3.2.1. Oscillation Startup Conditions. The evaluation of the oscillation startup conditions is, in fact, an evaluation of the stability of its DC solution. As already stated, this solution has to be unstable, with two poles $\sigma \pm j\omega_0$ on the right-hand side of the complex plane. When using a transistor, it is convenient to start the oscillator design by calculating, for given bias conditions, the stability factor μ [27] about the desired oscillation frequency ω_0 . This factor depends on the transistor scattering parameters and, thus, on its bias point. When the transistor is unconditionally stable ($\mu > 1$) about the desired oscillation frequency, a different bias point can be attempted. However, to ensure sufficient negative resistance, it is convenient to use a feedback network. Reactive elements are generally chosen to avoid the introduction of unnecessary loss. Different feedback networks are possible. A simple topology is obtained through series feedback, with either a capacitance or an inductance, as shown in Fig. 10a.

Figure 9. Variation of the third-order intermodulation distortion versus the gate voltage V_{GS} . Calculation from the envelope transient method, following the third-order intermodulation tone $\omega_{IM3,1}$. Comparison with the variation of $G_{m3,1}$.

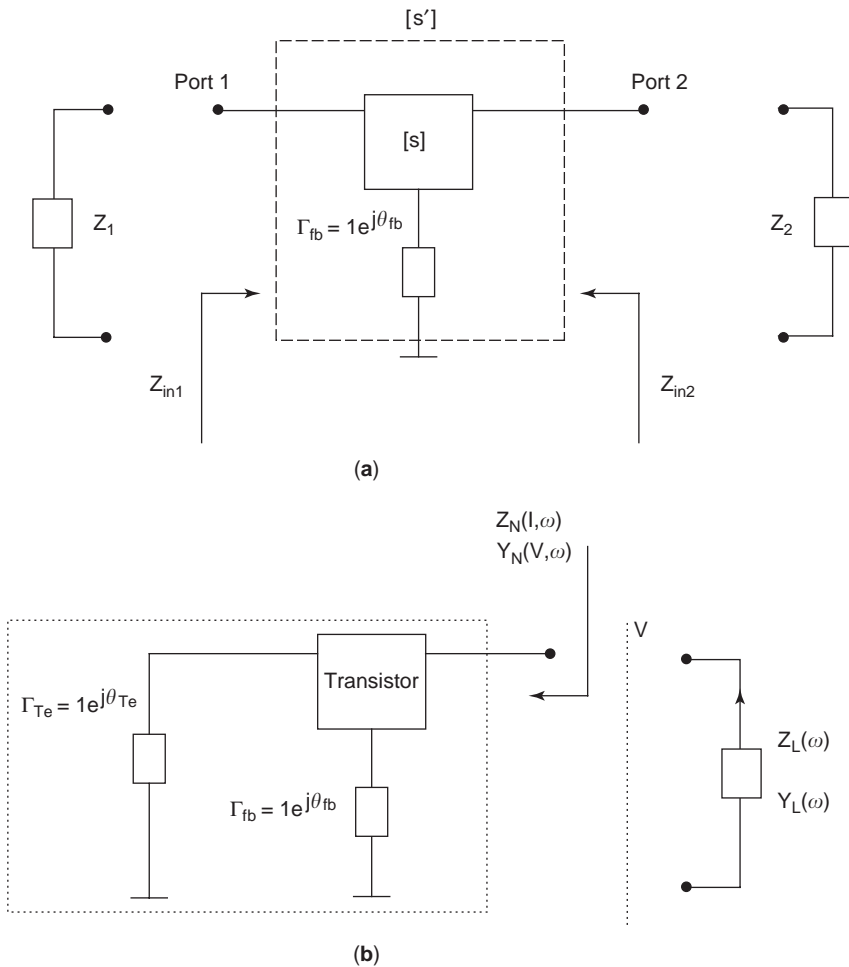

Figure 10. Transistor with series feedback to achieve negative resistance at the drain port: (a) two-port analysis; (b) one-port analysis, with a reactive terminal element at the gate port.

Topologies like the ones used in the Colpitts and Clapp–Gouriet oscillators [3,6] reduce the influence of the elements of the transistor model on the oscillation frequency.

A simple series feedback, at the transistor source, will be considered here (see Fig. 10a). A new two-port can be defined, including the transistor and the feedback elements. The two ports of the active network (including the feedback) will be denoted ports 1 and 2. The input impedance Z_{in1} at port 1 depends on the scattering parameters S , the feedback elements, and the circuit load at the other end Z_2 . In turn, the output impedance Z_{in2} at port 2 depends on S , the feedback elements, and Z_1 [3]. The oscillator synthesis can be carried out at either port 1 or port 2. The choice will depend on the particular oscillator configuration. Without loss of generality, port 2 will be selected here (see Fig. 10b).

The μ factor will now be analyzed, in the presence of series feedback, at the desired oscillation frequency ω_0 . To globally consider all the positive and negative reactive values, an ideal feedback element, defined by its reflection coefficient $\Gamma_{fb} = 1e^{j\theta_{fb}}$, will be used. For some values of θ_{fb} , a stability coefficient $\mu < 1$ will be obtained. Figure 11a shows the variation of μ versus θ_{fb} , for the transistor CFY30, when considering different values of gate bias. The drain voltage is in all cases $V_{DS} = 2.5$ V.

For $\mu < 1$, it will be possible to have source impedances such that $\text{Re}Z_{in2} < 0$. These are determined by tracing the

corresponding source stability circle on the Smith chart. This circle constitutes the border between the source impedances Z_1 for which $\text{Re}Z_{in2} < 0$ and those giving $\text{Re}Z_{in2} > 0$. For obvious reasons, provided the original scattering matrix of the transistor (referred to $50\ \Omega$) fulfills $|S_{22}| < 1$, the origin of the Smith chart will belong to the zone giving $\text{Re}Z_{in2} > 0$. The opposite is true for $|S_{22}| > 1$. Figure 11b shows the location of the stability circles, at the desired oscillation frequency $f_0 = 4.5$ GHz, for some θ_{fb} values, with $\mu < 1$.

In most cases, the impedance Z_1 is used to achieve the negative resistance only. It is often called *terminal impedance* Z_{Te} . For simplicity, and to avoid additional loss, a reactive value X_{Te} is usually chosen (Fig. 10b). However, in some cases, it will be necessary to consider a real part in Z_{Te} , especially when the objective is to synchronize the oscillator at a later stage, since the forcing generator, connected at port 1, will necessarily introduce a resistive value $\text{Re}Z_{Te} > 0$. If the oscillator is expected to operate in free-running regime, only Z_{Te} values on the border of the Smith chart will be selected. Although a single-terminal element (inductance or capacitance) will be considered here, it is also possible to use a resonator, with a high quality factor. As will be shown later, this reduces the phase noise spectral density.

As already mentioned, in order to fulfill the oscillation startup conditions, excess negative resistance and

Figure 11. Analysis of potential instability of the series feedback topology in Figure 10: (a) variation of the stability factor μ versus the phase θ_{fb} for different values of the gate bias voltage; (b) regions in the Z_1 plane, providing negative resistance at the drain port, obtained for θ_{fb} values for which $\mu < 1$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

resonance of the reactive elements must be achieved at port 2 in Fig. 10. This energy excess gives rise to the growth of the oscillation current. The oscillation startup conditions can also be evaluated in terms of the total impedance or the total admittance at port 2 (Fig. 10b). Actually, the connection of the linear and nonlinear networks of the oscillator circuit can be regarded as a series connection, which would require the sum $Z_{in2} + Z_2$, or as parallel connection, which would require the sum of the respective admittances $1/Z_{in2}$ and $1/Z_2$, specifically, $Y_T(V, \omega) = 1/Z_{in2} + 1/Z_2$, where V is the node voltage. Taking V as the independent variable, the negative-conductance excess, plus the resonance condition at ω_0 , will give rise to an oscillating transient of growing amplitude in this voltage variable. The choice of admittance functions is generally more convenient to make the design compatible with the later use of nonlinear simulation. Actually, the nonlinear circuit analysis is carried out using the node

voltages as the state variables. Thus, only admittance functions will be considered in the remainder of the text.

Analysis of Fig. 11b provides the values of the terminal impedance X_{Te} (on the border of the Smith chart) for which negative resistance (or conductance) is obtained at port 2 for different θ_{fb} values, with $\mu < 1$. However, it does not show the actual values of negative resistance/conductance. This requires an additional analysis that will allow the optimum selection of both the feedback and terminal element values. Again, to globally consider both inductive and capacitive values, this terminal impedance will be written $\Gamma_T = 1e^{j\theta_{Te}}$ (Fig. 10b). Renaming $Y_N \equiv 1/Z_{in2} = G_N + jB_N$, the variation of the function $G_N(\theta_{fb}, \theta_{Te})$, at the desired oscillation frequency ω_0 , will be analyzed by means of a double sweep in the two phases θ_{fb} and θ_{Te} .

Figure 12 shows the results of the application of the double-sweep technique to the MESFET oscillator, biased at $V_{GS} = -0.5$ V, $V_{DS} = 2.5$ V. The analysis frequency

Figure 12. Conductance variation versus the phase of the reactive terminal and feedback elements, respectively, given by θ_T and θ_{fb} . (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

agrees with the desired oscillation frequency $f_0 = 4.5$ GHz. Phase values between 0 and 180° will correspond to inductances, while phase values between 180° and 360° will correspond to capacitances. This distinction will be useful when a feedback or terminal element of a particular type is desired, as in the case of voltage-controlled oscillators (VCOs), for which a tuned capacitance is to be included as either terminal or feedback element. In the case of Fig. 12, the maximum conductance is obtained for the phase values $\theta_{fb} = 200^\circ$ and $\theta_{Te} = 130^\circ$. Thus, a capacitive feedback element $C = 4$ pF and an inductive terminal element $L = 0.82$ nH should be used.

After the choice of the optimum terminal and feedback elements, a load admittance $Y_L \equiv G_L + jB_L$ is connected to the nonlinear network

$$\begin{aligned} G_T(V \cong 0, \omega_0) &\equiv G_N(V \cong 0, \omega_0) + G_L(\omega_0) < 0 \\ B_T(V \cong 0, \omega_0) &\equiv B_N(V \cong 0, \omega_0) + B_L(\omega_0) = 0 \end{aligned} \quad (12)$$

where ω_0 is the desired oscillation frequency and $V \cong 0$ indicates small-signal voltage. These conditions establish the unbalance of the delivered and dissipated energy at the resonance frequency ω_0 . It is, in fact, an instability condition of the DC solution of the circuit at the selected bias point. In general, the circuit will evolve towards a stable oscillating solution for $(\partial B_T / \partial \omega)|_0 > 0$, as shown by Kurokawa [11]. In order to maximize the output power $P_o = \frac{1}{2} G_L V_o^2$, an empirical criterion is $G_L = -\frac{1}{3} G_N(V \cong 0, \omega_0)$.

In the case of the MESFET-based oscillator, $B_N(4.5 \text{ GHz}) = 0.069$ mhos. Thus, parallel inductance, of value $L = 0.511$ nH, should be introduced, to obtain $B_T = 0$. Figure 13 shows the fulfillment of the oscillation startup conditions at $f_0 = 4.5$ GHz. A design for specified output power P_o requires a nonlinear model of the active block $Y_N(V, \omega)$. The nonlinear oscillator design will be the object of the next section.

The sensitivity to perturbations of the oscillation frequency is smaller for higher slope of $B_T(\omega)$, at the resonance frequency ω_0 , as the oscillator quality factor Q is directly proportional to this derivative [28]. Thus, lower phase noise should be expected for larger $B_T(\omega)$. Dielectric resonators can be used to increase the Q factor [3,28]. They are made of ceramic material, being stable in temperature, with low loss and high dielectric constant. The resonator is placed in the neighborhood of a transmission line and is coupled to this line. Its equivalent circuit is a parallel resonant circuit, in series with the line, whose element values R , L , and C depend on the distance of the resonator from the transmission line and on the length of this transmission line that is actually coupled to the resonator [28].

As a final comment, it should be highlighted that in monolithic technologies, with high manufacturing reliability, the model parameters for different transistor devices will be very close in value. Thus, differential configurations can be used for oscillator design [29]. The negative resistance is provided by two transistors in cross-coupled configuration and biased by means of current source, at the emitter or source terminal. The resonance at the desired oscillation frequency may be achieved through an inductive divider and a capacitor, connected to the transistor collector or drain terminals. The technique presented here can also be used, with some modifications, for the types of steady-state design discussed in the following paragraphs.

3.2.2. Steady-State Design with One-Harmonic Accuracy. Assuming an ideal waveform $v(t) = V_o \cos(\omega_0 t)$, the steady-state oscillation condition, showing the balance between the delivered and dissipated energy, is given by

$$\begin{aligned} G_T(V_o, \omega'_0) &\equiv G_N(V_o, \omega'_0) + G_L(\omega'_0) = 0 \\ B_T(V_o, \omega'_0) &\equiv B_N(V_o, \omega'_0) + B_L(\omega'_0) = 0 \end{aligned} \quad (13)$$

Figure 13. Fulfillment of the oscillation startup conditions for $f_0 = 4.5$ GHz. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

As shown in these equations, the steady-state oscillation frequency will generally be different from the desired value ω_0 , at which the startup condition (12) is evaluated. This is due to the nonlinear dependence of both G_N and B_N on the amplitude V . Unlike the startup condition (12), the steady-state equation (13) requires a nonlinear model $Y_N(V, \omega)$ for the admittance of the active device. This equation will enable the approximate calculation (with one-harmonic component) of the oscillation output power and frequency. After the initial design, based on (13), a rigorous nonlinear analysis should be carried out, taking into account a sufficient number of harmonic terms, which will have some influence on both the oscillation frequency and the power.

The nonlinear function $Y_N(V, \omega)$ can be determined either empirically or analytically. The empirical determination is carried out by measuring the scattering parameters with respect to the input amplitude V , in a frequency band about the expected oscillation frequency. The analytical determination relies on the *describing function* [3,11]. In order to mathematically define the describing function, the nonlinear element $i(v)$ will be considered, excited by a sinusoidal signal $v(t) = V \cos(\omega t)$. This will give rise to a current through the element $i(t)$, which, in general, will not be sinusoidal. The describing function $Y_N(V)$ is given by the ratio between the first harmonic of the current $i(t)$ and the amplitude V : $Y_N(V) = i(t)_{1st \text{ harm}}/V$.

The describing function enables an analytical design of the oscillator from the steady-state equation $Y_T = Y_N(V) + Y_L(\omega) = 0$. For relatively simple topologies, it will be possible to carry out an analytical calculation of the oscillator steady state V_0, ω_0 [4], as well as an evaluation of the oscillation startup and stability conditions (to be shown later). Conversely, it will be possible to impose the desired oscillation solution V_0, ω_0 and determine the values of two circuit elements η_1, η_2 , so as to satisfy $Y_T(\eta_1, \eta_2) = 0$. However, when multiple nonlinearities are present,

as is the case with the transistor devices, the overall calculation of Y_N is demanding. It requires an individual describing function for each nonlinear element. Thus, all the nonlinear elements should be replaced with their describing functions. The technique is described in detail in Ref. 3. Due to the complexity of the circuit equations, a numerical resolution of the steady state equation $Y_T(V, \omega) = 0$ or $Y_T(\eta_1, \eta_2) = 0$ will generally be necessary. An example is presented in the following paragraphs.

A simple sweep technique can be used for an oscillator design at ω_0 , with specified output power P_o . It is assumed that the values of terminal and feedback element, ensuring that $G_N(V \cong 0, \omega_0) < 0$ have already been determined using the technique described in Section 3.2.1. Then a sweep in V is carried out, tracing both the real and imaginary parts of Y_N versus this variable. In Fig. 14, the technique is applied to the MESFET oscillator. If the goal is to obtain an oscillation at V_0, ω_0 , a load admittance Y_L such that $G_L(\omega_0) = -G_N(V_0, \omega_0)$ and $B_L(\omega_0) = -B_N(V_0, \omega_0)$ should be chosen.

The design for specified output power P_o is carried out by adding the curve $-G_L = -(2P_o/V^2)$ to the representation of Fig. 14. Two different curves, $-G_{L1}(V)$ and $-G_{L2}(V)$, have actually been considered, respectively corresponding to the output power $P_o = 7$ dBm and $P_o = 9.16$ dBm. In the case of $-G_{L1}(V)$, two different intersection points are obtained with $-G_N(V_0, \omega_0)$. The first intersection point, with $V = 0.33$ V requires the load resistance $R_L = 1/G_L = 10.87 \Omega$. This low value is impractical for circuit implementation. The second intersection point, with $V = 0.78$ V, requires a load resistance $R_L = 62.5 \Omega$, which is much better suited for implementation. Thus, the second intersection point is kept for the design.

The nonlinear susceptance varies from $B_N = 0.11$ mho, in small signal, to $B_N = 0.073$ mho, at the desired oscillation point. Thus, the required susceptance value of the

Figure 14. Approximate nonlinear design for specified output power, based on an amplitude sweep.

oscillator load will be $B_L = -0.073$ mho, which can be obtained with a parallel inductance, of value $L = 0.4845$ nH. Of course, for this design to be valid, the oscillation start-up conditions must still be fulfilled, with these load values, and the steady-state oscillation must be stable.

3.3. Steady-State Design Using CAD Tools

Provided HB software and a nonlinear model for the transistor device are available to the designer, an accurate oscillator synthesis can be carried out. The synthesis technique relies on the use of auxiliary generators, whose helpfulness for the analysis and design of oscillator circuits has been demonstrated in a number of works [4,8,16]. The auxiliary generator enables the evaluation of the impedance or admittance functions on which the oscillator synthesis is based.

The design using admittance equations requires an auxiliary generator of voltage type. This generator, of amplitude V_{AG} , is connected in parallel at the circuit node, at which the observation port is defined. In the case of the oscillator of Fig. 10, it would be connected between port 2 and ground, as shown in the sketch in Fig. 15. The auxiliary generator frequency will be ω_{AG} , while its phase, for the analysis of free-running oscillator circuits, may be ar-

bitrarily set to zero $\phi_{AG} = 0$. The voltage generator is connected in series to an ideal bandpass filter, exhibiting zero impedance at $\omega = \omega_{AG}$ and an infinite impedance at $\omega \neq \omega_{AG}$. The objective of this filter is to prevent the voltage generator from short-circuiting the frequency components different from $\omega = \omega_{AG}$.

Four different applications of the auxiliary generator technique to oscillator synthesis are presented next.

3.3.1. Approximate Nonlinear Design. The auxiliary generator enables a straightforward application of the approximate design technique described in Section 3.2.2 on HB software. Through simple Kirchhoff analysis, the ratio $Y_{AG} = I_{AG}/V_{AG}$, with I_{AG} entering the circuit, agrees with the sum $Y_N(V_{AG}, \omega_{AG}) + Y_L(\omega_{AG})$. As in the previous section, it is assumed that the values of terminal and feedback elements provide $G_N(V \cong 0, \omega_0) < 0$. For the approximate nonlinear design, the auxiliary generator frequency is $\omega_{AG} \equiv \omega_0$. Then, the transistor port 2 is loaded with a large resistor R , such that $Y_T(V, \omega) = Y_N + 1/R \cong Y_N(V, \omega)$ (see Fig. 15). A HB analysis is performed, sweeping the auxiliary generator amplitude from a small value to a few volts. The curves $\text{Re}(Y_{AG}(V, \omega_0))$ and $\text{Im}(Y_{AG}(V, \omega_0))$ are traced versus V . To obtain an oscillation at V_0, ω_0 , the load values $G_L = -\text{Re}(Y_{AG}(V_0, \omega_0))$ and $B_L(\omega_0) = -\text{Re}(Y_{AG}(V_0, \omega_0))$ should be selected. For specified output power, the curve $-G_L = -(2P_o/V^2)$, must be superimposed, which will enable an approximate design in the same manner as in Section 3.2.2.

3.3.2. Nonlinear Analysis. After implementation of the load circuit resulting from the approximate technique described in Section 3.3.1, the accuracy of the oscillator design is verified through a HB simulation. A sufficiently high number of harmonic components must be considered. Now, the auxiliary generator admittance function will be $Y_{AG} = Y_N + Y_L$, at $\omega = \omega_{AG}$, and $Y_{AG} = 0$ at $\omega \neq \omega_{AG}$, due to the ideal-filter action. If good accuracy has been obtained in the oscillator design, the ratio Y_{AG} , for $\omega_{AG} \equiv \omega_0$ and $V_{AG} \equiv V_0$, will be close to zero, $Y_{AG}(V_0, \omega_0) \cong 0$. Note that the harmonic termination mismatches will prevent the fulfilment of this oscillation condition.

The actual oscillator solution is obtained through the calculation/optimization of V_{AG}, ω_{AG} , in order to satisfy $Y_{AG} = 0$. This condition avoids the degenerate DC solution,

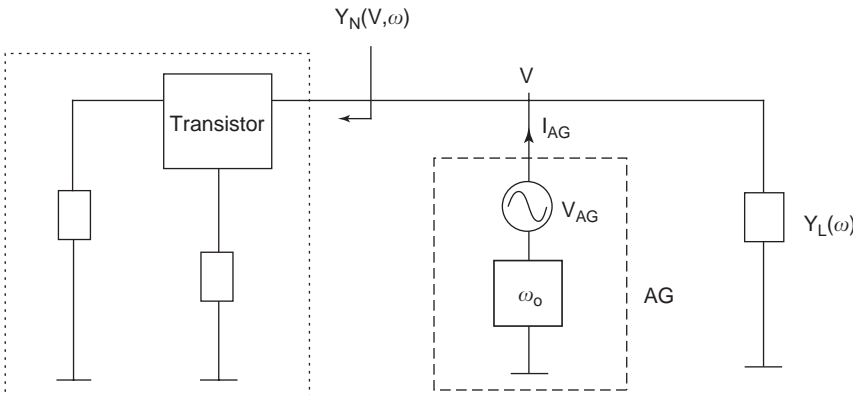

Figure 15. Auxiliary generator for oscillator analysis and design.

with $V_{AG} = 0$, that always coexists with the oscillating one. The condition $Y_{AG} = 0$ will be fulfilled for a first-harmonic amplitude V_0' and frequency ω_0' , where the prime signs point out the fact that the actual oscillation amplitude and frequency are different from those imposed at the design stage. Note that this approximate design was carried considering only one-harmonic component in the simulations. In the case of the MESFET oscillator, the oscillation frequency changes from $f_0 = 4.5$ GHz to $f_0' = 4.513$ GHz and the output power changes from $P_0 = 7$ dBm to $P_0' = 7.8$ dBm.

3.3.3. Nonlinear Optimization. The auxiliary generator can be used for a nonlinear optimization of the oscillator circuit, avoiding the shift from (V_0, ω_0) in the approximate design, to (V_0', ω_0') in the actual oscillator solution, when all the harmonic components are taken into account. For this purpose, the auxiliary generator amplitude and frequency are respectively set to $V_{AG} = V_0$ and $\omega_{AG} = \omega_0$. Then, two circuit elements η_1, η_2 , are optimized and/or calculated so as to satisfy $Y_{AG}(\eta_1, \eta_2) = 0$. This enables an accurate nonlinear design for prefixed oscillation power P_0 and frequency ω_0 .

The auxiliary generator technique is very useful for the sequential introduction of accurate models of the oscillator elements. It can be applied for the transmission-line implementation of lumped elements, avoiding any undesired shift of the oscillation frequency. This is done on an element-by-element basis. At each stage, the geometric dimensions of the new distributed element, length (l) and width (w), for instance, are optimized/calculated so as to fulfill $Y_{AG}(l, w) = 0$, with the auxiliary generator operating at the desired values $V_{AG} = V_0$ and $\omega_{AG} = \omega_0$. Accurate models for varactor diodes and packaged inductors or capacitors can also be progressively introduced, in a similar manner.

The technique described above has been used for the microstrip-line implementation of the terminal and load inductances of the MESFET oscillator (see Fig. 16a). In the MESFET oscillator, it has been used for the introduction of the DC block and feedback capacitor models, avoiding the shift of the oscillation frequency. The final oscillator solution, at exactly $f_0 = 4.5$ GHz, is shown in Fig. 16b, together with the experimental values.

3.3.4. Efficiency Maximization. The oscillator efficiency is defined as the ratio between the output power at ω_0 and the DC consumption: $E_{ff} = P_0/P_{DC}$. When high efficiency is required, a specific design technique is necessary to take this characteristic into account. The value of the oscillator load at different harmonic components has relevant influence on the efficiency, as shown by several authors [30,31]. Load pull can be used for the optimum selection of the harmonic impedances.

The load-pull system is implemented on HB software (see Fig. 17a). The load, at each harmonic component $n = 1 \dots N$, consists of an ideal bandpass filter, centered at $n\omega_0$ and terminated in a reflection coefficient $\Gamma_n = \rho_n e^{j\theta_n}$. The use of reflection coefficients is more convenient than the use of impedances or admittances, since all the possible passive terminations can be taken into account in the two

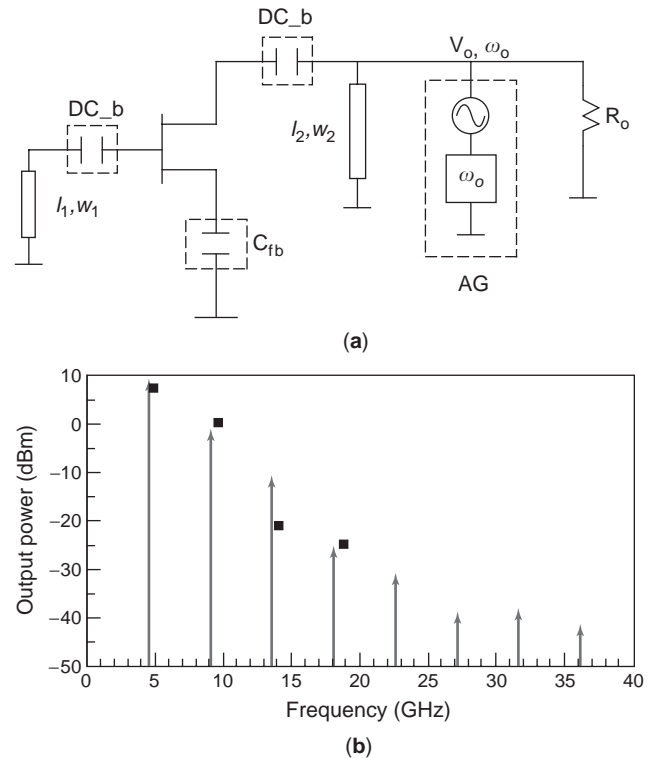

Figure 16. Oscillator circuit implemented on microstrip line using the auxiliary generator technique—accurate models have also been introduced for the packaged elements: (a) schematic; (b) output spectrum, with inclusion of experimental results.

bounded sweeps $\rho_n = 0 \dots 1$ and $\theta_n = 0 \dots 360^\circ$. The process starts with determination of the Γ_1 value, for maximum efficiency, when short-circuiting the higher harmonic terms, by making $\Gamma_n = 1 e^{j\pi}, n = 2 \dots N$. Note that, even when using these short-circuit terminations, the harmonic current still circulates inside the transistor device, as the i_{ds} current source is not short-circuited.

The optimum Γ_1 is determined through a double sweep in ρ_1, θ_1 . The auxiliary generator is maintained at the desired oscillation frequency ω_0 . The reactive feedback and terminal elements are calculated and/or optimized for each Γ_1 variation, in order to fulfill $Y_{AG} = 0$. Of course, because of the autonomous nature of the circuit, no solution will exist, for some Γ_1 values. Once the optimum Γ_1 has been determined, the influence of the higher-harmonic loads is analyzed, through consecutive sweeps, in the phases $\theta_2, \theta_3, \dots$. An example of application is shown in Fig. 17b, where the arrows indicate the order of the sweeps. The multiharmonic load will have to be implemented with a single passive network. An example of this implementation will be shown later, in Section 5.3. The fulfillment of the oscillation startup conditions must be verified for the final design.

3.4. Voltage-Controlled Oscillator

In a voltage-controlled oscillator (VCO), the oscillation frequency is tuned by modifying the bias voltage of a varactor diode. In reverse bias, the varactor diode is

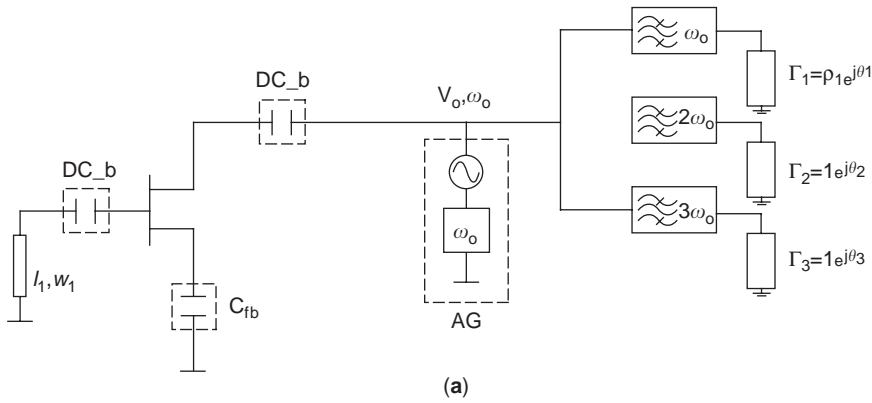

Figure 17. Load-pull system for maximization of the oscillator efficiency: (a) circuit schematic, with an ideal harmonic load; (b) maximization of the oscillator efficiency through the optimum selection of the harmonic loads.

essentially a voltage-dependent junction capacitance $C_j(v)$, in series with a loss resistance R_s . The junction capacitance varies according to $C_j(v) = C_{j0}/(1 - v/\phi_0)^{\gamma}$, where ϕ_0 is the built-in potential and C_{j0} is the capacitance value for zero bias voltage. The largest capacitance value is $C_{max} \cong C_{j0}$ and the region of maximum sensitivity corresponds to relatively small reverse-bias voltages.

