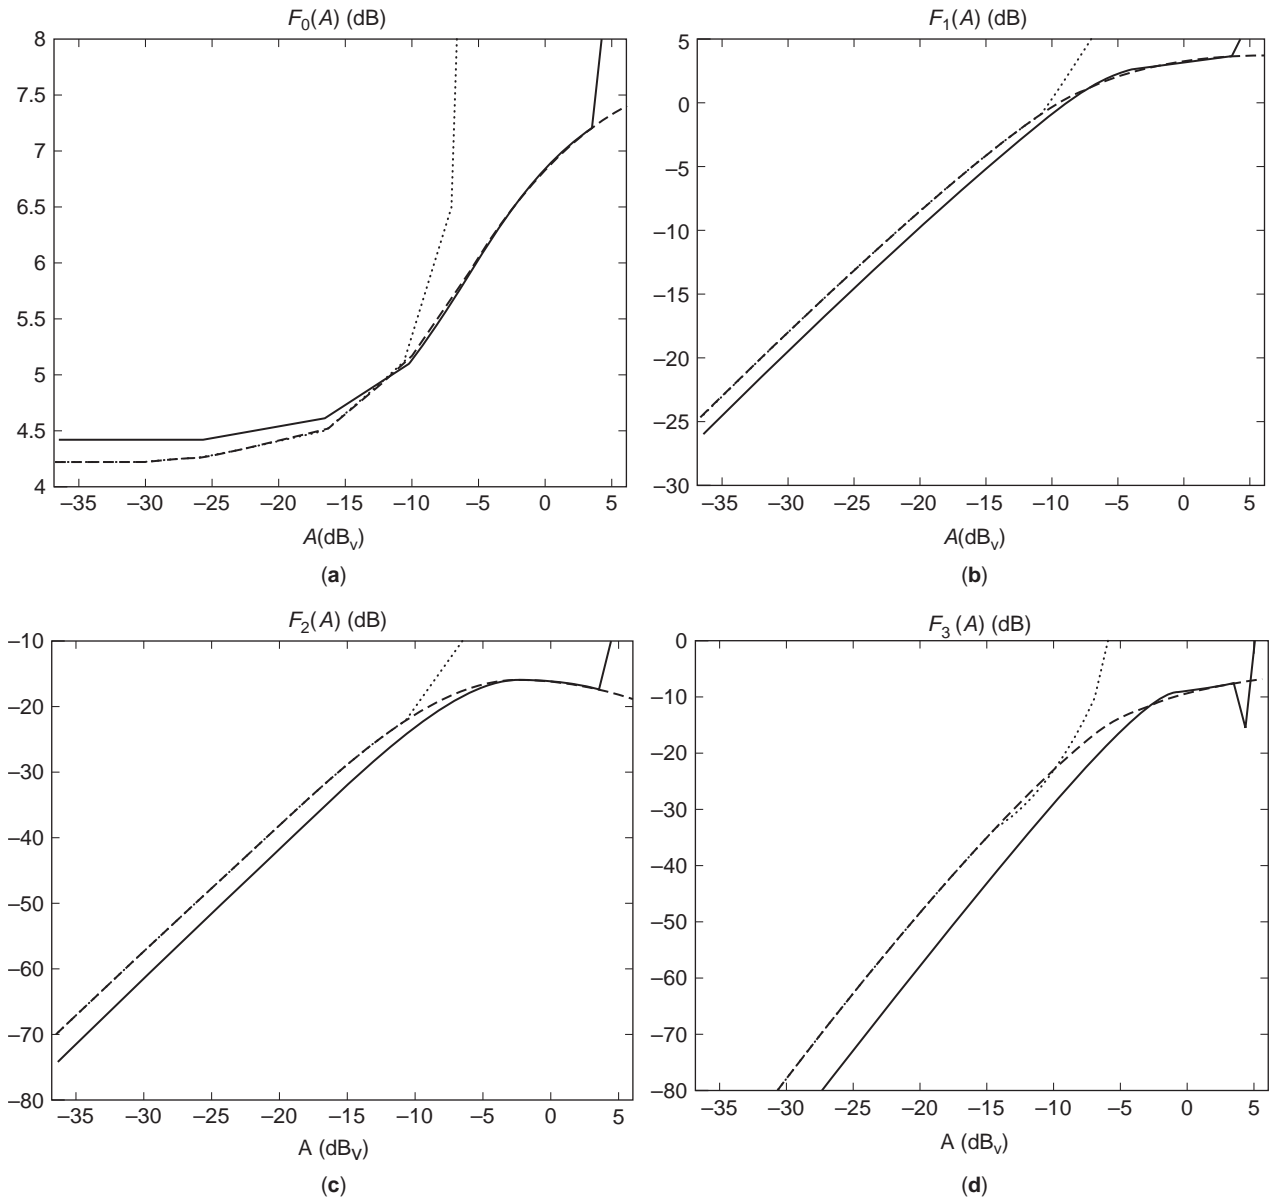

Figure 12. (a) DC component of the output of the transfer function $f[x(t)]$ (---) of its 10th-order Taylor series approximation (···) and Chebyshev polynomial (—), when excited by a CW input of amplitude $0.015\text{ V} < A < 1.95\text{ V}$; (b) fundamental component of output of transfer function $f[x(t)]$ (---) of its 10th-order Taylor series approximation (···) and Chebyshev polynomial (—), when excited by a CW input of amplitude $0.015\text{ V} < A < 1.95\text{ V}$; (c) second-harmonic component of output of transfer function $f[x(t)]$ (---) of its 10th-order Taylor series approximation (···) and Chebyshev polynomial (—), when excited by a CW input of amplitude $0.015\text{ V} < A < 1.95\text{ V}$; (d) third-harmonic component of output of unit transfer function $f[x(t)]$ (---) and its 10th-order Taylor series approximation (···) and Chebyshev polynomial (—), when excited by a CW input of amplitude $0.015\text{ V} < A < 1.95\text{ V}$.

contrary, the Chebyshev series is worse at those small-signal levels, but performs much better up to excitation amplitudes of 1.5 V . It behaves, therefore, as a global approximator. (In fact, the Chebyshev series is still a local approximator whose domain is no longer defined around the fixed quiescent point of 0 V , but around a new generalized dynamic quiescent point imposed by an input sinusoid of 1.5 V amplitude.) As any other mean-square error approximator, the Chebyshev polynomial wanders around the original nonlinearity (see Figs. 11a and 11b), obviously

failing the higher-order derivatives of the function. This is why, contrary to the Taylor series, which, by construction, osculates these derivatives, the Chebyshev series does not show good small-signal distortion behavior.

What we have just seen in this example is common to almost all empirical models and results in an important message as far as intermodulation distortion calculations are concerned. Simultaneously reproducing the device's mild nonlinear details (local characteristics) and the general trends (global properties) is so difficult that we should

never trust an empirical model unless we have guarantees that it was specifically tested for nonlinear distortion.

2.2. Nonlinear Models for Distortion Analysis at the Circuit Level

To perform intermodulation analysis at the circuit level, that is, to compute the distortion arising from a certain electronic circuit subject to a specific bandpass RF input signal stimulus, the device must be represented by some equivalent-circuit model [6]. This is the normal modeling requirement for using either time-marching algorithms, like the ones used by SPICE, or frequency-domain simulators, such as the harmonic-balance solvers. Such equivalent circuits have topologies and parameter sets usually supported from both physical and empirical data.

Linear, or bias-independent, elements are usually extracted from a broadband small-signal AC characterization. Nonlinear elements can be either voltage-controlled current sources (nonlinear device currents) $i(v)$, voltage-controlled electric charge sources (nonlinear capacitances) $q(v)$, or current-controlled magnetic flux sources (nonlinear inductances) $\phi(i)$. Each of these is assumed to be described by a static, or memoryless, function of its controlling variable(s), which can, again, be supported by both physical device knowledge or by empirical observations. Mostly in this latter case, it is the selection of these functions that determines the quality of the model for nonlinear distortion predictions. A small mean-square error between measured and modeled data in the whole range of device operation guarantees good global properties, but says nothing about local properties. To be able to also provide good predictability under small-signal regimes, the model must osculate at least the first three derivatives of the actual device function, which requires special model extraction procedures.

Although those derivatives can be obtained from successive differentiation of measured $i(v)$, $q(v)$, or $\phi(i)$ data, this is not recommended for at least two important reasons: (1) since most of the microwave transistors show low-frequency dispersion effects, differentiating DC data may not lead to the real AC behavior; and (2) the aggravation of measurement noise produced by numerical

differentiation. If we rely on averages (data integration) to reduce random measurement errors, it is natural to expect an aggravation of those errors if we go backward, that is, numerically differentiating measurement data. So, the best way to obtain these device derivatives is to measure entities that directly depend on them; and one good example of those entities is exactly the harmonic or intermodulation distortion produced by the device under a CW or a two-tone excitation.

As an example, the laboratory setup depicted in Fig. 13 uses exactly this principle to acquire the nine coefficients of the Taylor series expansion of the drain–source current of a FET:

$$i_{ds}(v_{ds}, v_{ds}) = G_m v_{gs} + G_{ds} v_{ds} + G_{m2} v_{gs}^2 + G_{md} v_{gs} v_{ds} + G_{d2} v_{ds}^2 + G_{m3} v_{gs}^3 + G_{m2d} v_{gs}^2 v_{ds} + G_{md2} v_{gs} v_{ds}^2 + G_{d3} v_{ds}^3 \quad (19)$$

Exciting the FET at the gate side with a sinusoid of frequency ω_1 and at the drain side with a sinusoid of frequency ω_2 allows the extraction of G_m from the output current component at ω_1 , G_{ds} from the component at ω_2 , G_{m2} from the component at $2\omega_1$, G_{md} from the component at $\omega_1 + \omega_2$, G_{d2} from the component at $2\omega_2$, and so on. Unfortunately, the actual procedure is not that simple. Although the unilateral properties presented by microwave FETs at low frequencies guarantee that v_{gs} will have only the ω_1 component, the requirement that the device is terminated at the drain side by a nonnull impedance determines that v_{ds} will have components at ω_1 , at ω_2 , and at all their mixing products. This impedes the orthogonal (or one-to-one) extraction just explained, demanding the solution of a 2×2 linear system for G_m and G_{ds} ; a 3×3 linear system for G_{m2} , G_{md} , and G_{d2} ; and a 4×4 linear system for extracting G_{m3} , G_{m2d} , G_{md2} , and G_{d3} [9]. Since the concept supporting this setup is general, it can be extended to other nonlinear current sources present in any nonlinear device equivalent-circuit model, or even to charge sources [10].

As an illustrative example, Fig. 14 shows all nine coefficients of (19) extracted with the setup of Fig. 13,

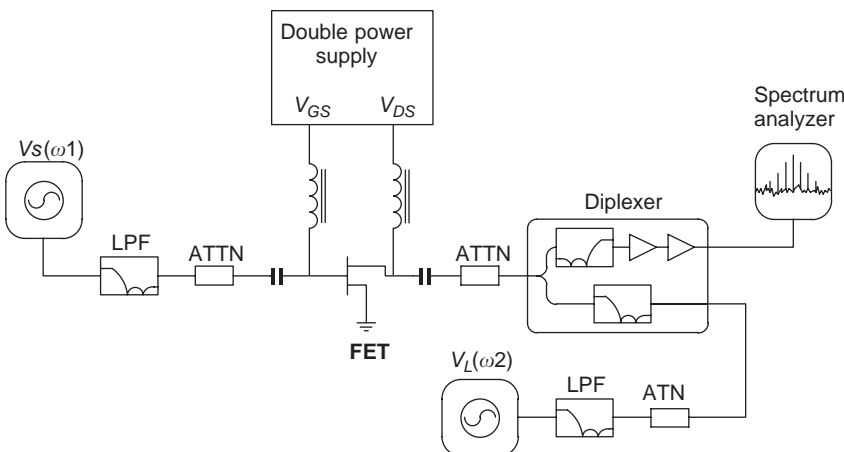

Figure 13. Laboratory setup used to extract the Taylor series coefficients of a bidimensional nonlinearity such as the $i_{ds}(v_{GS}, v_{DS})$ of a FET.

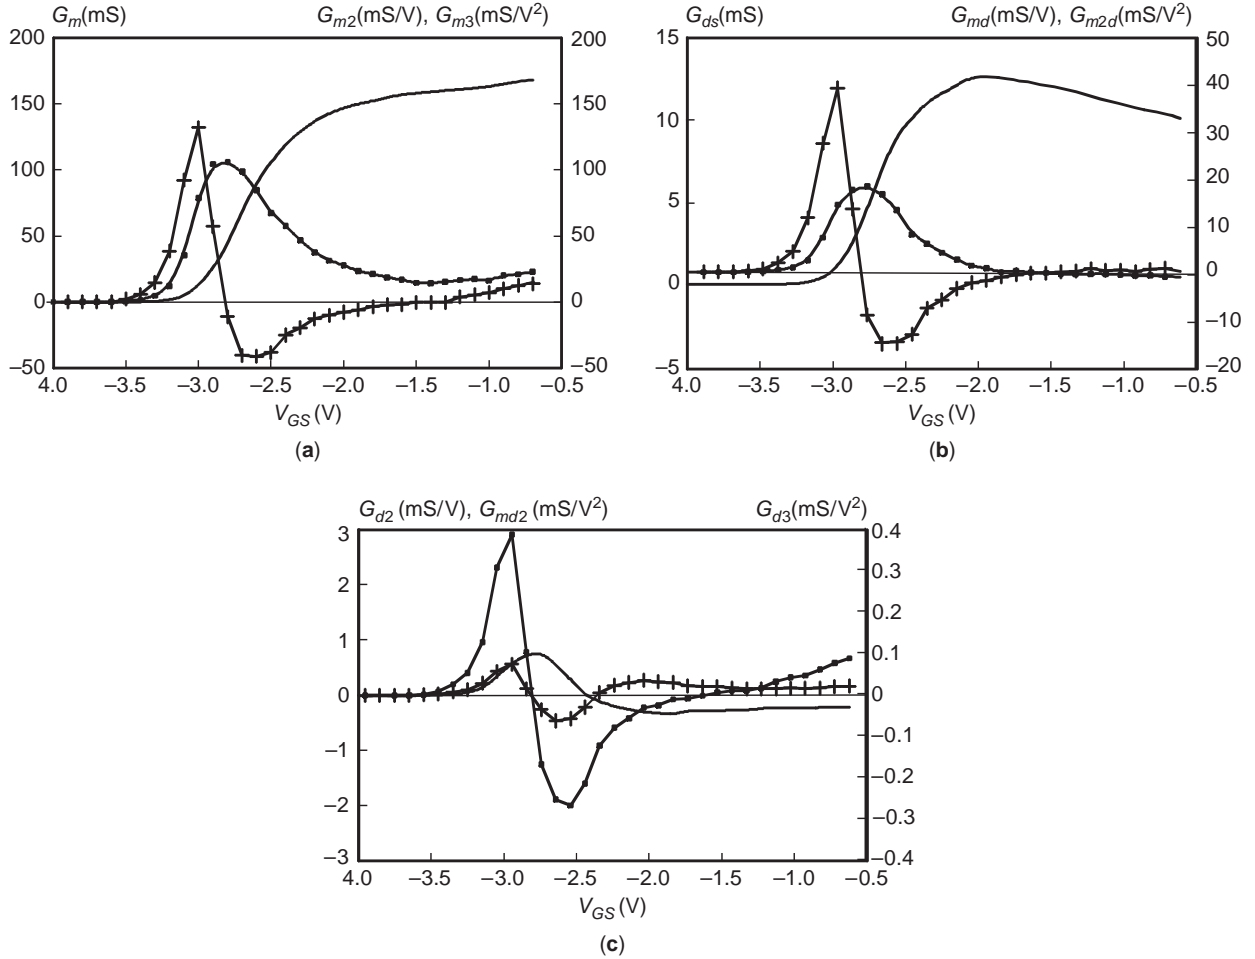

Figure 14. Taylor series coefficients of the bidimensional voltage-controlled $i_{DS}(v_{GS}, v_{DS})$ current source of a GaAs MESFET for a constant V_{DS} in the saturation zone: (a) G_m (—), G_{m2} (—●—), and G_{m3} (—+—); (b) G_{ds} (—), G_{md} (—●—) and G_{md2} (—+—); (c) G_{d2} (—), G_{md2} (—●—), and G_{d3} (—+—).

from a medium-power microwave GaAs MESFET biased in the saturation region.