The practical variation range is limited to $[C_{min} - C_{max}]$. With this given range, a simple technique can be applied to maximize the frequency-tuning interval [28]. The technique will be illustrated by means of its application to the FET oscillator circuit. The varactor diode is connected to a transistor terminal different from the one at which the series feedback is introduced. For source series feedback, it should be connected to the gate terminal, as the drain terminal provides the highest output power.

The transistor, together with the feedback and terminal elements, must exhibit negative conductance in a frequency interval containing the desired oscillation band (see Fig. 18a). For the approximate determination of this band, the small-signal susceptance $B(V \cong 0, \omega)$, seen from the varactor terminals, must be traced versus ω , together with the two straight lines $-C_{min}\omega$ and $-C_{max}\omega$. Then, the oscillation frequency interval is delimited by the two

intersection points of these two straight lines with the curve $B(\omega)$. This is shown in Fig. 18a, where the varactor diode has the capacitance variation range $C_{min} = 0.3 \text{ pF}$ to $C_{max} = 2 \text{ pF}$.

As shown in Ref. 28, the introduction of an inductor in parallel with $B(\omega)$ allows the flattening curve $B'(\omega) = B(\omega) - 1/(L\omega)$, which increases the frequency separation between the two intersection points. Provided the two points belong to the negative-resistance interval, a larger frequency-tuning range will be obtained. In Fig. 18a, the initial frequency bandwidth is $\Delta f = 734 \text{ MHz}$. After the introduction of the parallel inductance, the bandwidth increases to $\Delta f = 1.286 \text{ GHz}$. The nonlinear analysis of Fig. 18b, showing the variation of the oscillator frequency and power versus the varactor bias, confirms the validity of the technique. There is, however, a shift of the predicted band, due to nonlinear effects. The experimental values are in good agreement with the simulations.

3.5. Stability Analysis

As already mentioned, the startup condition (12), obtained from a small-signal impedance/admittance analysis, is, in

Figure 18. Design of a voltage-controlled oscillator: (a) method used to increase the frequency variation band, versus the varactor capacitance, through the introduction of an inductive element, in parallel; (b) frequency and output power variation versus the reverse bias voltage, obtained through a HB analysis. Experimental points are also included. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

fact, an instability condition of the DC solution. For a more rigorous analysis, a small-amplitude perturbation of complex frequency $\sigma + j\omega$ should be considered, in order to determine the value or number of unstable poles of the circuit linearization about the DC solution [4]. As already stated, for the oscillation startup, there must be a pair of unstable poles $\sigma \pm j\omega_0$, with $\sigma > 0$. Due to the complexity of the pole calculation, the Nyquist criterion is usually applied to the characteristic determinant associated with the linearized system.

The stability analysis of the steady-state oscillation is performed by considering a small-amplitude perturbation about this solution. The analysis is more difficult, due to the periodic nature of this steady-state regime. Two cases may be distinguished: a perturbation frequency satisfying $\omega = \omega_0 + \delta\omega$ and a perturbation frequency $\omega \neq \omega_0 + \delta\omega$. The first case enables the detection of instabilities giving rise to hysteresis phenomena. However, other instabilities,

such as the division by 2 of the fundamental frequency ω_0 or the onset of a second autonomous fundamental ω_a , nonharmonically related to the frequencies ω_0 , are also common.

The oscillator stability versus synchronous perturbations (fulfilling $\omega = \omega_0 + \delta\omega$) can be determined through the function proposed by Kurokawa [11]:

$$\xi = \frac{\partial G_T}{\partial V} \bigg|_0 \frac{\partial B_T}{\partial \omega} \bigg|_0 - \frac{\partial G_T}{\partial \omega} \bigg|_0 \frac{\partial B_T}{\partial V} \bigg|_0 \quad (14)$$

For $\xi > 0$, the solution will be stable against synchronous perturbations. For $\xi < 0$, it will be unstable. The stability function ξ can be easily evaluated with the aid of the same auxiliary generator that is used for the oscillator synthesis [32], the one satisfying $Y_{AG}(V_0, \omega_0) = 0$. The derivative calculation is carried out through increments in the two

variables V_{AG} and ω_{AG} , and the resulting values are introduced in (14). The stability condition can also be evaluated in a graphical manner. Defining the two vectors $\vec{Y}_v = [(\partial G_T/\partial V), (\partial B_T/\partial V)]_0$ and $\vec{Y}_\omega = [(\partial G_T/\partial \omega), (\partial B_T/\partial \omega)]_0$, the condition $\xi > 0$ is fulfilled for an angle $\vec{Y}_v \wedge \vec{Y}_\omega$ between 0 and 180°. In Fig. 19a, this condition is graphically verified for the MESFET oscillator circuit of Fig. 16a.

For the stability analysis when $\omega \neq \omega_0 + \delta\omega$, a small-amplitude perturbation of complex frequency $\sigma + j\omega$ should be considered, linearizing the HB equations about the steady-state periodic solution [4]. As already said, the free-running oscillator has a pair of complex conjugate poles, at the oscillation frequency $\pm\omega_0$. For stability, all the remaining

poles must have a negative real part. This may be verified by means of the Nyquist plot, tracing $\text{Im}[\det(\omega)]$ versus $\text{Re}[\det(\omega)]$, where $\det(\omega)$ is the determinant of the perturbed HB system. Since the oscillator system contains two poles at $\pm\omega_0$, the Nyquist plot of a stable oscillator solution must pass through the origin, without encircling it. This can be appreciated in the plot of Fig. 19b, showing the stability of the oscillator design of Fig. 16a.

The stability analysis of nonlinear regimes is seldom available in commercial HB. However, the user can perform this analysis externally, using auxiliary generators. For this purpose, a current generator of small amplitude I_p is introduced in parallel at a sensitive circuit node. The

Figure 19. Stability analysis of steady-state oscillation: (a) verification of the fulfillment of stability condition versus synchronous perturbations; (b) full stability analysis per the Nyquist stability criterion.

nonperturbing AG, used for the determination of the steady-state solution, is also maintained in the circuit, at the steady-state oscillation values $V_{AG} \equiv V_0$ and $\omega_{AG} \equiv \omega_0$. The frequency of the additional current generator is ω_p , nonharmonically related to ω_0 . This generator plays the role of a small perturbation and will enable the linearization of the circuit about its nonlinear steady-state regime. A two-tone HB analysis is carried out, at the frequencies ω_0 and ω_p , although only first-order terms are kept in ω_p , due to the smallness of the perturbation [34].

By calculating the relationship between the current delivered by the generator (and entering the circuit) and V_p , through two-tone HB, the circuit total admittance at the frequency ω_p is determined, performing $Y(\omega_p) = I_p/V_p$ [34]. Through a sweep in the perturbation frequency ω_p , the possible fulfillment of the instability condition $Re Y(\omega_p) < 0, Im Y(\omega_p) = 0$ can be checked. The fulfillment of this condition for a given ω_p would give rise to the establishment of a steady-state regime at the two frequencies: ω_0 and $\omega_a \cong \omega_p$.

Note that the technique described above generalizes the impedance/admittance analysis, used in (12) for the evaluation of the oscillation startup conditions, from a DC solution, to the case of a circuit operating in a large-signal periodic regime. This analysis may fail in the case of a reduced sensitivity at the auxiliary generator location or pole-zero cancellations. For a more rigorous analysis, pole-zero identification techniques [34] should be applied to the closed-loop transfer function $Y(\omega_p) = I_p/V_p$.

3.6. Phase Noise

Noise perturbations, originating at the circuit resistive elements and semiconductor devices, give rise to amplitude and phase noise in the oscillator signal. Due to the autonomy of the solution, the latter will have the biggest influence on the oscillator spectrum. The oscillation frequency depends on the values of the circuit elements and is modulated by the noise sources, which gives rise to phase noise [11,23]. In addition, the oscillator nonlinearity is responsible for the conversion to the carrier frequency of the noise perturbations about DC and the different harmonic components.

The oscillator phase noise is thus the result of two different phenomena: carrier frequency modulation, which is the dominant effect for small frequency offset from the carrier; and frequency conversion, as in a mixer, which is the dominant effect for relatively high offset. Thermal noise sources, in the resistive elements, and shot and flicker noise, in the transistor devices, should be considered [3]. The spectral density of flicker noise varies as $1/\Omega$. Because of its high amplitude for small Ω , it will have great influence on the oscillator spectrum.

Using the describing function, an approximate expression of carrier modulation noise can be derived. As usual, the oscillator is represented by the parallel connection of a linear block and a nonlinear block, with the latter modeled by its describing function. For simplicity, only white-noise sources about the oscillation frequency ω_0 will be considered. The oscillator solution is assumed $v(t) = V_0 \cos(\omega_0 t)$, and the steady-state equation of the noise-free oscillator is

$Y_T(V, \omega) = G_T + jB_T = 0$. Now, a current white-noise noise source will be introduced in parallel with the linear and nonlinear blocks. Assuming small-frequency perturbations, the steady-state oscillator equation may be expanded in a Fourier series about the steady-state oscillation solution, which provides the system

$$\begin{aligned} \frac{\partial G_T}{\partial V} \Big|_0 \Delta V(t) + \frac{\partial G_T}{\partial \omega} \Big|_0 \Delta \omega(t) &= \frac{I_{nr}(t)}{V_0} \\ \frac{\partial B_T}{\partial V} \Big|_0 \Delta V(t) + \frac{\partial B_T}{\partial \omega} \Big|_0 \Delta \omega(t) &= \frac{I_{ni}(t)}{V_0} \end{aligned} \tag{15}$$

where $I_{nr}(t)$ and $I_{ni}(t)$ respectively represent the real and imaginary parts of the white-noise current, averaged over one period [11]. The time derivative of the amplitude increment is ignored in (15). As can be appreciated, the oscillator carrier becomes modulated by the noise sources.

To determine the oscillator phase noise, the previous linear system is solved for $\Delta \omega(t)$. Then the Fourier transform is calculated, also taking into account $\Delta \phi(\Omega) = \Delta \omega(\Omega)/(j\Omega)$. This provides the equation

$$\Delta \phi(\Omega) = \frac{G_v B_n(\Omega) - B_v G_n(\Omega)}{j\Omega(G_v B_\omega - G_\omega B_v)} \tag{16}$$

where $Y_v \equiv (\partial Y_T/\partial V)|_0$ and $Y_\omega \equiv (\partial Y_T/\partial \omega)|_0$, and G and B respectively stand for the real and imaginary parts of these quantities. Note that these derivatives are calculated at the steady-state unperturbed oscillation and agree with those already used in (14) to evaluate the oscillator stability. For calculation of the phase noise spectral density, multiplication of (16) by $\Delta \phi^*(\Omega)$ is necessary. The following expression is obtained:

$$|\Delta \phi(\Omega)|^2 = \frac{|I_n|^2(G_v^2 + B_v^2)}{\Omega^2 V_0^2 (G_v B_\omega - G_\omega B_v)^2} \tag{17}$$

where equal phase noise spectral density has been assumed at both sidebands. Note that the validity of (17) is restricted to small-frequency offset from the oscillator carrier. In agreement with the predictions by Leeson's model [3], white noise contributes as $1/\Omega^2$. On the other hand, an essential contribution to the denominator of (17) is the derivative B_ω . This derivative increases with the load quality factor Q , so, for larger Q , smaller phase noise should be obtained.

The reader can easily verify that the carrier modulation by the $1/\Omega$ noise is due essentially to the derivatives $\partial G_T/\partial V_{dc}$ and $\partial B_T/\partial V_{dc}$ and, contributes as $1/\Omega^3$. To obtain this result, the steady-state solution $v(t) = V_{DC} + V_0 \cos(\omega_0 t)$ must be assumed, formulating the steady-state equations at DC and the first harmonic component.

The HB analysis of the carrier modulation noise requires a mixed-mode formulation. In this formulation, the oscillation frequency ω_0 is added to the set of unknowns, which now becomes \vec{V} , ω_0 [23]. To balance the equations, and due to the oscillator autonomy, the real or imaginary part of one of the components of \vec{V} is arbitrarily set to zero.

In the presence of noise perturbations, the system becomes

$$\begin{bmatrix} \frac{\partial \bar{\mathbf{E}}}{\partial \bar{\mathbf{V}}} \end{bmatrix}_0 \Delta \bar{\mathbf{V}}(\Omega) + \begin{bmatrix} \frac{\partial \bar{\mathbf{E}}}{\partial \omega} \end{bmatrix}_0 \Delta \omega_0(\Omega) = \bar{\mathbf{I}}_n(\Omega) \quad (18)$$

where $\bar{\mathbf{E}}(\bar{\mathbf{V}}, \omega)$ is the vector of HB errors and $\bar{\mathbf{I}}_n(\Omega)$ is the vector containing the frequency descriptions of the noise currents. The calculation of the phase noise spectral density requires solving for $\Delta \omega_0(\Omega)$ and multiplying by the adjoint $\Delta \omega_0^*(\Omega)$, to be able to introduce the spectral densities and correlations of the noise sources $\bar{\mathbf{I}}_n(\Omega) \cdot \bar{\mathbf{I}}_n^*(\Omega)$. To obtain the phase noise, the relationship $\Delta \phi(\Omega) = \Delta \omega_0(\Omega) / (j\Omega)$ must also be taken into account. It must be emphasized that this phase noise calculation is valid only for small frequency offset Ω from the carrier. For larger frequency offset, the conversion matrix approach should be applied [24].

For the phase noise analysis of the VCO, a flicker noise source has been considered, in parallel with the gate terminal. In Fig. 20a, the function $B_T(\omega)$, at the same location, is represented for three different values of the varactor bias voltage: $V_b = 0, 4, 8$ V. In each case, the zero value of the frequency increment corresponds to the steady-state oscillation. The highest slope, indicating the largest quality factor, is obtained for $V_b = 4$ V, in the middle of the oscillation band. Figure 20b shows the phase noise spectral density, calculated through the carrier modulation approach. As can be seen, the lowest phase noise is obtained for $V_b = 4$ V. The experimental phase noise values were -86 dBc, at 100 kHz frequency offset, for $V_b = 4$ V and -79 dBc, at the same offset, for $V_b = 0$ V.

4. FREQUENCY DIVIDERS

4.1. General Concepts about Frequency Dividers

The output signal of a frequency divider [37] satisfies the relationship $\omega_{\text{out}} = \omega_{\text{in}}/N$, where ω_{in} is the input generator frequency. The frequency dividers are used mostly in the feedback loops of frequency synthesizers, to obtain a signal in the order of the reference frequency, whose phase will be comparable with that of the reference oscillator. A high-frequency signal can also be divided to be easily amplified and then multiplied again, to the original frequency range. Another possible application is the demodulation of FM signals with high modulation index and the demodulation of the PSK signals.

There are digital and analog dividers. The digital dividers, also called “static”, are based on logic circuits operating as cycle counters [37]. They perform the frequency-division cycle by cycle and enable broad division band. The basic divide-by-2 configuration uses a flip-flop, with feedback, to produce one output cycle for every two cycles of the input signal. The ripple counters, based on a chain connection of flip-flops, register the number of applied pulses in a binary form, which allows frequency division by the order $N = 2^n$, where n is the number of stages. The implementation of the logic gates requires a high number of transistors. Thus, the static dividers

typically contain many transistor devices. In contrast, the analog frequency dividers, also called “dynamic” [7], can be achieved with very small number of devices. They make use of phenomena inherent to the nonlinear dynamics of injected oscillators, nonlinear reactances or regenerative feedback configurations. The small number of devices enables lower phase noise than the static dividers. The disadvantage, compared to these dividers, is the narrow frequency bandwidth.

The three main types of analog dividers are parametric dividers, regenerative dividers and harmonic injection dividers. Their principles are briefly introduced in the following paragraphs.

4.1.1. Parametric Dividers. Parametric dividers make use of the capabilities of a nonlinear reactance to exhibit negative resistance under strong pumping from a periodic external source at a given frequency ω_{in} [38]. The negative resistance usually appears about $\omega_{\text{in}}/2$, which, together with a resonance at this frequency, gives rise to the establishment of a divide-by-2 solution. Actually, one of the main types of instability of a nonlinear periodic regime is the division by 2 of the fundamental frequency. A typical example of parametric division is the frequency division by 2 obtained through the pumping of a N varactor diode, with very nonlinear capacitance about $V = 0$ [38].

4.1.2. Regenerative Dividers. The operation of regenerative dividers can be represented with the feedback system of Fig. 21 [39], where a relatively high input generator amplitude E_{in} gives rise to a nonlinear steady-state regime at the delivered frequency ω_{in} . From certain input amplitude $E_{\text{in}0}$, the system instability at $\omega_0 \cong \omega_{\text{in}}/N$, plus the harmonic synchronization $N\omega_0 = \omega_{\text{in}}$, enable the frequency division by order N . This instability is favored by the feedback at $(N-1)\omega_0$ and the mixer action, which gives rise to a difference frequency term at ω_0 .

4.1.3. Harmonic Injection Dividers. The harmonic injection divider by N is basically an oscillator, whose N th-order harmonic $N\omega_0$ synchronizes with an external source [8]. In contrast with the parametric and regenerative dividers, harmonic injection dividers exhibit a self-oscillation in the absence of input signal. Since an oscillation signal with frequency in the order of the desired output frequency is already available, they enable frequency division from very low input power.

As can be gathered from the paragraphs above, the analog frequency dividers have an inherently autonomous nature, which makes them their synthesis difficult. Here nonlinear design techniques for analog dividers, based on the use of transistor devices, will be presented. Two main types of dividers will be studied: the regenerative divider and the harmonic injection divider.

4.2. Design of FET-Based Regenerative Frequency Dividers

Let the regenerative divider of Fig. 21 be considered. The instability conditions of the regime at ω_{in} , giving rise to the onset of $\omega_0 \cong \omega_{\text{in}}/N$, will be $|H(E_{\text{in}}, \omega_0)| > 1$ and $\angle H(E_{\text{in}}, \omega_0) = 2k\pi$, where H is the closed-loop transfer

Figure 20. Phase noise analysis of the VCO: (a) variation of $B_T(\omega)$ about the oscillation frequency for three different values of the varactor bias, $V_b = 0$ V, 4 V, and 8 V; (b) analysis of phase noise spectral density with the carrier modulation approach.

function. These instability conditions will be fulfilled from a certain input amplitude E_{in0} . As appreciated in Fig. 21, the key elements for the onset of ω_0 are the feedback at

Figure 21. Operation principle of a regenerative frequency divider.

$(N - 1)\omega_0$ and the mixing of this frequency with the generator frequency at ω_{in} .

When using a FET transistor for the divider design, this device will perform both the mixing and amplification functions [7,40]. The transistor should be biased near pinchoff, where advantage can be taken of the quasiquadratic $I_{DS}(V_{GS})$ characteristic to efficiently perform the mixing function. As gathered from Fig. 21, the regenerative division by order 2 requires no frequency multiplier in the feedback loop and thus is easier to implement.

Figure 22 shows a general schematic of a FET-based frequency divider by 2, with series feedback. The input filter ensures the matching of the generator frequency ω_{in} . The transistor feedback $\omega_{in}/2$ enables the self-generation of this component. Finally, the output filter ensures the

matching to the load of this divided frequency. A divider configuration using parallel feedback is also possible [4]. Note that if a frequency divider by N is desired, the passive feedback network must be replaced by a multiplier by $N - 1$. As will be shown in Section 5, this multiplier can be implemented by means of a second transistor at a suitable bias point, together with a bandpass filter, for the selection of the harmonic component $(N - 1)\omega_{in}/2$.

Unlike the harmonic injection dividers, to be shown later, the regenerative divider does not oscillate in the absence of input generator signal. The quenching of the free-running oscillation may be achieved by reducing either the feedback amount or the transistor gain at $\omega_{in}/2$ [40]. It is generally more practical to limit the gain through a suitable selection of the transistor gate bias voltage. Let V_{GS0} be the threshold V_{GS} value, below which no oscillation is observed. The transistor must be biased with $V_{GS} < V_{GS0}$. Then, for relatively small input generator amplitude, the transistor gain is not sufficient to satisfy the instability conditions at $\omega_{in}/2$. As the input generator amplitude E_{in} increases, a larger fraction of the solution period satisfies $v_{GS}(t) > V_{GS0}$. Then, a threshold value E_{in0} may be reached, such that, for $E_{in} > E_{in0}$ the transistor gain at $\omega_{in}/2$ is large enough to fulfill the instability conditions $|H(E_{in}, \omega_{in}/N)| > 1$ and $\angle H(E_{in}, \omega_{in}/N) = 2k\pi$.

The instability condition for $E_{in} > E_{in0}$ may also be written in terms of the total admittance Y_T , at a sensitive circuit node (see Section 3). Note that it is the same function that had already been used for oscillator analysis and design. The regenerative divider will satisfy the following conditions:

$$\left. \begin{aligned} G_T(E_{in}, \frac{\omega_{in}}{2}) > 0 \\ B_T(E_{in}, \frac{\omega_{in}}{2}) = 0 \end{aligned} \right\} \text{for } E_{in} < E_{in0} \quad (19)$$

$$\left. \begin{aligned} G_T(E_{in}, \frac{\omega_{in}}{2}) < 0 \\ B_T(E_{in}, \frac{\omega_{in}}{2}) = 0 \end{aligned} \right\} \text{for } E_{in} > E_{in0}$$

Note that the resonance condition is easily satisfied, since the output filter and feedback networks are centered at this frequency.

The auxiliary generator technique, presented in Section 3, can be used for the evaluation of the conditions in (19). A voltage auxiliary generator, of small amplitude $V_{AG} = \varepsilon$ and frequency $\omega_{AG} = \omega_{in}/2$, is connected in parallel at a circuit node, while maintaining the input generator at the values E_{in}, ω_{in} . Then, the ratio between the current flowing through the AG (and entering the circuit) and the delivered voltage $Y_{AG} = I_{AG}/V_{AG}$ will agree with $Y_T = G_T + jB_T$. In contrast with the oscillator analysis, the AG phase ϕ_{AG} will now be a sensitive variable [4,41]. As shown in Ref. 42, the input amplitude threshold for the onset of the frequency division by 2 can be obtained through a double sweep in E_{in} and ϕ_{AG} , with the latter ranging between 0 and 180° .

Some efforts have been devoted to increasing the frequency bandwidth of the regenerative dividers. As an example, in Refs. 7 and 41, the input filter at ω_{in} is replaced by an amplifier at the same frequency, with broader bandwidth than the one expected for the frequency divider. The circuit elements are also tuned in a small-signal analysis, in order to decrease the frequency selectivity of the circuit, through a reduction of the positive slope $(\partial B_T/\partial \omega)|_{\omega_{in0}/2}$, where ω_{in0} is the central value of the input frequency band.

The HB simulation of frequency dividers is presented in detail in the NONLINEAR CIRCUIT ANALYSIS article, so only the essential aspects will be pointed out here. The major difficulty in this simulation comes from the coexistence of the frequency-divider solution at $\omega_{in}/2$, with a trivial solution, at the input generator frequency ω_{in} . The same auxiliary generator, used for the evaluation of (18), can be used to avoid undesired convergence to the solution at ω_{in} . The nonperturbation conditions will be as follows [4]:

$$\begin{aligned} Y_{AG}^r(V_{AG}, \phi_{AG}) &= 0 \\ Y_{AG}^i(V_{AG}, \phi_{AG}) &= 0 \end{aligned} \quad (20)$$

with $\omega_{AG} = \omega_{in}/2$. To obtain the frequency-division band versus the input generator frequency ω_{in} for given input power P_{in} , a sweep will be carried out in ω_{in} , calculating, at each sweep step, the auxiliary generator amplitude and phase V_{AG}, ϕ_{AG} .

As in the case of oscillator circuits, the AG technique can also be applied for the design of the frequency dividers. It will be possible to prefix the AG amplitude $V_{AG} \equiv V_{AG0}$ and input generator value E_{in}, ω_{in} and calculate and/or optimize two circuit parameters η_1, η_2 , together with ϕ_{AG} , in order to fulfill $Y_{AG} = 0$.

The auxiliary generator technique has been applied for a design of a frequency divider by 2, with 6 GHz input frequency. The MESFET transistor is biased with $V_{DS} = 3$ V and $V_{GS} = -1.5$ V, near pinchoff. In agreement with the block diagram in Fig. 22, the three main linear components of this divider circuit are an input filter at ω_{in} , an output filter at $\omega_{in}/2$, and a series feedback network at $\omega_{in}/2$. The simulation, for constant input power $P_{in} = 3.5$ dBm, is shown in Fig. 23a. The curve has been traced in terms of the average harmonic value. The undesired solution at ω_{in} can be observed. This solution is unstable between the two frequency values F_1 and F_2 and is stable outside this frequency interval. Figure 23b shows a comparison between simulated and experimental results, in terms of the output power.

4.3. Design of FET-Based Harmonic Injection Dividers

As already mentioned, the harmonic injection divider is basically an oscillator with one of its harmonic components synchronized with the input signal [4,8]. In contrast to the regenerative dividers, the circuit oscillates in the absence of input power. Using the block diagram of the regenerative divider (Fig. 21), a harmonic injection divider can also be obtained, if the system exhibits an oscillation at about ω_{in}/N , in the absence of input signal. In this case,

Figure 22. Block diagram of a FET-based analog frequency divider by 2.

the division can be achieved from very low input power, through the synchronization of the N th-harmonic component of the self-oscillation with the input source. However, harmonic injection division can be obtained from much simpler topologies than the one in Fig. 21. Actually, any oscillator circuit can be used for this kind of division, since the harmonic synchronization is a natural nonlinear phenomenon occurring in all oscillatory systems excited by a

periodic external source. The problem is that, unless a careful design is carried out, the synchronization bandwidth may be extremely narrow. The bandwidth also decreases with the division order N .

The frequency-division band of a harmonic injection divider can be approximately predicted by means of the describing function. Prior to the connection of the input generator, at the harmonic frequency, the circuit

(a)

(b)

Figure 23. Analysis of a frequency divider by 2, with 6 GHz input frequency: (a) coexistence of divider solution with a nondivided solution at input generator frequency; (b) output power variation in frequency-division band, with measurements superimposed.

is assumed to behave as a free-running oscillator, fulfilling the steady-state oscillation condition, $Y_T = Y_N(V_0, \omega_0) + Y_L(\omega_0) = 0$, where Y_N is the describing function. Under the influence of the harmonic generator $i_g(t)$, the oscillation amplitude will become V_s and the oscillation frequency will be ω_s , satisfying the relationship $\omega_{in} = N\omega_s$, where ω_{in} is the input generator frequency. For the determination of the frequency-division band, the input current generator will be expressed as $i_g(t) = \text{Re}(I_g e^{j(\omega_{in} + \phi)t})$, where ϕ is the opposite of the phase shift between node voltage at ω_s and the input generator. The equation for the harmonic injection divider will be [8]:

$$Y_T(V_s, \omega_s, I_g e^{j\phi}) V_s e^{j0} = 0 \quad (21)$$

For small input amplitude I_g , a Taylor series expansion about the free-running oscillation point ($V_0, \omega_0, I_g = 0$) can be carried out

$$\begin{aligned} & \frac{\partial Y_T}{\partial V_0} \Delta V_s + \frac{\partial Y_T}{\partial \omega_0} \Delta \omega_s \\ & = - \left. \frac{\partial Y_T}{\partial I_g} \right|_0 I_g \cos \phi - \left. \frac{\partial Y_T}{\partial I_g} \right|_0 I_g \sin \phi \end{aligned} \quad (22)$$

with $\Delta \omega_s = \omega_s - \omega_0$ and $\Delta V_s = V_s - V_0$. The solution of (22) is an ellipse in the plane defined by ω_s and V_s , centered about the free-running oscillation point ω_0, V_0 . The infinite-slope points of the synchronization ellipse determine the frequency-division bandwidth [4,8]. This bandwidth is given by twice the maximum value of the increment $\Delta \omega_s$ versus the phase shift ϕ , in (22). Assuming a simplified dependence $Y_T = Y_r(V) + Y_i(\omega)$, the division bandwidth by order N can be approached: $\Delta \omega_N = I_g |\partial Y_i / \partial I_g|_0 \omega_0 / (Q G_L)$, where Q is the quality factor and G_L is the load resistance.

As in the case of regenerative dividers, the HB analysis of harmonic injection dividers by order N is carried out by means of an auxiliary generator at $\omega_{AG} \equiv \omega_{in}/N$, with phase ϕ_{AG} and amplitude V_{AG} [4,8]. If variation of a parameter is considered (e.g., the input frequency ω_{in}), the solution

curves are obtained by sweeping ϕ_{AG} , between 0 and $2\pi/N$, and calculating V_{AG} and the particular parameter at each sweep step, in order to fulfill $Y_{AG} = 0$.