2.3. Nonlinear Models for Distortion Analysis at the System Level

Although system simulation for the modulated bandpass RF signals has already taken the first steps, system simulation at the complex envelope level is, by far, the most usual way to assess distortion performance of entire communication systems. It assumes that the amplitude/phase-modulated RF signal of (5) can be given by

$$\begin{aligned} x(t) &= A(t) \cos[\omega_c t + \theta(t)] \\ &= \text{Re}[A(t)e^{j\theta(t)}e^{j\omega_c t}] = \text{Re}[\tilde{x}(t)e^{j\omega_c t}] \end{aligned} \quad (20)$$

in which $\tilde{x}(t)$ is the complex envelope—the lowpass equivalent signal of $x(t)$ [11]—and that we are interested only in the system's in-band characteristics. Thus, the object of the analysis ceases to be the real bandpass RF-modulated signal to become only the complex lowpass envelope. In

this way, a significant improvement in simulation efficiency is achieved because time-domain simulations no longer need to be carried on with sampling rates imposed by the RF carrier and its harmonics, but only by the much slower envelope. So, the models required for these envelope-level system simulators are lowpass complex equivalent behavioral models of the original bandpass RF components [11]. They are, therefore, single-input/single-output maps, which may be either linear or nonlinear.

Linear maps are easily implemented as gain factors in the memoryless case, or as finite or infinite impulse responses, FIR or IIR, digital filters [11,12], when in presence of dynamic elements.

A linear dynamic complex envelope filter whose frequency response function is $\tilde{H}(j\tilde{\omega})$ can be directly derived from the corresponding circuit level filter $H(j\omega)$ by simply going through the following bandpass–lowpass transformation [11]

$$\tilde{H}(j\tilde{\omega}) = H[j(\tilde{\omega} + \omega_c)]u(\tilde{\omega} + \omega_c) \quad (21)$$

where $u(\omega)$ is the unity step function.

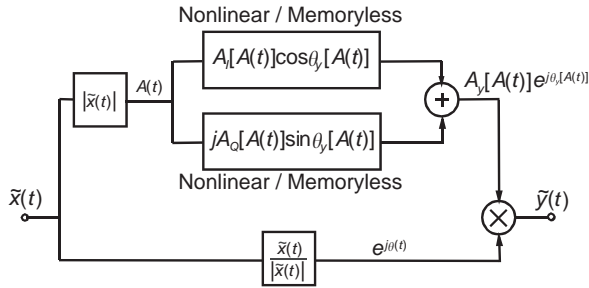

Figure 15. AM–AM and AM–PM memoryless lowpass equivalent behavioral model known as the *Saleh quadrature model*.

2.3.1. Memoryless AM–AM/AM–PM Models. In their most basic form, nonlinear complex envelope models simply try to describe the amplitude-dependent memoryless nonlinear effects observed for the amplitude and phase modulation content. They are the AM–AM/AM–PM models discussed above, and of which the quadrature Saleh model of Fig. 15 is one of the most widely known [13].

When modeled as a polynomial nonlinearity, this AM–AM/AM–PM model can include only odd-degree $(2n + 1)$ terms involving n negative carrier frequencies plus $(n + 1)$ positive ones [11]

$$\hat{y}(t) = \sum_{n=0}^{(N-1)/2} \frac{p_{2n+1}}{2^{2n}} \binom{2n+1}{n+1} \hat{x}(t) |\hat{x}(t)|^{2n} \quad (22)$$

where $\binom{m}{r}$ stands for the number of different combinations of r elements taken from a population of size m and p_{2n+1} are the polynomial coefficients, now having real and imaginary parts.

2.3.2. Dynamic AM–AM/AM–PM Models. As already seen in the introduction, when the system presents memory not only to the RF signal (as indicated by the AM–PM effect) but also to the slowly varying lowpass envelope, this AM–AM/AM–PM model becomes unsatisfactory and a true dynamic model is required. For example, one possibility for such an extension could be to make the in-phase $A_I(\cdot)$ and quadrature $A_Q(\cdot)$ static nonlinear functions dependent not on the amplitude envelope but on some dynamic version of it. In this way, the AM–AM and

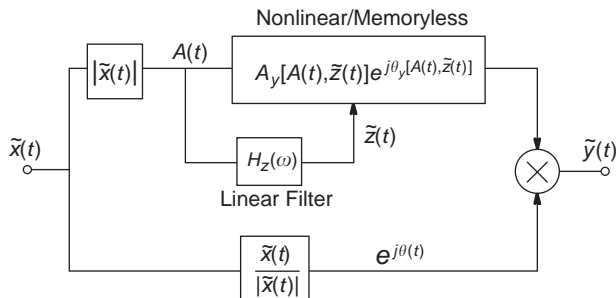

Figure 16. An AM–AM/AM–PM model in which the amplifier is modeled as a dynamic gain function of the envelope amplitude.

Figure 17. A three-box, or Wiener–Hammerstein, lowpass equivalent model.

AM–PM conversions would no longer be instantaneous functions of $A(t)$, but, as shown in Fig. 16, become instantaneous functions of an auxiliary dynamic variable $\tilde{z}(t)$, and thus dynamically varying with $A(t)$.

2.3.3. Memoryless Nonlinearity: Linear Filter Cascade Models. Beyond the methods described above, several other approximated topologies have been tried for building nonlinear dynamic models [14]. Some of those, like the two- or three-box models shown in Fig. 17, deserve mention because of their practical relevance. In fact, they somehow mimic the internal structure of typical RF devices (as microwave power amplifiers), which are usually constituted by a broadband (memoryless) nonlinear active device sandwiched between two linear dynamic input and output matching networks.

As shown in Fig. 17, these two- or three-box nonlinear dynamic models can be cascades of a linear filter followed by the measured memoryless AM–AM/AM–PM nonlinearity (known as the *Wiener model*), be cascades of this AM–AM/AM–PM memoryless nonlinearity followed by a linear filter (the *Hammerstein model*), or even be constituted by a combination of both (the *Wiener–Hammerstein model*). Other parallel combinations of memoryless nonlinearities and linear filters also became popular when an optimal extraction procedure was shown to be practically possible [15].

2.3.4. General Nonlinear Dynamic Models. Unfortunately, these three-box models become hopelessly inaccurate when the dynamic effects presented to the envelope are not due to the bandwidth limitations of the linear matching networks, but are intrinsically mixed with the nonlinearity [14]. That is the case, for example, with wireless power amplifiers whose nonlinear dynamic effects cannot obviously arise from bandwidth limitations—the RF signal can have bandwidths as narrow as 1% or 0.01%, but from the active device self-heating or from reactive (to the envelope) bias paths. In such cases, more general nonlinear dynamic models, as the ones briefly explained in the following paragraphs, must be attempted.

When the lowpass equivalent system is stable, continuous, and of fading memory (i.e., its response cannot keep memory from an infinitely remote past), mathematics operator theory has shown that its response $\hat{y}(t)$ to any input $\hat{x}(t)$ can be approximated, within any desired error margin, by

$$\hat{y}(s) = f_{\text{NL}}[\hat{x}(s), \hat{x}(s-1), \dots, \hat{x}(s-Q)] \quad (23)$$

where $f_{\text{NL}}(\cdot)$ is a $(Q + 1)$ -to-one static nonlinear function, s is the time instant in which the output is being calculated; $\hat{x}(s-1), \dots, \hat{x}(s-Q)$ are delayed, or past versions of the

input; $\tilde{x}(s)$; and Q is the system's finite memory span. Indeed, expression (23) simply states that the system output at a certain instant can be calculated as the nonlinear combination of the input at that instant and all its past versions within the memory span. There are basically two ways of implementing this nonlinear and dynamic input-output mapping, depending on whether $f_{NL}(\cdot)$ is approximated by a $(Q + 1)$ -to-one polynomial or by a neural network: polynomial filters [12] and artificial neural networks (ANNs) [16].

In the first case, (23) becomes

$$\tilde{y}(s) = \sum_{n=1}^N \tilde{y}_n(s) \tag{24a}$$

where

$$\begin{aligned} \tilde{y}_n(s) = & \sum_{q_1=0}^Q \cdots \sum_{q_{2n+1}=0}^Q \tilde{h}_{2n+1}(q_1, \dots, q_{2n+1}) \tilde{x}(s - q_1) \\ & \cdots \tilde{x}(s - q_{n+1}) \tilde{x}(s - q_{n+2})^* \cdots \tilde{x}(s - q_{2n+1})^* \end{aligned} \tag{24b}$$

Such a dynamic polynomial formulation (also known as a *Volterra filter* [12]) presents two important advantages:

1. Its various output components can be traced to a particular coefficient or term. Therefore, it leads to useful concepts as nonlinear order and gives insights into parameter extraction. In fact, this

immediately allows model implementations such as the ones depicted in Figs. 18a and 18b for the first- and third-order outputs, $\tilde{y}_1(s)$ and $\tilde{y}_3(s)$, respectively.

2. The second advantage, shared with all polynomial approximators, is that the formulation is linear in the parameters (although obviously nonlinear in the inputs). Thus, it allows a direct model parameter extraction based on the solution of a system of simultaneous linear equations.

Unfortunately, it also presents an important disadvantage. Like any other polynomial approximator, it is a local model.

It is mostly this drawback that justifies the alternative ANN formulation. A single hidden-layer ANN can be expressed as [16]

$$\tilde{u}_k(s) = \sum_{q=0}^Q [w_k(q)\tilde{x}(s - q)] + b_k \tag{25a}$$

$$\tilde{y}(s) = b_o + \sum_{k=1}^K w_o(k)f_o[\tilde{u}_k(s)] \tag{25b}$$

in which the $w_k(q)$ and $w_o(k)$ are weighting factors and b_o and b_k are bias values, constituting the model parameter set. $f_o(\cdot)$ are static single-input/single-output nonlinear functions (the so-called activating functions) of sigmoid shape. Because a sigmoid is an output-bounded function, an ANN is well behaved for all inputs.

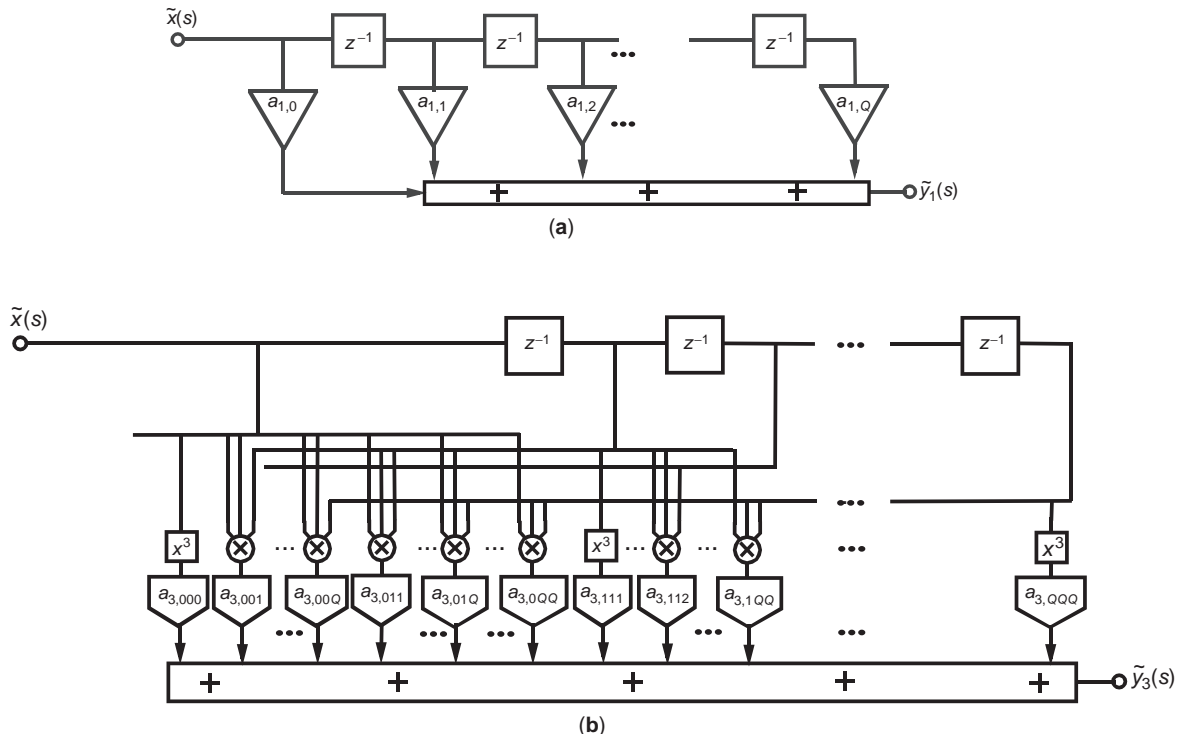

Figure 18. Implementation examples of first- (a) and third- (b) order kernels of a general polynomial filter.

Figure 19. Implementation of a nonlinear dynamic artificial neural network.

A direct implementation of a dynamic ANN is shown in Fig. 19. However, recognizing that (25a) constitutes a biased linear FIR filter, whose bias is b_k and impulse response is $w_k(\cdot)$, this dynamic ANN can also be implemented as a set of parallel branches of the Wiener type, as depicted in Fig. 20 [14].

Unfortunately, since all terms of the ANN are similar, there is no way to identify relations between the system's output properties and any particular ANN terms. Furthermore, as the model is now also nonlinear for the $w_k(q)$ and b_k parameters, the parameter extraction process must rely on some form of optimization. This optimization process, called "ANN training," is known to give results that are highly dependent on the input–output training data. Moreover, there is no guarantee that the parameter set found is unique or even optimum, which can constitute a severe limitation to the model's predictability.

2.4. A Glimpse of Nonlinear Simulation Algorithms for Distortion Prediction

In circuit-level simulators [17], the mathematical representation of the circuit is built by substituting each electronic element with its constitutive relation [e.g., a linear resistor can be represented as Ohm's law, $i = v/R$; a nonlinear resistor would be given by a voltage-controlled

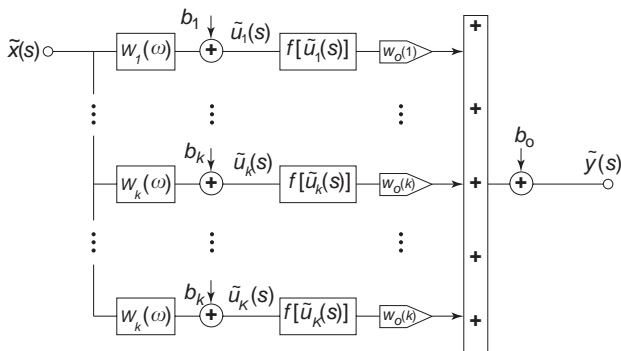

Figure 20. Alternative implementation of the model of Fig. 19, in which the ANN is rebuilt as a parallel combination of several biased linear filter/memoryless nonlinearity branches.

current source, $i(v)$; while a capacitor would be given by a linear or nonlinear charge, $q(v)$] and then applying Kirchhoff's current and voltage laws to the complete circuit. This leads to a system of ordinary nonlinear differential equations (ODEs) in time such as

$$\mathbf{i}[\mathbf{y}(t)] + \frac{d\mathbf{q}[\mathbf{y}(t)]}{dt} = \mathbf{x}(t) \quad (26)$$

where $\mathbf{x}(t)$ and $\mathbf{y}(t)$ stand for the time-domain waveform of the excitation and the state-variable vectors, respectively; $\mathbf{i}[\mathbf{y}(t)]$ represents memoryless linear or nonlinear elements, while $\mathbf{q}[\mathbf{y}(t)]$ models memoryless linear or nonlinear charges (capacitors) or fluxes (inductors). The objective of the simulation is to find the $\mathbf{y}(t)$ circuit solution vector given a known $\mathbf{x}(t)$ input excitation.

On the other hand, system-level simulators are usually implemented as either event-driven or envelope-driven machines. In both cases the simulator treats the system in the time domain, computing a set of time samples of the information signal.

Event-driven machines operate at a very high logic level, in which the information is simply a set of successive logic states. They are, therefore, state flow simulators, without enough subsystem description detail to allow distortion calculations.

Envelope-driven simulators operate with the analogue complex envelope. Hence, they do not handle the true bandpass RF blocks but simply their complex lowpass equivalents. Nevertheless, since these blocks are still nonlinear dynamic blocks, the lowpass equivalent system mathematical representation will again be an ordinary differential equation similar to (26) with the only difference that now both the excitation vector $\mathbf{x}(t)$ and the state variable vector $\mathbf{y}(t)$ are, in general, complex entities.

So, except for the type of signals handled, an ODE such as (26) can be used to represent bandpass RF circuits, bandpass RF systems, or even complex lowpass equivalent systems.