Figure 24 shows the schematic of a harmonic injection divider by $N=4$, with 18 GHz input frequency. Source feedback (with the inclusion of a varactor diode) is used to achieve the free-running oscillation. A bias point V_{GS1}, V_{DS1} is initially selected, fitting the gate circuit so as to obtain negative resistance at the drain terminal about the required oscillation frequency $f_0 = 4.5$ GHz. To complete the oscillator design, a load circuit, enabling resonance at f_0 , is introduced at the drain port.

For the divider design, an auxiliary generator is introduced at the desired oscillation frequency and amplitude $\omega_{AG} \equiv \omega_0$ and $V_{AG} \equiv V_0$. Then, the load circuit is optimized so as to fulfill the nonperturbation condition $Y_{AG} = 0$. The bias point is also tuned, in order to increase the gate voltage magnitude at the harmonic component $(N-1)\omega_0$, which, for the divider by $N=4$, corresponds to $3\omega_0$. The closed synchronization curves obtained when the input-generator is connected are shown in Fig. 25a, where different values of input generator power have been considered. Experimental points are shown in Fig. 25b.

As already mentioned, harmonic injection dividers usually exhibit narrow synchronization bandwidth. In a 1999 study [43], injection-locking, phase-locking techniques [8] have been applied to increase the operation bandwidth of harmonic injection dividers. The techniques rely on the use of a low-frequency feedback loop, which is added to the already designed harmonic injection divider (Fig. 24). The loop allows the use of the low-frequency intermodulation term $|f_{in} - Nf_0|$, provided by the $I_{DS}(V_{GS})$ nonlinearity, to increase the sensitivity to the input generator and thus enlarge the synchronization bands.

The intermodulation term $|f_{in} - Nf_0|$ gives rise to a low-frequency error voltage $v_D(t)$ at the transistor drain terminal. This signal is extracted through a choke (see Fig. 24) and amplified in the feedback loop. The differential amplifier compares the low-frequency signal extracted from the drain terminal with a DC reference voltage. The amplifier output is connected to the varactor diode, and

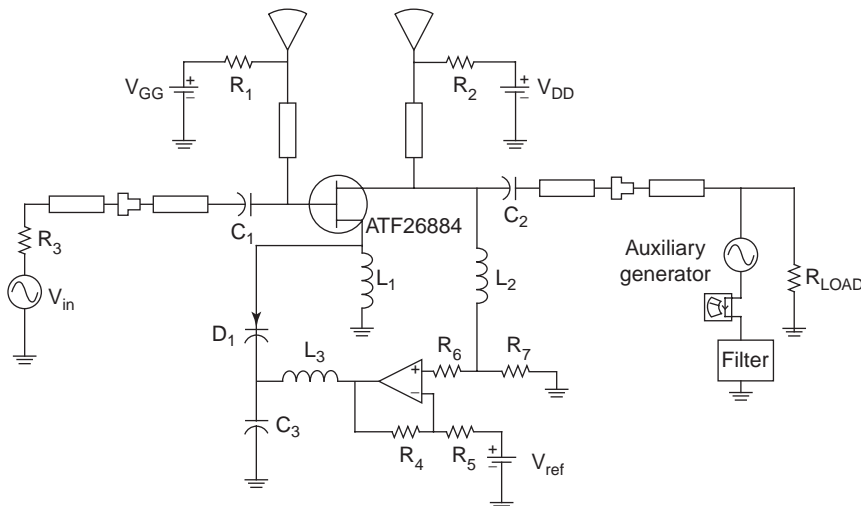

Figure 24. Harmonic injection divider by order $N=4$. The external low-frequency loop is introduced to increase the synchronization bandwidth through the combination of injection-locking and phase-locking effects [8,43].

this modifies the self-oscillation frequency so as to decrease the frequency error, as in a phase-locked oscillator. Thus, phase-locking techniques and harmonic injection are combined to increase the frequency-division bands. The enlargement of the synchronization bandwidth depends on the voltage gain G_a of the DC amplifier and the phase shift that this amplifier introduces in the low-frequency feedback signal [8,43].

In the case of the frequency divider studied here, the output of the feedback loop is connected to the cathode of the varactor diode. The application of the injection-locking, phase-locking technique enables, as shown in Fig. 25a, a substantial enlargement of the synchronization bandwidth. Measurements are shown in Fig. 25b.

5. FREQUENCY MULTIPLIERS

5.1. General Concepts about Frequency Multipliers

The signal generation is critical in communication systems, where high stability and low phase noise spectral density are required. At high frequencies, a common solution is the use of a low-noise source, at smaller frequency, and a frequency multiplier, to achieve the desired signal frequency ω_0 [10]. At the output, the phase noise spectral density roughly increases in $20 \log N$, where N is the multiplication factor, but, even so, the phase noise is generally lower than the one resulting from a direct oscillator design at ω_0 . More recent applications of multiplier circuits in communications systems include modulation

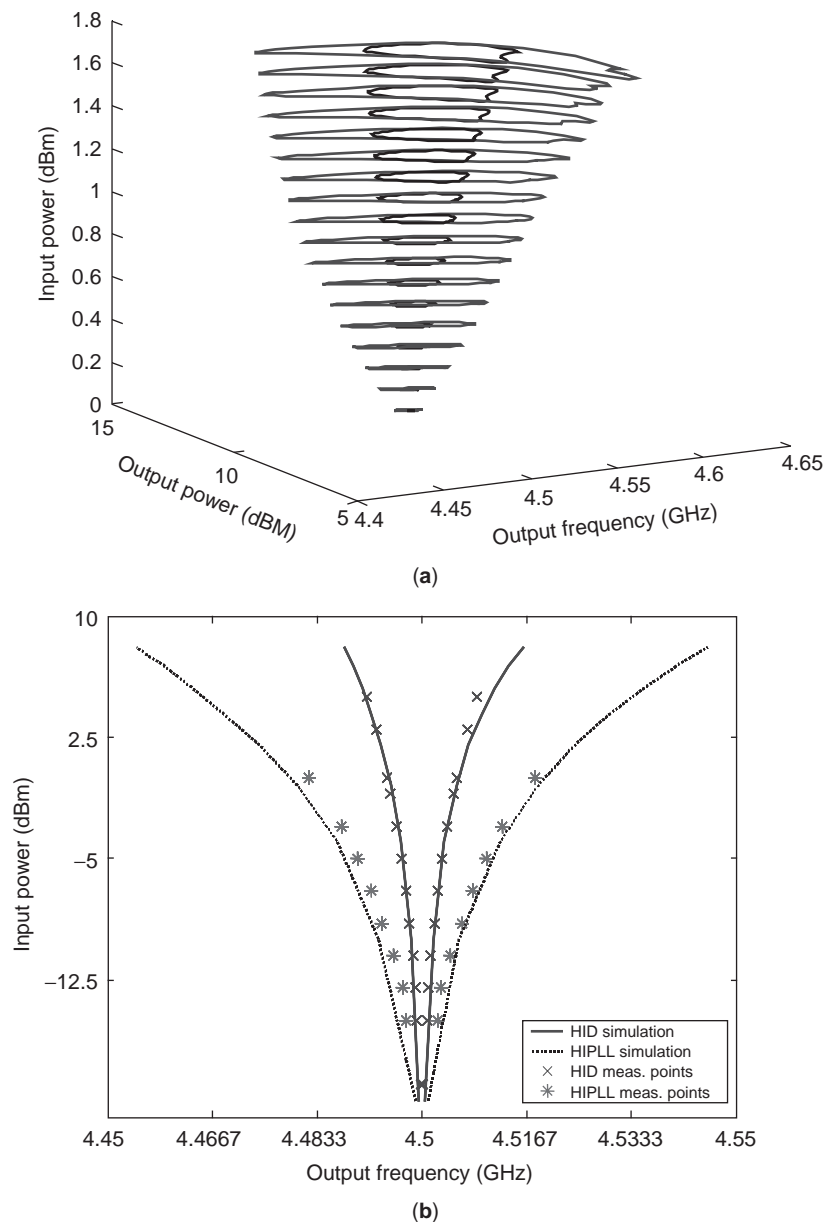

Figure 25. Response of the harmonic injection divider by $N=4$, with 18 GHz input frequency: (a) solution curves showing the frequency bandwidth for different values of the input generator power before and after the addition of the low-frequency feedback loop; (b) measurement of the synchronization bandwidth. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

and frequency translation. They can be used for direct modulation of FSK signals [44,45].

Frequency multipliers can be based on diodes or transistors. The diode multipliers enable a simple circuit design, with no need for biasing, and a broad operation band. Undesired harmonic components are suppressed through balanced configurations by phasing [9]. Unfortunately, conversion loss is high and thus frequency multipliers require high input power to achieve the necessary output power. The topologies employed may be difficult to integrate in the MMIC process. The transistor-based multipliers enable input-output isolation and are power-efficient. They are easily integrable in MMIC technology and can provide conversion gain [9,10]. By means of a single

FET, it is possible to obtain frequency multipliers up to order 5 or 6. Cascaded stages may be used for higher multiplication orders. In the following, a systematic design procedure for frequency multipliers is presented. The use of multiharmonic load pull for the optimization of the embedding linear networks is shown in Section 5.3.

5.2. FET-Based Multiplier Design

When using a FET transistor, the frequency multiplication by a factor N , is achieved by selecting a bias point, such that, under near-sinusoidal input voltage excitation at ω_0 , an output current is obtained, with high amplitude at the harmonic component $N\omega_0$. For optimal

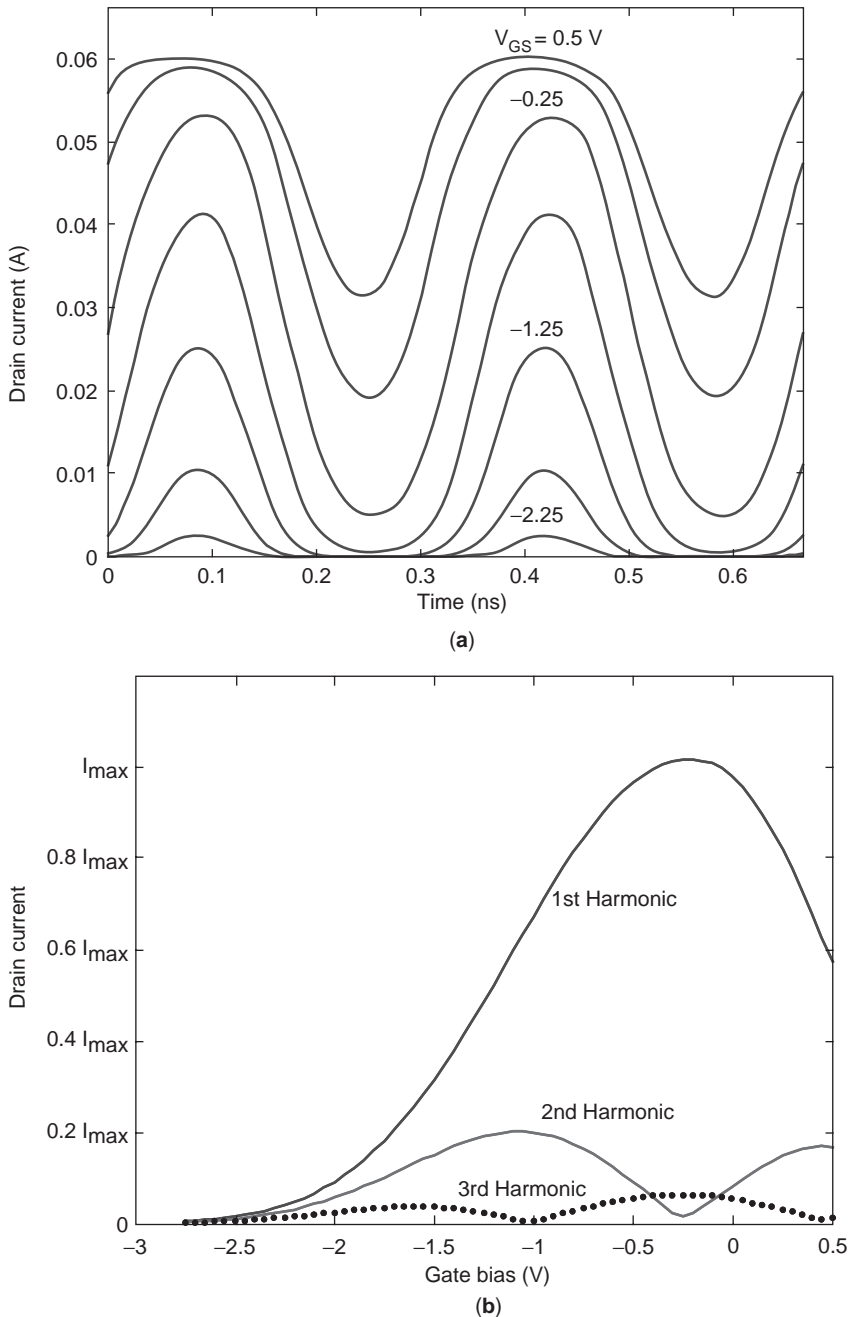

Figure 26. Selection of the gate bias voltage for the frequency multiplier: (a) drain current waveform for different gate bias values; (b) amplitude of the drain current harmonic components versus the gate bias voltage. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

performance, a transistor with a high maximum drain current value should be selected. The harmonic distortion is obtained by clipping the drain current waveform under relatively large input voltage excitation [9]. This can be done by biasing the transistor near forward conduction or by biasing the transistor near or below pinchoff. The latter choice is less hazardous for the transistor device. The transistor must be able to tolerate high reverse gate-to-drain voltage V_{GD} .

In Fig. 26a, a FET transistor, with $V_p = -1.5$ V, is considered. The figure shows the clipping of the $i_{ds}(t)$ waveform for different values of the gate bias and constant input power $P_{in} = 10$ dBm. For gate bias near forward conduction, the clipping takes place in the upper section of the $i_{ds}(t)$ waveform. Near or below pinchoff, the clipping takes place in the lower section. In the latter case, the conduction angle decreases for more negative gate bias and the peak value becomes smaller.

Let ω_0 be the multiplier input frequency. The conduction angle 2ϕ is defined as the fraction of 2π for which $\cos(\omega_0 t)$ is nonzero over one signal period $T = 2\pi/\omega_0$. In B class, $2\phi = \pi$; in C class, $2\phi < \pi$. However, very small conduction angles may be difficult to implement with FET devices. The amplitude of the different harmonic components of the drain current $I_{ds,n}$, where n is the harmonic order, depends on this conduction angle. For fixed drain bias voltage V_{DS} , this will depend on both the gate bias V_{GS} and the amplitude of the gate-to-source voltage waveform, which, in turn, depends on the input generator power and the input matching. Figure 26b shows the variation of the harmonic amplitude versus the gate bias. As an example, for the design of a frequency tripler $N=3$, the third-harmonic component must be maximized, which is done through the selection of the bias voltage $V_{GS} = -1.5$ V (see Fig. 26b).

Once the bias point and input amplitude are known, the input and output networks of the multiplier by N must be determined. In a simple design, the load impedance will consist of an output resistance, plus a parallel inductance L , calculated to resonate at $N\omega_0$ with the transistor output capacitance C_{ds} . The parallel resonant circuit $L-C_{ds}$ will act as a bandpass filter centred at $N\omega_0$. For a sufficiently

large quality factor, the harmonic components will be short-circuited [9]. The output resistance must provide sufficiently high output power at $N\omega_0$. On the other hand, the transistor input should also be matched to the input generator in order to maximize the conversion gain. However, an optimum design, exploiting all the capabilities of the transistor device, requires considering the influence of the device loads at the different harmonic frequencies. This can be done by means of the load-pull system, to be presented in the next section.

5.3. Harmonic Source/Load-Pull System

When using a HB simulator, a source/load-pull system may be implemented, in order to determine the optimum harmonic terminations. For the design of a multiplier by N , harmonic loads up to an order $n_{max} > N$ are considered at both the transistor input and output. Figure 27 shows the different harmonic blocks, each consisting of an ideal bandpass filter, centered at the particular harmonic component $n\omega_0$, plus a termination, given by a reflection coefficient of the form $\Gamma_n = \rho_n e^{j\theta_n}$, where $\rho_n \leq 1$, in order to ensure the load passivity. Initially, a perfect sinusoid at the input frequency ω_0 is imposed at the transistor gate, using short-circuit terminations in all the harmonic blocks, by making $\rho_n = 1, \theta_n = 180^\circ$, for $n > 1$. The first harmonic load is $Z_0 = 50 \Omega$, which is imposed, rendering $\Gamma_1 = 0$. In turn, a perfect sinusoid at the desired harmonic component $N\omega_0$ is imposed at the transistor output terminals, by making $\rho_n = 1, \theta_n = 180^\circ$, for $n \neq N$. Open-circuit terminations also reject undesired harmonic components, but they can give rise to high output voltages and thus to potential instability [6], so short circuits are preferred.

Using the harmonic terminations presented above, the harmonic load $\rho_{L,N}, \theta_{L,N}$ is optimized through a double sweep, keeping the values that maximize the output power at $N\omega_0$. This technique has been used here for the tripler design. The power variation is shown in Fig. 28a. The optimum values $\rho_{L,3}^o = 0.8, \theta_{L,3}^o = 120^\circ$ are kept for the following design stages. This reflection coefficient can be obtained through a resistance $R_3 = 111 \Omega$, in parallel with the inductance $L_3 = 1.608$ nH. The high resistance will

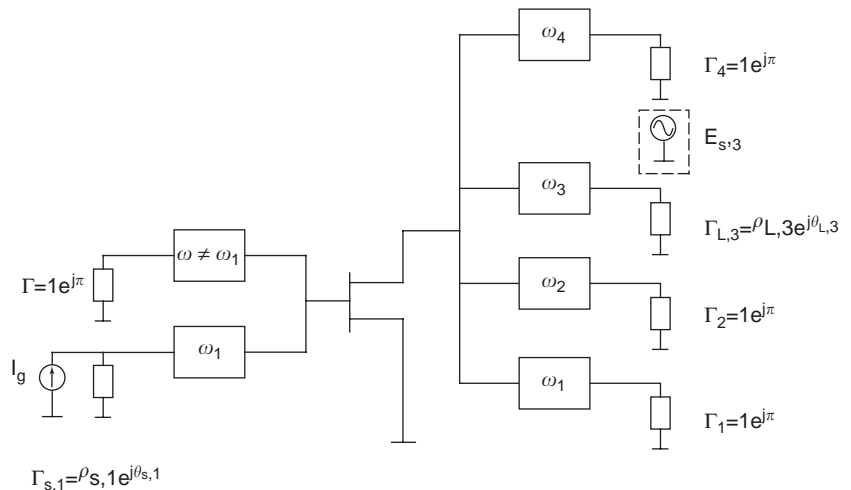

Figure 27. Harmonic load-pull system for the multiplier design. Instead of a reactive load Γ_3 , a substitution generator can also be used at this frequency component.

Figure 28. Selection of the optimum values of the third-harmonic load in terms of the amplitude and phase of the (a) reflection coefficient Γ_3 and (b) substitution generator. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

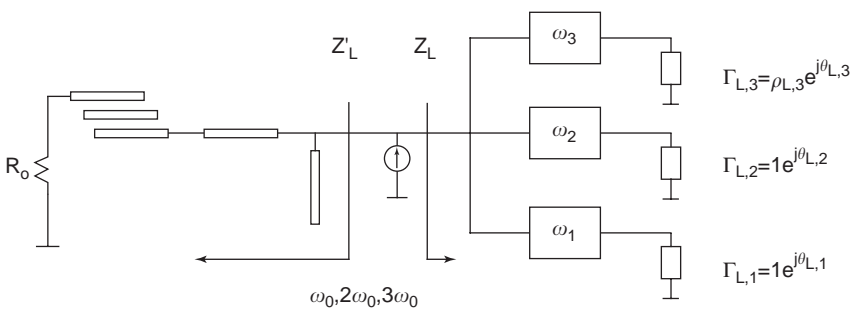

Figure 29. Arrangement for the distributed-line implementation of the multiharmonic load.

enable a large voltage swing at the third-harmonic component. The inductance enables the resonance with the transistor capacitive output, as already seen in Section 5.2.

A second option for determination of the optimum load value at the desired output frequency $N\omega_0$ is the use of a substitution generator [10] of voltage type, operating at $N\omega_0$ (see Fig. 27). This substitution generator is connected to the output of the bandpass filter at $N\omega_0$. Its amplitude and phase are $V_{s,N}, \phi_{s,N}$. To select the optimum generator values, a double sweep is performed in $V_{s,N}, \phi_{s,N}$, calculating, in each step, the output power by means of $P_N = [1/2\text{Re}(Z_{L,N})]V_{s,N}^2$, where $Z_{L,N} = V_{s,N}e^{j\theta_{s,N}}/I_N$ and I_N are the current entering the generator. To ensure that the load will be physically implementable at a later stage, the load must be passive; that is, the condition $\text{Re}(Z_{L,N}) > 0$ must be fulfilled.

Figure 28b shows the output power variations obtained through a double sweep in $V_{s,3}, \phi_{s,3}$. The peaks correspond to the sign changes in R_3 . Apparently, much higher values of the output power can be achieved through this technique. However, the output power increases fast as the resistance R_3 approaches the zero value and too low resistance values are not implementable. The practical values are, in fact, in the order of those obtained in the previous paragraph, through variation of $\rho_{L,3}, \theta_{L,3}$.

In a second design stage, the influence of the harmonic loading is analyzed. Note that when using short circuits $\rho_{L,n} = 1, \theta_{L,n} = 180^\circ$ at $n \neq N$, the harmonic currents still circulate inside the transistor device, reducing the efficiency and output power. The optimum operation would be obtained for short circuits at the internal drain source, instead of the transistor extrinsic drain terminal. In order to evaluate the influence of the first-harmonic load, this load is made equal to $\Gamma_{L,1} = 1e^{j\theta_{L,1}}$ and the phase $\theta_{L,1}$ is varied. The influence of other harmonic components may also be considered, although it generally will be small.

In a third design stage, the harmonic input network is synthesized in a single passive network. The first-

harmonic termination $\Gamma_1 = \rho_1 e^{j\phi_1}$ is calculated so as to match the RF generator to the transistor input. This will allow us to increase the conversion gain, which should be maximum for conjugate matching. The increase in conversion gain will enable a reduction of the input power, while maintaining the output power level. Note that the input is matched after the load circuit has been determined, since this load circuit affects the input impedance value. The influence of higher-harmonic components can also be analyzed, in similar manner. In the multiplier design carried out here, the matching of the input circuit has enabled a reduction of conversion loss from $L = 10$ dB to 4 dB, which is obtained for the impedance $Z_1 = 45 + j40 \Omega$.

In a final design stage, the multiharmonic networks should be implemented. In the case of the frequency tripler, the output load can be synthesized through the combination of a coupled-line bandpass filter at $3\omega_0$, a transmission line, and a stub [6]. The stub is an open-circuited quarter-wave line at $2\omega_0$, which ensures short-circuit terminations at all even harmonic terms. The coupled-line bandpass filter provides a 50Ω load at $3\omega_0$ and reactive impedances, with nearly 0 dB return loss, at the remaining harmonic components. The lengths of the transmission line and the stub should be determined so as to achieve the desired load impedance values at ω_0 and $3\omega_0$. This can be done as explained in the following paragraph.

The topology described for the passive network, containing the coupled-line bandpass filter, the transmission line, and the stub, is introduced in the circuit diagram of Fig. 29 [31]. The purpose is to obtain the values of the network elements through a simple optimization technique. A HB simulation, with the current generator delivering the three frequencies $\omega_0, 2\omega_0, 3\omega_0$, enables the simultaneous calculation of the impedance exhibited by the distributed network at these three frequency components. An error function is defined in terms of the difference between the ideal impedance values Z_L and those provided by the passive network Z_L' . The dimensions of the distributed passive network are optimized in order to minimize this error function. The final spectrum of the frequency tripler, after this implementation process, is shown in Fig. 30, where measurements are included.

NOTCH ANTENNAS

RICHARD Q. LEE
 NASA Glenn Research Center
 Cleveland, Ohio

1. INTRODUCTION

A notch antenna, also known as a *tapered slot antenna* (TSA), is an endfire traveling-wave antenna. Like microstrip antennas, the TSA features low profile, light weight, easy fabrication by photoetching, conformal installation, and compatibility with microwave integrated circuits (MIC). Performance-wise, TSA has demonstrated multioctave bandwidth, moderate gain (7–10 dB), and symmetric *E*- and *H*-plane beam patterns. However, TSA lacks the versatility of microstrip antennas in terms of multifunction operations such as dual frequency and dual polarization and loses its planar architecture when used as circularly polarized antennas or in 2D arrays. The antenna was first proposed by Lewis et al. [1] in 1974. Since then, much technological advances have been made in both designs and applications. In designs, various numerical techniques have been developed and applied to aid the design of the TSA antennas [2–4]. Full-wave numerical techniques based on the method of moments are now commercially available, providing the ability to shorten the design cycle as have been demonstrated in a CAD benchmark demonstration [5]. In applications, TSAs have been used mainly for spatial power combining and as focal plane feed array for imaging reflector systems [6,7]. In more recent applications, TSA arrays capable of multifunction operations are emphasized. Examples of these include the dual-band dual-polarized TSA array of nested lattice architecture [8], and multifrequency full-duplex phased-array system with notch elements [9].

This article focuses on the most recent advances in TSA and their applications. In order to provide some basic

understanding of the design issues, the article begins with some discussions on the design of single tapered slot antennas. Then, TSA arrays and their applications will be highlighted.

2. BASIC GEOMETRIES

A typical TSA consists of a tapered slot section produced by the gradual widening of a slotline. The antenna, excited by a slotline feed, is fabricated on a metallization layer with or without a supporting dielectric substrate. The tapered slot section which constitutes the radiating region can take on any of three geometric profiles: (1) nonlinear taper (Vivaldi, tangential, or parabolic), (2) linear taper (LTSA), and (3) constant width (CWSA) [10]. The majority of previous studies have been focused on TSA with linear and exponential profiles. Prasad and Mahapatra [11] first introduced the linearly tapered slot antenna (LTSA) in 1979. Their antenna of about one free-space wavelength long was etched on a 25-mil alumina substrate. In the same year, Gibson [12] reported a TSA with exponentially tapered profile, also known as the “Vivaldi” antenna, which demonstrated a bandwidth of 8–40 GHz. The schematics of the LTSA and the Vivaldi antennas are shown in Fig. 1. In later years, most of the subsequent developments of TSA arrays are derived mainly from these two antenna types.

Figure 2 shows some typical radiation patterns of a relatively short TSA ($L \leq 2\lambda_0$). As shown, the *H*-plane pattern is significantly broader than the *E*- and the diagonal *D*-plane patterns. In general, the basic geometry of a TSA (length, taper profile, etc.) has strong effects on the radiation patterns. These effects will be discussed in a later section.

In order to facilitate integration of antenna and devices at sub-millimeter-wave frequencies, a new variant of the TSA, generally known as “V-antennas”, was introduced in 1979 for coupling radiation into diode mixers [13]. Years later, other applications of V-antennas were demonstrated at microwave frequencies [14,15]. These antennas with finite-width ground planes can enhance antenna performance by suppressing the surface waves. Another advantage of the V-antennas is its compatibility with uniplanar feed structures that allow one to excite the antenna

Figure 1. Schematics of (a) LTSA and (b) Vivaldi antennas.

Figure 2. Typical radiation pattern for TSA of length $L = 0.93 \lambda_0$ and width $W = 0.68 \lambda_0$ tested at 11 GHz: 1— E plane; 2— H plane; 3— D plane.

with either a microstrip line or a waveguide [14]. The schematics of a V-LTSA and a V-Vivaldi excited by a coplanar stripline are shown in Fig. 3.

Another variant of the conventional TSA is the antipodal tapered slot antenna. In practice, the conventional planar TSA is fed by a balanced slotline. One serious drawback of the conventional TSA is in the fabrication and impedance matching of the slotline. Slotline fabricated on a low-dielectric-constant substrate has relatively high impedance, which makes matching to a microstrip feed very difficult. The antipodal TSA is designed to overcome this impedance-matching difficulty; however, it has exhibited very poor cross-polarization characteristics. The antenna is formed by gradually flaring the strip conductors of the balanced microstrip on opposite sides of the dielectric substrate with respect to the antenna axis, thus allowing the antenna to be directly fed by a microstrip feed [16]. To circumvent the high cross-polarization problem, a balanced antipodal Vivaldi consisting of three metallization layers was introduced. This new antenna, shown in Fig. 4, has demonstrated -15 dB lower cross-polarization across a 18–1 band as compared to the conventional Vivaldi antenna [17].

3. TSA DESIGN

For years, the design of TSA has been based primarily on empirical approach, which, as an initial step, could start with the following simple guidelines (where c is the veloc-

Figure 3. Schematics of (a) V-LTSA and (b) V-Vivaldi antennas.

ity of light, v is the velocity of field along the slot, and λ_0 is free-space wavelength):

Aperture width of the slot: $W \geq \lambda_0$

$1.05 \leq c/v \leq 1.2$

Effective thickness: $t_{\text{eff}} \leq 0.03 \leq \lambda_0$

Taper angle 2α typically $5\text{--}12^\circ$

Length of TSA L typically $2\text{--}12 \lambda_0$ wavelength.

With the availability of electromagnetic simulators, engineers can now check the accuracy of their designs before carrying out the actual fabrication and characterization. In general, design of the TSA involves two major tasks: (1) design of a broadband transition and feed structure with very wide frequency range and low return loss and (2) determining the dimensions and shape of the antenna in accordance with the required beamwidth, sidelobe, backlobe, and other parameters over the operating frequency range. The geometric parameters such as length, width, dielectric thickness, ground-plane size, and taper profile, which have direct impact on the impedance, directivity, bandwidth, and radiation pattern of the antenna will be discussed in the sections below.