2.4.1. Time-Domain Techniques. The most intuitive way to solve (26) is to covert it into a difference equation

$$\mathbf{i}[\mathbf{y}(s)] + \frac{\mathbf{q}[\mathbf{y}(s)] - \mathbf{q}[\mathbf{y}(s-1)]}{T_s} = \mathbf{x}(s) \quad (27a)$$

or

$$\mathbf{i}[\mathbf{y}(s)]T_s + \mathbf{q}[\mathbf{y}(s)] = \mathbf{x}(s)T_s + \mathbf{q}[\mathbf{y}(s-1)] \quad (27b)$$

in which T_s is the sampling period, and then determine all time samples of $\mathbf{y}(t)$, $\mathbf{y}(s)$, starting from a known initial state $\mathbf{y}(0)$. Because we are integrating the nonlinear ODE in a set of discretized timesteps, this is known as *timestep integration*, and constitutes the basic approach adopted in all time-domain circuit simulators (time-marching machines) such as SPICE, or system simulators like Simulink¹.

¹Simulink is a general-purpose system simulation package that is supported by the Matlab scientific computation software platform.

Although timestep integration is still the nonlinear analysis method of wider acceptance, it suffers from several disadvantages in the RF distortion circuit simulation field. First, since it was conceived to compute the circuit’s transient response, while our interest normally resides in the steady state, it becomes quite inefficient as it has to wait until all transients have vanished. Also, by operating in the time domain, it cannot handle linear elements having a frequency-domain description, such as dispersive distributed transmission media. Finally, even if that drawback is circumvented (e.g., by approximating these elements by lumped networks of reduced order), the necessity of operating in the time domain, while the input and resulting signals are usually handled in frequency domain, would end up in all difficulties associated with the discrete Fourier transform (DFT), namely, spectral leakage when transforming quasiperiodic multitone signals. Fortunately, some time-domain alternatives to the initial timestep integration method, like the “shooting Newton” [17], can bypass the transient response, therefore obviating the waste of time needed to let it vanish.

Furthermore, time-domain methods benefit from two important advantages: (1) since they rely on the SPICE simulator engine, they are well known and available in many electronic design automation tools; and (2) as they use time as a natural continuation parameter [17], they are especially suitable for supporting strong nonlinear regimes. Envelope-driven system-level simulators must handle the information envelopes, which are aperiodic by nature. So, timestep integration does not suffer from the inefficiency attributed to the calculation of the periodic steady-state response, becoming the obvious choice in solving (26).

2.4.2. Frequency-Domain Techniques. Frequency-domain techniques no longer seek a set of time samples of the circuit output or the state variables’ waveforms but a spectral representation of them. In their most simple form, they assume that both the steady state of the excitation and the ODE solution are periodic in time, so that they can be expanded in a truncated DFT of $(2K + 1)$ frequency points. For example, the state variables vector would be represented by

$$\mathbf{y}(t) = \sum_{k=-K}^K \mathbf{Y}(k\omega_0) e^{jk\omega_0 t} \tag{28}$$

Since, in the frequency domain, time-domain derivatives are transformed into products by $j\omega$, substituting (28) into (26) leads to

$$\mathbf{I}[\mathbf{Y}(\omega)] + j\Omega\mathbf{Q}[\mathbf{Y}(\omega)] = \mathbf{X}(\omega) \tag{29}$$

which is a nonlinear algebraic function in the DFT coefficients $\mathbf{Y}(k\omega_0)$. The orthogonality between different frequency components provided by the DFT determines that, despite its appearance, this is not a single equation but can be expanded in a set of $(2K + 1)$ equations, each of these must be fulfilled for its harmonic component; in other words, the LHS and RHS (left- and right-hand side)

components must be in equilibrium, which is why (29) is known as the “harmonic-balance equation.”

Since this harmonic-balance (HB) technique computes the periodic steady state directly, it circumvents most of the disadvantages attributed to time-marching techniques. Its only drawbacks are that, depending on the DFT, it can handle only moderate nonlinear regimes, where the $\mathbf{y}(t)$ can be described by a relatively small number of harmonics, and that it requires both the excitation and the vector of state variables to be periodic. As we have already seen in Section 1, the excitations used for intermodulation distortion analysis are often of the two-tone or multitone type. In general, the frequencies of these tones do not constitute any harmonic set (they cannot be made harmonics of a common fundamental), and the corresponding waveform is aperiodic. (Such multitone signals are actually said to be quasiperiodic waveforms.) One way to circumvent this problem consists in imagining that a multitone time-domain waveform is evolving, not in the natural time t , but in a number of artificial timescales equal to the number of nonharmonically related tones, τ_1, \dots, τ_Q . For example, for a two-tone regime, the ODE in time becomes a multirate partial-differential equation (MPDE) in τ_1 and τ_2 :

$$\mathbf{i}[\mathbf{y}(\tau_1, \tau_2)] + \frac{\partial \mathbf{q}[\mathbf{y}(\tau_1, \tau_2)]}{\partial \tau_1} + \frac{\partial \mathbf{q}[\mathbf{y}(\tau_1, \tau_2)]}{\partial \tau_2} = \mathbf{x}(\tau_1, \tau_2) \tag{30}$$

Since $\mathbf{y}(\tau_1, \tau_2)$ is now double-periodic in τ_1 and τ_2 , it admits a bidimensional Fourier expansion

$$\mathbf{y}(\tau_1, \tau_2) = \sum_{k_1=-K}^K \sum_{k_2=-K}^K \mathbf{Y}(k_1\omega_1, k_2\omega_2) e^{j(k_1\omega_1\tau_1 + k_2\omega_2\tau_2)} \tag{31}$$

which, substituted in (30), results in a new bidimensional HB equation. This is the technique known as the *multi-dimensional discrete Fourier transform harmonic-balance* (MDFT HB).

2.4.3. Time-Domain/Frequency-Domain Hybrid Techniques. When the excitation is a RF carrier of frequency ω_c , modulated by some independent baseband modulation signal, like the one expressed in (5), it can be again conceived as varying according to two independent timescales: one, τ_1 , with fast evolution, for the carrier; and another, τ_2 , slower, for the modulation. So, the circuit can again be described by a bidimensional MPDE such as (30). If we now recognize that this regime is periodic for the carrier but aperiodic for the modulation, we immediately conclude that simulation efficiency would be maximized if we treated the carrier evolution in τ_1 in the frequency domain, but kept the baseband evolution τ_2 in time. This supposes a solution in which the vector of state variables is decomposed in a τ_2 time-varying Fourier series

$$\mathbf{y}(\tau_1, \tau_2) = \sum_{k=-K}^K \mathbf{Y}(k\omega_c, \tau_2) e^{j(k\omega_c\tau_1)} \tag{32}$$

which, substituted in (30), leads to

$$\begin{aligned} \mathbf{I}[\mathbf{Y}(k\omega_c, \tau_2)] + j\Omega_c \mathbf{Q}[\mathbf{Y}(k\omega_c, \tau_2)] \\ + \frac{\partial \mathbf{Q}[\mathbf{Y}(k\omega_c, \tau_2)]}{\partial \tau_2} = \mathbf{X}(k\omega_c, \tau_2) \end{aligned} \quad (33)$$

Solving (33) for the envelope, with a timestep integration scheme, and for the carrier, with harmonic balance, leads to the following recursive HB equation:

$$\begin{aligned} \mathbf{I}[\mathbf{Y}(k\omega_c, s)]T_s + j\Omega_c \mathbf{Q}[\mathbf{Y}(k\omega_c, s)]T_s + \mathbf{Q}[\mathbf{Y}(k\omega_c, s)] \\ = \mathbf{X}(k\omega_c, s)T_s + \mathbf{Q}[\mathbf{Y}(k\omega_c, s-1)] \end{aligned} \quad (34)$$

By handling the RF signal components in the frequency domain and the envelope in the time domain, (34) is particularly appropriate to bridge the gap between circuit and envelope-driven system simulation. In fact, we can conceive of a simulator in which all except a few circuits of a communication system are treated as system-level complex equivalent lowpass behavioral input–output blocks—for maximized computational efficiency—while the remaining circuits are treated at the RF bandpass circuit level—for maximum accuracy.

2.4.4. Volterra Series. Although the Volterra series method is not very widely used outside the intermodulation prediction field, it plays a determinant role for the analysis and design of very-low-distortion circuits.

In comparison with the previously mentioned methods, Volterra series no longer tries to find a solution in an iterative and numerical way, but seeks for an analytic solution of a polynomial approximation of the original circuit or system. In fact, it assumes that if the nonlinearities of the original circuit or system can be decomposed in a Taylor series around a certain fixed quiescent point

$$\mathbf{i}(\mathbf{y}) = \mathbf{g}_1 \mathbf{y} + \mathbf{g}_2 \mathbf{y}^2 + \mathbf{g}_3 \mathbf{y}^3 \quad (35)$$

$$\mathbf{q}(\mathbf{y}) = \mathbf{c}_1 \mathbf{y} + \mathbf{c}_2 \mathbf{y}^2 + \mathbf{c}_3 \mathbf{y}^3 \quad (36)$$

then, the solution can be approximated by the following functional series in the time domain:

$$\begin{aligned} \mathbf{y}(t) &= \mathbf{y}_1(t) + \mathbf{y}_2(t) + \mathbf{y}_3(t) \\ &= \int_{-\infty}^{\infty} \mathbf{h}_1(\tau) \mathbf{x}(t - \tau) d\tau \\ &+ \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathbf{h}_2(\tau_1, \tau_2) \mathbf{x}(t - \tau_1) \mathbf{x}(t - \tau_2) d\tau_1 d\tau_2 \\ &+ \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathbf{h}_3(\tau_1, \tau_2, \tau_3) \mathbf{x}(t - \tau_1) \\ &\times \mathbf{x}(t - \tau_2) \mathbf{x}(t - \tau_3) d\tau_1 d\tau_2 d\tau_3 \end{aligned} \quad (37)$$

If the excitation can be expressed as a frequency-domain sum of complex exponentials (possibly, but not necessarily,

harmonically related sinusoids)

$$\mathbf{x}(t) = \sum_{q=-Q}^Q \mathbf{X}(\omega_q) e^{j\omega_q t} \quad (38)$$

then we obtain a frequency-domain version of (37)

$$\begin{aligned} \mathbf{y}(t) &= \sum_{q=-Q}^Q \mathbf{H}_1(\omega) \mathbf{X}(\omega_q) e^{j\omega_q t} \\ &+ \sum_{q_1=-Q}^Q \sum_{q_2=-Q}^Q \mathbf{H}_2(\omega_{q_1}, \omega_{q_2}) \mathbf{X}(\omega_{q_1}) \mathbf{X}(\omega_{q_2}) e^{j(\omega_{q_1} + \omega_{q_2})t} \\ &+ \sum_{q_1=-Q}^Q \sum_{q_2=-Q}^Q \sum_{q_3=-Q}^Q \mathbf{H}_3(\omega_{q_1}, \omega_{q_2}, \omega_{q_3}) \\ &\times \mathbf{X}(\omega_{q_1}) \mathbf{X}(\omega_{q_2}) \mathbf{X}(\omega_{q_3}) e^{j(\omega_{q_1} + \omega_{q_2} + \omega_{q_3})t} \end{aligned} \quad (39)$$

in which the $\mathbf{h}_n(\tau_1, \dots, \tau_n)$ of (37) and the $\mathbf{H}_n(\omega_1, \dots, \omega_n)$ of (39) are the n th-order impulse responses and the n th-order nonlinear transfer functions, respectively. Each of these sets can be obtained from the other by the direct application of a n -dimensional Fourier transform pair.

The Volterra series method consists in determining the set of $\mathbf{h}_n(\cdot)$ or of $\mathbf{H}_n(\cdot)$ (as occurs with conventional linear systems, the frequency-domain version is usually preferred), which then becomes a true nonlinear dynamic model of the system. In fact, note that if one knows all the $\mathbf{H}_n(\omega_1, \dots, \omega_n)$ of a circuit or system, up to a certain order, one immediately knows its response up to that order [from (39)] to any multitone input represented by (38).

To show how these nonlinear transfer functions can be determined, let us consider again the general circuit or system described by the ODE of (26). Substituting (35), (36), and (39) into (26), and assuming that the input is now a first-order elementary excitation of

$$\mathbf{x}(t) = e^{j\omega t} \quad (40)$$

the orthogonality of the complex exponentials leads us to the conclusion that $\mathbf{H}_1(\omega)$ must be given by

$$\mathbf{H}_1(\omega) = \frac{1}{\mathbf{g}_1 + j\omega \mathbf{c}_1} \quad (41)$$

In fact, this $\mathbf{H}_1(\omega)$ is merely the usual transfer function of the linear circuit or system obtained from a linearization around the quiescent point.

To obtain the second-order nonlinear transfer function, we would now assume that the system is excited by a second-order elementary excitation of

$$\mathbf{x}(t) = e^{j\omega_1 t} + e^{j\omega_2 t} \quad (42)$$

Substituting (35), (36), (39), and (42) into (26), and collecting components in the second-order mixing product of

$\omega_1 + \omega_2$ would lead to

$$\mathbf{H}_2(\omega_1, \omega_2) = -\frac{\mathbf{g}_2 + j(\omega_1 + \omega_2)\mathbf{c}_2}{\mathbf{g}_1 + j(\omega_1 + \omega_2)\mathbf{c}_1} \mathbf{H}_1(\omega_1)\mathbf{H}_1(\omega_2) \quad (43)$$

Similarly, the calculation of the third-order nonlinear transfer function assumes an input of

$$\mathbf{x}(t) = e^{j\omega_1 t} + e^{j\omega_2 t} + e^{j\omega_3 t} \quad (44)$$

and leads to

$$\begin{aligned} \mathbf{H}_3(\omega_1, \omega_2, \omega_3) = & -\frac{2}{3} \frac{\mathbf{g}_2 + j(\omega_1 + \omega_2 + \omega_3)\mathbf{c}_2}{\mathbf{g}_1 + j(\omega_1 + \omega_2 + \omega_3)\mathbf{c}_1} \\ & \times [\mathbf{H}_1(\omega_1)\mathbf{H}_2(\omega_2, \omega_3) + \mathbf{H}_1(\omega_2) \\ & \times \mathbf{H}_2(\omega_1, \omega_3) + \mathbf{H}_1(\omega_3)\mathbf{H}_2(\omega_1, \omega_2)] \quad (45) \\ & -\frac{\mathbf{g}_3 + j(\omega_1 + \omega_2 + \omega_3)\mathbf{c}_3}{\mathbf{g}_1 + j(\omega_1 + \omega_2 + \omega_3)\mathbf{c}_1} \\ & \times \mathbf{H}_1(\omega_1)\mathbf{H}_1(\omega_2)\mathbf{H}_1(\omega_3) \end{aligned}$$

The terms $-\frac{2}{3}[\mathbf{g}_2 + j(\omega_1 + \omega_2)\mathbf{c}_2]\mathbf{H}_1(\omega_1)\mathbf{H}_1(\omega_2)$ in (43) and the terms

$$\begin{aligned} & -\frac{2}{3}[\mathbf{g}_2 + j(\omega_1 + \omega_2 + \omega_3)\mathbf{c}_2] \\ & \times [\mathbf{H}_1(\omega_1)\mathbf{H}_2(\omega_2, \omega_3) + \mathbf{H}_1(\omega_2)\mathbf{H}_2(\omega_1, \omega_3) \\ & + \mathbf{H}_1(\omega_3)\mathbf{H}_2(\omega_1, \omega_2)] \end{aligned}$$

$$\text{and } -\frac{1}{3}[\mathbf{g}_3 + j(\omega_1 + \omega_2 + \omega_3)\mathbf{c}_3]\mathbf{H}_1(\omega_1)\mathbf{H}_1(\omega_2)\mathbf{H}_1(\omega_3)$$

in (45) are known as the *elementary second-order* and *third-order nonlinear sources*, respectively. In fact, comparing (43) and (45) with (41), we immediately conclude that for the calculation of first-, second-, and third-order solutions, what we have been doing was to always analyze the same linearized version of the original ODE with the appropriate elementary nonlinear sources at ω for first order, at $\omega_1 + \omega_2$ for second order, and at $\omega_1 + \omega_2 + \omega_3$ for third order. That is why the method of Volterra series analysis is known to solve a forced n th-order nonlinear dynamic problem, solving n times the same linear problem, with the appropriate (1st, 2nd, ..., n th)-order forcing functions, in a recursive way. As it is based on a polynomial approximation of the nonlinearities, the Volterra series is a local model restricted to small-signal levels, or mildly nonlinear regimes. In practice, it can be used only for calculating the distortion in nonsaturated mixers, small-signal amplifiers, or nonsaturated power amplifiers, that is, well below the 1-dB compression point. However, because it is a closed-form nonlinear model, it provides qualitative information on the nonlinear circuit or system's operation, giving, for instance, insight into the physical origins of nonlinear distortion, and can be directly used for circuit and system's design.