3.1. Feeding Methods

Almost always planar tapered slot antennas such as LTSA and Vivaldi are excited by a slotline; thus, feeding a TSA requires building a transition between the slotline and other transmission media. In the case of microstrip or coaxial lines, the transition is a balun. In general, the transition should have small parasitic inductance and capacitance for wide bandwidth, and hence, electromagnetic coupling is preferred over wire bonding or solder connection. In the following, we will consider three basic feed structures: (1) coplanar waveguide (CPW), (2) microstrip line, and (3) coaxial lines.

3.1.1. Coplanar Waveguide-Feed. CPW possesses many useful design characteristics such as low radiation loss, less dispersion, and uniplanar configuration. In Ref. 10, we have presented several feeding techniques where the transmission media are CPW, which excite the TSA via electromagnetic coupling. Figure 5a shows a strip-to-slot coupled LTSA excited by a conductor-backed finite ground-plane CPW feed. In the figure, the distance L_s from the short termination of the slotline, as well as the distance L_w from the open termination of the extended center strip conductor to the CPW-to-slotline junction, is about a quarter-wavelength at the center frequency of 20 GHz; and Z_{os} and Z_{ow} are the characteristic impedances of the slotline and the CPW center strip conductor extension, respectively. The antenna has demonstrated a VSWR of 2–1 over nearly 3–1 bandwidth as indicated by the measured return loss shown in Fig. 5b.

The TSA can also be excited by direct slot-to-slot feeding where the CPW and the antenna are on the same side of the substrate. In order to excite the odd mode where the electric fields in both slots of the CPW have the same amplitude but opposite direction, a bondwire is usually placed across the slots to keep the two ground planes at equal potential. The CPW feed enables direct integration

Figure 4. Balanced antipodal Vivaldi antenna. (From Ref. 17 with permission from IEE.)

of active solid-state devices with the antenna. Figure 6 shows the layout of a LTSA integrated with a FET amplifier that demonstrated a gain of more than 14 dB over a bandwidth of 1.75 GHz [18].

CPW can be designed as a tapered CPW with constant characteristic impedance, but with different ratio of slot to center strip widths [19]. This unique feature is useful for exciting twin tapered slot antennas of large separations.

Figure 7 shows the application of tapered CPW transitions to twin Vivaldi antennas to achieve pattern diversity for transponders and monopulse systems through even- and odd-mode excitations [20]. As shown, when the distance between the slotlines equal to $n\lambda_g$, where λ_g is the guide wavelength of the microstrip line, the even mode with in-phase electric fields is excited producing a maximum radiation in the broadside direction. Conversely, when the distance between the slotlines is $(2n + 1)\lambda_g/2$, the odd mode with opposite electric fields is excited, producing a minimum radiation in the boreside direction.

Figure 6. Circuit configuration of CPW cross-feed LTSA amplifier: $L_1 = 32$ mm, $L_2 = 8$ mm, $L_3 = 1.5$ mm, $S_1 = 0.5$ mm, $S_2 = 0.2$ mm, $H = 20.5$ mm, $W = 1.4$ mm. (From Ref. 18 with permission from IEE.)

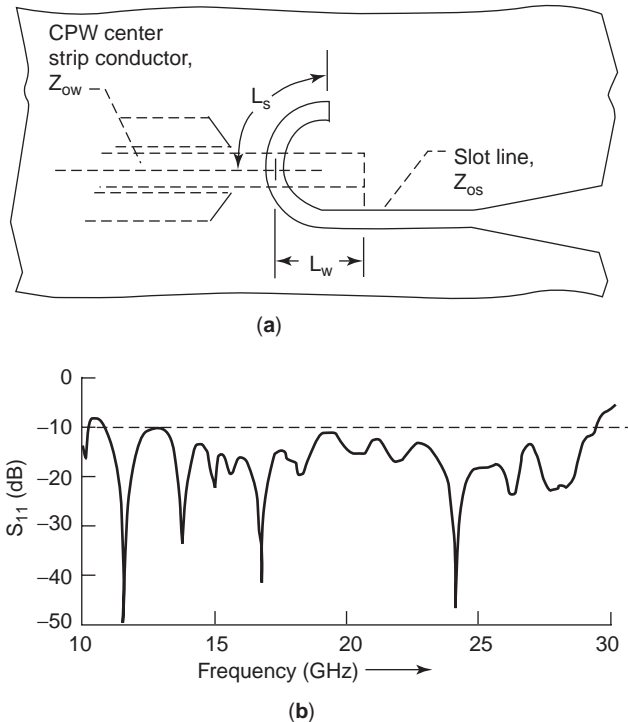

Figure 5. (a) CPW strip-to-slot transition; (b) measured return loss for the strip-to-slot coupled TSA.

Figure 7. Twin LTSAs fed with tapered CPW transitions.

3.1.2. Microstrip Line Feed. Microstrip line is in widespread use in power combining circuit. Since microstrip line is an unbalanced line and slotline is a balanced line, feeding a TSA with a microstrip line requires a balanced-to-unbalanced transition (balun) to avoid compromising the broadband antenna performance. The most common microstrip/slot transition, the Marchand balun [21], has demonstrated a VSWR of 2–1 over an octave bandwidth with an integrated wideband V-Vivaldi antenna [22]. The transition and the corresponding transmission-line model are shown in Fig. 8. The balun consists of four quarter-wave sections with the end open-circuited section extended past the center of the slotline by about one-quarter of a guided wavelength. Further broadening of the bandwidth can be achieved when the microstrip is terminated by a radial stub and the slotline is terminated by an elliptical shaped cavity [10].

Figure 8. Schematic of (a) Marchand balun with interface to antenna element and (b) transmission-line model of the balun. (From Ref. 22 with permission from IEEE.)

The double-Y balun is another microstrip-to-slotline transition that has no inherent bandwidth limitation other than parasitic inductances and capacitances. As indicated in Fig. 9, the double-Y balun is based on the six-port double-Y junction that consists of three balanced and three unbalanced lines placed alternately around the center of the structure. For the balun to provide perfect transmission between an opposite balanced and unbalanced ports, opposite pairs of lines should have reflection coefficients with opposite phases, thus requiring one pair of lines to be short-circuited and the other, open-circuited. TSA with double-Y balun feed structure has achieved an impedance bandwidth of more than 2–1 [23].

The balun requirement often complicates the feed design and limits the antenna bandwidth if it is not designed properly. The V- and antipodal tapered slot antennas offer a way to circumvent this problem since they are not directly fed by a slotline. Figure 10 shows a V-LTSA with a uniplanar microstrip-to-coplanar stripline feed [24]. In the feed network, a microstrip line of characteristic impedance of 50Ω and width w_1 is coupled to two orthogonal microstrip lines of characteristic impedance of 70Ω and width w_2 through a quarter-wave impedance transformer of width w_1 . The mean pathlength of the folded loop “a through b” is equal to half a guide wavelength λ_g of the $70\text{-}\Omega$ microstrip line at the design frequency. However, for wideband operation, the mean pathlength needs to be increased to $0.638 \lambda_g$ to compensate for the right-angle bend parasitic elements. This design ensures that the signal phase from points a to b are 180° out of phase; thus the coupled microstrip lines are excited in the odd mode with the electric field predominantly across the gap S_2 . The dimension of S_2 is chosen such that the characteristic impedance of the coupled microstrip line is 50Ω . The measured return loss of the V-LTSA is better than 10 dB over the frequency range of 5–15 GHz.

Figure 11 shows an antipodal LTSA with a microstrip-to-balanced microstrip feed. The balanced microstrip is formed with the ground plane tapered to a width equal to the strip width w_l (0.71 mm), and the arc radius R_2 is

Figure 9. Double-Y microstrip-to-slotline transition.

Figure 10. V-LTSA with a uniplanar microstrip line-to-coplanar stripline feed: $L = 50.8$ mm, $\alpha = 12.5^\circ$, $W_l = 0.229$ mm, $W_1 = 0.328$ mm, $W_2 = 0.102$ mm, $l_1 = 4.9$ mm, $l_2 = 2.771$ mm, $S_1 = 2.098$ mm, $S_2 = 0.102$ mm, $h_1 = 0.541$ mm, $h_2 = 1.339$ mm.

arbitrarily chosen to provide a smooth taper transition for matching the characteristic impedance of the conventional microstrip to the balanced microstrip.

The electric field lines at different cross sections along the feed and the antenna are illustrated in Fig. 12. The electric field lines, which are spread out in the conventional microstrip structure, concentrate between the metal strip of the balanced microstrip, and finally rotate while traveling along the LTSA. The field rotation inadvertently introduces higher cross-polarizations in these types of antennas. The antipodal LTSA has demonstrated over 4–1 (8–32 GHz) bandwidth for 2–1 VSWR at a design frequency of 18 GHz [25].

3.1.3. Coaxial Feed. Coaxial line is useful as a feed structure because of its compatibility with the slotline, coplanar microstrip, or balanced microstrip to form wide-band transitions; thus, it can be used to excite all three variants of TSA described above. The disadvantage is that it is not planar and has high losses at high frequencies. Further, coaxial line is an unbalanced feedline. All the currents flow inside the line, namely, the inner conductor and the inside of the shield. Feeding a balanced antenna with unbalanced coaxial feed may cause currents to flow on the outside the shield, which could result in significant power loss and serious distortion in radiation pattern. Since the magnitude of the current on the outside

Figure 11. Antipodal LTSA and feed network: (a) top metallization; (b) bottom metallization.

Figure 12. Electric field distribution at cross sections of (a) conventional microstrip, (b) balanced microstrip, and (c) antenna radiating edge.

shield is a function of the impedance to ground of the conductor, one common approach to cutoff the flow of current is with an open circuit that is created by placing a “skirt” a quarter-wavelength long around the outside shield and short-circuited to the shield at a quarter-wavelength away from the load.

The most direct way of exciting a TSA with a coaxial feed is to extend its center conductor over the slotline section of the TSA and anchor the coaxial feed with solder connection to the ground plane. An improved balun design that has direct application to V-antennas has been proposed [26]. The balun impedance is tapered by cutting open the outer wall of the coax so that the reflections at the input are minimized. The length of the balun is determined by the lowest operating frequency and the maximum reflection coefficient that occurs in the passband. Figure 13 shows the cross section of the tapered coaxial-line balun and its integration with a V-Vivaldi antenna.

4. RADIATION CHARACTERISTICS

A good understanding of the effects of the design parameters (length, width, dielectric thickness, ground-plane size, taper profile, etc.) on antenna characteristics would facilitate the task of antenna design. TSA is known to

Figure 13. Coaxially-fed TSA with tapered coaxial line balun. (From Ref. 26 with permission from IEEE.)

have good performance over a wide bandwidth. In practice, the operating bandwidth is often limited by the slot-line-to-feedline transition and by the finite width of the antenna. To achieve wideband operation requires the TSA to operate in a traveling-wave mode with perfect impedance match at both the feed transition and the slot termination. In this section, some important characteristics of TSA, which are based on experimental data as well as from previous publications, will be presented.

4.1. Effect of Length, Width, and Taper Profiles

Tapered slot antennas radiate in the endfire direction with fairly symmetric radiation patterns, but have high cross-polarization levels in the diagonal plane. The lowest cross-polarization level in the diagonal plane is about 10–15 dB higher than that of the principal planes, which are typically better than -15 dB. In general, the cross-polarization characteristics of planar TSA are superior to those corresponding to their antipodal counterparts. Because this is a traveling-wave antenna, the phase velocity and guide wavelength λ_g varies with any change in the geometric and material parameters of the antenna, which in turn impacts the radiation characteristics of the antenna. The gain of a TSA increases with the length L of the antenna typically from a few decibels to over 10 dB as L increases from 2 to 5 λ_g [10]. Maximum measured gain of 16–17 dB with radiation efficiency of 80% has been reported for long TSA with L greater than $6\lambda_0$ [27]. Similarly, the beamwidths, which are inversely proportional to gain, decrease rapidly as the length is increased; however, the H -plane beamwidth varies more slowly in comparison to the E -plane beamwidth, particularly for L less than $5\lambda_g$.

The taper profile has been found to have strong effects on both the beamwidth and sidelobe level of the antenna. In general, the beamwidths are narrower for the CWSA, followed by the LTSA, and then Vivaldi for antennas with the same length, same aperture size, and on the same substrate. Similarly, the sidelobes are highest for the CWSA, followed by the LTSA, and the Vivaldi.

As a traveling-wave antenna, the H -plane beamwidth follows $1/\sqrt{L}$ dependence, while the E -plane beamwidth depends more on the aperture width or tapered angle [28]. Varying the tapered angle will change the phase velocity and hence λ_g , which will in turn change the E -plane beamwidth. Thus, constant beamwidth in both E and H planes can be achieved with proper choices of L and tapered angles. Gibson obtained approximately constant beamwidth in both E and H plane for a Vivaldi antenna fabricated on alumina substrate with tapered profile defined by [12]

$$y = \pm 0.125e^{0.052x}$$

where x and y are variables for the two principal axis of the rectangular coordinates. Approximately constant E - and H -plane beamwidths over a 6–8 GHz bandwidth have been demonstrated for a balanced antipodal antenna with elliptical radiating taper [17], and nearly identical E - and H -plane 3-dB beamwidth was observed for a LTSA with tapered angles in the range of 15–20° [29].

Figure 14. Micromachined tapered slot antenna. (From Ref. 32 with permission from IEEE.)

4.2. Effect of Dielectric

The performance of a TSA is sensitive to the thickness and dielectric constant of the dielectric substrate. The presence of a dielectric substrate has the primary effect of narrowing the mainbeam of the antenna. The effects of dielectric substrates on the *E*- and *H*-plane beamwidths of a Vivaldi antenna on polyethylene have been investigated at 18.5 GHz [30]. By varying substrate thickness from 10 to 15 and 27 mils, the *H*-plane beamwidths become narrower, while the *E*-plane beamwidths remain essentially constant, indicating that the dielectric has a strong effect on the *H* fields. Increasing the dielectric thickness generally results in increased gain, but with higher sidelobes. For good performance, a TSA should have an effective substrate thickness in the range of $0.0025\lambda_0 \leq t_{eff} \leq 0.028\lambda_0$ where $t_{eff} = t(\sqrt{\epsilon_r} - 1)$ is the effective thickness of the substrate. For substrate thickness above the upper bound of $0.028\lambda_0$, unwanted substrate modes develop that degrade the antenna performance, resulting in low efficiency and narrow bandwidth, particularly for dielectrics with high dielectric constants. Further, for millimeter-wave operations, the upper bound on the effective thickness constrains to using mechanically fragile substrates with thickness of only a few hundreds of micrometers. To overcome these problems, it has been proposed to fabricate notch antennas either on thick perforated substrates with an array of regularly and closely placed holes [31] or on photonic bandgap dielectrics

Figure 15. *H*-plane patterns at 11 GHz for a LTSA with a foam spacer: 1—with no ground plane; 2—with a ground plane and no spacer; 3—with a ground and a 0.3175-cm foam spacer; 4—with a ground plane and a 0.635-cm foam spacer.

as shown in Fig. 14 [32]. The former approach reduces the effective substrate thickness, while the latter approach suppresses the excitation of the surface modes.

4.3. Ground-Plane Effect

Placing a ground plane immediately below the TSA will cause the mainbeam to steer away from the endfire direction by about 50° in the *H* plane [10]. The amount of scan will be reduced as the distance between the ground plane and the antenna increases, and becomes negligible when the distance of separation is sufficiently large. For the *E*-plane patterns, no significant change was observed except that the TSA had to be tilted in the elevation to receive full power. Figure 15 shows measured *H*-plane patterns for a LTSA over a ground plane with a foam spacer in between.

5. IMPEDANCE CHARACTERISTICS

5.1. Input Impedance

The impedance characteristic of TSA is important for designing match transitions; yet very little information is

Figure 16. (a) Real and (b) imaginary parts of the input impedance ($\alpha = 5^\circ$ and $L = 2.54$ cm).

Figure 17. Vivaldi antenna with a dielectric impedance-matching transformer: $L_1 = 4$ mm, $L_2 = 4$ mm, $L_3 = 5$ mm, $L_4 = 10$ mm.

Figure 18. (a) Real and (b) imaginary parts of the input impedance.

available from previous publications. Based on conformal mapping method for a fin antenna without a dielectric, Yngvesson et al. reported that the impedance of a LTSA with thin dielectric is essentially constant at frequencies from 4 to 12.4 GHz and is close to 80 Ω [33]. In another study, the input impedance of LTSA was measured using a microwave wafer probe and a set of on wafer thru-reflect-line (TRL) slotline standards [34]. The LTSA was excited through a short length of a slotline by a ground-signal microwave probe (Picoprobe, Inc.). In the measurement, the reflection coefficient of the LTSA is deembedded from the measured reflection coefficient at the input terminal of the slotline using the NIST deembedded software [35]. Figure 16 shows the real and imaginary parts of the input impedance Z_{in} versus frequency for a LTSA with $\alpha = 5^\circ$ and $L = 2.54$ cm.

The impedance plot exhibits a series of resonance over the frequency band from 2 to 26.5 GHz. These resonances are caused by imperfect impedance match transitions at the feed end and the termination end of the LTSA. The first resonance mode at frequencies below 4 GHz has very large input impedance, typically over 1000 Ω , which could be caused by large electric fields associated with a very small W/λ_0 . For frequencies above 4 GHz, the impedances are bounded between 145 and 40 Ω with a mean value of about 92 Ω . Similar results were also obtained for LTSA of different lengths and tapered angles [10].

5.2. Impedance Matching

Impedance matching of TSA has commonly been performed at the feed end of the antenna. An approach illustrated in Fig. 17 for impedance matching at the termination end of the antenna has been proposed [36].

The new approach uses a two-step dielectric transformer to match the antenna to free space. The deembedded real

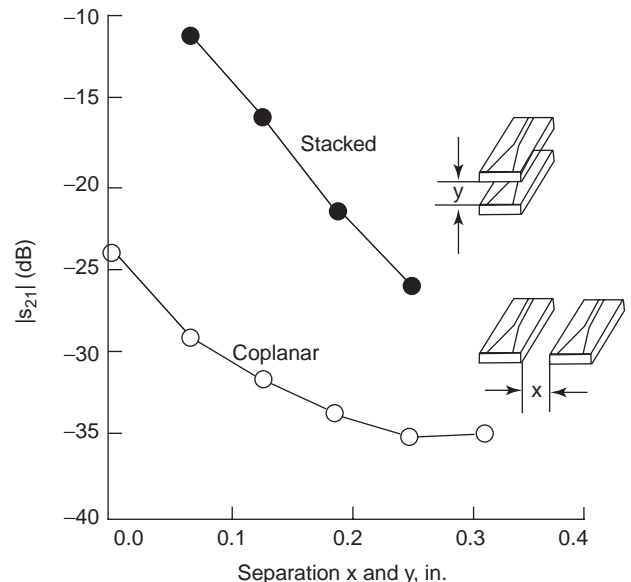

Figure 19. Measured mutual coupling between two LTSAs in coplanar and stacked arrangements as a function of separation.

and imaginary parts of the input impedance with and without the dielectric transformer are shown in Fig. 18.

5.3. Mutual Impedance

Mutual coupling can produce profound impacts on the performance of an antenna array, causing impedance mismatch and scanning blindness, particularly for antennas on thick dielectric substrates. In general, mutual coupling can occur between two TSAs arranged in either coplanar or stacked configurations. The mutual coupling between two LTSAs in close proximity and excited by two calibrated ground-signal microwave probes has been obtained from a *S*-parameter measurement of $|S_{21}|$ [37]. Figure 19 shows the measured mutual coupling between two LTSAs in coplanar and stacked arrangement as a function of separations. Results indicate that the mutual coupling decreases with the distance of separation.

The coupling coefficients as a function of frequencies were also measured first with the LTSAs fabricated on a continuous substrate and then repeated after a narrow slot was cut in the dielectric. In the latter case, coupling between antennas were confined to space waves only. Results indicate stronger mutual coupling for the TSAs on continuous substrate as a result of additional coupling through the supporting dielectric; however, both cases display decreasing $|S_{21}|$ with frequencies [10]. This is due to the fact that at higher frequencies the separation is electrically larger and separations between antennas are greater with respect to wavelengths.

6. TSA ARRAY AND APPLICATIONS

Over the years, many different applications of TSA arrays have been reported in the literature. TSA arrays have been successfully applied as focal-plane feed arrays for a multibeam imaging reflector system. For the same beamwidth, a TSA array occupies about 1/4 of the area of a feed array with waveguide elements; thus, an imaging system with TSA focal plane array can be designed to yield high angular resolution [27].

TSA arrays have also been advantageously used for spatial power combining to achieve power amplification and harmonic generation. In 1999 a 120-W, X-band spatially combined solid-state amplifier was demonstrated [6]. The spatial combiner consists of six identical “trays” with each containing four input/output broadband TSA integrated with four MMIC amplifiers via a slot-to-microstrip transition. Space power combining can be applied to large antenna aperture such as space-fed lens arrays. The concept of space power amplification has been demonstrated experimentally with a three-element LTSA array module. Figure 20 shows a photo of the array module and the measured *H*-plane pattern.

Figure 24. Photographs of dual-polarized TSA array: (a) 8×8 array; (b) orthogonal subarray element pair.

In this approach, an array of active antenna modules, constructed from nonplanar TSAs and monolithic microwave integrated circuit (MMIC) multistage GaAs power amplifiers, receives the signal at lower power and after amplification reradiates the signal into free space. Polarization diversity is employed to permit accurate measurement of the amplified signal radiated from the transmitting array. With the amplifiers turned on, the three-element active array module produced a gain of 30 dB at 20 GHz [38]. Replacing the MMIC multistage power amplifier with a broadband, GaAs MMIC distributed amplifier, frequency multiplication, and space power combining were demonstrated with the same active LTSA array module, which receives signals at 9.3 GHz, and after amplification, radiates the second harmonic signal into free space. Results indicated a fundamental-to-second-harmonic conversion efficiency of 8.1% [39]. For experimental details and measured results, the reader is referred to Ref. 10.

With the rapid development of the wireless industry, a K-band circular LTSA array, shown in Fig. 21, has been proposed for mobile communications [40]. The 16-element array is fed by a 1–16 microstrip line power splitter composed of T junctions and right-angle bends. The output ports of the splitter are electromagnetically coupled to the slotline of the LTSA through a microstrip-to-slotline transition with the slotline and microstrip line characteristic impedances chosen to be 120 and 100 Ω , respectively. The array was placed over a reflecting ground plane to displace the beam above the horizon, and foam spacers of different thickness are used to control the amount of scan. Figure 22 shows the measured *E*- and *H*-plane patterns for $0.286\lambda_0$ separation. As shown, the circular LTSA array produces an omnidirectional pattern in the azimuthal plane and a beam displacement of about 28° in the elevation plane.

Using a similar approach, an omnidirectional quasi-optical circular array of 12 Vivaldi-coupled oscillator elements has been designed for LMDS (local multipoint distribution services) applications [41]. The array, which

is powered from a single direct-current power supply, has demonstrated an 87% power combining efficiency, and 144 mW radiated power at 28 GHz.

TSA array has found applications in intelligent transportation systems. A wide-scan spherical lens antenna at millimeter-wave frequency (77 GHz) has been introduced for automobile radars [42]. The multibeam antenna system is composed of planar TSAs positioned around a homogeneous spherical Teflon lens. Beamscanning is achieved by switching between elements. Figure 23 shows a 33-beam spherical Teflon lens system that has demonstrated an angular resolution of 5.5° and -3.5 dB cross-over of adjacent beams.

Figure 25. Sketch of a 20-element dual-band dual-polarized multilevel antipodal Vivaldi array. (From Ref. 8 with permission from IEEE.)

Figure 26. Multifrequency and full-duplex Vivaldi phased-array system with dual-PET phase controls. (From Ref. 9 with permission from IEEE.)

In shared aperture technology development where the functionality of several antennas are combined into one aperture using wideband multiple beam technology, dual-polarized tapered slot antennas with “double Y” microstrip-to-slotline transition have been used to achieve wideband operations [43]. To realize horizontal and vertical linear polarizations, two TSA elements of like polarization are first combined into a two-element subarray. Then, two such subarrays are joined at a 90° angle through a mechanical slot cut in the top of one subarray and the bottom of the other subarray to form a quad-element subarray module. Figure 24 shows an 8×8 array composed of quad-element subarray modules as building blocks. To obtain right- and left-hand circular polarization, the horizontal and vertical polarizations are combined with a 90° phase offset in a quadrature hybrid circuit.

Combining the functionality of several antennas into one shared aperture presents many technical challenges. In 2003 a dual-band dual-polarized nested antipodal Vivaldi array was developed for a new radiotelescope, the Square Kilometer Array (SKA) [8]. In order to meet the 5–1 bandwidth (0.8–4.0 GHz) requirement, the array consists of a lower-band and an upper-band subarray with each made up of different-size antipodal Vivaldi quad elements having overlapping bandwidths. The array of nested lattice architecture has multilevel ground planes that allow height adjustment to achieve optimization of the array performance. A sketch of a 20-element dual-band dual-polarized multilevel nested antipodal Vivaldi array is shown in Fig. 25.

In a more recent development of a low-cost, multifrequency and full-duplex phased-array transceiver that transmits at 10 or 19 GHz and receives at 12 or 21 GHz, Vivaldi antennas were used to achieve wideband performance. In addition, the system, as illustrated in Fig. 26, features a low-loss and low-cost multilayer phase shifter controlled by dual piezoelectric transducers (PETs) and four-channel microstrip multiplexers [9]. The array system has demonstrated scan angles of about 40° at 10–21 GHz using the PET phase controls. The use of PET

greatly simplifies the integration and high insertion loss problems generally associated with solid-state type phased shifters used in conventional phased arrays.

7. CONCLUSION

The objective of this article is to provide an overview of notch antennas including underlying principles and limitations, general design guidelines, performance characteristics, and new applications. Due to limited coverage, the article focuses mainly on LTSA and Vivaldi, while many other noteworthy works have not been able to include in the discussion. The general design guideline outlined here is intended as an initial step in the experimental or analytical processes leading to the final design. The discussions on feeding techniques and antenna characteristics are useful in understanding the design and the radiation process of notch antennas. Finally, the article ends with some more recent advances and innovative applications of TSA arrays based on shared aperture technology.

1. INTRODUCTION

Orthomode transducers (OMTs) are microwave components commonly used in receivers and transmitters, especially in the microwave frequency range from about 1 GHz up to a few hundred gigahertz. Telecommunications and radio astronomy are typical operative environments using OMTs that thus serve both civilian and scientific applications.

This device works as a polarization diplexer; in transmitters, it combines two separate signals from separate input channels into two orthogonally polarized signals in a single output channel so that information is still separated, or, equivalently, the two signals are uncoupled. In receivers, it separates an incoming dual-polarized signal into two output channels, each carrying the information associated with one of the two polarization states of the input. The polarization state may be linear or circular; in this second case the OMT is more properly termed a *polarizer*.

An initial classification of OMT is given in the paper by Boifot et al. [1], while an excellent description of practical OMT and polarizer configurations is provided in the book by Uher et al. [2].

In the following we use the term *common port* to refer to the port where the two signals are mixed and *single-mode port*, to the other two ports.

The need for such a device originated primarily in (1) civilian applications, where resources in terms of frequency bands are very limited compared with the growing demands for new communication channels, thus generating interest in a device that doubles the number of channels in a given frequency band by using two separate polarizations and (2) modern scientific applications, such as astrophysics, to detect the polarization state of the signal coming from the sky, as this provide important information on fundamental cosmological parameters.

The aim of this article is to give fundamental information on OMT operative aspects, introducing few OMT models to help the reader understand the basic concepts of OMT architectures. Gaining this insight is very important because, unfortunately, analytical tools are not available to design OMTs in a direct and simple manner, so it is necessary to resort to computer software employing

numerical techniques to perform analysis and design. For this reason, numerical techniques are of primary importance, and an in-depth knowledge of these methods is fundamental for modern microwave engineers. Here there is space to give the reader only a brief insight into these techniques, but Itoh treats this argument in greater depth [3]. Finally, advanced OMT and polarizer design examples are presented to better illustrate the state of art of these devices.

2. ORTHOMODE TRANSDUCER FUNDAMENTALS

Because OMT operation is based on wave propagation in structures whose dimensions are of the order of the wavelength, OMT theory is based on the transmission-line approach, which is developed in the frequency-space domain. Also, even if—from a mechanical perspective—OMTs have three physical ports, the fact that the common port has two modes implies that, electrically speaking, the OMT schematic consists of a four-port device as shown in Fig. 1, with the two single-mode ports 3,4 and the two ports 1,2 at the common-port side.

OMTs are commonly characterized by means of the scattering coefficients [4] giving the ratio of the incident and reflected wave coefficients, which are complex quantities, at the various ports with a particular setting; where S_{ij} is the ratio between the amplitude of the field that comes out at port i and the amplitude of the incident field at port j , provided only port j is excited and any other port l , $l \neq j$, is connected to a matched load. A more meaningful parameter, from a physical perspective, is given by the square amplitude of the scattering coefficients: $|S_{ij}|^2$; this represents the fraction of the total power incident at port j which comes out from port i .