3. INTERMODULATION DISTORTION IN SMALL-SIGNAL AMPLIFIERS

First, let us clarify the meaning of “small-signal amplifiers,” as most of us would expect no appreciable nonlinear distortion from these circuits. This term is used to distinguish low-noise or high-gain amplifiers from the essentially different power amplifiers, treated in the next section. While the small-signal amplifiers referred to here always supposedly operate in highly backed-off class A regimes, power amplifiers are operated close to saturation, usually even in strongly nonlinear modes as class AB, B, or C.

So, now, one question comes to our minds: “What are the mechanisms capable of causing significant nonlinear distortion in small-signal amplifiers?” To advance with an answer, let us consider the case of the low-noise amplifier of a wireless communication receiver front end. This is a circuit that faces, beyond the very weak desired channel, many other incoming channels present in the same communication system's band. For example, a low-noise front end of a handset can be simultaneously excited by the desired channel coming from a remote base station, and by another channel coming from a nearby transmitter handset. Since the ratio of distances between our receiver and the base station, and our receiver and the perturbing transmitter, can easily be on the order of several kilometers to one meter, the ratio of incoming powers can be higher than 10^8 to 1. Therefore, the signal-to-perturbation ratio can be as poor as -70 or -80 dB, and, if it is true that a desired signal of, say, -70 dBm cannot generate any significant nonlinear distortion, that is no longer the case for the $+10$ dBm perturbation.

Indeed, as seen in Section 1, this high-level perturbation can produce nonlinear distortion sidebands falling over the desired channel, cross-modulation, and desensitization. These effects are illustrated in Fig. 21 and can constitute a severe limitation to the performance of RF front ends. In fact, they allow the definition of a very important signal fidelity figure of merit, the dynamic range, which is the ratio between the amplitudes of the highest and lowest incoming detectable signals that still guarantee the specified signal-to-noise ratio SNR. The lowest-amplitude detectable signal—the receiver's sensitivity S_i —is the one that stands the desired SNR over the noise floor. The highest-amplitude detectable signal, P_{\max} , is defined as the one that generates a nonlinear distortion perturbation whose power equals the noise floor. So

$$\text{DR} \equiv \frac{P_{\max}}{S_i} \quad \text{or} \quad \text{DR}_{\text{dB}} \equiv P_{\max_{\text{dBm}}} - S_{i_{\text{dBm}}} \quad (46)$$

where DR is the dynamic range.

Since signal excursions appearing at the nonlinear active device are always kept much smaller than the applied DC voltages and currents, the amplifier can be approximately described by a local model. For example, considering the ideal (low-frequency) situation in which the only nonlinear effects can be attributed to the $i_{\text{ds}}(v_{\text{gs}}, v_{\text{ds}})$ current of a FET, the amplifier would be described by the equivalent circuit depicted in Fig. 22,

Figure 21. Nonlinear distortion impairments in a mildly nonlinear receiver system: illustration of the concepts of receiver's desensitization and dynamic range.

while the nonlinearity would be represented by the Taylor series of (19).

Although the model shown in Fig. 22 is very simplified, it will already give us some insight onto the mechanisms controlling IMD generation in these small-signal amplifiers. For that, we will first redraw this circuit as the one of Fig. 23 over which a Volterra series analysis will then be performed.

Note that ports 1 and 2 in Fig. 23 handle the amplifier's input and output, respectively, but were defined after the terminal admittances Y_S and Y_L were incorporated into the main circuit. port 3 serves to define v_{gs} , one of the control voltages of the i_{ds} nonlinearity, and port 4 serves to define v_{ds} , the other control voltage. Furthermore, since Fig. 23 is the linearized equivalent-circuit version of the original circuit of Fig. 22, its only $i_{ds}(v_{gs}, v_{ds})$ components are the first-order ones: $G_m v_{gs}$ and $G_{ds} v_{ds}$. All the other nonlinear terms of (19) will behave as nonlinear sources that will be incorporated as independent current sources applied to port 4 [6,7].

Assuming that the equivalent Norton current excitation corresponds to a narrowband two-tone stimulus, this circuit can be represented by the following $[Z]$ matrix and input and output boundary conditions:

$$\begin{bmatrix} V_1(\omega) \\ V_2(\omega) \\ V_3(\omega) \\ V_4(\omega) \end{bmatrix} = \begin{bmatrix} Z_{11} & Z_{12} & Z_{13} & Z_{14} \\ Z_{21} & Z_{22} & Z_{23} & Z_{24} \\ Z_{31} & Z_{32} & Z_{33} & Z_{34} \\ Z_{41} & Z_{42} & Z_{43} & Z_{44} \end{bmatrix} \cdot \begin{bmatrix} I_1(\omega) \\ I_2(\omega) \\ I_3(\omega) \\ I_4(\omega) \end{bmatrix} \quad (47a)$$

$$I_1(\omega) = I_s(\omega) : i_s(t) = I_{s1} \cos(\omega_1 t) + I_{s2} \cos(\omega_2 t) \quad (47b)$$

$$I_2(\omega) = 0 \quad (47c)$$

$$I_3(\omega) = 0 \quad (47d)$$

If the two-tones are closely separated in frequency, the circuit reactances are similar for all in-band products. So, using ω_0 as the center frequency [$\omega_0 = (\omega_1 + \omega_2)/2$], $Z_{ij}(\omega_1) \approx Z_{ij}(\omega_2) \approx Z_{ij}(2\omega_1 - \omega_2) \approx Z_{ij}(2\omega_2 - \omega_1) \approx Z_{ij}(\omega_0)$ for any $i, j = 1, 2, 3, 4$.

After determining the linear equivalent-circuit $[Z]$ matrix, the nonlinear currents' method of Volterra series analysis [6,7] proceeds by determining first-order control voltages $V_{3,1}(\omega_0)$ and $V_{4,1}(\omega_0)$ ($q = 1, 2$) and first-order output voltage $V_{2,1}(\omega_0)$, from the excitation $I_s(\omega_0)$:

$$V_{gs,1}(\omega_1), V_{gs,1}(\omega_2) : V_{3,1}(\omega_0) = Z_{31}(\omega_0) \frac{I_s(\omega_0)}{2} \quad (48a)$$

$$V_{ds,1}(\omega_1), V_{ds,1}(\omega_2) : V_{4,1}(\omega_0) = Z_{41}(\omega_0) \frac{I_s(\omega_0)}{2} \quad (48b)$$

$$V_{L,1}(\omega_1), V_{L,1}(\omega_2) : V_{2,1}(\omega_0) = Z_{21}(\omega_0) \frac{I_s(\omega_0)}{2} \quad (49)$$

From these first-order control variables, the second-order nonlinear current of i_{ds} at $\omega_1 - \omega_2 \equiv \Delta\omega$ and $\omega_1 + \omega_2 \equiv \Sigma\omega$,

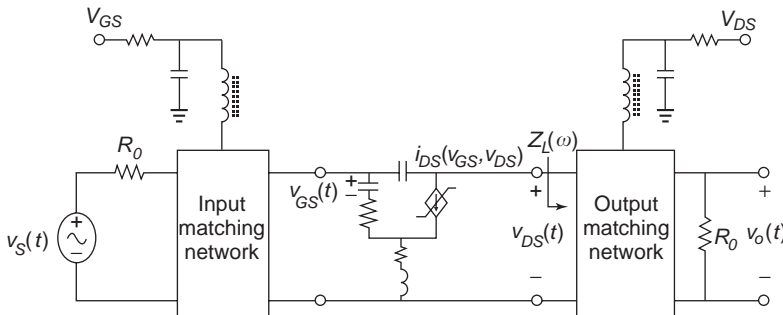

Figure 22. Model of a mildly nonlinear amplifier for small-signal distortion studies.

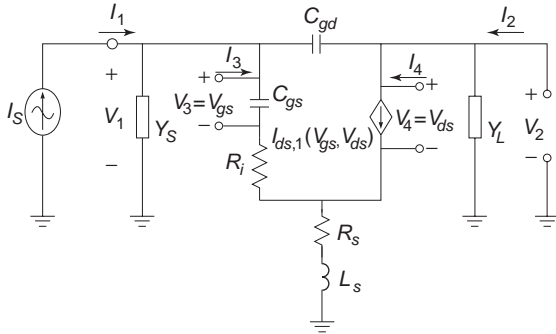

Figure 23. Linearized equivalent-circuit model of a FET-based mildly nonlinear amplifier used in Volterra series calculations.

$I_{4,2}(\omega)$ should now be determined:

$$I_{4,2}(\Delta\omega) = -[2G_{m2}|Z_{31}(\omega_0)|^2 + G_{md}Z_{31}(\omega_0)Z_{41}(\omega_0)^* + G_{md}Z_{31}(\omega_0)^*Z_{41}(\omega_0) + 2G_{d2}|Z_{41}(\omega_0)|^2] \frac{|I_S|^2}{4} \quad (50)$$

$$I_{4,2}(\Sigma\omega) = -2[G_{m2}Z_{31}(\omega_0)^2 + G_{md}Z_{31}(\omega_0)Z_{41}(\omega_0) + G_{d2}Z_{41}(\omega_0)^2] \frac{I_S^2}{4} \quad (51)$$

Then, the linear circuit should be analyzed again for this new second-order current source, determining the second-order control voltages at the difference $\omega_1 - \omega_2 \equiv \Delta\omega$ and sum $\omega_1 + \omega_2 \equiv \Sigma\omega$ frequencies, $V_{3,2}(\omega)$ and $V_{4,2}(\omega)$:

$$V_{3,2}(\Delta\omega) = Z_{34}(\Delta\omega)I_{4,2}(\Delta\omega) \quad (52)$$

$$V_{3,2}(\Sigma\omega) = Z_{33}(\Sigma\omega)I_{3,2}(\Sigma\omega) + Z_{34}(\Sigma\omega)I_{4,2}(\Sigma\omega) \quad (53)$$

$$V_{4,2}(\Delta\omega) = Z_{44}(\Delta\omega)I_{4,2}(\Delta\omega) \quad (54)$$

$$V_{4,2}(\Sigma\omega) = Z_{43}(\Sigma\omega)I_{3,2}(\Sigma\omega) + Z_{44}(\Sigma\omega)I_{4,2}(\Sigma\omega) \quad (55)$$

The last step consists in calculating the third-order nonlinear current of i_{ds} at $2\omega_1 - \omega_2$, $I_{4,3}(2\omega_1 - \omega_2)$ from first- and second-order control voltages $V_{3,1}(\omega)$, $V_{3,2}(\omega)$, $V_{4,1}(\omega)$, and $V_{4,2}(\omega)$:

$$\begin{aligned} I_{4,3}(2\omega_1 - \omega_2) = & -[2G_{m2}Z_{31}(\omega_0)^*Z_{34}(2\omega_0)I_{4,2}(2\omega_0) \\ & + G_{md}Z_{31}(\omega_0)^*Z_{44}(2\omega_0)I_{4,2}(2\omega_0) \\ & + G_{md}Z_{41}(\omega_0)^*Z_{34}(2\omega_0)I_{4,2}(2\omega_0) \\ & + 2G_{d2}Z_{41}(\omega_0)^*Z_{44}(2\omega_0)I_{4,2}(2\omega_0)] \frac{I_S^*}{2} \\ & - [2G_{m2}Z_{31}(\omega_0)Z_{34}(\Delta\omega)I_{4,2}(\Delta\omega) \\ & + G_{md}Z_{31}(\omega_0)Z_{44}(\Delta\omega)I_{4,2}(\Delta\omega) \\ & + G_{md}Z_{41}(\omega_0)Z_{34}(\Delta\omega)I_{4,2}(\Delta\omega) \\ & + 2G_{d2}Z_{41}(\omega_0)Z_{44}(\Delta\omega)I_{4,2}(\Delta\omega)] \frac{I_S}{2} \end{aligned}$$

$$\begin{aligned} & -[3G_{m3}Z_{31}(\omega_0)|Z_{31}(\omega_0)|^2 \\ & + G_{m2d}Z_{31}(\omega_0)^2Z_{41}(\omega_0)^* \\ & + 2G_{m2d}|Z_{31}(\omega_0)|^2Z_{41}(\omega_0) \\ & + G_{md2}Z_{31}(\omega_0)^*Z_{41}(\omega_0)^2 \\ & + 2G_{md2}Z_{31}(\omega_0)|Z_{41}(\omega_0)|^2 \\ & + 3G_{d3}Z_{41}(\omega_0)|Z_{41}(\omega_0)|^2] \frac{I_S|I_S|^2}{8} \quad (56) \end{aligned}$$

and then, finally, determine third-order output voltage at the IMD frequency $2\omega_1 - \omega_2$:

$$V_{2,3}(2\omega_1 - \omega_2) = Z_{24}(\omega_0)I_{4,3}(2\omega_1 - \omega_2) \quad (57)$$

Now we are in a position to calculate the amplifier's signal-to-IMD ratio (IMR) by first determining output power at the fundamental

$$P_L = \frac{1}{2}G_L(\omega_0)|V_L(\omega_0)|^2 = \frac{1}{2}G_L(\omega_0)|Z_{21}(\omega_0)|^2|I_S|^2 \quad (58)$$

and IMD components

$$P_{L_3} = 2G_L(\omega_0)|V_{2,3}(2\omega_1 - \omega_2)|^2 \quad (59)$$

where $G_L(\omega)$ is the real part of load admittance $Y_L(\omega)$. A full expression for this IMR would be very complex. But, under the assumptions that internal feedback is negligible [$Z_{34}(\omega) \approx 0$] and that both second-harmonic and $\omega_1 - \omega_2$ distortion will be very small (usually verified in small-signal amplifiers), it can be approximated by

$$\begin{aligned} \text{IMR} \approx & 16 \left| \frac{A_v(\omega_0)}{Z_D(\omega_0)} \right|^2 \cdot |3G_{m3} + G_{m2d}A_v(\omega_0)^* \\ & + 2G_{m2d}A_v(\omega_0) + G_{md2}A_v(\omega_0)^2 \\ & + 2G_{md2}|A_v(\omega_0)|^2 \\ & + 3G_{d3}A_v(\omega_0)|A_v(\omega_0)|^2|^{-2}|V_S|^{-4} \end{aligned} \quad (60)$$

where $Z_D(\omega) \equiv 1/[G_{ds} + Y_L(\omega)]$, $A_v(\omega)$ is the intrinsic voltage gain defined by $A_v(\omega) \equiv V_{ds}(\omega)/V_{gs}(\omega)$, and V_S is the voltage amplitude of the signal source, $V_S(\omega) = Z_S(\omega)I_S(\omega)$.

If we now study the variation of various third-order current components with V_{GS} bias, as shown in Fig. 24 for a typical general-purpose small-signal MESFET, we conclude that there are two very good points of IMD performance, the so-called small-signal IMD "sweet spots." The first one is located at the FET's threshold voltage [6] and thus has a very small associated power gain. The other is located in high- V_{GS} regions, and although it may not correspond to very good noise figures, it is definitely useful for designing high-gain, highly linear small-signal amplifiers. Unfortunately, this latter small-signal IMD "sweet spot" is a peculiarity of only some GaAs MESFETs, and was never observed on HEMTs, MOSFETs or BJTs.

Figure 24. Magnitude of total $i_{ds}(v_{gs}, v_{ds})$ third-order current components $N_{I_{d3}}$ (—) and its various components due to G_{m3} $N_{IG_{m3}}$ (—●—), G_{m2d} $N_{IG_{m2d}}$ (—+—), G_{md2} $N_{IG_{md2}}$ (···), and G_{d3} $N_{IG_{d3}}$ (---) as a function of V_{GS} bias.

Turning now our attention to the IMR variation with source impedance, we can conclude that since P_L can also be given by $P_L = \frac{1}{2} G_L(\omega_0) |A_v(\omega_0)|^2 |V_S|^2$, Eq. (60) confirms the empirical observation that, for constant output power, third-order distortion in FET-based small-signal amplifiers is almost independent of input termination $Z_S(\omega)$.

As far as the IMR variation with load impedance is concerned, Fig. 24 and (60) indicate that, for typical V_{GS} bias, the nonlinear current contributions of G_{m3} and G_{m2d} have effects on IMR that are important but, fortunately, opposite in sign. Since $N_{IG_{m2d}}$ is proportional to voltage gain, and thus to $Z_L(\omega)$, this implies that a maximization of voltage gain can also be beneficial to IMR. This hypothesis was indeed fully confirmed by the measured and simulated IMR_3 load-pull data [9], showing that an optimum $Z_L(\omega)$ really exists and it tends to coincide with the one that maximizes small-signal voltage and power gains in MESFET-based small-signal amplifiers [6,9].

Since BJTs and HBTs have mildly nonlinear characteristics that are completely different from those of FETs, these results cannot be directly extrapolated to bipolar-based small-signal amplifiers. For example, while the most important nonlinearity source, $i_{DS}(v_{GS}, v_{DS})$, is located at the FET's output, in bipolars it is manifested in both the input, $i_B(v_{BE}, v_{CE})$, and the output, $i_C(v_{BE}, v_{CE})$ [6].