For an ideal OMT, referring to the sketch in Fig. 1, the scattering matrix is given by the following expression

$$S = \begin{bmatrix} 0 & 0 & e^{j\alpha} & 0 \\ 0 & 0 & 0 & e^{j\beta} \\ e^{j\alpha} & 0 & 0 & 0 \\ 0 & e^{j\beta} & 0 & 0 \end{bmatrix} \quad (1)$$

where α and β are, in general, real constants. We can see that it is matched at all the ports, with the diagonal

Figure 1. OMT schematic.

elements of S equal to zero. From the first row of S ($s_{13} = e^{j\alpha}$) we conclude that all the power incident at the single-mode port 3 comes out from port 1, which is associated with one of the two polarizations at the common port. Because of device reciprocity, the signal from port 1 must exit from port 3 ($s_{31} = s_{13} = e^{j\alpha}$). In a similar way ports 2 and 4 are coupled; thus $s_{24} = s_{42} = e^{j\beta}$. All the other entries of the S matrix are equal to zero in the ideal OMT. For practical OMTs, nonidealities are summarized in Table 1.

OMTs are formed by using essentially the following basic types of guiding structures: the rectangular, square, and circular waveguides; the microstrip line; and the coaxial cable. All these guiding structures support multi-mode field configuration, but, generally, in the operative OMT bandwidth, only the fundamental mode propagates. Each mode has its own electric and magnetic field distribution, knowledge of which, together with knowledge of the associated propagation constant, is fundamental in order to fully understand the behavior of OMTs and to obtain the required background for OMTs design. To satisfy this objective another aspect that must be developed with high accuracy is field polarization.

These arguments are discussed with sufficient accuracy here to enable the reader to understand the OMT aspects presented in this article, but we recommend a much more in-depth treatment for further details; for a very accurate description of field distribution and propagation in those kind of waveguides, we suggest Ref. 4, while for the full theory on field polarization, we recommend Ref. 5.

2.1. Coaxial Cable

Coaxial cable is used in OMTs as a single-mode port because its fundamental mode, as we shall see, has a single polarization configuration, avoiding the possibility of propagating two uncoupled signals. It is a structure allowing the propagation of electromagnetic (EM) energy in the whole frequency spectrum. The fundamental mode of propagation is transverse electromagnetic (TEM) with both the electric and magnetic field vectors on the plane orthogonal to the direction of propagation. As shown in Fig. 2, it is composed of two coaxial circular conductors of radii a and b , $b > a$, with, normally, a homogeneous dielectric material as interconductor medium to provide

Table 1. OMT Operative Parameters

Description	Scattering Coefficient

Single-mode port crosstalk	$ S_{34} $

Figure 2. Coaxial cable: reference sketch.

mechanical stability. The structure is rotationally symmetric; a longitudinal slice is cut in the figure only to clarify the internal configuration. By applying a potential difference V_0 between the two conductors, a TEM field propagating in the medium can be expressed as follows:

$$\mathbf{E} = \frac{V_0}{\ln(b/a)} \frac{1}{\rho} \mathbf{u}_\rho e^{-j\beta z};$$

$$\mathbf{H} = Y_0 \mathbf{u}_z \times \mathbf{E};$$

$$a \leq \rho \leq b, \quad 0 \leq \varphi < 2\pi$$
(2)

The field, whose configuration is given in Fig. 3, is represented here in cylindrical coordinates ρ, φ, z , with unit vectors $\mathbf{u}_\rho, \mathbf{u}_\varphi, \mathbf{u}_z$, and the propagation is assumed e^{-jkz} type in only the z direction. The properties of the medium are expressed in the field impedance $Z_0 = Y_0^{-1} = (\mu/\epsilon)^{1/2}$, where ϵ and μ are, respectively, the dielectric permittivity and magnetic permeability of the dielectric material. The

Figure 3. Coaxial cable: electromagnetic field distribution for the TEM fundamental mode.

electrical characteristics of the coaxial cable as a transmission line are expressed by the characteristic impedance $Z_c = Z_0 \ln(b/a)/(2\pi)$ and the propagation constant $\beta = k = \omega (\epsilon\mu)^{1/2}$ is equal to the medium wavenumber k and where $\omega = 2\pi f$ is the angular frequency (f is the frequency). The geometric parameters of the cable also determine the upper frequency limit; this is commonly associated with the cutoff frequency of the first higher-order mode (TE₁₁), which is given with very good accuracy by setting the cutoff wavelength equal to the circumference associated to the mean radius. Thus

$$\lambda_{11} = \pi(a + b); \Rightarrow f_{11} = \frac{c(\epsilon_r)^{-1/2}}{\lambda_{11}} = \frac{c(\epsilon_r)^{-1/2}}{\pi(a + b)} \quad (3)$$

where c is the light velocity in vacuum and ϵ_r the relative dielectric constant (i.e., the ratio between the permittivity of the dielectric material and the permittivity of vacuum). For a more in-depth treatment on coaxial cable higher-order modes, we suggest the book by Marcuvitz [6].

2.2. Microstrip Line

Like coaxial cables, the microstrip line (Fig. 4) is used essentially as a single-mode port as, in the same way, it supports a single fundamental mode, which propagates in the z direction from zero frequency upward. It is a structure belonging to the family of planar transmission lines that are used largely in modern microwave applications. As shown in Fig. 4, it is formed by a conducting strip of width w and thickness t placed on a dielectric substrate of relative dielectric constant ϵ_r and thickness h that is grounded on the other side by a conducting layer. The major advantages of the microstrip line are as follows:

- It can be fabricated using low-cost printed circuit board (PCB) technology with good mechanical tolerances in the microwave range.
- It allows very easy integration of elementary linear and nonlinear devices, making it possible to realize complex circuits directly on a single board; these circuits are commonly referred to as *integrated circuits*, while the single board is termed a “chip”.

Figure 4. Microstrip line: geometry.

- It can be easily coupled with square or circular waveguides to form OMTs’.

The main drawbacks of the microstrip is that the medium in which the EM field propagates is nonhomogeneous. Differently from the coaxial cable, since the EM field propagates in both air and the dielectric material, the propagation constant does not depend linearly with the frequency, causing frequency distortion of wavepackets. The fundamental mode has the transverse field configuration shown in Fig. 5. Unfortunately there are no simple analytical solutions expressing the EM field distributions, but we would like to emphasize the close analogy with the coaxial cable, with the electric field lines directed mostly from one conductor to the other and the magnetic field lines as deformed circles around the smaller conductor. The strip guides the EM wave in the z direction whose energy is most concentrated in the dielectric medium, in the region between the strip itself and the ground plane, with such an effect emphasized by increasing ϵ_r . The fundamental mode is termed “quasi-TEM” because a longitudinal component of the associated EM field exists but is very small compared to the transverse ones. The characterization of the microstrip may be given, with very good approximation for our practical purposes, by using transmission-line concepts that are discussed later in this article; for a reader interested in more details, we suggest Refs. 4 and 7.

Although the transmission-line characterization is, in principle, quite simple, determined essentially by only two parameters, the characteristic impedance Z_c and the propagation constant of the fundamental mode β , closed formulas for these parameters are quite elaborate because of the complexity of the structure.

The propagation constant is usually expressed in terms of the *effective relative dielectric constant* ϵ_{e} , representing the dielectric constant of an equivalent homogeneous

Figure 5. Microstrip line: field configuration of the quasi-TEM dominant mode.

TEM line, thus satisfying

$$\beta = \frac{\omega(\epsilon_e)^{-1/2}}{c} \tag{4}$$

The propagation factor is $e^{-j\beta z}(e^{+j\beta z})$ for waves traveling in the $+z$ ($-z$) direction.

The effective relative dielectric constant ϵ_e is a function of the geometry according to

$$\begin{cases} \epsilon_e = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left[\left(1 + 12\frac{h}{w}\right)^{-1/2} + 0.04\left(1 - \frac{w}{h}\right)^2 \right] \frac{w}{h} \leq 1 \\ \epsilon_e = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left(1 + 12\frac{h}{w}\right)^{-1/2} \frac{w}{h} \geq 1 \end{cases} \tag{5}$$

The characteristic impedance can also be expressed as a function of the effective relative dielectric constant ϵ_e , thus assuming different forms according to the ratio between the strip width w and the dielectric thickness h :

$$\begin{cases} Z_c = \frac{\mu c}{2\pi(\epsilon_e)^{1/2}} \ln\left(8\frac{h}{w} + 0.25\frac{w}{h}\right) \frac{w}{h} \leq 1 \\ Z_c = \frac{\mu c}{(\epsilon_e)^{1/2}} \left[\frac{w}{h} + 1.393 + 0.667 \ln\left(\frac{w}{h} + 1.444\right)\right]^{-1} \frac{w}{h} \geq 1 \end{cases} \tag{6}$$

These formulas give accuracy better than 1 percent for practical values of w , h , and ϵ_r [4].

To attain a better accuracy, the finite thickness t of the strip has to be considered. This can be done by replacing the actual strip width (w) and dielectric height (h) with the corresponding *effective* values w' and h' defined as

$$\begin{cases} w' = w + \frac{t}{\pi} \left[\ln\left(2\frac{h}{t}\right) + 1 \right] \\ h' = h - 2t \end{cases} \tag{7}$$

and by modifying the expression defining the effective dielectric constant ϵ_e as

$$\epsilon'_e = \epsilon_e - \frac{\epsilon_r - 1}{4.6} \frac{t/h}{(w/h)^{1/2}} \tag{8}$$

The upper frequency limit to prevent higher-order mode propagation is given by the following formula

$$f_c = \frac{150}{\pi h} \left(\frac{2}{\epsilon_r - 1}\right)^{1/2} \tan^{-1}(\epsilon_r) \tag{9}$$

where f_c is expressed in gigahertz and h in millimeters.

2.3. Rectangular Waveguide

The rectangular waveguide is the most versatile structure for OMT applications because it is used as both a single-mode port and a common port.

In contrast to the previous transmission lines, the rectangular waveguide does not support TEM (or quasi-TEM) propagation mode, and this fact has some important consequences:

- Rectangular waveguides cannot be characterized easily by resorting to circuit parameters such as like characteristic impedance and a propagation constant, but we have to use a full-field approach.
- The fundamental mode has a nonzero frequency cut-off below which no energy can be propagated.
- The propagation constant has a nonlinear variation with frequency causing signal dispersion; this effect is noticeable mainly in the lower side of the single-mode band.

Notwithstanding these drawbacks, the rectangular waveguide is widely used in the microwave range because

- Fields are known analytically, thus making available very simple, efficient, and accurate design tools.
- They exhibit very low losses and very high power-handling capabilities.
- They are inexpensive and easily machined structures.

Figure 6 shows the transverse section of a rectangular waveguide. The electromagnetic field excitation in a rectangular waveguide may be done in different ways. Microwave energy is able to propagate if the cutoff condition is satisfied. To determine this condition, we define the generic transverse eigenvalue:

$$\begin{aligned} k_{t,mn} &= [k_{xm}^2 + k_{ym}^2]^{1/2}, \\ k_{xm} &= \frac{m\pi}{a}; \\ k_{yn} &= \frac{n\pi}{b} \end{aligned} \tag{10}$$

which represents the wavenumber lower limit for both the TE_{mn} mode and the TM_{mn} mode under which the mode cannot propagate. Thus the cutoff condition for the two mn

Figure 6. Rectangular waveguide: geometry.

modes is given by

$$k = \omega(\epsilon\mu)^{1/2} > k_{t,mn} \quad (11)$$

This relation gives directly the cutoff frequency f_c by

$$k = k_{t,mn} \Rightarrow f_c = \frac{ck_{t,mn}}{2\pi} \quad (12)$$

The propagation constant is given by

$$k_{mn} = -j(k_{t,mn}^2 - k^2)^{1/2} = \begin{cases} \beta > 0, & k > k_{t,mn} \\ -j\alpha, & \alpha > 0, k < k_{t,mn} \end{cases} \quad (13)$$

The propagation factor is $e^{-jk_{mn}z}(e^{+jk_{mn}z})$, for a wave traveling in the $+z$ ($-z$) direction. Each wave is associated with a complex wave intensity a_{mn} (b_{mn}), which is diff, in general, between TE_{mn} and TM_{mn} modes; finally, to obtain the total field, we have to consider another factor that accounts for the field dependence on the guide transverse section (xy):

For the TE_{mn} mode

$$\begin{cases} \mathbf{E}_{mn} = k_{yn} \cos(k_{xm}x) \sin(k_{yn}y)\mathbf{u}_x - k_{xm} \sin(k_{xm}x) \cos(k_{yn}y)\mathbf{u}_y \\ \mathbf{H}_{mn} = Y_{mn} \mathbf{u}_k \times \mathbf{E}_{mn} - \frac{k_{t,mn}^2}{j\omega\mu} \cos(k_{xm}x) \cos(k_{yn}y)\mathbf{u}_z \end{cases} \quad (14)$$

For the TM_{mn} mode.

$$\begin{cases} \mathbf{H}_{mn} = k_{yn} \sin(k_{xm}x) \cos(k_{yn}y)\mathbf{u}_x - k_{xm} \cos(k_{xm}x) \sin(k_{yn}y)\mathbf{u}_y \\ \mathbf{E}_{mn} = Z_{mn} \mathbf{H}_{mn} \times \mathbf{u}_k - \frac{k_{t,mn}^2}{j\omega\epsilon} \sin(k_{xm}x) \sin(k_{yn}y)\mathbf{u}_z \end{cases} \quad (15)$$

In these expressions $Y_{mn} = (k_{mn}/\omega\mu)$ is the TE field admittance, $Z_{mn} = (k_{mn}/\omega\epsilon)$ is the TM field impedance and \mathbf{u}_k is the unit vector associated to the direction of propagation ($\mathbf{u}_k = \pm \mathbf{u}_z$).

The fundamental mode in a rectangular waveguide is the TE_{10} mode, provided $a > b$. The field configuration of the TE_{10} mode is given in Fig. 7 showing no variation along the y coordinate and a sinusoidal taper with respect to the x coordinate.

The single-mode bandwidth for the rectangular waveguide depends on the value of b . If $a > 2b$, then the first higher-order mode is the TE_{20} and the relation between the cutoff frequencies of TE_{10} and TE_{20} is $f_{c20} = 2f_{c10}$; otherwise, in the case $b < a < 2b$ the first higher-order mode (TE_{01}) frequency is given by $f_{c01} = (a/b)f_{c10}$. In practice almost all the standard waveguides have $a = 2b$ giving the maximum bandwidth minimizing ohmic losses.

A particular configuration of the rectangular waveguide is used largely in OMT applications. In the case

Figure 7. Rectangular waveguide: field configuration of the TE_{10} mode.

$a = b$, the square waveguide results with the properties that two uncoupled signals, having orthogonal field configurations, can propagate with the same propagation properties constituting a very attractive structure for OMT common ports. The two signals are associated with the TE_{10} and TE_{01} modes whose fields are represented in Fig. 8 showing a behavior the same as that of the standard waveguide fundamental mode. It is important to note that the single-mode bandwidth (or, in this case, more properly the double-mode bandwidth) of the square waveguide is less than half that of the standard waveguide, since the cutoff frequencies of both TE_{11} and TM_{11} are a $2^{1/2}$ factor greater than those of TE_{10} and TE_{01} . However, in structures with certain symmetries, these the first higher-order modes are not excited, so that the bandwidth can be increased in practice.

2.4. Circular Waveguide

The circular waveguide is another structure of interest because, like the square waveguide, it has very useful properties in use as a common port in OMTs.

Figure 8. Square waveguide: field configuration of the TE_{10} and TE_{01} modes.

For the circular waveguide the same considerations given for the rectangular waveguide with respect to the non-TEM features of the fundamental mode are valid. While the square waveguide is better suited to feed pyramidal horns [8], the circular waveguide is better suited to feed circular horns [9] or corrugated circular horns [10]. The EM field propagation and configuration in a circular waveguide are often schematically represented as sketched in Fig. 9.

Similar to the rectangular waveguide, in a circular waveguide microwave energy is able to propagate if the cutoff condition is satisfied. In a circular waveguide the transverse eigenvalue generic expressions for the TE (h) case and the TM(e) case are different:

$$k_{t,mn}^h = \frac{p'_{mn}}{R}; \quad k_{t,mn}^e = \frac{p_{mn}}{R} \tag{16}$$

In these formulas p_{mn} and p'_{mn} are the n th zero of the m th-order Bessel function of first kind J and its derivative, respectively. New indices e and h are introduced here for the sake of brevity; the index indicates the longitudinal field component, which differs from zero, that is, $H_z \neq 0$ for TE modes (thus h) and $E_z \neq 0$ for TM modes (thus e). These zeros are obviously independent of frequency and geometry and are known and tabulated. The cutoff condition, the cutoff frequency, and the propagation constant for the e and h modes in a circular waveguide are again given by the same rectangular case formulas (11)–(13) with the position $k_{t,mn} = k_{t,mn}^h$ and $k_{t,mn} = k_{t,mn}^e$.

Also the propagation factor has the same expression $e^{\mp jk_{mn}^h z}$ ($e^{\mp jk_{mn}^e z}$), according to the direction of propagation $\pm z$ of the wave and the mode type, TE (TM). Each wave is associated with a complex coefficient, which varies, in general, between TE $_{mn}$ and TM $_{mn}$ modes; for instance, a TE $_{mn}$ wave propagating in the $+z$ direction is characterized by a factor $a_{mn}^h e^{-jk_{mn}^h z}$. Finally, to obtain the total field, we have to consider the transverse dependence whose analytical expression in circular waveguide is given as follows:

Figure 9. Circular waveguide: geometry.

For the TE $_{mn}$ mode

$$\begin{cases} \mathbf{E}_{mn} = \frac{m}{\rho} J_m(k_{t,mn}^h \rho) [V_{mn}^h \sin(m\phi) + H_{mn}^h \cos(m\phi)] \mathbf{u}_\rho \\ + \frac{\partial}{\partial \rho} J_m(k_{t,mn}^h \rho) [V_{mn}^h \cos(m\phi) - H_{mn}^h \sin(m\phi)] \mathbf{u}_\phi \\ \mathbf{H}_{mn} = Y_{mn}^h \mathbf{u}_k \times \mathbf{E}_{mn} - \frac{(k_{t,mn}^e)^2}{j\omega\mu} J_m(k_{t,mn}^h \rho) \\ \times [V_{mn}^h \cos(m\phi) - H_{mn}^h \sin(m\phi)] \mathbf{u}_z \end{cases} \tag{17}$$

and by

For the TM $_{mn}$ mode

$$\begin{cases} \mathbf{H}_{mn} = \frac{m}{\rho} J_m(k_{t,mn}^h \rho) [V_{mn}^e \cos(m\phi) - H_{mn}^e \sin(m\phi)] \mathbf{u}_\rho \\ - \frac{\partial}{\partial \rho} J_m(k_{t,mn}^e \rho) [V_{mn}^e \sin(m\phi) + H_{mn}^e \cos(m\phi)] \mathbf{u}_\phi \\ \mathbf{E}_{mn} = Z_{mn}^e \mathbf{H}_{mn} \times \mathbf{u}_k - \frac{(k_{t,mn}^e)^2}{j\omega\epsilon} J_m(k_{t,mn}^h \rho) \\ \times [V_{mn}^e \sin(m\phi) + H_{mn}^e \cos(m\phi)] \mathbf{u}_z \end{cases} \tag{18}$$

In these expressions $Y_{mn}^h = (k_{mn}^h / \omega\mu)$ is the TE field admittance, $Z_{mn}^e = (k_{mn}^e / \omega\epsilon)$ is the TM field impedance, and \mathbf{u}_k is the unit vector associated with the direction of propagation ($\mathbf{u}_k = \pm \mathbf{u}_z$). The V and H coefficients may be regarded to as normalization constants associated with one of the two independent polarization states in which each circular waveguide mode can exist, for $m > 0$; if $m = 0$, a unique polarization state does exist for each mode because the field is independent of the azimuth coordinate. In the case of the fundamental TE $_{11}$ mode, V and H may be interpreted as *vertical* and *horizontal*, associated with the direction of the electric field vector. The V and H field configurations are shown, respectively, in Figs. 10 and 11.

The fundamental TE $_{11}$ mode is associated with approximately $p'_{11} = 1.841$. The single-mode bandwidth for the rectangular waveguide does not depend on geometry, in contrast to the rectangular case, but it is fixed; the first higher-order mode is the TM $_{01}$ having approximately $p_{01} = 2.405$. The ratio between the cutoff frequencies of the TM $_{01}$ and the TE $_{11}$ modes equals the ratio of the associated zeros, so we have $f_{c01}^e = 1.3f_{c11}^h$, characterizing the bandwidth. Properties given by symmetric structures to produce, in practice, a larger bandwidth also exist in the circular waveguide, similarly to the square waveguide; in fact, we are interested mainly in circular waveguide structures having discontinuities only in the radial direction, implying that the first excited higher-order mode is the TM $_{11}$ mode having $p_{11} = 3.832$ and giving a fractional bandwidth of about $f_{c11}^e / f_{c11}^h = 2.08$.

For the same reasons regarding the TE $_{10}$ and TE $_{01}$ modes in a square waveguide, the properties of the V and H polarizations of the TE $_{11}$ mode (which we will refer to as TE $_{11v}$ and TE $_{11h}$) are very attractive for the common-port modes of OMTs.

Figure 10. Circular waveguide: field configuration of the TE_{11v} mode.

3. PRACTICAL CONFIGURATIONS OF ORTHOMODE TRANSDUCERS

Different models of orthomode transducers have been developed, each matching a set of practical requirements, mainly electromagnetic requirements (return loss, ohmic losses, isolation, operative bandwidth) and mechanical/economical requirements (low cost, easy fabrication, easy

Figure 11. Circular waveguide: field configuration of the TE_{11h} mode.

interfacing with devices to which they are connected). Basic configurations will be shown in the subsequent sections.

We must note the importance of numerical methods in the computer-aided design of such devices. Many of these methods exhibit distinct features and have been developed through the increasing processing power of modern computers. Among these methods, in particular three are very useful in the design of the OMTs presented here—the finite-difference time-domain method (FDTD), the finite-element method (FEM), and the mode-matching (MM) method, each of which are only briefly introduced at this point. These three methods are particularly useful in solving electromagnetic boundary value problems in closed domains as in the case of OMTs.

The FDTD method is based on the finite-difference approximation applied directly to the differential form of Maxwell equations in the time domain and operating on a rectangular elementary cell-based mesh subdividing the entire domain of analysis. To give sufficient accuracy, these elementary cells should be small with respect to the minimum wavelength of the spectrum of the signal exciting the EM field. Also, the time elementary step, approximating the differential part of the derivative with respect to time in Maxwell equations, must satisfy certain constraints; specifically, it must be smaller than the ratio between the elementary cell dimension and the light velocity in the medium. Information regarding the boundary conditions, including the excitation signal, is the final requirement. FDTD leads directly to the solution with no matrix inversion; however, it is a bit time-consuming. Also, if the analysis is in the time domain, it is nevertheless possible to obtain frequency-related parameters, which in many cases are much more useful, using the fast Fourier transform algorithm.

FEM is actually a frequency-domain method also based on a discretization of the domain under analysis but giving more flexibility than FDTD in choosing the element cells, which may be of different shape and also within a single domain. This flexibility in the discretization is obtained at the expense of a more complex electromagnetic formulation. When boundary conditions are imposed, the EM problem becomes an algebraic linear system of equations that must be solved using conventional linear system methods. Since the system is sparse, very efficient solvers can be applied.

MM is a frequency-domain method based on the analytical field expansion into eigenfunctions in the region under analysis, leading, when boundary conditions are imposed, to an algebraic linear system, requiring in the solution the inversion of matrices that are quite full.

Nevertheless, when the geometry of the problem is simple, it is possible to describe it in terms of a cascade of waveguide sections (rectangular, circular, or coaxial), in which the solution of the Maxwell equations are known analytically, MM is perhaps the most suitable method, giving low calculation time and very high accuracy and requiring very low computation resources.

3.1. Coaxial-Cable-Coupled OMT

A very easy-to-fabricate and low-cost OMT is shown in Fig. 12. It is formed by the junction of two coaxial cables whose inner conductors intersect a circular waveguide section, where the axes of all three guiding structures are mutually orthogonal, with the coaxial external conductors electrically connected to the circular waveguide wall. On one side the waveguide is typically short-circuited by a metallic plane, while the common port is located on the other side and the two orthogonal modes TE_{11v} and TE_{11h} , associated with ports 1 and 2, respectively, can propagate. Inside the waveguide, the inner conductor of each coaxial cable is typically a quarter-wavelength long, and the distance of these cables from the waveguide short circuit is also about a quarter-wavelength. A square waveguide can replace the circular waveguide without changing the basic properties of this kind of OMT.

The ideal scattering behavior is given by the matrix (1), while the principle of operation is described in the following text. By the physical laws of the electromagnetic interaction between fields and their sources, in free space an electrical dipole radiates a field having an electric field that is oriented in the same general direction as the dipole with the property that in the far-field region the radial component tends to zero. In a bounded region, as in a waveguide, the situation is analogous; in the case of this OMT, if we consider the TE_{11v} mode (port 1) by the symmetry of its field configuration, we can note that it has a global resultant electric field that is directed vertically; thus it couples to the coaxial cable associated with port 3, with its inner conductor behaving as a vertical dipole; on the contrary, this field configuration ideally induces no currents on port 4, resulting in no field coupling between ports 1 and 4. By analogy, the TE_{11h} mode (port 2) couples to port 4 and does produce ideally no field excitation in the coaxial cable of port 3. If we assume

Figure 12. Coaxial-cable-coupled OMT: basic configuration.

perfect matching at the four ports and no coupling between ports 1 and 2 and between ports 3 and 4, we account for all the entries of the scattering matrix. This is, of course, ideal and untrue. It is very difficult to obtain perfect matching at all ports of this junction; a realistic value for measured junctions is $s_{ii} < (-15, -20)$ dB, and only if some matching elements, such as steps in a circular guide, are used, and this in a bandwidth no greater than 10–15%. Regarding the isolation between the uncoupled ports, we note that the azimuthal symmetry of the structure is of very high importance, avoiding the excitation of higher-order spurious modes, which results in a sensitive degradation of all the performance and a reduction in bandwidth. To be more precise, of prime importance is the symmetry with respect to the two polarization planes, which are the planes defined in the common-port waveguide by the field polarization of the two fundamental modes and the waveguide axis. In this case the structure configuration breaks the symmetries in the region of interaction with the coaxial cables, leading to severe performance degradation. On the other hand, one should observe that the presence of the short circuit does not violate any symmetry; it totally reflects only the incident mode without exciting any higher-order one.

3.2. Microstrip-Line-Coupled OMT

A more practical and widely used OMT device is shown in Fig. 13. It is formed by the junction of two microstrip lines on a common substrate, with the strips intersecting at 90° angles each other, as described in Section 3.1. Also, in this OMT the lines enter normal to the waveguide axis by the waveguide wall. The microstrip line is typically enclosed in a metallic box connected electrically to the waveguide wall; the lower side of this metallic box constitutes the microstrip ground plane, although in the region inside the waveguide the ground plane is usually removed to ensure conditions more favorable for optimum coupling. Also in

Figure 13. Microstrip-line-coupled OMT: basic configuration.

this configuration one side of the waveguide is typically short-circuited by a metallic plane while on the other side the two orthogonal modes TE_{11v} and TE_{11h} , associated with the ports 1 and 2, respectively, can propagate. The usual quarter-wavelength section is used in this case also, for both the length of the strips inside the waveguide and their distance from the short circuit ($d + h$ in Fig. 13), with care taken to consider the right wavelength. In the first case it is the wavelength in the microstrip; in the second case there is an appropriate combination, according to the lengths d and h of the respective regions, of the wavelengths in the waveguide both without and with the dielectric. A square waveguide can replace the circular waveguide without changing the basic properties of this type of OMT.

Regarding performance, we note that the optimization of the transition between a microstrip and a waveguide is currently a hotly debated point in scientific research. This is because this structure is used heavily in the front end of the receivers of the satellite TV broadcasting, directly connected to the horn feeding the 80-cm–1.2-m parabolic antenna on residential rooftops. In fact, satellite TV broadcasting uses, for each frequency band, two channels, V and H , differing only for the polarization, thus requiring an OMT to separate these two channels in the receiver.

Even if, in this case, the lack of symmetry with respect to the polarization planes does not provide high performance and broadband operation, this configuration nevertheless has two major advantages with respect to the coaxial cable configuration:

- It is very easy to fabricate matching networks with the present state-of-the-art microstrip technology using both lumped and distributed elements.
- It is very easy to accommodate on a microstrip the active circuitry to efficiently process the incoming radiofrequency signal, which requires low noise amplification as one of the first steps in preventing degradation of the signal-to-noise ratio. On a single microstrip card of a few centimeters, we can have the OMT part, matching networks, low-noise amplifiers, mixers, and other parts, with built-in hybrid microwave integrated circuit technology, so that the output signal from the microstrip is at such a low frequency that it can be transmitted through meters and meters of common TV coaxial cables for connection to the TV set without appreciably degrading the quality of the signal itself.

The principle of operation is basically the same as discussed in Section 3.1, with the coupling between TE_{11v} mode (port 1) and strip v (port 3) and between TE_{11h} mode (port 2) and strip h (port 4), thus providing the same ideal scattering matrix representation as shown in (1).

Regarding nonidealities, typical performance of this type of OMT in a 10–15% band exhibits a minimum of 15–20 dB return loss, a limit of 25–30 dB isolation between the various ports, and losses of a few tenths of a decibel.