4. INTERMODULATION DISTORTION IN HIGH-POWER AMPLIFIERS

Let us now turn our attention to power amplifiers (PAs). Contrary to small-signal amplifiers where noise figure and gain are of primary concern, power amplifiers are designed for high output power P_{out} and power-added efficiency (PAE).

In a well-designed PA, maximum output power is determined by the loadline (load impedance termination)

and available output signal excursion. Power-added efficiency is dependent mostly on the PA operation class (quiescent point) and on a convenient output voltage and current waveform shaping, specifically, selection of harmonic terminations. Therefore, it seems that little is left for optimizing intermodulation distortion. Fortunately, as we will see, that is not necessarily the case.

Since real devices do not present abrupt turnon points, it is difficult to precisely define the PA operation class. So, to prevent any ambiguity in the following discussion, we will first define classes A, AB, B, and C. Taking into account the discussion in Ref. 6, we will adopt the following definitions: (1) the turnon bias V_T is defined as the input quiescent point to which the turnon small-signal IMD “sweet spot” corresponds (see Fig. 24); (2) biasing the device below V_T corresponds to class C ($G_{m3} > 0$); (3) biasing it exactly at V_T corresponds to class B ($G_{m3} = 0$); and (4) biasing it above V_T will determine the usual class AB or class A ($G_{m3} < 0$).

The first design step to be taken when designing a PA is to decide whether precedence should be given to PAE or to IMD specs, as they generally lead to opposite design solutions. The traditional PA design rules state that a PA optimized for IMD requires unsaturated class A operation; that is, the device should be biased and always kept comfortably inside the linear amplification zone (saturation region of FETs and the active region of BJTs or HBTs).

On the other hand, a PA optimized for PAE is usually biased near class B or slightly into class C—that is, with a quiescent point where output voltage is halfway between knee voltage and breakdown, and output current is close to turnon—and then is allowed to be driven into saturation. This leads to saturated classes such as classes E and F [18]. Unfortunately, as such operation classes achieve their high efficiencies by operating the active device in an almost switching mode, their associated nonlinear distortion is also huge. In fact, recognizing that a switching power amplifier turns any waveform into a constant-amplitude square wave, it is easy to conclude that those class E or F PAs cannot be used when the amplitude of the RF-modulated signal also carries information content (modulation formats of non-constant-amplitude envelope).

The basic goal when designing linear PAs is to get class B PAE with class A IMD—and, although this is seldom possible, there are some particular PA features that provide a means to escape from this apparent deadend. One that has been receiving a great deal of attention is the so-called large-signal IMD sweet spots [19]. Contrary to their small-signal counterparts studied above, which were associated to a particular quiescent point and found effective only at very-small-signal levels, these are peculiar points of the IMD–input power characteristic (see Fig. 25) where only a few decibels of output-power backoff (and thus a few percent of efficiency degradation) can lead to astonishingly high levels of IMD reduction.

To understand how this curious effect takes place, we need to abandon our small-signal local model, since, for the signal levels where these large-signal IMD sweet spots are observed, the Taylor expansion of (19) presents an unacceptable error or simply may not converge. Instead, we are

Figure 25. Different IMD versus P_{in} patterns showing large-signal IMD “sweet spots” for a HEMT device.

forced to rely on qualitative solutions of approximated global models. For that, we will transform the bidimensional dependence of (19) on the input and output control voltages, $v_{GS}(t)$ and $v_{DS}(t)$, into a one-dimensional model, generating in this way an equivalent single-input/single-output transfer function (TF), $i_{DS}[v_{GS}(t)]$. This assumes an output boundary condition imposed by load impedance, $Z_L(\omega)$, $V_{ds}(\omega) = V_{DC} - Z_L(\omega)I_{ds}(\omega)$, where V_{DC} is the applied output quiescent voltage, beyond knowledge of the active device nonlinear model $i_{DS}[v_{GS}(t), v_{DS}(t)]$.

In order to describe, with enough generality, the global nonlinearities of the device, we will also consider that turnon can be represented by an exponential of input voltage. This method is commonly adopted to represent subthreshold conduction in FETs, and is even more faithful for describing $i_C(v_{BE})$ in common-base or common-emitter bipolar devices. Then, for increasing v_{GS} voltages, it is assumed that the FET passes through a nearly quadratic zone, which, because of short-channel effects, tends to become linear for even higher v_{GS} . This $i_{DS}(v_{GS})$ behavior was shown to be well reproduced by the following empirical expression [20]

$$i_{DS}(v_{GS}) = \beta \frac{[smt(v_{GS})]^2}{1 + \theta smt(v_{GS})} \quad (61a)$$

where $smt(v_{GS})$ is a smooth turnon function of v_{GS} given by

$$smt(v_{GS}) = K_V \ln\left(1 + e^{\frac{v_{GS}}{K_V}}\right) \quad (61b)$$

and β , θ and K_V are empirical scaling parameters.

If we now take the output boundary into account, $i_{DS}(v_{DS})$ will be almost unchanged unless v_{GS} is so high that $R_L \cdot i_{DS}$ becomes close to V_{DC} . There, v_{DS} is so small that the FET enters the triode region (the saturation region for a bipolar based PA). v_{GS} rapidly loses control over i_{DS} , and the TF saturates (the PA enters into strong compression). So, the global transfer characteristic $i_{DS}(v_{GS})$ presents a distinct sigmoid shape.

Assuming again a two-tone stimulus, several qualitative conclusions may be drawn for large-signal operation. One of the most important is that when the amplifier is driven into harder and harder nonlinear regimes, its gain goes into compression, which means that the phase of the in-band nonlinear distortion components must oppose those of the fundamentals. So, PA energy balance considerations derived in Section 1 show that the large-signal asymptotic phase value of the IMD sidebands, at $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$, must tend to a constant value of 180° [19].

On the other hand, we also know that small-signal IMD phase is determined by the sign of the TF local derivatives, determined by the active device’s quiescent point. As seen above, G_{m3} is positive below V_T (class C operation), is null exactly at V_T (class B) and is negative above V_T (classes AB and A). So, since small-signal IMD sign can be made positive, and tends to negative values in the large-signal asymptotic regime, the Bolzano–Weierstrass theorem guarantees the existence of at least one IMD null somewhere in between. This will be observed as a more or less pronounced notch in an $IMD-P_{in}$ plot, constituting a large-signal IMD sweet spot.

From these general conclusions it is clear that the existence of a large-signal IMD sweet spot depends on the small-signal IMD phase and on the physical effects that determine large-signal gain compression. So, each operation class will have its own particular IMD behavior.

Under class C, $V_{GS} < V_T$, $G_{m3} > 0$, the PA presents gain expansion and a high IMD level with 0° phase. When the signal excursion reaches a strong nonlinearity as the gate–channel junction conduction, gate–channel breakdown, or, more likely, the saturation–triode region transition, the PA enters into compression and an IMD notch is observed. So, a large-signal IMD sweet spot should be expected for class C amplifiers when the signal excursion is at the onset of saturation, not far from the PA’s 1-dB compression point. Although the PAE is not yet at its maximum, it may present an interesting value.

In class A, $V_{GS} > V_T$, $G_{m3} < 0$, the PA starts at small signal with almost unnoticeable gain compression and a very small level of IMD with 180° phase. As this phase is maintained when the device enters strong compression, no IMD sweet spot will be generated. Thus, and unless the PA is biased above the small-signal IMD sweet spot found for high V_{GS} bias in certain MESFETs [9], no large-signal IMD sweet spot will be observed. On the contrary, a sudden increase of IMD power at the on-set of saturation is the usual outcome of class A PAs.

In class AB, where V_{GS} is only slightly higher than V_T and $G_{m3} < 0$, the PA again shows a very shallow gain compression and a low-level IMD of 180° phase. Hence, similar to what was concluded for class A operation, no IMD sweet spot should be expected. Nevertheless, depending on the abruptness of turnon and succeeding linearization of the TF characteristic, it can be shown that a transition from 180° to 0° IMD phase can occur at lower values of output power [20,21] generating an IMD sweet spot. At this stage, the circuit begins to behave as a class C PA, with 0° IMD phase and gain expansion. Consequently, a new IMD sweet spot will have to occur at large signal when gain compression will finally take place. In

Figure 26. IMR versus P_{out} power plots of typical MOSFET-based PAs at the three operation classes studied: C (· · ·), AB (- - -) and A (—).

summary, depending on the actual device’s transfer characteristic and on the adopted quiescent point, class AB may be significantly different from class A in that it may even present two IMD sweet spots, one for small to moderate levels of P_{in} and another for the onset of saturation.

When the device is biased for class B (i.e., $V_{GS} = V_T$ and $G_{m3} = 0$), there is no small-signal IMD to be compensated by the large-signal distortion behavior. The PA presents very low levels of small-signal distortion (remember that it was biased at a small-signal IMD sweet spot) and then presents a sudden rise of distortion power at the onset of saturation. To illustrate the results of this analysis, Fig. 26 shows three IMR– P_{in} patterns typically observed in MOSFET-based PAs biased for classes A, AB, and C, respectively.

To close this qualitative analysis, let us draw some conclusions about the dependence of large-signal IMD sweet spots on impedance terminations. Starting with source impedance, it is intuitive to realize that, because the $i_{DS}(v_{GS}, v_{DS})$ nonlinearity is located at the output, the large-signal IMD behavior will be mostly invariant with

$Z_S(\omega)$, as was the case studied earlier for small-signal amplifiers. Note that this conclusion may not be extrapolated to bipolar based amplifiers, in which there is an input nonlinearity due to the base–emitter junction, and an output nonlinearity due to the active-to-saturation region transition [6,22].

As seen from the small-signal Volterra series analysis above, the dependence of i_{DS} on v_{DS} should also produce its own impact on the large-signal IMD sweet spot, via $Z_L(\omega)$. In fact, since these sweet spots were related to the output signal excursion that crosses the saturation-to-triode region transition, and as the loadline slope determines that signal level (see Fig. 27), it should be expected that the P_{in} for which the IMD sweet spot is observed will be strongly dependent on load termination. This is illustrated in Figs. 27a and 27b, where a shift of the simulated IMD sweet-spot position is evident when loadline slope $1/R_L$ is varied.

Furthermore, if the PA output is not perfectly matched, the intrinsic load impedance actually presented to the nonlinear current source may have a certain nonnull phase. The output-induced large-signal distortion components will no longer be in exact opposite phase with the small-signal ones, and the previously observed large-signal IMD sweet spots cease to be sharp dips of IMD power to become more or less smooth valleys.

Further conclusions can also be drawn about the impact of out-of-band terminations on the large-signal IMD sweet spots [6,22]. As was seen above from the small-signal analysis, the presence of even-order mixing products—which, as we have already seen, can be remixed with the fundamentals—will generate new odd-order products. But, contrary to the small-signal case in which it was assumed that the quasilinear operation of the amplifier would determine a minor effect to these indirect odd-order products, that is no longer valid for a PA, and its analysis becomes again much more complex:

1. Efficiency considerations may have previously dictated a certain second-harmonic termination. Further, if in most usual situations we seek a squared output voltage waveform, that is, without even-order harmonics, there are situations (e.g., the

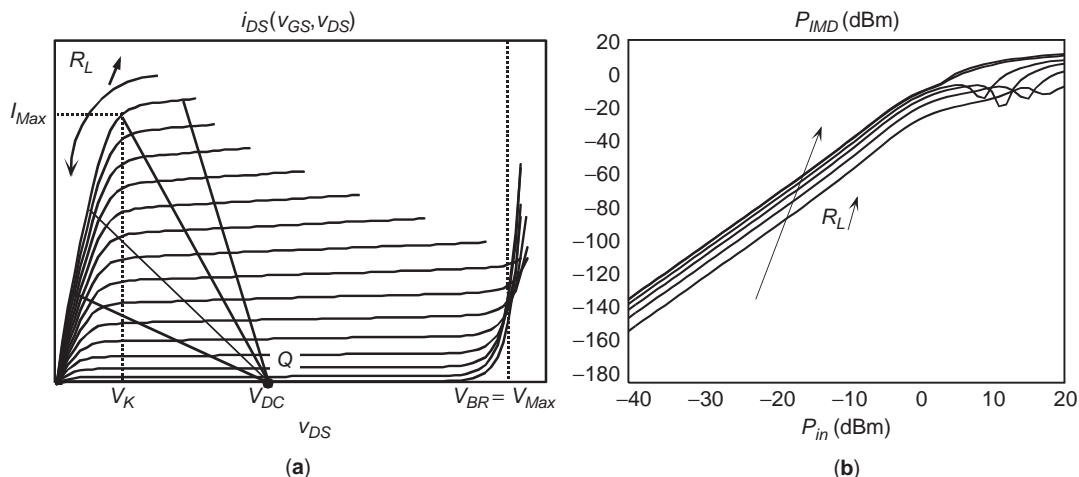

Figure 27. Impact of PA loadline slope $1/R_L$ on large-signal IMD “sweet spots”.

so-called inverse class F [18,23]) in which those even harmonics are indeed maximized.

2. If, in small-signal amplifiers, there would be no difficulty in designing bias networks presenting a very low impedance to the modulation baseband ($\omega_2 - \omega_1$), in PAs that is again incomparably more difficult. Indeed, as output currents may be on the order of several amperes, any parasitic resistance or inductance may immediately develop a nonnegligible output voltage.
3. There will be even additional, contributing baseband reactances in PAs from more or less unexpected physical origins. That is the case of trap-induced low-frequency dispersion presented by some microwave active devices [24], and dynamic self-heating, common to almost all PAs [25].

Depending on the phase of the out-of-band terminations, these new indirect odd-order products may have a phase that either reinforces or reduces the directly generated IMD. As far as the even-harmonics-induced products are concerned, since the modulation bandwidth (or the two-tone separation $\Delta\omega$) is usually much smaller than the PA bandwidth, it may be assumed that $Z_L(2\omega_1) \approx Z_L(2\omega_2) \approx Z_L(2\omega_0)$. So, no important IMD behavior variation within the bandwidth should be expected; that is, the indirect odd-order distortion products may reduce, reinforce, or be in quadrature with the direct ones, but their impact will be the same along the whole modulation bandwidth.

The situation regarding the baseband-induced products is completely different. Now, $Z_L(\Delta\omega)$ may vary significantly within the modulation bandwidth, especially if the bias networks present resonances. Therefore, it is likely that IMD power will vary within that bandwidth, and the amplifier will show (undesirable) long-term memory effects. Moreover, the complex conjugate symmetry of load impedance requires that the imaginary part of $Z_L(\omega_2 - \omega_1)$ have a sign opposite that of $Z_L(\omega_1 - \omega_2)$. So, if some other odd-order products (e.g., the ones due to the presence of second harmonics) also have significant imaginary parts, their addition will even produce asymmetric IMD sidebands [22].

These strange IMD effects have received a lot of attention more recently as their induced long-term memory immensely complicates the design of PA linearizers. Fortunately, since direct static IMD usually dominates this indirect dynamic distortion, those long-term memory effects are seldom noticed. They would be evident only if the

direct static odd-order products were reduced. Unfortunately, IMD sweet spots are, by nature, exactly one of these situations, and so the selection of these out-of-band impedances should not be overlooked during the PA design and implementation phases.

5. INTERMODULATION DISTORTION IN MICROWAVE AND RF MIXERS

A mixer can be viewed as a special kind of amplifier in which the bias supply no longer provides a constant voltage or current, but one that varies in time—the local oscillator. In the same way, an amplifier is a device where the constant quiescent point is perturbed by a certain dynamic signal; a mixer is a similar device where the local-oscillator (LO) time-varying “quiescent point” is perturbed by a dynamic radiofrequency (RF) excitation. Assuming that the mixer is operated in an unsaturated mode, as is the case of most practical interest, the RF signal level is much smaller than the LO level, and the mixer can be analyzed, for the RF signal, as a mild nonlinearity. Thus, it admits a low-degree polynomial expansion in the vicinity of the time-varying LO quiescent point. That constitutes the standard large-signal/small-signal analysis of mixers [7,26]. Mixer distortion analysis can thus follow exactly the one already carried out for small-signal amplifiers, with the exception that now we must start by determining the strong nonlinear regime imposed by the LO and, eventually, some DC bias. The voltage and current waveforms calculated in this way constitute the time-varying quiescent point. Despite the sinusoidal form of the LO excitation, the device’s strong nonlinearities will determine a periodic regime composed by the LO frequency ω_{LO} and its harmonics. So, referring to the illustrative case of the active FET mixer depicted in Fig. 28, the time-varying quiescent voltages that control the FET’s $i_{DS}(v_{GS}, v_{DS})$ nonlinearity will be given by

$$v_{GS}(t) = \sum_{k=-K}^K V_{gs}(k\omega_{LO})e^{jk\omega_{LO}t} \tag{62a}$$

$$v_{DS}(t) = \sum_{k=-K}^K V_{ds}(k\omega_{LO})e^{jk\omega_{LO}t} \tag{62b}$$

Then, the nonlinearity must be approximated by a local polynomial model. For instance, a Taylor series such as

Figure 28. Simplified schematic of the active FET mixer used in the mixer distortion analysis.