3.3. Sidearm-Coupled OMT

A very widely used OMT is the one shown in Fig. 14, which we refer to as the *sidearm-coupled OMT*. It is developed entirely in the waveguide, a solution adopted when high performance (typically, return loss > 20 dB, isolation > 30 dB, losses < 0.2 dB) is desired. However, because of the asymmetry of the structure, the operative bandwidth is theoretically limited, in the square waveguide case, to the cutoff frequency f_{c11} of the TE_{11}/TM_{11} modes, giving a relative fractional bandwidth of about $(f_{c11} - f_{c10}) / (f_{c11} + f_{c10}) / 2 = 34\%$, where f_{c10} indicates the fundamental TE_{10} cutoff frequency. The version shown in Fig. 14 is based on the H -plane side coupling; an E -plane side coupling version also exists (see Fig. 15).

The H -plane side is associated with either of the two walls of the waveguide normal to the H plane, while the E -plane side is associated with each of the other two walls normal to the E -plane; for example, in the case of a TE_{10} single-mode standard waveguide with $a = 2b$, the H -plane sides are the walls associated with b while the E -plane sides are the ones associated with a . In both versions the common port and one of the rectangular single-mode ports are coaxial and the side port is orthogonal to them; this means that the structure exhibits geometric symmetries corresponding to very important electromagnetic properties that are of prime relevance in the proper operation of this type of OMT.

The H -plane sidearm-coupled OMT functions as follows. A vertically polarized TE_{10} wave (port 1) originating from the common port and crossing the side waveguide (port 4) excites, in this port, higher-order modes that, by symmetry, are $TE_{(m)(2n+1)} TM_{(m+1)(2n+1)}$, where m and n are integers. If this waveguide, in the operative band, is single-mode, the fundamental TE_{10} mode is not excited, thus resulting in the TE_{10} mode from the common port perceiving the side waveguide as a reactive load and no active power transfer between ports 1 and 4. On the other hand, traveling forward to port 3, this mode does excite a particular subset of modes, depending on the symmetries (E -plane, H -plane, or both), containing in any case the fundamental TE_{10} mode of port 3, which usually is a single-mode waveguide also in the operative band.

In the other case, the common-port horizontally polarized TE_{01} mode (port 2) does produce in port 4 a subset of

Figure 14. H -plane sidearm-coupled OMT: basic configuration.

Figure 15. *E*-plane sidearm-coupled OMT: basic configuration.

modes $[TE_{(m)(2n)} TM_{(m+1)(2n+2)}]$ which, compatible with TE_{10} excitation, allows coupling between ports 2 and 4. On the other hand, port 3 behaves like a reactive load with respect to this common-port polarization, inducing a field expansion in modes $[TE_{(2m)(n)} TM_{(2m+2)(n+1)}]$.

The *E*-plane sidearm-coupled OMT obviously exhibits similar behavior but the electromagnetic coupling is of a different nature. If we again consider a vertically polarized TE_{10} wave (port 1) originating from the common port and crossing the side waveguide (now port 3), in this port it excites higher-order modes, which, when the a dimension of the side waveguide equals the side of the square of the common port section, are $TE_{1(n)}$ and $TM_{1(n+1)}$, where m and n are integers. If this waveguide, in the operating bandwidth, is single-mode, then only the fundamental TE_{10} mode can propagate. On the other hand, geometric symmetry implies that, if the a dimension of the through waveguide equals the side of the square common-port section, the modal expansion in port 4 is of the $TE_{0(2n+1)}$ type, not including this port fundamental TE_{10} mode. Thus the mode of port 1 perceives port 4 as a reactive load and active power transfer is allowed only between port 1 and port 3. The behavior of a horizontally polarized TE_{01} wave (port 2) in the *E*-plane sidearm-coupled OMT is essentially the same as that of the vertically polarized TE_{10} wave (port 1) in the *H*-plane sidearm-coupled OMT, also if the electromagnetic interactions between the ports are slightly different; that is, the side port is a reactive load and the active power from port 2 is coupled only to port 4.

Summarizing, because of the numbering unique to each port, these two kinds of OMT once again have the same ideal scattering matrix representation, as given in (1). In some applications this version of OMT is used with the common port in circular waveguide, basically exhibiting the same properties and performance, only giving a better mechanical interface when feeding, for example, a circular horn.

3.4. Finline-Based OMT

To enlarge the bandwidth (30–40%), an improved version of the OMT described in Section 3.3, with only a small performance degradation (typical values are 15 dB return loss, 30 dB isolation, and 0.5 dB loss), is obtained by

introducing a shaped metallic septum that constitutes in the common waveguide a tapered finline, coupled by a finline 90° *E*-plane band to the sidearm waveguide. This type of OMT [11], shown in Fig. 16, takes advantage of the finline waveguide properties. The single-mode bandwidth of a finline is a bit greater than that of the standard waveguide, depending essentially on the width between the ridges. Another feature of primary importance for the operation of the derived OMT is the fact that the electromagnetic field energy is concentrated increasingly in the region between the ridges, as this becomes smaller and smaller.

The principle of operation of the finline-based OMT is quite simple. A vertically polarized TE_{10} wave (port 1) coming from the common port is not perturbed by the presence of the metallic septum if its thickness is small with respect to the waveguide dimensions. The side waveguide can be seen as a reactive load because, by the *H*-plane symmetry of the problem, in this waveguide, which by assumption is single-mode in the OMT operative bandwidth, only the evanescent $TE_{(2m)(n)}$, $TM_{(2m+2)(n+1)}$ modes, with m and n integers, are excited. Thus the port coupling active power with port 1 is port 3.

In the other case, a horizontally polarized TE_{01} wave (port 2) originating from the common port is even more confined in the region closed to the gap between the finline center conductor as this gap becomes thinner. Approaching the sidearm junction, the curvature of the gap drives the electromagnetic energy to port 4, which propagates with a gradual transformation between a finline mode (in the region close to the junction) to a pure rectangular waveguide TE_{10} (in the region close to port 4). Regarding the coupling with the other port, the common-port TE_{01} mode, approaching the discontinuity, excites in port 3 a reactive field given (in this case we have *E*-plane symmetry) by the superposition of evanescent $TE_{(m)(2n+1)}$, $TM_{(m+1)(2n+1)}$ modes.

As a final consideration, we have an ideal scattering matrix for the finline-based OMT given by (1).

3.5. Dual-Junction-Based OMT

When higher performance levels are required in a broad band, an OMT with geometric symmetries on both *E* and

Figure 16. Finline-based OMT.

H planes is required. One of the most commonly used configurations of this type is the dual junction (Fig. 17), from which the dual-junction-based OMT is derived. The most important property responsible for its excellent electromagnetic behavior is that its dual-plane symmetry avoids excitation of the TE_{11} and TM_{11} modes, the first higher-order modes, and the most critical regarding performance degradation.

The dual-junction OMT consists of a common port, typically a square waveguide, coupling to two 90° lateral waveguides and two directly facing waveguides; the latter are obtained by simply splitting the common waveguide by means of a metallic septum.

To ensure high performance levels, the septum is shaped relative to the region of the side branches (Fig. 17) and to even further improve bandwidth and performance, two wire posts are placed in the center of the side waveguides parallel to the principal side.

The behavior of the dual-junction OMT is thus quite simple and partially analogous to that of, the E -plane sidearm-coupled OMT.

A vertically polarized TE_{10} wave (port 1) incident from the common port basically doesn't feel the presence of the metallic septum and is reactively loaded by port 4 (ports 4a and 4b), thus coupling with port 3 (ports 3a and 3b). This may be explained by noting that, because of the dual-plane symmetry, the modes excited in the discontinuity region of the waveguide intersection must have the same index parity of the excitation mode, namely, $TE_{(2m+1)(2n)}$, $TM_{(2m+1)(2n+2)}$, where m and n are integers. It is worth stressing, as mentioned above, that this modal subset does not contain TE_{11} and TM_{11} modes having, in the common-port square waveguide, cutoff frequencies a factor $2^{1/2}$ greater than in the fundamental mode. Furthermore, in the side waveguides this modal subset corresponds to a superposition of $TE_{(2m)(n)}$, $TM_{(2m+2)(n+1)}$ modes, not including the TE_{10} mode, and providing rationale for the reactive coupling given by the side waveguide to this polarization.

On the contrary, a horizontally polarized TE_{01} wave (port 2) incident from the common port basically perceives port 3 (3a and 3b) as a reactive load, exciting by symmetry $TE_{(2m)(n)}$, $TM_{(2m+2)(n+1)}$ modes. This polarization is driven by the particular shape of the upper part of the

metallic septum to port 4, in which the above mentioned modal expansion corresponds to an appropriate superposition of $TE_{(2m+1)(n)}$, $TM_{(2m+1)(n+1)}$ modes, including the TE_{10} mode and allowing ports 2–4 coupling.

To ensure a canonical OMT configuration, ports 3a and 3b, as well as ports 4a and 4b, must be combined to give a standard waveguide access to the OMT. If this appears quite simple for ports 3a and 3b by means of a stepped transformer, this is a bit more complex (and this is a consistently encountered drawback of this OMT) for ports 4a and 4b requiring E -plane or H -plane bends (or both) and a carefully designed combiner.

Typical performance levels for this OMT are >20 dB return loss and >35 dB isolation over a bandwidth approaching the $\sim 40\%$ standard waveguide bands.

4. EXAMPLE DESIGN OF A DUAL-JUNCTION-BASED OMT

To give the reader a clearer idea of practical applications, in this example we present a 20% band OMT operating at 30 GHz for a radio astronomy receiver, developed, built, and measured at the Institute of Radioastronomy of the Italian National Research Council.

The design is based on the dual junction with no posts and a triangle-shaped septum.

The prototype OMT, shown in Fig. 18, was fabricated by using aluminum material and then gold-plated with an approximate global dimension of 5 cm for the side cube. The sidearms are recombined through H -plane bends and a stepped combiner.

Figures 19 and 20 show the high performance levels of the overall OMT in comparison with the expected results for the standalone dual junction obtained by simulations with FEM-based commercial software.

In Fig. 19 the simulated reflection coefficient of the vertically polarized TE_{10} wave (port 1) of the dual-junction common port is shown together with the measured data of the corresponding measurement of the overall OMT and one of the coupled ports (V port = port 3).

Figure 20 shows analogous parameters of the horizontal polarization: the simulated reflection coefficient of the horizontally polarized TE_{01} wave (port 2) of the dual-junction common port, the measured data of the reflection coefficient of the same wave in the operative complete configuration and that in the coupled port (H port = port 4), which is the recombination of the side arms (4a and 4b).

It is worth noting the accuracy of the numerical method by comparing simulations with measured data; the dual-junction behavior is accurately predicted by the software, and the differences between the curves are due to the other components (bends, stepped transitions, combiner), which have been designed with much higher performance levels than in the dual junction itself. Thus the overall OMT has an oscillatory behavior of electromagnetic features across an approximately mean-value curve corresponding to dual-junction performance, according to in-phase or out-of-phase combinations of the scattered field, due to the different electrical lengths produced by changing the frequency.

Figure 17. Dual-junction-based OMT.

Figure 19. Dual-junction-based OMT: V-channel reflection coefficients.

Figure 20. Dual-junction-based OMT: H-channel reflection coefficients.

These curves are, however, below -20 dB, with a mean value of approximately -25 dB, in a 20% band centered at 30 GHz. Losses were measured to be <0.4 dB for the vertical channel (ports 1–4) and <0.8 dB for the horizontal channel (ports 2–3).

5. POLARIZERS

Polarizers change the EM field polarization from linear to circular. They have, as do OMTs, three physical ports and may be represented with four electrical ports, as shown in Fig. 21, with two single-mode ports 3,4 and two ports 1,2 at the common physical port. In free space, a deterministic (nonrandom) monochromatic field has, in general, a transverse elliptical polarization. In frequency-domain phasor notation, in a generic point of the space, the elliptical polarization may be fully characterized by two complex orthogonal vectors with different amplitude and phase \mathbf{p} and \mathbf{q} , which are normal to the direction of propagation associated with a unit vector \mathbf{z} . The main physical meaning of this is that any elliptical polarization may be obtained as the superposition of two phase-shifted and orthogonal linearly polarized fields. In particular, when the phases of \mathbf{p} and \mathbf{q} are equal, we have a linearly polarized field in a particular direction depending on the amplitude relation between \mathbf{p} and \mathbf{q} . When \mathbf{p} and \mathbf{q} have the same amplitude and are 90° phase-shifted, we have a circularly polarized field, where the tip of the electric field describes a circumference as time varies.

Figure 21. Polarizer schematic.

If the wave travels toward \mathbf{z} and

$$\frac{\mathbf{p} \times \mathbf{q}}{|\mathbf{p} \times \mathbf{q}|} = \mathbf{z} \quad (19)$$

then two independent circular polarization states are possible.

A right-hand circular polarization (RHCP) is obtained when the phase shift is as follows:

$$\arg(\mathbf{p}) - \arg(\mathbf{q}) = 90^\circ \quad (20)$$

We have a left-hand circular polarization (LHCP) if

$$\arg(\mathbf{p}) - \arg(\mathbf{q}) = -90^\circ \quad (21)$$

Once again suggesting Ref. 5 for a more in-depth treatment on field polarization, from a polarizer perspective, it is important to highlight the following properties of circular polarization:

1. Any deterministic and monochromatic field polarization may be obtained as the superposition of two independent circular polarizations: one LHCP and the other RHCP.
2. Waveguide circular polarizations (both LHCP and RHCP) are easily obtained in both circular and square waveguides by the superposition of the two fundamental modes, TE_{11v} and TE_{11h} in the circular waveguide, and TE_{10} and TE_{01} in the square waveguide, with the same amplitude and 90° phase-shifted.

Property 1 ensures that the polarizer can process any deterministic and monochromatic field configuration without any lack of representation, while property 2 basically allows us to adopt the same schematic notation used for OMTs, associating the ports of the common inputs 1 and 2 with the fundamental modes in the related waveguide: TE_{10} and TE_{01} in the square waveguide and TE_{11v} and TE_{11h} in the circular waveguide, respectively.

Thus, for an ideal polarizer, referring to the sketch in Fig. 21, the scattering matrix is given by the following expression:

$$S = 2^{-(1/2)} \begin{bmatrix} 0 & 0 & 1 & e^{j(\pi/2)} \\ 0 & 0 & e^{j(\pi/2)} & 1 \\ 1 & e^{j(\pi/2)} & 0 & 0 \\ e^{j(\pi/2)} & 1 & 0 & 0 \end{bmatrix} \quad (22)$$

We can see that it is matched at all the ports, with the diagonal elements of S equal to zero. From the third column of S we conclude that the power incident at the single-mode port 3 comes out 3 dB down from port 1 (x polarization) and port 2 (y polarization), with the x -polarization 90° retarded with respect to the y polarization, meaning that, as the outward travel of the wave is \mathbf{z} -directed, a pure LHCP is excited at the common port. From the fourth column we see analogously that, because this time the x polarization is retarded 90° in advance with

respect to the y polarization, at the common port a pure RHCP is excited.

Regarding the incident signals from the common port, it is more instructive to proceed in the following manner. If a pure LHCP polarization impinges on the common port, we can say that port 1 (x polarization) phasor is $2^{-(1/2)}$ while port 2 (y polarization) is 90° retarded with a phasor $2^{-(1/2)}e^{-j(\pi/2)}$. Thus, multiplying the scattering matrix by the incident vector associated with a common port incoming LHCP with unit power, we have

$$2^{-(1/2)} \begin{bmatrix} 0 & 0 & 1 & e^{j(\pi/2)} \\ 0 & 0 & e^{j(\pi/2)} & 1 \\ 1 & e^{j(\pi/2)} & 0 & 0 \\ e^{j(\pi/2)} & 1 & 0 & 0 \end{bmatrix} 2^{-\frac{1}{2}} \begin{bmatrix} 1 \\ e^{-j(\pi/2)} \\ 0 \\ 0 \end{bmatrix} \quad (23)$$

$$= \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \end{bmatrix}$$

meaning that all the power comes from port 3, as expected by polarizer reciprocity. If the common-port incident wave is a unit power RHCP, we obtain analogously

$$2^{-(1/2)} \begin{bmatrix} 0 & 0 & 1 & e^{j(\pi/2)} \\ 0 & 0 & e^{j(\pi/2)} & 1 \\ 1 & e^{j(\pi/2)} & 0 & 0 \\ e^{j(\pi/2)} & 1 & 0 & 0 \end{bmatrix} 2^{-\frac{1}{2}} \begin{bmatrix} e^{-j\pi/2} \\ 1 \\ 0 \\ 0 \end{bmatrix} \quad (24)$$

$$= \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}$$

confirming this time that RHCP is coupled to port 4.

Except for the channel crosstalk of the isolation OMT parameters of Table 1, all the other parameters are also meaningful for polarizers.

There is an additional parameter useful in describing polarizer nonidealities: the axial ratio (AR); that is the ratio, usually expressed in decibels, between the major and the minor axis of the polarization ellipse [thus $0 \leq \text{AR}(\text{dB}) < \infty$] of the elliptical polarization generated.

From an operative perspective, commonly used devices may be divided in two groups: double polarization conversion polarizers and septum polarizers.

5.1. Double-Polarization Conversion Polarizers

These devices are divided in two sections: a first section that converts two circularly polarized signals (LHCP, RHCP) in two linear and orthogonal polarizations (V, H) within a single common waveguide and an OMT (second section) of the already analyzed type, which splits the two linear polarizations into two separate waveguides.

Because we have already discussed OMTs, we will discuss only the first section, which is referred to as a *differential phase shifter* (DPS) because it introduces a 90° differential phase shift between the two fundamental modes.

A differential phase shift is given by the difference between two phase delays associated with each wave traveling from the input to the output of the device. As mentioned previously, 90° is the ideal differential phase shift of interest in the case of polarizers.

Operation of a DPS is shown in Fig. 22. If we assume that a structure exists having the property of introducing a 90° phase shift difference between an y -polarized signal and an x -polarized signal traveling from the input to the output port, it consequently transforms a LHCP signal incident at the input port in a linearly polarized, vertically directed ($V, \varphi = 45^\circ$) one, while converting a RHCP signal into a linearly polarized, horizontally directed ($H, \varphi = -45^\circ$) one, so that the two linear polarizations are orthogonal. These two linear polarizations V and H are associated, respectively, with the single-mode ports 3 and 4 of the OMT, so the scattering matrix of the resulting polarizer is the one given in (22).

If the ports are circular waveguides, there is no need to use any other device to complete the polarizer configuration using one of the OMT configurations shown earlier, but if the ports are square, a waveguide transition has to be used that rotates the square exactly 45° from input to output, by maintaining the same H or V direction of polarization. This transition from a square to a 45° -rotated square may be obtain by smooth tapering (Fig. 23) or by an

Figure 23. Square to 45° -rotated square transition.

abrupt junction, eventually with a circular section to improve performance.

Three of the most commonly used DPS configurations are shown in Fig. 24, in which the coordinate system is congruent with the one shown in Fig. 22. A simple rectangular waveguide (Fig. 24a) is an elementary DPS provided both the TE_{10} and the TE_{01} modes propagate. The polarization with the lower cutoff frequency has a greater propagation constant, so the phase shift between the two waves can be $\pm 90^\circ$ with an appropriate choice of the rectangular section length. An analogous circular waveguide port DPS can be obtained, as an optimum solution, with an elliptical waveguide section. This type of DPS is very simple, but in practice a differential phase shift close to 90° can be obtained only in a narrow band.

Figure 22. Differential phase shifter electromagnetic behavior.

An enlargement of the bandwidth may be obtained if we place an on-axis dielectric septum parallel to one of the two fundamental field polarizations (and orthogonal to the other) in a square (Fig. 24b) or circular waveguide. We obtain a DPS because the parallel component has a propagation constant greater than the one of the other polarization, obtaining again a $\pm 90^\circ$ differential phase shift by appropriate selection of the longitudinal length (z direction) of the septum.

However, the optimum solution for a DPS, with a broad band and without the problems encountered with dielectric materials (losses, mechanical interfacing, etc.), is the two-wall corrugated waveguide (Fig. 24c), which has an analogous configuration in circular waveguide using very thin elliptic section, more practically approximated by two transverse straight ridges, placed at 180° angles to each other, which partially fill the circular waveguide. The vertical x polarization, normal to the corrugations, has a propagation constant that is greater than the horizontal one, so in this case $\pm 90^\circ$ differential phase shift is also given by accurately designing the corrugation geometry. The dispersion characteristic (i.e., variation of the propagation constant with frequency) properties of the two polarizations give a very good flatness in the axial ratio curve with frequency, with two points at AR 0 dB very close in the frequency band, allowing the design of dual-band very-high-performance polarizers as well as broadband high-performance polarizers; in fact, the typical 40% standard waveguide band may be easily obtained by using these devices with an axial ratio below 1 dB.

5.2. Septum Polarizers

At the expense of a reduced operating bandwidth, a much more compact and simpler solution than any double-polarization conversion device is the septum polarizer, which is most commonly used in its square waveguide configuration (Fig. 25), but that exists also in circular, showing, in both cases, bandwidths of $\sim 12\text{--}15\%$.

This device can be called a “true” polarizing microwave junction, as the asymmetric triangular section performs the full double task, at least ideally, of differential phase-shifting the x and y polarizations of the common port and dividing, at the same time, the two recombined linear polarization signals into two separate waveguides.

Figure 24. Differential phase shifter examples: rectangular waveguide (a), waveguide with a dielectric septum (b), two-wall corrugated waveguide (c).

Figure 25. Septum polarizer.

Consider, for example, the RHCP signal in Fig. 26, whose principle of operation is as follows. The vertical ($-x$ in this case), polarization is not affected by the presence of the septum and travels almost unperturbed, dividing in the single-mode ports at 3 dB and in phase (with respect to the x direction); this is schematically shown in the right part of the RHCP sketch of Fig. 26. On the contrary, the shaped metallic septum significantly perturbs the propagation of the horizontal polarization ($-y$ in this case), causing electric field diffraction at the edge of the septum (left part of RHCP sketch in Fig. 26). Moreover, the field diffraction and the different propagation constant cause this $-y$ polarization to travel more slowly, thus retarding, ideally, at an angle of 90° with respect to the other $-x$ polarization. This behavior is schematically given by the successive dual chain of differently spaced field configurations and produces an in-phase combination at port 4(R) and an out-of-phase recombination at port 3(L) of the two polarizations if the incoming signal from the common port is RHCP, thus transferring its total power, ideally, to 4(R) and producing a null output signal from 3(L).

Explanation of the LHCP case is analogous to the difference that now the horizontal $-y$ polarization travels more slowly than the x polarization, thus retarding, ideally, at an angle of 90° with respect to the x polarization and producing a total power recombination at port 3(L) and a null signal at port 4(R). The scattering matrix representation of the septum polarizer, in the configuration shown in Fig. 25, is again given by (22).

Figure 26. Septum polarizer electromagnetic behavior.

Figure 27. Septum polarizer design at 6.7 GHz.

6. EXAMPLE DESIGN OF A SEPTUM POLARIZER

As an example, the design of a septum polarizer, developed, built, and measured at the Institute of Radioastronomy of the Italian National Research Council, is given in this paragraph. The device, operating at 6.7 GHz in a room-temperature receiver for radio astronomy, has to be connected to a circular corrugated horn on one side and to a standard WR-137 waveguide-fed receiver on the other side. Thus it has a common port in circular waveguide and two single-mode ports in WR-137 rectangular waveguide as shown in Fig. 27. In this case, because the polarizing junction, formed by the metallic shaped septum region, is better designed in square waveguide, a circular to square-shaped transition has been designed. Moreover, as the polarizing junction provides only ~75° differential phase shifting, a two-wall corrugated waveguide providing 15° of further shifting, to obtain the

Figure 28. Septum polarizer at 6.7 GHz. (Courtesy of the Institute of Radioastronomy of the Italian National Research Council.)

Figure 29. 6.7GHz septum polarizer electromagnetic performances.

desired 90° one, is introduced. The last complication in the design was the need to employ a stepped transition to connect the polarizing junction to the WR-137 standard waveguides.

The additional 15° could be achieved by carefully optimizing the septum profile. This can provide a more compact device, but having two separate components leads to greater design freedom and easier manufacturing.

An aluminum, direct-machined device has been fabricated on the basis of this design (Fig. 28) (the dimensions are about $50 \times 30 \times 15$ cm) and it was tested highlighting very good results in the 13% bandwidth centered at 6.7 GHz (Fig. 29), with an axial ratio below 0.8 dB and showing a very good agreement with expected results.

University of Hannover
Germany

1. INTRODUCTION

The development of electronic oscillators was closely related to the invention of the vacuum tube at the beginning of the twentieth century. First oscillator circuits were presented, for example, by Meissner, Hartley, Colpitts, and the basic ideas for a theory of such circuits were presented by Vallauri in 1917 [97]. In 1914 Zenneck considered an oscillatory arrangement with an arc as the active device and discussed nonlinear aspects of electronic oscillators by means of an energy balance equation. Unfortunately he did not derive the corresponding differential equations for the currents and voltages. A differential equation for a triode oscillator was presented for the first time by van der Pol in 1920. His studies became the starting point for a long series of research in mathematics, physics, as well as electrical engineering on oscillatory networks and systems. As a result a first monumental monograph about this subject was published by Andronov et al. [1] that included the essential aspects of the theory of oscillatory circuits and systems where these authors illustrated their theory by means of many examples. At the same time Krylov and Bogoliubov [55] published essential results on the analysis of oscillatory circuits. Both groups started from the work of van der Pol and used ideas and results from the work of the famous French mathematician and physicist Henry Poincaré. Short presentations of the history of these methods can be found in Sanders and Verhulst [86] and Mathis [66]. Although the results of these Russian authors were discussed several times in the literature, most of them were unknown to many researchers until the late 1960s. Maybe this is one of the reasons why, in contrast to the linear analysis of oscillatory circuits and systems, the details of the nonlinear theory due to the abovementioned Russian research groups were not included into a design theory of oscillators. We will show in this article that the design of oscillators can be clarified if their ideas are included.

2. FOUNDATIONS

2.1. Properties of Electrical Oscillators

In order to understand the difficulties related to electronic oscillators, it is useful to discuss the main properties of the behavior of such electronic circuits and consider some aspects of its modeling. It is well known that the basic behavior of an electronic oscillator should be characterized as follows: [79]:

- Some voltages and/or currents should behave in a periodic manner. The most essential shapes of the

output can be sinusoidal, sawtooth, and square waves.

- The oscillator frequency should be accurately determined.
- After a transient behavior the oscillator amplitude should be accurately determined and independent of the initial conditions.
- Perturbations of the oscillatory behavior in the steady state should have died out after some transient behavior.
- The oscillatory behavior should not be destroyed by parasitic circuit elements (structural stability).

From these qualitative properties the main features of electronic oscillators can be extracted and serve as main specifications:

- Oscillator frequency
- Oscillator amplitude
- Velocity of the startup and dying-out behavior

Obviously we have to add further properties if electronic oscillators will be designed. The signal-to-noise ratio and the stability of oscillator frequency and amplitude as well as the distortions with respect to a desired waveform are a few of these properties. Note that the basic behavior of electronic oscillators cannot be realized or modeled by using linear (time-invariant) circuits because these circuits have to be nondissipative (no Ohmic resistors are included) if periodic behavior is desired. Therefore the energy is conserved and their oscillatory amplitude depends on the initial conditions. Furthermore these linear (nondissipative) oscillator models are not structural stable (see characterization of oscillators) because the periodic behavior is destroyed by arbitrary small dissipative elements (e.g., Ohmic resistors). As a conclusion, mathematical models of electronic oscillators have to be nonlinear. In 1963 it was emphasized by Hale [40] that our knowledge of nonlinear systems is still far from being complete and only a few mathematical techniques are available to analyze such models. Although intensive research activities have been carried out in this area since the early 1970s, many problems still have to be solved to obtain a satisfying theory. Good illustrations of this statement can be found in Guckenheimer's discussion of the van der Pol equation [38].

2.2. Oscillator Models

Although linear LC circuits without dissipation are not suitable as a complete model for electronic oscillators, it is useful to start with such a circuit and to introduce the following changes:

- Compensation of the dissipation with negative resistors or positive feedback
- Comparison of the oscillator amplitude with a prescribed value in an implicit or explicit manner and control the negative resistor or the feedback

It should be emphasized that compensation is a linear technique whereas amplitude control by using parameter variation is an inherently nonlinear technique. These two steps can be described mathematically if we start from the differential equation for an LC circuit with a rather small resistor (dissipation)

$$\ddot{x} + \gamma\dot{x} + \omega_0^2 x = 0 \quad (1)$$

where γ is proportional to the (positive) resistance. Using a compensation technique the γ will be canceled. For example, this can be done by adding a negative resistor in series (or parallel) to the positive resistor with the same amount of resistance. If Eq. (1) is converted into the state space form $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ by the notations $x_1 := x$, $x_2 := \dot{x}$, it is easy to see that application of a compensation technique results in a pair of eigenvalues of \mathbf{A} on the imaginary axis. In more general cases the state space has a dimension $n > 2$ following more than two reactances. Usually the matrix \mathbf{A} has at least one pair of eigenvalues beside other eigenvalues with negative real parts. In Section 3.1 several approaches are discussed that can be used to find a set of parameters where a pair of eigenvalues with zero real part occur. Furthermore it should be emphasized that it is not necessary that we start with an LC circuit since it is possible, for example, to realize inductors in an active manner by means of resistors, capacitors, and (operational) amplifiers. In contrast to LC oscillators, these kinds of oscillators are called RC oscillators [e.g., 74]. The first RC oscillator was presented by Heegner [43] in 1927; see also Sidorowicz [91] further references.

If the resistor or, in other words, γ is controlled by the state variables (x, \dot{x}) , we get the following nonlinear differential equation:

$$\ddot{x} + \gamma(x, \dot{x})\dot{x} + \omega_0^2 x = 0 \quad (2)$$

Special choices of the function $\gamma = \gamma(x, \dot{x})$ lead to certain nonlinear oscillator models. In the next subsection this problem is discussed by means of the Poincaré–Andronov–Hopf theorem. As mentioned above, the van der Pol equation (vdP) was the first model of an oscillator circuit. The normalized version of this equation has the following form (with normalized $\omega_0^2 = 1$):

$$\ddot{x} + \varepsilon(x^2 - 1)\dot{x} + x = 0 \quad (3)$$

Note that this differential equation is of the abovementioned form. We mention that another differential equation of a similar type is the Rayleigh equation (R) (with normalized $\omega_0^2 = 1$):

$$\ddot{x} + \varepsilon(\dot{x}^2 - 1)\dot{x} + x = 0 \quad (4)$$

Unfortunately the equilibrium solution $\mathcal{O} := \{x(t) = 0 | t \in \mathbb{R}\}$ is the only solution that is known in exact terms. All other solutions and especially the periodic solution have to be calculated with perturbation methods. Therefore we consider a modified differential equation (with

normalized $\omega_0^2 = 1$)

$$\ddot{x} + \varepsilon(x^2 + \dot{x}^2 - 1)\dot{x} + x = 0 \quad (5)$$

with a periodic solution $x_p(t) := \{x(t) = \cos t | t \in \mathbb{R}\}$, which can be calculated in a simple manner. Obviously this solution is unique up to an additive phase φ and the periodic solution does not depend on the parameter ε . An advantage of this equation is that it can be interpreted very easily. For this reason $x_p(t)$ is represented in the state space ($x_1 := \dot{x}$, $x_2 := x$) as a circle. The state space representation of Eq. (5) is

$$\dot{x}_1 = -x_2 - \varepsilon(x_1^2 + x_2^2 - 1)x_1 \quad (6)$$

$$\dot{x}_2 = x_1 \quad (7)$$

Within this circle the (nonlinear) coefficient of the second term in Eq. (5) is negative and outside the circle the coefficient is positive. If this coefficient is constant both differential equations correspond to the descriptive equation of an *LC* circuit with linear damping that is an Ohmic resistor. If we assume the (nonlinear) coefficient in Eq. (5) to be constant for a moment, the first case corresponds to an *LC* circuit with a negative resistor and the second case, to a circuit with a positive resistor. From this heuristic point view it is easy to interpret the global behavior of Eq. (5). Although its solutions cannot be calculated analytically if the initial conditions are prescribed within or outside the circle x_p , the qualitative behavior of the differential equation follows from the analogy with an *LC* circuit with damping. We find that the amplitude of every solution that starts within the circle increases and approaches $x_p(t)$ as $t \rightarrow \infty$. On the other hand, the amplitude of every solution that starts outside the circle decreases and approaches to $x_p(t)$ as $t \rightarrow \infty$. From a physical point of view the two-dimensional state space of the differential equation (5) is decomposed by the circle x_p into two areas that have different meanings:

- The negative damping area (inner of the circle) where energy is supplied to the system
- The positive damping areas (outer of the circle) where energy is thrown away by the system

The periodic solution x_p can be interpreted as a dynamical equilibrium between the negative and the positive damping area. Stable periodic solutions of this kind are called *limit cycles* [e.g., 47]. In contrast to limit cycles, a stable equilibrium \mathcal{O} is embedded in a positive damping area. Both types of solutions are called *steady-state solutions*. In Fig. 1 the state space and the steady-state solutions of Eq. (5) are shown together with the damping area.

The physical situation of this rather special differential equation is the typical case in two-dimensional state space systems. In Fig. 2 we show the damping areas of the van der Pol equation and of the Rayleigh equation, which extend infinitely in the x_2 and x_1 directions, respectively. Obviously it is clear why sinusoidal solutions are impossible since the damping areas are not symmetric with respect to the unstable zero solution point.

Figure 1. Negative damping area of the Rayleigh–van der Pol equation.

The parameter ε can be interpreted as a measure of deviation from the sinusoidal case. If $\varepsilon \ll 1$, we have a sinusoidal oscillator, which is discussed in the next sections. For large $\varepsilon \gg 1$, we obtain a relaxation oscillator that is considered in Section 3.4. The latter case is much more complicated from a mathematical point of view because circuits of this kind have to be described by differential-algebraic equations or analyzed by singular perturbation methods (see, e.g., Mathis [66]). However, the design of square-wave oscillators can be simplified if the transistors are modeled as switches. Such models are piecewise linear. In the case of sinusoidal oscillators an overall model is available.

2.3. The Mandelstam–Papalexi–Andronov Oscillator Model

Although the simple oscillator equations in the last section are very suitable for illustrating the physical

Figure 2. Damping areas: vdP—van der Pol Equation, R—Rayleigh equation.

rationale of periodic steady-state solutions, a more extensive model should be considered that includes additional parameters. From a systematic point of view a family of differential equations is considered that is parameterized by means of the mentioned parameter and the following questions are studied:

- Is there a subset of equations that permit a periodic steady-state solution?
- If yes, what is the critical value of the parameter where a qualitative change within the family arises?

These questions are crucial for the design of electronic oscillator circuits. Therefore these problems were studied around 1930 by Mandelstam et al. [63] and Andronov [64] using ideas from Poincaré’s theory of celestial mechanics. As a result, they proved a theorem including a criterion about the occurrence of a limit cycle in differential equations depending on a certain parameter. In the mathematical literature this theorem is known as the *Hopf bifurcation theorem* since Hopf reinvented this theorem in 1944 while studying problems in hydromechanics (see Arnold [11], p. 271 for further information about the reception of this theorem). The Mandelstam–Papalexi–Andronov oscillator model contains a parameter that is suitable for generating a limit cycle if a critical value is passed. In oscillator design this parameter corresponds to a circuit parameter (e.g., the load resistor). We will demonstrate the birth of a limit cycle before the Poincaré–Andronov–Hopf theorem is formulated. For this purpose a modification of Eq. (5) is used since it can be solved exactly. This equation is formulated in the state space representation [e.g., 77]:

$$\dot{x}_1 = -x_2 - (x_1^2 + x_2^2 - \mu)x_1 \tag{8}$$

$$\dot{x}_2 = x_1 - (x_1^2 + x_2^2 - \mu)x_2 \tag{9}$$

The parameter is included in another way. To solve this differential equation, we transform it into the magnitude and phase angle representation:

$$\dot{r} = \mu r - r^3 \tag{10}$$

$$\dot{\phi} = 1 \tag{11}$$

Obviously the system of two differential equations is decoupled, and in this case solutions of both equations are known. We have

$$r = r(t) = \sqrt{|\mu|} \frac{\exp \mu t}{\sqrt{1 + \exp 2\mu t}} \text{ and } \phi = \phi(t) = \phi_0 + t \tag{12}$$

In Fig. 3 the steady-state behavior of Eqs. (8) and (9) is illustrated for $\mu < 0$ and $\mu > 0$, and we find that in the latter case we have the desired limit cycle. The abovementioned critical parameter value is zero.

It can be shown that this case already describes a very general situation. If we consider n -dimensional systems of differential equations that describe more complicated electronic oscillators, the so-called center manifold

Figure 3. Bifurcation of a limit cycle: (a) $\mu < 0$; (b) $\mu > 0$.

theorem can be used to reduce the dimension of the system to 2. For details of this theorem, we refer to the monograph of Arrowsmith and Place [13]. Then the former case is obtained, but in this introductory article we cannot discuss further details and therefore the reader is referred to, for example, Hassard et al. [41]. In the following, the Poincaré–Andronov–Hopf theorem is formulated, which is very important for oscillatory circuits and systems.

Theorem 1 Poincaré–Andronov–Hopf. Let

$$\dot{x} = f(x, \mu) \tag{13}$$

a system of differential equations where $f(0, \mu) = 0$ for all μ in a neighborhood of 0. The Jacobian $D_x f(0, 0)$ of f in $(0, 0)$ has the eigenvalues $\lambda_{1,2} = \pm j\omega$ with $\omega \neq 0$ and other $n - 2$ eigenvalues λ_k with $\Re\{\lambda_k\} < 0$. Furthermore $(d/d\mu) \Re\{\lambda_1(\mu)\}|_{\mu=0} > 0$, and the equilibrium point 0 is a stable spiral in $\mu = 0$. Under these assumptions sufficiently small positive numbers μ_1 and μ_2 exist such that for all $\mu \in (-\mu_1, 0)$ the equilibrium point 0 is a stable spiral and for all $\mu \in (0, \mu_2)$ the equilibrium point 0 is an unstable spiral. In the last case the unstable spiral is surrounded by a stable limit cycle whose amplitude increases with μ .

If for some parameter value the assumption of this theorem are fulfilled, it is denoted as the Poincaré–Andronov–Hopf bifurcation point. Note that the necessary condition of imaginary eigenvalues of the Jacobian for the bifurcation point corresponds to the condition that the dynamical systems has to be nonhyperbolic in this point. We know from the Hartman–Grobman theorem (see, e.g., Arrowsmith and Place [13]) that only in this case can we expect a behavior of the system that is different from a linear system.

Instead of a proof (see, e.g., Hassard et al. [41] or Mathis [66]), this theorem is illustrated by the van der Pol equation.

Example 1. The van der Pol equation (3) can be formulated by a standard transformation $y = x$ into a system of differential equations of first order. Using the normalization $u := \sqrt{\epsilon}x$ and $v := \sqrt{\epsilon}y$, the following differential equations result:

$$\dot{u} = v \tag{14}$$

$$\dot{v} = -u - (u^2 - \epsilon)v \tag{15}$$

The eigenvalues of the Jacobian matrix are

$$\lambda_{1,2} = \frac{\varepsilon}{2} \pm \sqrt{\left(\frac{\varepsilon}{2}\right)^2 - 1} \tag{16}$$

and therefore $\lambda_{1,2} = \pm j$ (for $\varepsilon = 0$) and $(d/d\varepsilon)\Re\{\lambda_1(\varepsilon)\}|_{\varepsilon=0} = \frac{1}{2} > 0$. It can be shown that if $\varepsilon = 0$ the equilibrium point $(u, v) = (0, 0)$ is a stable spiral. It results from the Poincaré–Andronov–Hopf theorem that a stable limit cycle is generated for $\varepsilon > 0$ that encloses an unstable spiral. This oscillator model and the theorem was formulated for the first time by Andronov and his coworkers in 1934 while studying electronic oscillator circuits, but it was 1979 before Mees and Chua published theoretical considerations about oscillator design using this theorem [72]. On the other hand, a necessary condition of this theorem—Barkhausen’s oscillatory condition—was a known long time ago and became the basis of a linear design theory for oscillators.

3. DESIGN ASPECTS

3.1. The Linear Design Theory of Sinusoidal Oscillators

It is known from the Poincaré–Andronov–Hopf theorem that a pair of eigenvalues has to cross the imaginary axis whereas the other eigenvalues have to remain within the left half-plane of the complex plane. Obviously it is a necessary condition that oscillator circuits have a pair of eigenvalues on the imaginary axis for a certain value of some circuit parameter.

It was mentioned that all oscillatory criteria for sinusoidal oscillators known by electronic engineers are in essential criteria searching for nonhyperbolic cases, although this was never emphasized.

It is mentioned in Section 2.2 that this condition can be interpreted as the compensation step of oscillator design, which is possible in a linear manner using a linear negative resistor. This necessary assumption of the Poincaré–Andronov–Hopf theorem was already known since the first oscillator paper of Vallauri [97] in 1917 and during the following few years several variants of his results were published. One of the most popular criteria was the Barkhausen oscillatory condition (see, e.g., Millman and Grabel [74]). All these variants can be classified using the following topological structures of oscillator circuits:

- Negative impedance/admittance model
- Positive feedback model

and apply corresponding methods of network analysis. It has been known for a long time that these two models are equivalent from a network theoretical point of view. It is emphasized that many oscillator circuits contain tubes or transistors. In the case of tuned-circuit oscillators it is more efficient to describe the circuit as an active three-pole with a passive impedance embedding (see Fig. 4).

This was done for the first time in 1920 by Hazeltine [42]. He showed that the nature of the impedances $Z_1, Z_2,$

Figure 4. Active three-pole structure of transistor oscillators.

and Z_3 have to be capacitive and inductive, respectively. The reader will find systematic considerations about this subject in the books of Spence [93] and Cassagnol [19]. Since this rather restricted model for oscillator circuits can be reformulated in the form of a negative impedance/admittance model or the positive feedback model, we discuss the usage of the latter models in more detail. For this purpose we consider a rather simple oscillator circuit in order to avoid tedious calculations; further examples can be found in electronics textbooks [e.g., 74]. As the first step the network elements of a concrete oscillator circuit have to be associated with the defining blocks of the abovementioned models. In general this step includes some arbitrariness. The second step uses the conditions that a pair of eigenvalues with vanishing real parts have to occur where these conditions are formulated for the special topology of the models. As a result, we obtain (necessary) conditions for the occurrence of oscillations with respect to the oscillator frequency and the gain of the active elements parameterized by means of the network parameters of a concrete oscillator circuit. These conditions represent the linear part of the design of oscillator circuits.

Now we compile the corresponding conditions for the abovementioned oscillator models: [79, Chap. 1]:

- *Negative impedance model*—the real and imaginary parts R and X , respectively, of the model in Fig. 5 have to satisfy the conditions

$$R_g = -R_L, \quad X_g = -X_L \tag{17}$$

- *Negative admittance model*—the real and the imaginary parts G and B , respectively, of the model in

Fig. 5 have to satisfy the conditions

$$G_g = -G_L, \quad B_g = -B_L \quad (18)$$

- *Positive feedback model*—the open-loop gain consisting of the transfer functions $A(s)$ and $\beta(s)$, respectively, of the active block and the passive block (see Fig. 6) has to satisfy the condition

$$A \cdot \beta = 1 \Leftrightarrow \Re\{A \cdot \beta\} = 1, \quad \Im\{A \cdot \beta\} = 0 \quad (19)$$

- In the literature these conditions are called the *Barkhausen criterion* [74]. Instead of the decomposition of the complex equation into real and imaginary parts, a representation with magnitude and phase angle is preferred.

Of course, a network analysis in a straightforward manner leads to equivalent conditions for the occurrence of oscillations. For this purpose we consider the AC network model of an oscillator circuit that contains no independent sources and derive its network equations in the frequency domain. As a result we obtain a homogeneous system of linear equations

$$\mathbf{M}(j\omega)\mathbf{x} = \mathbf{0} \quad (20)$$

with the oscillation frequency $j\omega$ as the parameter. Note that an oscillator circuit contains only constant independent sources. Therefore these sources are omitted in the small-signal model. The matrix coefficients contain the network parameters. It is known from linear algebra that nontrivial solutions are obtained if the condition

$$\det(\mathbf{M}(j\omega)) = 0 \quad (21)$$

is satisfied. The equivalence of this expression with the other criteria can be shown. There is another method that is equivalent with a circuit analysis under certain conditions. In this case a transfer function is defined with

Figure 5. Negative impedance and admittance oscillator model.

Figure 6. Feedback oscillator model.

respect to a (sinusoidal) input source and two terminal as the output port. This approach can be applied in a successful manner only if

- The input current or voltage source does not change the oscillator circuit substantially, that is, if we receive the initial circuit if the input source vanishes
- The circuit is controllable and observable with respect to the chosen input and output ports

The first condition is satisfied if we use a pliers entry and an independent voltage source or soldering-iron entry and an independent current source (see, e.g., Desoer and Kuh [26]). For the second condition a careful analysis of the circuit is needed before the two ports are chosen.

Example 2 Tunnel Diode Oscillator. [72]. The nonlinear network equations of the circuit in Fig. 7 can be formulated as (if $R \approx 0$)

$$\frac{d}{dt} \begin{pmatrix} i_L \\ \tilde{u}_C \end{pmatrix} = \begin{pmatrix} 0 & 1/L \\ -1/C & 0 \end{pmatrix} \begin{pmatrix} i_L \\ \tilde{u}_C \end{pmatrix} + \begin{pmatrix} 0 \\ (1/C)g(U_0 - \tilde{u}_C) \end{pmatrix} \quad (22)$$

where $\tilde{u}_C := U_0 - u_C$. Since the constant solution can be calculated in a simple manner as

$$i_L^0 = g(U_0), \quad \tilde{u}_C^0 = 0 (u_C = U_0) \quad (23)$$

Figure 7. Tunnel diode oscillator model.

The AC network model (linearized network equations) can be derived where a distinction between large and small signal currents and voltages is omitted; g' is the derivative of g with respect to its argument. The transformation of this equation into the frequency domain leads to the following condition:

$$\det \begin{pmatrix} 0 & 1/L \\ -1/C & -(1/C)g'(U_0) \end{pmatrix} = \lambda^2 + \frac{1}{C}g'(U_0)\lambda + \frac{1}{LC} = 0 \quad (24)$$

The roots of this quadratic equation are

$$\lambda_{1,2} = -\frac{1}{2C}g'(U_0) \pm \sqrt{\left(\frac{1}{2C}g'(U_0)\right)^2 - \frac{1}{LC}} \quad (25)$$

and therefore a purely imaginary pair of eigenvalues is obtained if the condition

$$\frac{1}{C}g'(U_0) = 0 \quad (26)$$

is satisfied. In this case we have the oscillator frequency $\omega_0^2 = 1/(LC)$. We find from the tunnel diode characteristic that this is possible if the operating point of the diode is located in its maximum or minimum, where the derivative $g'(U_0)$ vanishes. If the AC network model of this tunnel diode circuit is interpreted as the negative conductance model, we find the oscillatory conditions

$$g'(U_0) = 0, \quad \omega_0 C - \frac{1}{\omega_0 L} = 0 \quad (27)$$

Obviously these conditions are equivalent to the former one. A negative-resistance model is not suitable in this example. If the negative-conductance model is assumed, a transfer function is determined if an extra (index E) independent sinusoidal voltage source U_E is located as an input quantity in series with the linearized tunnel diode resistor and the capacitor voltage U_C is used as output quantity; both U_E and U_C are represented in the frequency domain. The corresponding transfer function can be derived:

$$H(j\omega) = \frac{U_C}{U_E} = \frac{g'(U_0)j\omega L}{1 - \omega^2 LC + j\omega g'(U_0)L} \quad (28)$$

The zeros of the denominator are the eigenvalues of this circuit. Under the same condition ($g'(U_0) = 0$) on the voltage U_0 , we obtain a pair of imaginary eigenvalues and the oscillatory frequency $\omega^2 = 1/LC$. Finally we consider the approach where the positive feedback model is applied. For this purpose we reformulated the negative-conductance model such that the conductances $Y_g = g'(U_0)$ and $-Y_L(j\omega) = -1/Z_L(j\omega)$ become identical, that is, the sum of the admittances Y_g and Y_L has to be zero. By means of $Z_L(j\omega)$, an interpretation as a product is possible if the

sum is reformulated as

$$Y_g \cdot Z_L(j\omega) = g'(U_0) \cdot \frac{-1}{j\left(\omega_0 C - \frac{1}{\omega_0 L}\right)} = 1 \quad (29)$$

This is Barkhausen's condition if Y_g and $-Z_L(j\omega)$ are interpreted as transfer functions of a feedback model. Since this reformulation is derived by means of equivalent calculation steps, the same conditions for the occurrence of oscillations are obtained. Probably it is rather a problem of taste and/or experience which approach is used to derive the oscillatory conditions. For example, Parzen [79] discusses the design of tuned-circuit oscillators with transistors and therefore uses the abovementioned active three-pole representation with passive embedding. Based of this model, the author applies the negative-resistance/conductance model to calculate the oscillatory conditions. Mauro [71] prefers the positive feedback model and derives similar conditions for tuned-circuit oscillators as well as RC oscillators. In general both approaches can be used in a successful manner, and therefore the special choice makes no difference from a theoretical point of view.

3.2. The Nonlinear Design Aspects of Sinusoidal Oscillators

Although many aspects of the nonlinear theory of oscillator circuits are known, it is not trivial to make use of this knowledge to construct a systematic design concept for these circuits. At least theoretical results are suitable for a classification of oscillator circuits and for the construction of simulation tools. We will discuss these subjects in this and the following sections. Just as in other cases of circuit design, an oscillator circuit is determined if its network topology as well as its network parameters are known. A design process starts with some specifications of the desired oscillator circuit, and then we try to find an oscillator topology together with a certain set of network parameters in order to fit these specifications. For this purpose, the following approach can be used. Further details can be found in, for example, the monograph by Parzen [79].

1. *Basic specifications*, where the form of the oscillator behavior (sinusoidal, rectangle, triangle, etc.), frequency of the oscillator, the amplitude, and other parameters are considered
2. *Choice of the circuit devices*, where application of the oscillator circuit, the working temperature, and other factors are considered
3. *Choice of resonator type*, where the frequency stability, amplitude stability, variability of the frequency, and economic expense are accounted for
4. *Choice of the kind of limiting that maintains the oscillator amplitude*, where a self-limiter, an external limiting, or an automatic level control limiting can be chosen
5. *First draft of the oscillator circuit*, where the aspects listed above are considered

6. *Determination of circuit parameters*, where the actual circuit devices and its circuit parameters have to be chosen
7. *Optimization process*, where circuit simulations and/or an experimental realization are necessary— if the circuit does not meet the specifications, then some steps have to be repeated

This design outline shows that each design process of an oscillator circuit is a rather individual problem. However, we will add some remarks based on the theoretical considerations above. Although the frequency of an sinusoidal oscillator can be determined by a linear analysis (see the Barkhausen condition in Section 2.4), following the Poincaré–Andronov–Hopf theorem nonlinearities are essential for the functionality of oscillators (see Section 2.2). We already mentioned in Section 2.2 that a nonlinearity is necessary for limiting the amplitude, which can be done in one of three ways:

1. *Self-Limiting*. The inherent linearity of an active device (tube, transistor, operational amplifier, etc.) is used to build up a nonlinear differential equation with a stable limit cycle. In this case the amplitude is fixed implicitly by the type of nonlinear characteristic. The only thing that can be done is to calculate the amplitude with a suitable model of the nonlinear device.
2. *External Limiting*. This is a variant of the first case since the resonance circuit works in a linear mode and the limiting will be introduced by an additional device (Zener diode, symmetric clippers, thermistors, etc.).
3. *Automatic Level Control Limiting*. The rather natural approach to limiting is amplitude control, that is, measuring the amplitude, comparing it with a desired amplitude value, and controlling (if necessary) a circuit parameter that varies the damping of the circuit in the sense of a suitable control strategy. Even if the resonance circuit is approximately linear, the entire circuit, including the control part, is nonlinear because there is a coupling between at least one state variable and a circuit parameter. A suitable discussion for the construction of such control devices can be found in the monograph of Parzen [79] and the dissertation of Meyer-Ebrecht [73].

The first kind of limiting of the oscillator amplitude is a rather simple way to construct an oscillator circuit, but in this way the damping element is influenced by the large-signal gain factor. Unfortunately this gain factor varies with the instantaneous amplitude of the oscillator and results in spectral distortions. This is an essential disadvantage in the case of sinusoidal oscillators. If such an oscillator with low distortion is desired, the nonlinear damping should depend on an indefinite integral $\int x(t) dt$ of the amplitude $x(t)$ instead of the instantaneous amplitude. In mathematical terms, this statement can be formulated as follows if we restrict our discussion to an oscillator circuit of van der Pol type. Then the descriptive

equation is of the form

$$\ddot{x} + \gamma \left(\int x(t) dt \right) \dot{x} + \omega^2 x = 0 \quad (30)$$

instead of

$$\ddot{x} + \gamma(x)\dot{x} + \omega^2 x = 0 \quad (31)$$

Although the structure of an oscillator circuit and its amplitude stabilization are essential, analysis methods are necessary in order to calculate at least the amplitude and the frequency as a function of certain circuit parameters for a suitable design of sinusoidal oscillator. Since analytical solutions of the corresponding network equations of an oscillator are not available, perturbation methods have to be applied for this purpose. Several approaches are available:

- Perturbation methods
- Averaging methods or harmonic balance
- Describing function method
- Volterra series method

Most of the different variants of perturbation methods start with some Fourier polynomial and, based on this ansatz, a set of associated differential equations will be derived. Therefore these methods can be interpreted as time-domain methods, which are considered and illustrated in the monograph by Nayfeh [76]. Especially the first-order perturbation results are of some interest in practical oscillator design. Also the average or harmonic balance methods can be interpreted as time-domain methods. A very efficient variant of an average method that can be implemented in a computer algebra program uses Lie series [52]. It was applied for studying electronic oscillators by Keidies and Mathis [51]. Newer results for more complex oscillators (e.g., Clapp oscillator) were published by Prochaska and Mathis [80], where the average approach of Keidies and Mathis is combined with singularly perturbation method.

Another time-domain method can be interpreted as an extension of the convolution description of linear time-invariant input–output systems, which is called *Volterra series methods*. In this case a series of integrals is used as an ansatz and the coefficients are convolution kernels of higher order. Illustrations of this method are included in the paper by Chua and Tang [22].

An efficient iterative procedure for calculating the steady-state output waveform of almost sinusoidal nonlinear oscillators using the feedback formulation is presented by Buonomo and Di Bello [16]. In their paper this method is compared with the alternative methods of Mathis and Keidies as well as Chua and Tang. Just like the other methods, the interactive approach can be implemented by means of a computer algebra system, too.

Since frequency-domain methods are very successful in the case of linear time-invariant circuits and systems, many electrical engineers are very interested in

extensions of these approaches to nonlinear circuits and systems. The describing function method is very popular because it can be interpreted as an extension of the transfer function method that is a standard method in the analysis of linear time-invariant networks. We have to assume that only the first-harmonic part of the reaction of a nonlinear block to a sinusoidal input function is interesting because the other parts will be filtered out. If functionality of the sinusoidal oscillator is interpreted by the feedback structure in Fig. 6, this filter is realized within the feedback loop. Although the nonlinear block produces an entire spectrum of output frequencies as a reaction to a sinusoidal input function, only the first-harmonic part is essential for the functionality of a sinusoidal oscillator. Therefore the describing function method is illustrated by means of the feedback model of a sinusoidal oscillator, although extensions of the negative-impedance and admittance models, respectively, are possible [19]. We restrict our discussion to the case where only the A block in Fig. 6 contains nonlinear elements and the input signal is $x(t) = \hat{x} \cos \omega t$. Then a first-harmonic part can be extracted from the output signal

$$y(t) = y_1 \cos(\omega t + \varphi_1) + y_2 \cos(2\omega t + \varphi_2) + \dots \quad (32)$$

where we assume that no constant part is included in the output signal. Clearly the amplitudes y_1, y_2, \dots and the phases $\varphi_1, \varphi_2, \dots$ depend on \hat{x} and ω . The describing function is defined by

$$N(\hat{x}, \omega) = \frac{y_1(\hat{x}, \omega)}{\hat{x}} e^{j\varphi_1(\hat{x}, \omega)} \quad (33)$$

As a result, we obtain a generalization of the Barkhausen oscillatory condition

$$N(\hat{x}, \omega) \cdot \beta(\omega) = 1 \quad (34)$$

In many cases $N(\hat{x}, \omega)$ is independent of ω . Now $\beta(\omega)$ can be plotted as a single polar curve in the complex plane graduated in ω as well as the locus of $-1/N(\hat{x})$ graduated in \hat{x} . The intersection of these curves corresponds to a limit cycle whose stability properties can be studied. More details of this approach are included in the monograph by Mees [72], where the problems of this method are also discussed.

3.3. Theoretical Aspects of Noise in Oscillators

Obviously functionality of electronic oscillators and adaptation to specifications (frequency, amplitude, etc.) are a main subjects of oscillator design. Both subjects can be studied using concepts from the mathematical theory of dynamical systems. However, the amplitude of modern oscillator circuits is low and therefore the signal-to-noise ratio also can be low. Consequently, studying noise behavior of oscillator has become another main subject in oscillator design since the mid-1990s. In this section some theoretical aspects of noise in oscillators circuits will be discussed. In Section 5 advanced numerical

methods for noise analysis are described in further detail.

The first results in noise analysis of electrical oscillators were published as early as 1960 or so by Stewart, Edson, Mullen, Hafner, Lax, Leeson, and others; corresponding references can be found in the monograph by Hajimiri and Lee [39]. The popular Leeson model is discussed in the same book. However, more in-depth mathematical results about noise in oscillatory circuits were presented by the Russian researchers Kuznetsov, Stratonovich, and Tikhonov in the early 1950s; see a collection of papers by these authors [60].

More recently several papers have been published considering heuristic approaches on phase noise in electronic oscillators. Many material of that research is included in the books of Hajimiri and Lee [39] as well as Demir and Sangiovanni-Vincentelli [25]; the last book contains the framework of stochastic processes and stochastic differential equations. The main progress was done by Kärtner (a former Ph.D. student of the second author of this article) in his paper from 1990 [49], where he suggested a certain decomposition of limit cycle solutions. Many authors use Kärtner's device. A detailed description is contained in Section 5.