(19), in the vicinity of this time-varying LO quiescent point, $[v_{GS}(t), v_{DS}(t)]$, where the small-signal component, $i_{ds}(v_{gs}, v_{ds})$, is determined by the small-signal RF excitation. Since the coefficients of such Taylor series depend on the control voltages $v_{GS}(t)$ and $v_{DS}(t)$, they will also be time-variant:

$$\begin{aligned} i_{ds}(v_{gs}, v_{ds}) = & G_m(t)v_{gs}(t) + G_{ds}(t)v_{ds}(t) \\ & + G_{m2}(t)v_{gs}(t)^2 + G_{md}(t)v_{gs}(t)v_{ds}(t) \\ & + G_{d2}(t)v_{ds}(t)^2 + G_{m3}(t)v_{gs}(t)^3 \\ & + G_{m2d}(t)v_{gs}(t)^2v_{ds}(t) + G_{md2}(t)v_{gs}(t)v_{ds}(t)^2 \\ & + G_{d3}(t)v_{ds}(t)^3 \end{aligned} \quad (63)$$

As $v_{GS}(t)$ and $v_{DS}(t)$ are periodic, the coefficients of (63) are again periodic obeying a Fourier expansion of the form

$$g(t) = \sum_{k=-K}^K G(k\omega_{LO})e^{jk\omega_{LO}t} \quad (64)$$

Assuming that the RF signal is a two-tone signal

$$v_{RF}(t) = V_{RF} \cos(\omega_1 t) + V_{RF} \cos(\omega_2 t) \quad (65)$$

(in which we consider, without any lack of generality, that $\omega_1 < \omega_2 < \omega_{LO}$), the small-signal components of $v_{GS}(t)$, $v_{DS}(t) - v_{gs}(t)$, $v_{ds}(t)$ – are again two-tone signals. Substituting (64) and (65) in (63) determines a small-signal current $i_{ds}(t)$, whose components obey $k\omega_{LO} \pm m_1\omega_{RF_1} \pm m_2\omega_{RF_2}$ (k is any integer number and $m_1, m_2 \in \{-3, -2, -1, 0, 1, 2, 3\}$, $|m_1| + |m_2| \leq 3$) and thus include the input tone frequencies at $\omega_{RF_{1,2}}$ ($k=0$), the intermediate frequencies IF at $\omega_{IF_{1,2}} = \omega_{LO} - \omega_{RF_{1,2}}$ ($k=1$), its second and third harmonics at $2\omega_{IF_{1,2}} = 2\omega_{LO} - 2\omega_{RF_{1,2}}$ ($k=2$), and $3\omega_{IF_{1,2}} = 3\omega_{LO} - 3\omega_{RF_{1,2}}$ ($k=3$), respectively, and second- and third-order intermodulation products at $\omega_{IF_{2A}} = \omega_{IF_2} - \omega_{IF_1} = \omega_{RF_2} - \omega_{RF_1}$ ($k=0$) and $\omega_{IF_3} = 2\omega_{IF_2} - \omega_{IF_1} = \omega_{LO} - (2\omega_{RF_2} - \omega_{RF_1})$ ($k=1$), respectively.

One surprising conclusion that may be drawn from this analysis is that, contrary to an amplifier in which a single Taylor coefficient determines both n th-order harmonics and intermodulation products, in a mixer, for example, the baseband second-order products are determined by the DC component of the Fourier expansion of a coefficient while the second harmonic is determined by the component at $2\omega_{LO}$. Similarly, it is the ω_{LO} Fourier component that determines the in-band third-order products, while the third harmonic is controlled by the Fourier component at $3\omega_{LO}$. Therefore, contrary to what happens in a memoryless amplifier, the behavior of the harmonics of a memoryless mixer may say nothing about the behavior of the corresponding in-band distortion products. A detailed analysis of the distortion arising in a mixer is quite laborious and requires a full small-signal/large-signal analysis using the conversion matrix formalism [6,7,26]. However, some qualitative insight can already be obtained

if we consider the ideal situation of a unilateral gate mixer (total absence of feedback) where the input is tuned for ω_{RF} and ω_{LO} and the output is tuned for ω_{IF} . $v_{gs}(t)$ will have only ω_{RF} components, while $v_{ds}(t)$ will have only the resulting ω_{IF} components and its in-band distortion products ω_{IF_3} .

In such an ideal case the FET's $i_{ds}(t)$ current component at the IF fundamental frequencies will be given by

$$\begin{aligned} I_{ds}(\omega_{IF}) \approx & G_{m1}V_{gs}(-\omega_{IM}) \\ & + G_{m-1}V_{gs}(\omega_{RF}) + G_{ds0}V_{ds}(\omega_{IF}) \end{aligned} \quad (66)$$

where G_{m_k} and G_{ds_k} stand for the k th-order harmonic of the Fourier expansion of $G_m(t)$ and $G_{ds}(t)$, as expressed by (64), and $V_{gs}(\omega)$ and $V_{ds}(\omega)$ represent the $v_{gs}(t)$ and $v_{ds}(t)$ components at ω . ω_{IM} is the so-called image frequency. Because it is symmetrically located near the RF components, taking ω_{LO} as the symmetry axis (since, in the present case, $\omega_{RF} = \omega_{LO} - \omega_{IF}$, then $\omega_{IM} = \omega_{LO} + \omega_{IF}$), it will be also converted to the IF output, thus constituting additive interference.

If now the third-order intermodulation product components of $i_{ds}(t)$, $I_{ds}(\omega_{IF_3})$, were calculated, we would have

$$I_{ds3}(\omega_{IF_3}) \approx G_{m3-1}V_{gs}^3(2\omega_{RF_1} - \omega_{RF_2}) \quad (67)$$

in which $V_{gs}^3(2\omega_{RF_1} - \omega_{RF_2})$ stands for the terms at ω_{IF_3} that result from the frequency-domain convolutions of $V_{gs}(\omega) * V_{gs}(\omega) * V_{gs}(\omega)$ or the time-domain products of $v_{gs}(t)^3$. Expressions (66) and (67) show that a mixer designed for high linearity, namely, one in which conversion gain is maximized and IMD is minimized, requires a (V_{GS}, V_{DS}) bias point and a LO drive level that maximize first-order Fourier component of the time-varying transconductance $G_m(t)$ and minimize first-order Fourier component of $G_{m3}(t)$. Unfortunately, these are conflicting requirements since maximizing G_{m1} or G_{m-1} means searching for a $G_m(t)$ waveform of highest amplitude and odd symmetry, while reducing G_{m3-1} implies reducing $G_{m3}(t)$ swing and a $G_{m3}(t)$ waveform of even symmetry, which, as we will see next, cannot be accomplished simultaneously. So, a compromise should be sought in terms of conversion gain and linearity optimization.

To illustrate this simplified analysis, Fig. 29a shows three $G_m(t)$ waveforms for three distinct V_{GS} bias points, Fig. 29b shows the corresponding $G_{m3}(t)$ waveforms, and, finally, Fig. 29c shows the resulting conversion gain and IMD ratio $[I_{ds}(\omega_{IF})/I_{ds}(\omega_{IF_3})]$ for the whole range of V_{GS} bias.

As stated above, there is indeed a compromise between linearity and conversion gain. Although very high IMR values can be obtained for particular bias points, none of them coincides with the zone of highest conversion gain. In a typical sigmoidal $G_m(v_{GS})$ (such that depicted in Fig. 14a), conversion efficiency is optimized when the FET is biased for maximum $G_m(v_{GS})$ variation, that is, for the $G_{m2}(v_{GS})$ peak. Unfortunately, that maximized variation of $G_m(v_{GS})$ is accompanied by an also nearly ideal odd symmetry of $G_{m3}(v_{GS})$, which is responsible for the

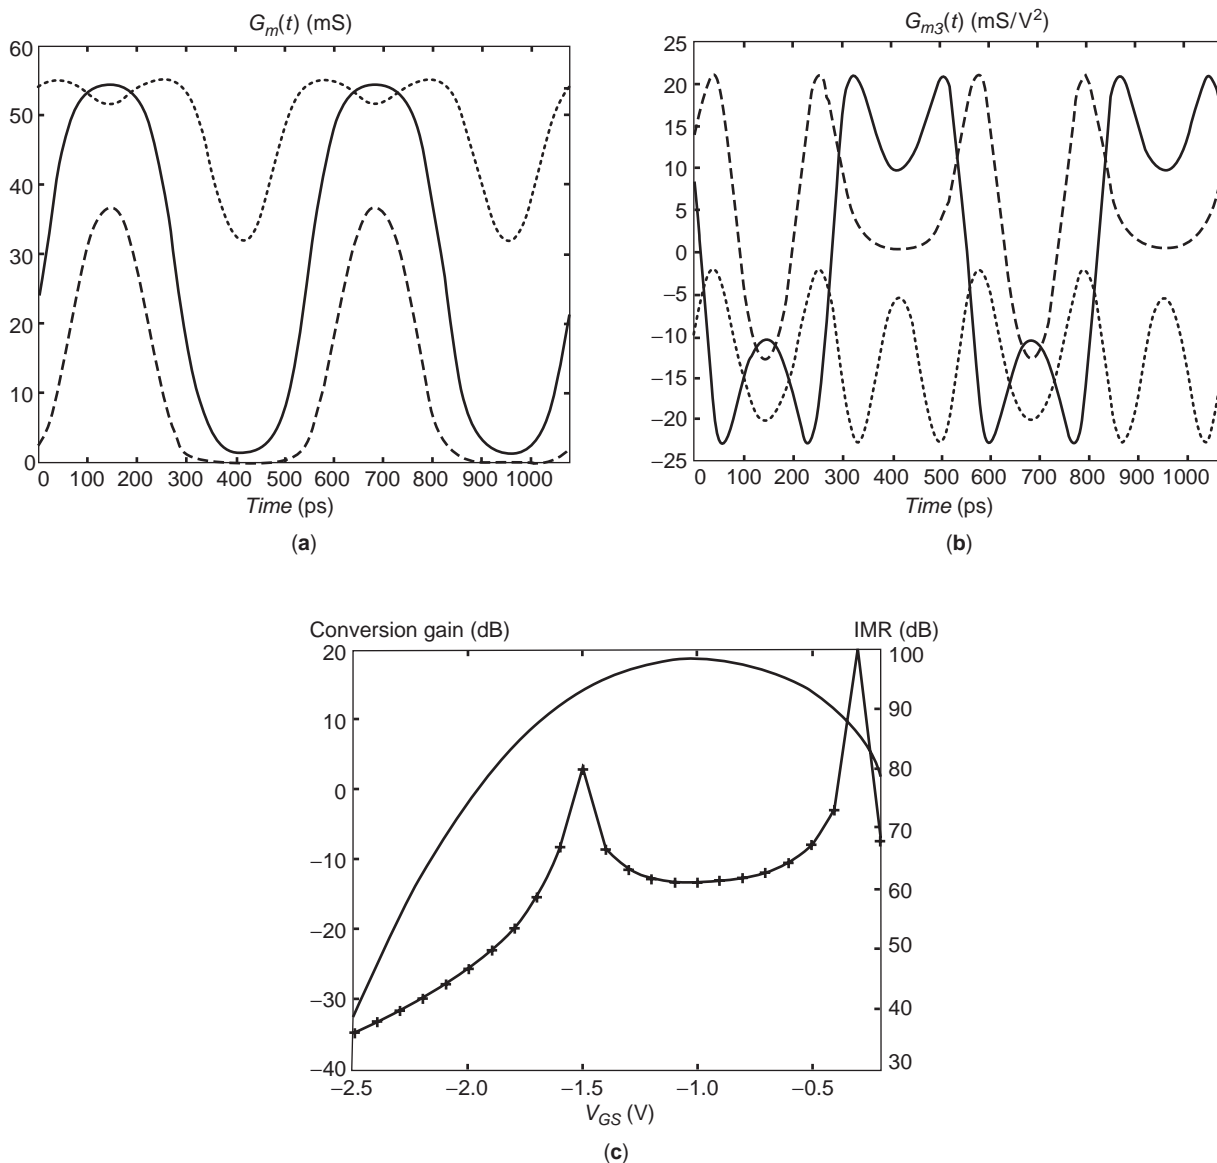

Figure 29. (a) Time-domain waveforms of $G_m(t)$ for three different V_{GS} bias points: $V_{GS} = -1.5$ V (- - -), $V_{GS} = -1.0$ V (—), and $V_{GS} = -0.6$ V (· · ·); (b) corresponding time-domain waveforms of $G_{m3}(t)$ for the same three V_{GS} bias points; (c) conversion gain (—) and IMD ratio (-+-) for the whole range of the FET's V_{GS} bias.

observed IMD impairment. Furthermore, this simplified analysis also shows that, as was previously studied for amplifiers, IMD behavior of mixers strongly depends on the actual shape of the device's nonlinearity. (For example, the very sharp peaks of IMR shown in Fig. 29c are due to the ideal symmetric sigmoidal model used for the simulated FET's transconductance.) So, different devices will show quite distinct IMR patterns, impeding a straightforward extrapolation of these active FET mixer results to diode mixers [6,27] or even resistive FET mixers [28,29].

6. CONCLUSIONS

This article showed that the study of nonlinear distortion mechanisms is a subject of fundamental interest that

spreads through almost all microwave and RF signal processing circuits and systems. Involving various scientific disciplines that range from the physical level of the active-device modeling, to the circuit and system's level of communication links, it requires a broad range of microwave knowledge. Hence, and despite the now more than 40 years of continued progress, intermodulation distortion is still an exciting and challenging field of strong active research both in industry and academia.

1. INTRODUCTION

Virtually all electronic circuits and systems exhibit nonlinear input–output transfer characteristic. Mixers, frequency multipliers, modulators, and square-law detectors represent examples of intentional class members, while linear power amplifiers, active filters, and microwave transmitters, in which nonlinearity represents an undesirable deviation of the system from ideal, linear operation, are examples of unintentional members.

Whenever a number of signals of differing frequencies pass through a nonlinear device, energy is transferred to frequencies that are sums and differences of the original frequencies. These are the intermodulation products (IMPs). In such cases, the instantaneous level of one signal may effectively modulate the level of another signal;

hence the term *intermodulation*. In a transmitting system, the results of excessive intermodulation are unwanted signals that may cause interference. In a receiver, internally generated intermodulation can hinder reception of the desired signals. It is interesting to note that the ear's cochlea has a similar nonlinear response and produces sums and differences of the input frequencies in the same way, particularly with loud sounds [1].

It has also been found that passive components, normally considered to be linear, can also generate IMPs. A variety of situations can arise in which nonlinear resistance junctions can be formed at metallic mating surfaces. Such junctions may result from salt or chemical depositions or from corrosion. The result is sometimes known as the "rusty bolt effect" because rusted bolts in structures have been known to exhibit such nonlinearities. This phenomenon is referred to as *passive intermodulation* (PIM). Sources of PIM include waveguides, directional couplers, duplexers, and antennas [2–6].

Intermodulation may also occur at the amplifier–loud-speaker interface [7], or in general as a result of the nonlinear interaction between the input signal of a two-port and a signal injected to the output port and propagating into the input via a feedback network [8]. Externally induced transmitter intermodulation, also known as *reverse intermodulation*, *backward intermodulation*, and *antenna-induced intermodulation*, is the mixing of a carrier frequency with one or more interfering signals in a transmitter's final stage [9]. Moreover, lack of screening of open-wire transmission lines can result in significant coupling to adjacent lines frequently giving rise to intermodulation products [10]. Furthermore, intermodulation may arise when an array of receiving antennas is illuminated with a transient impulsive electromagnetic plane wave [11].

In discussing the sources of IMPs it is convenient to divide nonlinear mechanisms yielding IMPs into two principal forms. The first is due to a nonlinear amplitude input/output characteristic (AM/AM), which causes amplitude compression with increasing input amplitude. The second mechanism occurs because of the variation of phase shift through the device, or the system, as the input amplitude is changed (AM/PM).

Depending on the signal characteristics, sources of IMPs can be divided into two categories: (1) static nonlinearity, depending solely on the amplitude of the signal, and (2) dynamic nonlinearity, depending not only on the amplitude but also on the time properties or frequency composition of the signal.

Static nonlinearities usually encountered in electronic circuits and systems can be classified into clipping, crossover, and soft nonlinearities [12] as shown in Fig. 1. Among the hard nonlinearities of clipping (which is significant near maximum input amplitudes) and crossover (significant mostly at small input amplitudes), the soft nonlinearity is usually the most important in the transfer characteristic of an electronic circuit. If the frequency content or the time properties of the input signal affect the transfer characteristic of the circuit or the system, the resulting nonlinearities may be called *dynamic*. Intermodulation products resulting from dynamic nonlinearities are

Figure 1. Different types of static nonlinearities: (a) clipping; (b) soft; (c) crossover.

referred to as *transient intermodulation* (TIM), *slew-induced distortion* (SID), or *dynamic intermodulation distortion* (DIM) [13–16].

2. SIMPLE INTERMODULATION THEORY

IMP occurs when two or more signals exist simultaneously in a nonlinear environment. In general, if N signals with frequencies f_1 to f_N are combined in a static nonlinearity, the output will contain spectral components at frequencies given by

$$\sum_{n=1}^N k_n f_n$$

where k_n is a positive integer, a negative integer, or zero, and $\sum_{n=1}^N |k_n|$ is the order of the IMP. Even with a small number of input signals N , a very large number of IMPs are generated. Fortunately, not all products are equally troublesome. Depending on the system involved, some of these IMPs can be neglected since they will be filtered out at some point. For example, most of the communication systems operate over a limited frequency band. Thus, IMPs falling out of the band will be attenuated. Moreover, amplitudes of the IMPs generally decrease with the order of the products, and high-order products can often be neglected. Low-order intermodulation components such as the second-order component $f_m - f_n$ and $f_m + f_n$ and the third-order components occurring at frequencies $2f_m - f_n$ and $f_m + f_n - f_q$ are usually the most troublesome, having the largest magnitudes and/or lying close to the originating frequencies, making their removal by filtering practically difficult. However, a salient characteristic of PIM, as distinguished from the conventional IM counterpart, discussed above, is that the PIMs causing trouble are of a high order, say, 11th–21st.

Analysis of nonlinear systems differs from that of linear systems in several respects: (1) there is no single analytical approach that is generally applicable (such as Fourier

or Laplace transforms in linear systems); (2) closed-form analytical solutions of nonlinear equations are not ordinarily possible; and (3) there is rarely sufficient information available to enable a set of equations that accurately model the system to be derived. These factors preclude the exact analytical determination of nonlinear effects, such as IMPs, in the general case. In order to get anything done at all, it is usually necessary to make various simplifying assumptions and then use an approximate model that will provide results of acceptable accuracy for the problem in hand.

A simple approach, therefore, is to use frequency-domain techniques that provide a separate solution for each frequency present in the output. In general, such methods are (1) centered around a description of the nonlinear mechanism by a continuous function type of characteristic, for example, a polynomial or a Fourier series representation of the output in terms of the input; and (2) based on the simplifying assumption that this characteristic does not vary with frequency, in other words, that it is a memoryless characteristic.

Memoryless nonlinear circuits are often modeled with a power series of the form

$$V_{\text{out}} = \sum_{n=0}^N k_n V_i^n \quad (1)$$

The first coefficient, k_0 , represents the DC offset in the circuit. The second coefficient, k_1 , is the gain of the circuit associated with linear circuit theory. The remaining coefficients, k_2 and above, represent the nonlinear behavior of the circuit. If the circuit were completely linear, all the coefficients except k_1 would be zero.

The model can be simplified by ignoring the terms that come after the k_3 term. For soft nonlinearities, the size of k_n decreases rapidly as n gets larger. For many applications the reduced model of Eq. (2) is sufficient, since the second-order and third-order effects dominate. However, many devices, circuits, and systems present difficulties for the polynomial approximation:

$$V_{\text{out}} = k_0 + k_1 V_i + k_2 V_i^2 + k_3 V_i^3 \quad (2)$$

Assuming that the input signal is a two-tone of the form

$$V_i = V_1 \cos \omega_1 t + V_2 \cos \omega_2 t \quad (3)$$

then combining Eqs. (2) and (3), yields

$$\begin{aligned} V_{\text{out}} = & a_0 + b_1 \cos \omega_1 t + c_1 \cos \omega_2 t + b_2 \cos 2\omega_1 t \\ & + c_2 \cos 2\omega_2 t + b_3 \cos(\omega_1 + \omega_2)t + c_3 \cos(\omega_1 - \omega_2)t \\ & + b_4 \cos 3\omega_1 t + c_4 \cos 3\omega_2 t + b_5(\cos(2\omega_1 + \omega_2)t \\ & + \cos(2\omega_1 - \omega_2)t) + c_5(\cos(2\omega_2 + \omega_1)t \\ & + \cos(2\omega_2 - \omega_1)t) \end{aligned} \quad (4)$$

where

$$\begin{aligned} a_0 &= k_0 + \frac{k_2}{2}(V_1^2 + V_2^2) \\ b_1 &= k_1 V_1 + \frac{3}{4}k_3 V_1^3 + \frac{3}{2}k_3 V_1 V_2^2 \\ c_1 &= k_1 V_2 + \frac{3}{4}k_3 V_2^3 + \frac{3}{2}k_3 V_1^2 V_2 \\ b_2 &= \frac{1}{2}k_2 V_1^2 \\ c_2 &= \frac{1}{2}k_2 V_2^2 \\ b_3 &= c_3 = k_2 V_1 V_2 \\ b_4 &= \frac{1}{4}k_3 V_1^3 \\ c_4 &= \frac{1}{4}k_3 V_2^3 \\ b_5 &= \frac{3}{4}k_3 V_1^2 V_2 \\ c_5 &= \frac{3}{4}k_3 V_1 V_2^2 \end{aligned}$$

For equal-amplitude input tones, Eq. (4) shows that the second-order terms, of amplitudes b_2, c_2, b_3, c_3 will be increased 2 dB in amplitude when input tones are increased by 1 dB. The third-order terms, of amplitudes b_4, c_4, b_5, c_5 , are increased by 3 dB in amplitude when the input tones are increased by 1 dB.

While Eq. (1) is adequate, and widely used, to predict the intermodulation performance of a wide range of devices, circuits, and systems, it seldom can be used. Examples include, but are not restricted to, prediction of spectral regrowth in digital communication systems, transient intermodulation and frequency-dependent nonlinearities, and passive intermodulation.

3. SPECTRAL REGROWTH

When a modulated signal passes through a nonlinear device, its bandwidth is broadened by odd-order nonlinearities. This phenomenon, called *spectral regrowth* or *spectral regeneration*, is a result of mixing products (intermodulation) between the individual frequency components of the spectrum [17]. The spectral regrowth can be classified in the two following categories: (1) in-band intermodulations and (2) out-of-band intermodulations. The first cannot be eliminated by linear filtering and are responsible for the signal-to-noise ratio degradation and, consequently, for the bit error rate (BER) degradation in digital communication systems. The second generates the interference between adjacent channels and can be filtered out at the nonlinear device output with certain output power penalty that is caused by the filter insertion losses. This spectral regrowth causes adjacent-channel

interference (ACI), which is measured by the adjacent-channel power ratio (ACPR).

The ACPR is the power in the main channel divided by the power in the lower plus upper adjacent channels. Considering just the lower channel yields $ACPR_{lower}$ and the upper channel alone yields $ACPR_{upper}$. Analog cellular radio uses frequency or phase modulation, and the ACPR is adequately characterized by intermodulation distortion of discrete tones. Typically, third-order intermodulation product (IMP3) generation, in a two-tone test, is adequate to describe spectral regrowth. Thus, distortion in analog radio is accurately modeled using discrete-tone steady-state simulation. Digital radio, however, uses complex modulation, and adjacent-channel distortion has little relationship to intermodulation in a two-tone test [18,19]. A modulated input signal applied to radiofrequency (RF) electronics in digital radio is a sophisticated waveform resulting from coding, filtering, and quadrature generation. Neither can it be represented by a small number of discrete tones (or frequencies), nor can the waveform be represented in a simple analytic form. Thus, in digital radio, ACPR is more difficult to predict than one- or two-tone responses since it depends not only on the intrinsic nonlinear behavior of the device (e.g. amplifier) but also on the encoding method (i.e., the statistics of the input stream) and the modulation format being used. The only way the input stream can conveniently and accurately be represented is by its statistics, and transforming these using an appropriate behavioral model provides accurate and efficient modeling of ACPR [20]. While in Ref. 20 the input signal is assumed Gaussian, digital communication signals are often far from being Gaussian. In Ref. 21 the input is assumed stationary but not necessarily Gaussian.

ACPR is, therefore, defined differently in the various wireless standards. The main difference is the way in which adjacent-channel power affects the performance of another wireless receiver for which the offending signal is cochannel interference [20]. In general the ACPR can be defined as [20]

$$ACPR = \frac{\int_{f_3}^{f_4} S(f)df}{\int_{f_1}^{f_2} S(f)df} \quad (5)$$

where $S(f)$ is the power spectral density (PSD) of a signal whose channel allocation is between frequencies f_1 and f_2 , and its adjacent channel occupies frequencies between f_3 and f_4 . Regulatory authorities impose strict constraints on ACPR and accurate methods of its determination are of particular interest to those involved in wireless system design.

4. SIMPLE TRANSIENT INTERMODULATION THEORY

To illustrate how TIM distortion arises, consider a differential amplifier with negative feedback applied between the output and the inverting input and a voltage step applied to the noninverting input. If the open-loop gain of the amplifier were flat and the time delay through it were zero, the voltage step would instantaneously propagate undis-

torted through the amplifier, back through the feedback loop, and into the inverting input, where it would be subtracted from the input signal, and the difference signal, which is a voltage step occurring at the same time that the input voltage does, would be amplified by the amplifier. However, this is not the case when the open-loop gain of the amplifier is not flat and the time delay through it is not zero. When the voltage step occurs, the limited high-frequency response of the amplifier prevents the appearance of a signal at the amplifier output terminal until the internal capacitors of the amplifier can charge or discharge. This causes the momentary absence of a feedback signal at the inverting input to the amplifier, possibly causing the amplifier to severely overload until the feedback signal arrives.

If the input signal to the differential amplifier is formed of a sine wave superimposed on a square wave, the amplifier will exhibit the same response to the abrupt level changes in the square wave as it did to the voltage step discussed above. During the momentary absence of the feedback when the square wave changes level, the amplifier can either saturate or cut off. If this occurs, the sine wave momentarily disappears from the signal at the output terminal of the amplifier, or it momentarily decreases in amplitude. This happens because the saturated or cut-off amplifier appears as a short circuit or open circuit, respectively, to the sine wave, and this component of the input signal is interrupted from the output signal, thus resulting in TIM [16].

A point to be noted is that if the term were understood literally, this would imply transients of both high and low frequencies and/or high or low operating levels, in other words, all transients. In actual practice, however, TIM occurs only for signals with simultaneous high level and high frequencies—not lower levels or lower frequencies. The key parameter of such signals is that they are characterized by high signal slopes, not just high frequencies or high levels. Neither high frequencies nor high levels in themselves necessarily result in distortion, unless their combination is such that a high effective signal slope is produced. TIM is actually generated when the signal slope approaches or exceeds the amplifier slew rate. This can happen for either transient or steady-state signals. Thus, a more easily understood term to what actually happens would be one that relates both slew rate and signal slope. A more descriptive term to describe the mechanism would, therefore, be the slew-induced distortion (SID); other descriptive variations of this term are “slew rate distortion” or “slewing distortion” [22].

Because of the complexity of the mechanism resulting in TIM, especially handling the frequency dependence of the amplifier nonlinearity and incorporation of the feedback, Eq. (1) cannot be used to predict the TIM performance of nonlinear devices, and recourse to other analytical techniques, for example, Volterra series or harmonic balance analysis, would be inevitable.

5. VOLTERRA SERIES AND HARMONIC BALANCE ANALYSIS

Volterra series describes a system with frequency-dependent nonlinearity in a way that is equivalent to the

manner in which Taylor series approximates an analytic function. Depending on the amplitude of the exciting signal, a nonlinear system can be described by a truncated Volterra series. Similar to the Taylor series representation, for very high amplitudes the Volterra series diverges. Volterra series describe the output of a nonlinear system as the sum of the response of a first-order operator, a second-order one, a third-order one, and so on [23]. Every operator is described in either the time domain or the frequency domain with a kind of transfer function called a *Volterra kernel*.

In Volterra series analysis the nonlinear circuit is treated purely as an AC problem. Assuming that none of the input signals are harmonically related, an iterative solution can be applied for circuits not operated under distortion saturation conditions. First the circuit is solved for the input signals. These results are then used to calculate the second-order distortion products, and these are treated as generators at a different frequency to the input signals and the network is again solved. This is then repeated for higher-order distortion products. This leads to extremely fast calculation of distortion behavior. Simulation at higher power levels can be achieved by feeding back contributions from higher-order distortion products [24]. The use of Volterra series to characterize the output as a function of the input [25,26] can, therefore, provide closed-form expressions for all the distortion products of a frequency-dependent nonlinearity excited by a multisinusoidal signal.

However, techniques using Volterra series suffer from the disadvantage that a complex mathematical procedure is required to obtain a closed-form expression for the output amplitude associated with a single component of the output spectrum. Moreover, the problem of obtaining output products of orders higher than the third becomes prohibitively difficult unless it may be assumed that higher-order contributions vanish rapidly [27]. The Volterra series approach is, therefore, most applicable to mild nonlinearities where low-order Volterra kernels can adequately model the circuit behavior. With appropriate assumptions and simplifications, many useful features of the Volterra series technique can be used to find approximate expressions for TIM (SID). These are quite accurate for relatively small distortion conditions [28,29].

Alternatively, most RF and microwave circuit analysis are based on the harmonic balance analysis [30]. The harmonic balance technique works by processing the linear part of the circuit in the frequency domain and the nonlinear part in the time domain. Computation in the frequency domain is very fast and efficient, especially for frequency-selective components such as transmission lines and resonant circuits. Computations in the time domain are followed by Fourier transform. Harmonic balance analysis can, therefore, handle intermodulation distortion provided there are not too many excitation tones. In the harmonic balance technique an initial estimate is required for the final waveshape, and this is refined interactively during analysis. The harmonic balance method computes the response of a nonlinear circuit by iteration, and the final result is a list of numbers that do not indicate which nonlinearities in the circuit are mainly

responsible for the observed nonlinear behavior. Hence such a method is suitable for verification of circuits that have already been designed. This method does not present information from which designers can derive which circuit parameters or circuit elements they have to modify in order to obtain the required specifications [31]. While Volterra series analysis can provide such information, it is applicable only to weak nonlinearities.

While viewed as a universal solution, and has been widely used, the harmonic balance analysis may be unnecessarily slow, cumbersome, and prone to subtle errors [32], especially for weak nonlinearities or when a nonlinear device is excited by very small signals. Volterra series analysis is generally more accurate than harmonic balance for these types of problems, and it is several orders of magnitude faster than a harmonic balance analysis [32]. Moreover, Volterra series analysis integrates well with linear analysis tools, supporting simultaneous optimization of several parameters of the nonlinear system. Therefore, Volterra theory appears to be an ideal tool for circuits and systems that are not strongly nonlinear but have aspects of linear and nonlinear circuits [32]. However, Volterra series analysis becomes very cumbersome above third-order products, and for products above fifth order, it loses most of its advantages over the harmonic balance analysis. The major disadvantage of Volterra series is the occasional difficulty in deciding whether the limitations to weakly nonlinear operation have been exceeded.

In fact, Volterra-series analysis and the harmonic balance technique complement each other [32]. Thus, while the Volterra series analysis works well in those cases where harmonic balance works poorly, the harmonic balance works well where the Volterra series works poorly. Volterra series analysis is, therefore, not appropriate for mixers, frequency multipliers, saturated power amplifiers, and similar strongly driven and/or hard nonlinearities. Volterra series analysis is suitable for small-signal amplifiers, phase shifters, attenuators, and similar small-signal and/or soft nonlinearities.

Another technique for analyzing nonlinear systems is the describing function. This approach can yield closed-form expressions for a feedback system that contains an isolated static nonlinearity in the feedback loop [33]. Since it is not possible to map all nonlinear circuits and systems to such a feedback system, the describing function method has restricted applications.

6. PASSIVE INTERMODULATION (PIM)

While the concept of intermodulation in active devices such as amplifiers, filters, and mixers is familiar and well documented, the effects of intermodulation in passive components such as directional couplers, cables, coaxial connectors, power splitters, antennas, and electromechanical and solid-state programmable attenuators are less familiar and less documented. More recently, evidence has emerged that PIM has an impact in other system equipment, such as amplifiers and extenders, fiber nodes, and interface units [34]. Poor mechanical contact, dissimilar metals in direct contact, ferrous content in the conductors,

debris within the connector, poor surface finish, corrosion, vibration, and temperature variations are among the many possible causes of PIM. The sources of PIM have been studied extensively; see Refs. 35–43 and the references cited therein. Similar to the intermodulation products in active devices, PIM is generated when two or more RF signals pass through RF passive devices having nonlinear characteristics [41,42]. Generally the nonlinearities of RF passive devices consist of contact nonlinearity and material nonlinearity [43]. *Contact nonlinearity* refers to all metal contact nonlinearities causing nonlinear current–voltage behavior, such as the tunneling effect, micro-discharge, and contact resistance. *Material nonlinearity* refers to the bulk material itself. Magneto-resistivity of the transmission line, thermal resistivity, and nonlinear hysteresis of ferromagnetic material are good examples [43]. PIM generation in RF passive devices is caused by the simultaneous appearance of one or more of these PIM sources, and the overall performance is often dominated by one principal PIM source [43]. In the case of antennas, PIM is generated not only by the same PIM sources as in general RF passive components but also by the external working environment, such as conducting metal materials.

Over the years Eq. (1) was used to describe the nonlinear current/voltage conduction characteristics of passive components, (see, e.g., Refs. 37–39 and the references cited therein). While this approach results in simple expressions for the magnitudes of the harmonics and intermodulation products resulting from multisinusoidal excitations, it suffers from the following shortcomings. In order to predict high-order harmonic or intermodulation product magnitudes, it is necessary to determine coefficients of terms of similar order in the polynomial. A prerequisite to obtaining coefficients of high-order polynomial terms is measurement of output products of the same order. For example, to obtain the coefficients of a fifth-order polynomial, it is necessary to measure the output fifth-order components. With increasing use of narrowband components in multicouplers used in base stations of mobile radio systems, it becomes difficult to determine high-order coefficients in the nonlinear characteristic because the measured high-order product amplitudes from which they are computed are influenced to an unknown extent by the system selectivity [44]. To overcome these problems, an exponential method has been used to predict the intermodulation arising from corrosion [45].

7. INTERMODULATION CHARACTERIZATION

Although it is important to understand the origin of intermodulation and the engineering techniques for avoiding it, it is equally important to be able to characterize it objectively, preferably in a way that correlates well with the subjective perception of the intermodulation. The ability to characterize an imperfection in this way is an important step toward eliminating it as a system performance degradation.

Several techniques for characterizing intermodulation distortion have been proposed. While some of these

techniques measure the total intermodulation distortion, others distinguish between the various intermodulation products. The latter are preferred, for subjective perception of intermodulation shows that equal amounts of total intermodulation distortion differ widely in their effect according to how the total is made up.

Depending on the signal characteristics, techniques for characterization of intermodulation distortion can be classified into two categories: (1) *steady-state techniques*, where characterization is performed on the assumption that the input to the system under consideration is a multisinusoidal signal, and (2) *dynamic techniques*, where characterization is performed on the assumption that the input to the system under consideration is formed of a sinusoidal signal superimposed on another signal characterized by rapid changes of state, for example, a square wave or a sawtooth wave. While steady-state techniques can be used to characterize both RF and audio systems, dynamic techniques are generally used for characterizing only audio systems.

7.1. Steady-State Techniques

7.1.1. The Intercept Point. Increasing the signal level at the input to a weakly nonlinear device will cause the IMPs to increase at the output. In fact, the increase in IMP amplitudes is faster than the increase in the output version of the input signal. For increasing fundamental input power, the fundamental output power increases in a linear manner, according to the gain or loss of the device. At some point, gain compression occurs and the fundamental output power no longer increases with input power. The output power of the second-order intermodulation products also increases with fundamental input power, but at a faster rate. Recall that, according to the simple intermodulation theory, the second-order intermodulation changes by 2 dB per 1 dB of change in the fundamental. Similarly, the third-order intermodulation changes by 3 dB per 1 dB of change in the fundamental. Thus, on a logarithmic scale, as shown in Fig. 2, the lines representing the second- and third-order intermodulation products have twice and three times, respectively, the slope of the fundamental line.

If there were no gain compression, the fundamental input power could be increased until the second-order intermodulation eventually caught up with it, and the two output power levels would be equal. This point is referred to as the *second-order intercept point* (IP2). The third-order intermodulation product also increases faster than the fundamental, and those two lines will intersect at the third-order intercept point (IP3). Rarely can either of these two points be measured directly, due to the gain compression of the fundamental. Instead, the intercept points are extrapolated from measurements of the fundamental and intermodulation products at power levels below the point where gain compression occurs. The intercept points are usually specified in dBm and may refer to either the output or the input; the two points will differ by the gain of the system under consideration. The second-order and third-order intercept points are figures of merit that are independent of the signal level.

Figure 2. Third-order and second-order intercept points are determined by extending the fundamental, the second- and the third-order intermodulation transfer function lines: (a) Fundamental transfer function, slope = 1; (b) second-order intermodulation, slope = 2; (c) third-order intermodulation, slope = 3. IP3—third-order intercept point; IP2—second-order intercept point.

Therefore, the intermodulation performance of two different systems can be compared quite easily if their intercept points are known [46].

Using the intercept point it is easy to calculate the relative intermodulation level corresponding to a given input signal level. In fact, the difference between the level of the second-order intermodulation and the fundamental signal level is the same as the difference between the fundamental signal level and the intercept point. Thus, if the second-order intercept point is +15 dBm and the fundamental signal level is -10 dBm (both referred to the output of the device), the difference between these two values is 25 dB. Therefore, the second-order intermodulation products will be 25 dB below the fundamental, or -35 dBm. So the intercept point allows easy conversion between fundamental signal level and the intermodulation level.

The difference between the level of the third-order intermodulation products and the fundamental signal level is twice the difference between the fundamental signal level and the third-order intercept point. (Note that the second-order intercept point is not the same as the third-order intercept point.) Suppose that the third-order intercept point is +5 dBm and the fundamental signal is -25 dBm, both referred to the output of the device. The difference between the intercept point and the fundamental is 30 dB, so the third-order intermodulation products will be 2 times 30 dB down from the fundamental. The relative distortion level is -60 dB, and the absolute power of the intermodulation products is -85 dBm.

It is important, however, to note that the preceding analyses assume that the second-order and third-order intermodulation curves have slopes of 2 and 3 dB/dB, respectively. Thus, theoretically, the intercept points are not functions of the input power level. If a power sweep is performed, it is expected that the intercept points will remain constant. The intercept points can, therefore, be calculated from measurements at only one power level. However, if the input signal exceeds a certain limit, the amplitudes of the output fundamentals and the resulting intermodulation products will start to saturate, and the intercept points will usually drop off, indicating an invalid measurement. It is essential to know this limit. It is particularly useful for high-dynamic-range circuits and systems with relatively low output powers where the intermodulation is low, but only for signals that are low enough. Expanding the model of Eq. (2) to include fourth- and fifth-order terms [47] can achieve this.

Moreover, at low power levels, the intercept points will start to change as the noise floor of the measuring instrument, usually a spectrum analyzer, is approached, thus indicating an invalid measurement. It is important, therefore, to look at the variation of the intercept points as functions of power as this provides a good way of checking the valid measurement range.

7.1.2. Two-Tone Test. The two-tone test is extensively used in characterizing a wide range of devices. Magnetic tapes [48]; microwave and millimeter-wave diode detectors [49]; analog-to-digital converters [50,51]; gamma correctors [52]; and electrical components such as resistors, capacitors, inductors, as well as contacts of switches, connectors, and relays [53] are a few examples. The two-tone test is also used to characterize the performance of the basilar membrane of the cochlea [54].

The two-tone test can also be used to determine the transfer characteristic of a nonlinear device modeled by the polynomial approximation of Eq. (2). With the input formed of two properly selected frequencies ω_1 and ω_2 , and if the second-order and third-order intermodulation products are measured separately, it is possible to find, from the measured data, the coefficients of the quadratic and cubic terms k_2 and k_3 , respectively, in the polynomial approximation of Eq. (2). If in addition, the IMPs are measured at two sets of values of ω_1 and ω_2 , it is possible to identify the dominant physical nonlinear process from the variation of IMPs with test frequencies [13].

The two-tone test can also be used to determine the complex transfer characteristic of a nonlinear device exhibiting AM/AM nonlinearity only with fixed phase shift between the output and the input. In this case a complete set of measurement for all the two-tone intermodulation products produced by the nonlinearity at two different power levels is necessary [55]. If the device under consideration exhibits both AM/AM and AM/PM nonlinearities, then determination of a unique set of polynomial coefficients requires a complete set of intermodulation measurements at three different power levels [55]. The set obtained at the highest power level will decide the amplitude range within which the characterization will be valid.

According to the basic assumption that the nonlinearities are represented by polynomials, high-accuracy representation of the device characteristics will require difficult accurate measurements of higher-order intermodulation products, in addition to increased complications and considerable efforts involved in the analysis [55]. Another difficulty from which this method suffers arises from the necessity of measuring complete sets of two-tone intermodulation products spread over a relatively wide frequency range, which consequently may impose stringent specifications on the measuring instruments and techniques if accurate measurements are to be achieved.

In the two-tone test the inband IMPs are used to describe a device, a circuit or a system nonlinearity. Measurements are made in or near the frequency range of interest. In this test, the input signal consists of two frequencies, ω_1 and ω_2 of equal amplitude and a fixed amount of frequency spacing. At the output of the circuit or the system under test the amplitudes of the third-order intermodulation products $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$ are measured. The *intermodulation distortion* is defined as the ratio between the root sum square of the intermodulation products and the root sum square of the twin-tone amplitudes.

Unless a wave analyzer or a spectrum analyzer is available, the implementation of the two-tone test invariably require amplification of the whole output spectrum to obtain components ω_1 and ω_2 on a normalized value (100%). Then, ω_1 and ω_2 are suppressed, and the remaining components $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$ are measured with an AC voltmeter or oscilloscope. Especially at audiofrequencies, this approach requires steep filters, one set of filters for each set of ω_1 and ω_2 . For the same reason $\omega_2 - \omega_1$ cannot be too low, so it will never be a really narrowband system. This narrowband aspect is particularly important for higher frequencies, where equalizers, in the reproduction audio channel, may give unequal amplification of the components in the spectrum [56]. In the audiofrequency range several versions of the two-tone test are available [56–59].

7.1.3. Three-Tone Test. In this test, again, specific inband IMPs are selected to characterize the overall system nonlinearities [60]. The more even spectral distribution and flexibility, while still allowing discrete frequency evaluation, make this an attractive test for multifrequency systems such as communication and cable television systems. In this test three equal-amplitude tones are applied to the input of the nonlinear system under consideration. Thus

$$V_i = V(\cos \omega_1 t + \cos \omega_2 t + \cos \omega_3 t) \quad (6)$$

Combining Eqs. (2) and (6), and using simple trigonometric identities, it is easy to show that the third-order term, $k_3 V_i^3$ will contribute, to the output spectrum, the following:

1. Three components at frequencies ω_1 , ω_2 and ω_3 each with amplitude given by

$$A_1 = \frac{15}{4} k_3 V^3 \quad (7)$$

2. Three components at frequencies $3\omega_1$, $3\omega_2$, $3\omega_3$ each with amplitude given by

$$A_3 = \frac{1}{4} k_3 V^3 \quad (8)$$

3. Twelve components at frequencies $2\omega_m \pm \omega_n$, $m, n = 1-3$, each with amplitude given by

$$A_{21} = \frac{3}{4} k_3 V^3 \quad (9)$$

4. Four components at frequencies $\omega_m \pm \omega_n \pm \omega_p$, $m, n, p = 1-3$, each with amplitude given by

$$A_{111} = \frac{3}{2} k_3 V^3 \quad (10)$$

Equations (9) and (10) show that an intermodulation product of frequency $\omega_m \pm \omega_n \pm \omega_p$ is 6 dB higher in level than an intermodulation product of frequency $2\omega_m \pm \omega_n$. *Intermodulation distortion* is defined as the ratio between the amplitude of one of the intermodulation products of frequency $\omega_m \pm \omega_n \pm \omega_p$ and the amplitude of one of the three output tones. In this test the choice of frequencies $\omega_1, \omega_2, \omega_3$ used to perform the measurement is important. This is because a system's intermodulation performance may not be constant over its operating frequency range.

The three-tone test is widely used to characterize the performance of RF amplifiers used in television broadcast transposers, where the vision carrier, color subcarrier, and sound carrier frequency components interact in the presence of amplifier nonlinearities. If the three frequency components are represented as single frequencies (ω the vision carrier, ω_{sc} the color subcarrier, and ω_s the sound carrier with amplitudes V_v , V_{sc} , and V_s , respectively), then the input signal can be expressed as

$$V_i = V_v \cos \omega_v t + V_{sc} \cos \omega_{sc} t + V_s \cos \omega_s t \quad (11)$$

Combining Eqs. (2) and (11), and using simple trigonometric identities, it is easy to show that the third-order term of Eq. (2) produces, among others, two in-band intermodulation components given by

$$\begin{aligned} V_{ip} = & \frac{3}{2} k_3 V_v V_{sc} V_s \cos(\omega_v + \omega_s - \omega_{sc})t \\ & + \frac{3}{4} k_3 V_s V_{sc}^2 \cos(2\omega_{sc} - \omega_s)t \end{aligned} \quad (12)$$

Intermodulation performance of the transposer is measured by taking the transposer out of service and using the three-tone simulation of a composite video and sound signal, given by Eq. (11), as its input. The three levels and frequencies vary from system to system. Typical levels, below the peak synchronous pulse level, are $V_v = -6$ dB, $V_{sc} = 17$ dB, and $V_s = -10$ dB. Under these conditions, the first term of Eq. (12) is the most visible, and the second term will be much lower in amplitude, typically 17 dB less. Using a spectrum analyzer, the relative amplitude of the major in-band intermodulation is measured and

referenced to the level of peak synchronous pulse. Usually, the permissible level of the major in-band intermodulation component is -53 dB below the reference level. This three-tone test method is slow and requires spectrum analyzers with relatively wide dynamic ranges. Moreover, it measures the system performance at one luminance level and one chrominance level. Thus, it does not test the system over its full operating range [61].

The inadequacy of the internationally accepted three-tone test method can be overcome by using a modified colorbar test signal [61]. The colorbars are applied to the transposer via a test transmitter. The colorbars and sound carrier therefore apply the three tones to the transposer, changing levels in rapid succession. With suitable processing, based on sampling the demodulated colorbar signal for short intervals corresponding to a selected color, intermodulation levels can be measured simultaneously at seven different luminance levels and can be shown in histogram form [61].

7.1.4. Noise Power Ratio (NPR) Test. In the NPR test, the input to the device under test is obtained from a white-noise source that is bandlimited to the instantaneous frequency range of interest. This emulates a situation with many simultaneous input signals. Provided that none of the signals dominate, according to the central-limit theorem, the resulting voltage obtained when many uncorrelated signals are added will approach a Gaussian distribution. True white noise covers a frequency range of interest continuously, unlike discrete signals.

The NPR test measures the amount of intermodulation products power between two frequency ranges of white Gaussian noise. A white-noise generator is used with its output frequency range limited by a bandpass filter according to the bandwidth of the device under test. A quiet channel is formed by a switchable band-reject filter, as shown in Fig. 3. Then, the resulting white-noise signal is applied to the input of the device under test. At the output of the device under test is a receiver which is switch-tuned to the frequency of the band-reject filter used to produce the quiet channel. The NPR test is widely used for evaluating the intermodulation performance of systems whose input signal spectrum distribution can be approximated by that of white noise. However, the NPR may be degraded by the noise floor of the system under test, especially

Figure 3. The output spectrum of a noise-power ratio measurement. (a) injected noise; (b) noise and intermodulation generated in the measurement bandwidth $\delta\omega$ by the DUT. $\text{NPR} = A - B$.

under very low loading conditions. It may also be degraded by the distortion products produced under high loading conditions [62].

7.1.5. Cross-Modulation. Cross-modulation occurs when modulation from a single unwanted modulated signal transfers itself across and modulates the wanted signal. Cross-modulation is troublesome primarily if the desired signal is weak and is adjacent to a strong unwanted signal. Even when the carrier of the strong unwanted signal is not passed through the system, the modulation on the undesired carrier will be transferred to the desired carrier. Cross-modulation is, therefore, a special case of intermodulation. Recall that when the input to a non-linear system is formed of a two-tone signal of the form of Eq. (3), then the amplitudes of the output components at frequencies ω_1 and ω_2 will be given by

$$b_1 = k_1 V_1 + \frac{3}{4} k_3 V_1^3 + \frac{3}{2} k_3 V_1 V_2^2 \quad (13)$$

and

$$c_1 = k_1 V_2 + \frac{3}{4} k_3 V_2^3 + \frac{3}{2} k_3 V_1^2 V_2 \quad (14)$$