Another approach for analyzing noise in nonlinear systems uses the Stratonovich concept of nonlinear nonequilibrium thermodynamics. As a result, an exact noise theory for the probability density of a large class of nonlinear circuits was founded by Weiss and Mathis (overview and further references given in Ref. 69). Unfortunately it is restricted at first to reciprocal circuits such that a Langevin approach is discussed by these authors. On the basis of a Langevin description of oscillator circuits

$$dx = F(x)dt + \sigma(x)\xi \quad (35)$$

where ξ is a stochastic process with certain properties (e.g., stationary Gaussian process), Mathis and Prochaska [70] discuss a stochastic Andronov–Hopf bifurcation approach for nonlinear electronic oscillators using more recent mathematical results; see the monograph by Arnold [12] for an overview. The mathematical details of this approach are beyond the scope of this article, but there are in fact two types of bifurcation: (1) *P bifurcation*, where the quality of a probability density changed and (2) *D bifurcation*, where a so-called invariant measures that replace equilibrium solutions in deterministic cases changed. There are systems with *P* bifurcations but no *D* bifurcations and converse. Further interesting results can be expected using these mathematical concepts.

3.4. Design of Two-Port Oscillators

In the following we consider the two-port oscillator formed by a frequency-dependent linear feedback two-port and a nonlinear active two-port as depicted in Fig. 8. The output signal of the linear two-port is amplified in the non-linear active two-port and then feedback to the input of the linear two-port. A necessary condition for the occurrence

Figure 8. Two-port oscillator.

of a stationary harmonic oscillation is that the phase and the amplitude of the signal, after passing both two-ports, are unchanged. Due to the frequency-dependent linear feedback two-port, the phase condition is only fulfilled for one frequency. Because of the nonlinearity of the active two-port, the amplitude condition is fulfilled for only one value of the amplitude of the signal.

In our example we consider the simple model of an active two-port formed by a voltage-controlled current source. The voltage-current characteristic of the voltage-controlled current source is assumed to be nonlinear. If the active two-port contains additional linear elements, these elements may be moved to the linear two-port. In our example the linear frequency-dependent two-port consists of a transformer with the primary inductance L_1 , the secondary inductance L_2 , the mutual inductance M , a capacitor C , and a conductor G . The primary and secondary coils of the transformer are in antiphase and therefore $M < 0$. The secondary inductance L_2 and the capacitor C together form a parallel-resonant circuit. This inductor-coupled resonant circuit is the most compact model that we can establish for the linear feedback circuit. In more complex cases we can replace the reactive part of the feedback two-port by the canonical Foster representation [14]. In the neighborhood of the resonant frequency the essential part of the canonical Foster realization is given by a transformer-coupled resonant circuit as assumed in our model. In the case of small losses it is also possible to include the losses in this model [65]. The conductor G accounts for the losses in the passive and the active two-ports. At the resonant frequency of the parallel resonant circuit

$$\omega_0 = 1/\sqrt{L_2 C} \tag{36}$$

the phase change in the linear two-port is 180° . This compensates for the 180° phase change occurring in the active circuit and the phase condition for oscillation is fulfilled.

The nonlinear dependence of the output current $i_{2a}(t)$ of the linear two-port on its input voltage $u_{1a}(t)$ is given by

$$i_{2a}(t) = f(u_{1a}(t)) \tag{37}$$

The active two-port is considered to be frequency-independent. It is assumed that all reactive elements of the active element have been moved to the linear two-port. This can be done easily if the reactive elements are linear, and if it is possible to concentrate all reactive elements in

a π equivalent circuit. The relation between the spectra of the input current $I_{1l}(\omega)$ and the output voltage $U_{2l}(\omega)$ of the linear feedback network is given by

$$I_{1l}(\omega) = A_{21}(\omega)U_{2l}(\omega) \tag{38}$$

where A_{21} is the matrix element of the chain two-port representation. According to Fig. 8, we obtain $u_{1a} = u_{2l}$ and $i_{1l} = -i_{2a}$. Furthermore, we consider $i_{1l}(t) \circ \dots \bullet I_{1l}(\omega)$ and $u_{2l}(t) \circ \dots \bullet U_{2l}(\omega)$, where $(\cdot)(t) \circ \dots \bullet (\cdot)(\omega)$ denotes in a symbolic manner a pair of Fourier transformed functions in time and frequency domains.

We assume that in the oscillator circuit (Fig. 8) oscillations are excited by an initial perturbation. After some period of growth of amplitude due to the nonlinearity of the active element, the oscillator will saturate in a stationary state oscillating at a frequency ω_0 . In the case of a weak nonlinearity the oscillation exhibits only low harmonics. The linear feedback network acts as a bandpass filter and attenuates the harmonics. In the case of a sufficiently high Q factor of the resonant circuit and a weakly nonlinear active element, the transient of the oscillator from excitation to the stationary state exceeds the period of oscillation by orders of magnitude. We also can assume that the time constants governing the decay of the perturbation of the stationary state of the oscillator exceed the period of oscillation by orders of magnitude. Under these assumptions we can make for u_{2l} the ansatz

$$u_{2l}(t) = V(t) \cos(\omega_0 t + \varphi(t)) \tag{39}$$

where $V(t)$ and $\varphi(t)$ denote the amplitude and the phase of the oscillator signal. Due to the nonlinearity of the active two-port, the output amplitude I at the fundamental frequency ω_0 depends nonlinearly on the input amplitude V . With $\omega_0 t = \xi$, we obtain from (37) the fundamental frequency component of the output current:

$$I(V) = \frac{1}{\pi} \int_0^{2\pi} f(V \cos \xi) \cos \xi d\xi \tag{40}$$

This relation also holds for slowly time-varying amplitudes, and we obtain

$$i_{2a} = I(V(t)) \cos(\omega_0 t + \varphi(t)) \tag{41}$$

With $a_{21}(t) \circ \dots \bullet A_{21}(\omega)$ we obtain from (38) the relation between the input current in $i_{1l}(t)$ and the output voltage $u_{2l}(t)$ of the linear feedback circuit in the time domain:

$$i_{1l}(t) = \int_{-\infty}^{+\infty} a_{21}(t - t_1)u_{2l}(t_1) dt_1 \tag{42}$$

Representing (41) by

$$u_{2l}(t) = \Re\{V(t) \exp(j(\omega_0 t + \varphi(t)))\} \tag{43}$$

and expanding into a first-order power series yields

$$u_{2l}(t_1) = \Re\{[V(t) + (t_1 - t)(\dot{V}(t) + j\dot{\phi}(t)V(t))] \exp j \times (\omega_0 t_1 + \phi(t))\} \quad (44)$$

Inserting this expression into (42) gives

$$i_{1l}(t) = \Re\left\{V(t)e^{j\phi(t)} \int_{-\infty}^{+\infty} a_{21}(t - t_1)e^{j\omega_0 t_1} dt_1 - \right. \quad (45)$$

$$\left. (\dot{V}(t) + j\dot{\phi}V(t))e^{j\phi(t)} \int_{-\infty}^{+\infty} (t - t_1)a_{21}(t - t_1)e^{j\omega_0 t_1} dt_1\right\} \quad (46)$$

With the substitution $t - t_1 = t_2$ we obtain

$$i_{1l}(t) = \Re\left\{\left[V(t) \int_{-\infty}^{+\infty} a_{21}(t_2)e^{j\omega_0 t_2} dt_2 - \right. \quad (47)$$

$$\left. (\dot{V}(t) + j\dot{\phi}V(t)) \int_{-\infty}^{+\infty} t_2 a_{21}(t_2)e^{-j\omega_0 t_2} dt_2\right] e^{j(\phi(t) + \omega_0 t)}\} \quad (48)$$

Using $a_{21}(t) \circ \dots \bullet A_{21}(\omega)$ and $ta_{21}(t) \circ \dots \bullet jA'_{21}(\omega)$ with $A'_{21}(\omega) = dA_{21}(\omega)/d\omega$, we obtain

$$i_{1l}(t) = \Re\{[V(t)A_{21}(\omega_0) + (\dot{\phi}V(t) - j\dot{V}(t))A'_{21}(\omega_0)]e^{j(\omega_0 t + \phi(t))}\} \quad (49)$$

With (41) and $i_{1l} = -i_{2a}$, it follows

$$\Re\{[\Im(\mathfrak{B}(t)) + \mathfrak{B}(t)\Re(\omega) + (\phi\mathfrak{B}(t) - j\dot{V}(t))A'_{21}(\omega_0)]e^{j(\omega_0 t + \phi(t))}\} = 0 \quad (50)$$

Introducing the conductance G_0 and the susceptance B_0 by

$$G_0(\omega_0) = -\Re\{A_{21}(\omega_0)\}, \quad B_0(\omega_0) = -\Im\{A_{21}(\omega_0)\} \quad (51)$$

yields

$$I(V) - VG_0 - \dot{\phi}VG'_0 - \dot{V}B'_0 = 0 \quad (52)$$

$$VB_0 + \dot{\phi}VB'_0 - \dot{V}G'_0 = 0 \quad (53)$$

where the prime (\cdot)' denotes the derivative with respect to ω estimated for $\omega = \omega_0$. For the stationary state it follows that

$$I(V_0) - V_0G_0(\omega_0) = 0 \quad (54)$$

$$B_0(\omega_0) = 0 \quad (55)$$

We now investigate the influence of small perturbations V_1 of the stationary amplitude V_0 . With the ansatz

$$V = V_0 + V_1 \quad (56)$$

we linearize $I(V) - VG_0$ in a neighborhood of the stationary amplitude V_0 . With

$$I(V) - VG_0 \doteq I(V_0) + V_1I'(V_0) - V_0G_0 - V_1G_0 = V_1(I'(V_0) - G_0) \quad (57)$$

we obtain for small amplitude deviations V_1 from the stationary state the linear differential equation

$$\dot{V}_1 + \frac{B'_0(G_0 - I')}{B_0^2 + G_0^2} V_1 = 0 \quad (58)$$

The stationary state of oscillation is stable if any perturbation V_1 is decaying. This holds for

$$\frac{dB_0}{d\omega} \left(G_0 - \frac{dI}{dV}\right) > 0 \quad (59)$$

The relation between I and V may be expressed by a nonlinear transconductance S given by

$$S(V) = \frac{I}{V} \quad (60)$$

In this case the stability condition (59) can be written in the following form:

$$\frac{dB_0}{d\omega} \frac{dS}{dV} < 0 \quad (61)$$

For the Meissner oscillator with transformer feedback circuit according to Fig. 8, the parameters G_0 and B_0 are given by

$$G_0 = \frac{L_2}{|M|} G \quad (62)$$

$$B_0 = \frac{L_2}{|M|} \left(\omega C - \frac{1}{\omega L_2}\right) \quad (63)$$

The condition (55) yields the frequency of oscillation ω_0 in the stationary state according to (36). Due to (54), the stationary amplitude V_0 can be determined from

$$S(V_0) = \frac{L_2}{|M|} G \quad (64)$$

From

$$\left.\frac{dB_0(\omega)}{d\omega}\right|_{\omega=\omega_0} = 2 \frac{L_2 C}{|M|} \quad (65)$$

and (61) it follows that the stationary state of the two-port oscillator considered is stable for

$$\frac{dS}{dV} < 0 \quad (66)$$

that is, for a transconductance S that decreases with increasing amplitude V .

3.5. Design of Relaxation Oscillators

In Section 2.2 it was mentioned that the van der Pol equation is also suitable as a model for relaxation oscillators if $\epsilon \ll 1$ is considered. Unfortunately, analytical solutions are not available in this case, and for the derivation of approximative solutions advanced mathematical methods are necessary (see, e.g., Andronov et al. [1] or Mathis [66]). In Mishchenko and Rozov [83] the singular perturbation method is used to study relaxation oscillatory systems in a more sophisticated manner, but their approach is beyond the scope of this article. Therefore almost all design methods for relaxation oscillators are based on more simplified models for the active devices (e.g., transistors or operational amplifiers), and the transition part is not included in these considerations.

If the transistors are replaced by switches [e.g., 45], we obtain piecewise linear oscillator models; note that such models are nonlinear, as was always the case. Some disadvantages of this approach are known:

- The transient behavior to the steady state (or limit cycle) cannot be obtained in a simple manner.
- A limit cycle has to be assumed.
- The results are independent of certain parameters of the active devices.

However, under these assumptions simple design formulas can be derived since only linear (time-invariant) networks have to be analyzed. We illustrate this approach in the case of a symmetric multivibrator that is working in saturated mode. More complicated situations (e.g., if transistors are not working in saturated mode) will be found in the literature [e.g., 37].

Example 3 Symmetric Multivibrator. We consider the multivibrator shown in Fig. 9. Let us assume that at the initial instant $t = 0$, the left transistor T_1 conducts and the right transistor T_2 is cut off. If the voltage across the left capacitor is near zero while that across the right capacitor reaches the voltage U_0 , a switching event occurs. During

Figure 9. Symmetric multivibrator.

the commutation where T_1 switches to the cutoff state while T_2 changes to the conducting state, the left capacitor charges and the right capacitor discharges. The situation for $t > 0$ can be analyzed by means of a simple analysis of the network in Fig. 10. The following differential equation results

$$R_b C \frac{du_C}{dt} + u_C = U_0 \tag{67}$$

where $u_C(0) = U_0$. The solution is derived by well known calculations

$$u_C(t) = -U_0(1 - 2e^{-t/R_b C}) \tag{68}$$

A switching event takes place if $u_C(t)$ that corresponds to the base-emitter voltage of T_2 exceeds the cutoff voltage (which is simplified to zero in our case). From the solution above we have

$$t_{sw} : = R_b C \cdot \ln 2 \approx 0.69 \cdot R_b C \tag{69}$$

and therefore the period of the square wave is $T \approx 1.38 \cdot R_b C$. It is an easy matter to include cutoff and saturation quantities of the transistors [e.g., 19]. In the same way, results for other relaxation oscillators can be derived that include operational amplifiers or digital gates [see, e.g., Horenstein [45] or Kurz and Mathis [59]]. Furthermore, sawtooth wave oscillators can be analyzed if piecewise linear models of the active devices are used. The reader is referred to the literature for further details [e.g., 24].

Figure 10. Dynamical operation.

4. ADVANCED MICROWAVE OSCILLATOR DESIGN TOOLS

4.1. Problems in Microwave Oscillator Design

Although this article is dedicated to design methods of all kinds of oscillators, the design of microwave oscillators has been studied intensively since 1989. Many results are published in the literature. Therefore an overview is presented in this section. But it should be mentioned that almost all methods can be used to design other kinds of oscillators. The design of monolithic integrated microwave and millimeterwave oscillators requires accurate and efficient tools for numerical modeling and optimization. Today the design of microwave oscillators in many cases is based on a linear analysis of the oscillation conditions. To predict and to optimize the oscillator output power or the oscillator spectral behavior, a nonlinear design approach is indispensable. The task of oscillator modeling can be separated into two parts:

- Nonlinear modeling of the unperturbed oscillator
- Modeling of the noise properties of the oscillator

The nonlinear modeling of the unperturbed oscillator may be done in the time domain by numerical integration [4,21,89], in the frequency domain using harmonic balance or Volterra series methods [20,46,61,81,82], or by using combined time-frequency domain methods [29,31,56,90]. Microwave oscillators may be subdivided into a linear embedding circuit and one or more nonlinear subcircuits. By this subdivision, the computational effort may be reduced considerably. The easiest approach is to subdivide the active element of the oscillator into a linear embedding network and one single nonlinear controlled source. In this way, the modeling may be improved compared with the linear approach, as shown, for example, in Refs. 27 and 36. This method is restricted to one single dominant nonlinearity in the oscillator circuit. A more accurate circuit modeling requires the inclusion of numerous nonlinear circuit elements in the simulation. Approximating the distributed elements within a broad but finite frequency interval by a lumped-element equivalent circuit facilitates the description of the unperturbed network by a set on nonlinear and autonomous first-order differential equations in the normal form

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}(\mathbf{x}), \quad \mathbf{x} \in \mathbb{R}^N \quad (70)$$

The components of the vector \mathbf{x} are the state variables of the system. Time-domain integration of the network equations describing the equivalent lumped-element circuits usually yields an enormous computational effort, since the system of differential equations is usually high-dimensional and also exhibits high stiffness. One method for reducing of the computational effort is to combine time-domain and frequency-domain calculations [90]. The periodic steady-state solution can be found in the time domain by solving the periodic boundary value problem [4]. The solution obtained in the time domain is exact and

in this respect superior to harmonic balance. Using the multiple shooting algorithm of Bulirsch, the convergence of the time-domain boundary value problem may be improved [17,18]. Schwab has applied the time-domain boundary value method to the self-consistent determination of the steady-state solution of oscillators [89]. The time-domain method has the advantage that it is not necessarily restricted to a certain number of harmonics of the signals. The most common method for frequency-domain analysis of oscillators is the harmonic-balance method. Using the harmonic balance method a nonlinear system of equations

$$\mathbf{F}(\mathbf{X}, \omega_0) = \mathbf{0}, \quad \mathbf{X} \in \mathbb{C}^{n(2k+1)} \quad (71)$$

has to be solved. In this equation \mathbf{X} is the system state vector summarizing the signal amplitudes of n signals at the fundamental frequency ω_0 and at k harmonics [20,46,61,81,82]. The advantage of the harmonic-balance (HB) method is that distributed circuits can also be considered in the analysis. In the combined time/frequency-domain method, the oscillator circuit is subdivided into a linear circuit and a nonlinear circuit [56,90]. The linear part of the circuit is described in the frequency domain, whereas a state variable description in time domain is applied to the nonlinear part. This allows one to combine the advantage of frequency-domain and time-domain methods. In the linear part of the circuit, distributed circuit elements can also be considered.

4.2. Time-Domain Method

The computation of the steady-state solution of the oscillator by solving the initial value problem Eq. (87) for $t \rightarrow \infty$ has the disadvantage of high numerical effort. For most practical cases, interest is restricted to the periodic steady-state solution $\mathbf{x}(t) = \mathbf{x}(t + T^0)$ of the nonlinear oscillator waveform. The period of oscillation T^0 is not known. In order to determine the period of oscillation, we add T^0 as an additional variable to the state variables \mathbf{x} and introduce the normalized time variable $\tau = t/T^0$. We now have to solve the two-point boundary value problem for $\tau \in [0, 1]$:

$$\frac{d}{d\tau} \mathbf{x} = \mathbf{f}(\mathbf{x})T^0, \quad \frac{dT^0}{d\tau} = 0, \quad \tau = \frac{t}{T^0} \quad (72)$$

The $n + 1$ boundary conditions are

$$\mathbf{x}(0) = \mathbf{x}(1), \quad x_\kappa = a \quad (73)$$

where the latter condition fixes the phase of the limit cycle. Let us denote the solution of the initial value problem (72) at $\tau_{\mu+1}$ with the initial conditions \mathbf{s}_μ at τ_μ by $\mathbf{e}(\mathbf{s}_\mu, \tau_\mu, \tau_{\mu+1})$. The solution of the boundary value problem is equivalent to the determination of the zeros of the vector-valued function

$$\mathbf{G}(\mathbf{x}(0), T^0) = \begin{pmatrix} \mathbf{x}(\tau=0) - \mathbf{e}(\mathbf{x}(0), \tau_1=0, \tau_2=1) \\ x_k(0) - a \end{pmatrix} \quad (74)$$

This algorithm is called the “single-shooting method,” which generally has only a small domain of convergence. A better way to solve the boundary value problem is to use the multiple-shooting algorithm [17,18,90]. This algorithm is more stable and has a wider domain of convergence than does the single-shooting one. Using this method the region between the boundaries is divided into several subregions

$$0 = \tau_0 < \tau_1 < \dots < \tau_{\mu-1} < \tau_\mu = 1 \tag{75}$$

and for every subregion a starting point is chosen:

$$\begin{aligned} \mathbf{s}_0 &= \mathbf{x}(\tau = \tau_0) \\ \mathbf{s}_1 &= \mathbf{x}(\tau = \tau_1) \\ &\dots \end{aligned} \tag{76}$$

$$\mathbf{s}_{\mu-1} = \mathbf{x}(\tau = \tau_{\mu-1}) \tag{77}$$

These starting points are varied until a continuous solution fulfilling the boundary condition is found, which can easily be seen to be the zero of the vector-valued function

$$\mathbf{u}(\mathbf{s}_0, \mathbf{s}_1, \dots, \mathbf{s}_{\mu-1}) = \begin{pmatrix} \mathbf{e}(\mathbf{s}_0, \tau_0, \tau_1) - \mathbf{s}_1 \\ \mathbf{e}(\mathbf{s}_1, \tau_1, \tau_2) - \mathbf{s}_2 \\ \dots \\ \mathbf{e}(\mathbf{s}_{\mu-1}, \tau_{\mu-1}, \tau_\mu) - \mathbf{s}_0 \\ x_k(0) - a \end{pmatrix} \tag{78}$$

where the last two lines represent the boundary conditions and the others, the continuity conditions. Because of the special structure of Eq. (78), the zeros can be computed in a very efficient way [17]. To achieve starting values for T_0 and \mathbf{x} , the set of nonlinear differential equations (87) is linearized at the unstable stationary point \mathbf{x}_0 , with the Jacobian

$$\mathbf{J} = \left. \frac{\partial \mathbf{F}(\mathbf{x})}{\partial \mathbf{x}} \right|_{\mathbf{x}=\mathbf{x}_0} \tag{79}$$

with \mathbf{x}_0 given by $\mathbf{F}(\mathbf{x}_0) = 0$. Then T^0 and $\mathbf{x}(t)$ can be estimated by

$$\mathbf{x}(t) = a\mathbf{e}_v e^{j\lambda_v t}, \quad T^0 = \frac{2\pi}{\text{Im}\{\lambda_v\}} \tag{80}$$

where $\lambda_1, \dots, \lambda_n$ are the n eigenvalues and n_1, \dots, n_n the corresponding eigenvectors of the Jacobian $\mathbf{J} \cdot \lambda_v$ is the eigenvalue with $\text{Re}\{\lambda_v\} > 0$. The stiff-stable gear algorithm [21] has proved to be an effective method for numerical integration.

4.3. Frequency-Domain Method

Using the HB technique the steady state of the unperturbed oscillator may be computed in the frequency domain. The n state variables of the oscillator are

summarized in the state vector \mathbf{X} :

$$\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_n)^T \tag{81}$$

Since all state variables are periodic in the limit cycle, the time-domain state variables x_i can be expanded into Fourier series with the Fourier coefficients $X_{i,l}$. The frequency range considered is limited to k harmonics:

$$\begin{aligned} \mathbf{X}_i &= (X_{i,-k}, X_{i,-k+1}, \dots, X_{i,0}, \dots, X_{i,+k})^T \\ \text{with } \mathbf{X}_i &\in \mathbb{C}^{2k+1} \end{aligned} \tag{82}$$

The Fourier coefficients of the state variables \mathbf{X}^0 are determined by the solution of a nonlinear system of equations:

$$\mathbf{F}(\mathbf{X}^0, \omega_0) = \mathbf{0} \tag{83}$$

This nonlinear system of equations (83) with dimension $n(2k + 1)$ and $n(2k + 1)$ unknowns exhibits an infinite one-dimensional manifold of solutions since the phase of a free-running oscillator is arbitrary. The solution can be made unique by specifying the phase of one Fourier coefficient. The frequency of oscillation is an unknown variable and is also determined by solutions of the system equations.

4.4. Time/Frequency-Domain Method

Time-domain methods are efficient for the analysis of circuits exhibiting strong nonlinearities. However, it is not possible to include linear distributed circuits in the time-domain analysis. Especially in microwave oscillator design, the linear embedding circuits usually contain distributed circuits. The method described in the following is based on the subdivision of the oscillator network into the following two subsets:

- The linear embedding network
- The nonlinear subnetworks with neighboring low-pass structure

Therefore the network can be represented by a circuit model as shown in Fig. 11.

The linear embedding network may be described effectively in the frequency domain. The linear and nonlinear parts of the oscillator network are connected via a number of M ports. The port voltages and currents are described by the vector $\mathbf{U}(t) = [\mathbf{v}_T(t), \mathbf{i}_T(t)]^T$. Nonlinear resistors and nonlinear conductances are replaced by voltage and current sources and described in common with all other sources within the nonlinear subnetwork by the vector $\mathbf{U}(t) = [\mathbf{v}_0(t), \mathbf{i}_0(t)]^T$. In a subsequent step the linear and the nonlinear subnetworks are separated from each other, and the port voltages and currents represented by the vector $\mathbf{U}(t)$ are also replaced by voltage and current sources, as shown in Fig. 12.

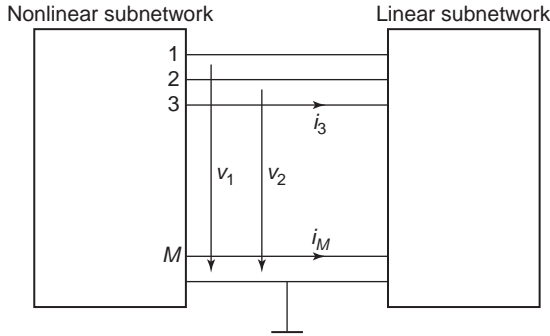

Figure 11. Linear and nonlinear parts of an oscillator network.

Based on the time-domain description [21], the nonlinear subnetwork is characterized by

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{w} + \mathbf{C}\dot{\mathbf{w}} + \mathbf{D}\mathbf{l} \quad \mathbf{x} \in \mathbb{R}^N, \mathbf{l} \in \mathbb{R}^M \quad (84)$$

where \mathbf{x} are the independent state variables and \mathbf{w} is a function of the state variables and their time derivatives $\mathbf{w} = \mathbf{w}(\mathbf{w}, \dot{\mathbf{x}})$. The matrices \mathbf{A} , \mathbf{B} , \mathbf{C} , and \mathbf{D} , representing also nonlinear capacitors and inductors, depend on \mathbf{x} and $\dot{\mathbf{x}}$. Due to the dependence of the matrices $\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D}$ and the vector \mathbf{w} on $\dot{\mathbf{x}}$, the system of differential equations (84) is implicit. This system of differential equations can be made explicit and put into the normal form by imposing the condition that the matrices $\mathbf{A}, \mathbf{B}, \mathbf{D}$ and vector \mathbf{w} depend only on \mathbf{x} and not on $\dot{\mathbf{x}}$. This condition is fulfilled if

- In the nonlinear subnetwork no current source is connected to a node that is connected only to current sources and to inductors.
- In the nonlinear subnetwork no voltage source is within a mesh containing only voltage sources and capacitors.

Under these conditions the matrix \mathbf{C} vanishes. If we also require that \mathbf{w} depends only on the system state variables \mathbf{x} and not on their time derivatives, we obtain from Eq. (84)

$$\dot{\mathbf{x}} = \mathbf{A}(\mathbf{x})\mathbf{x} + \mathbf{B}(\mathbf{x})\mathbf{w}(\mathbf{x}) + \mathbf{D}(\mathbf{x})\mathbf{l}(t) \quad (85)$$

The vector $\mathbf{c}^T(t) = [\mathbf{i}_r(t), \mathbf{u}_r(t)]$, dual to $\mathbf{l}(t)$ is given by

$$\mathbf{c}(t) = \mathbf{F}\mathbf{x} + \mathbf{G}\mathbf{w} + \mathbf{H}\mathbf{l} \quad (86)$$

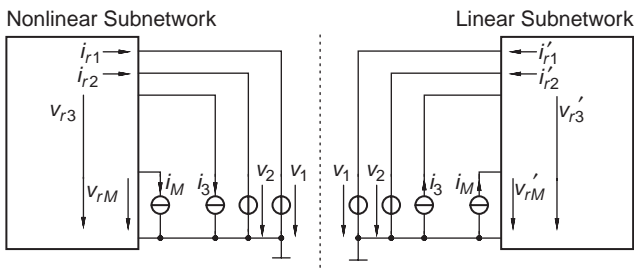

Figure 12. Separation of linear and nonlinear network parts.

By appropriate separation into a nonlinear and a linear subnetwork, large time constants originating, for example, from feedback loops or bias networks may be eliminated. As a result the differences between the time constants are smaller and the stiffness of the system is reduced considerably. If we treat the whole network totally in the time domain, the linear subnetwork does not exist and therefore the term $\mathbf{D}(\mathbf{x})\mathbf{l}(t)$ in Eq. (85) vanishes, and we obtain

$$\dot{\mathbf{x}} = \mathbf{A}(\mathbf{x})\mathbf{x} + \mathbf{B}(\mathbf{x})\mathbf{w}(\mathbf{x}) = \mathbf{F}(\mathbf{x}) \quad (87)$$

The nonlinear oscillator subnetwork is described by Eqs. (85) and (86). In addition to the periodic boundary condition $\mathbf{x}(t) = \mathbf{x}(t + T^0)$, the voltages and currents of $\mathbf{c}(t)$ and $\mathbf{c}'(t)$ must coincide. $\mathbf{c}'(t)$ may be expressed by

$$\mathbf{c}'(t) = \int_{-\infty}^{+\infty} \mathbf{V}(t)\mathbf{l}(t - t_1) dt_1 = \mathbf{V}(t) * \mathbf{l}(t) \quad (88)$$

where $\mathbf{V}(t)$ is the impulse response of the linear subnetwork. As in the previous section, we normalize the time variable with respect to T^0 and obtain

$$\frac{d\mathbf{x}}{d\tau} = (\mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{w} + \mathbf{D}\mathbf{l})T^0, \quad \frac{dT^0}{d\tau} = 0, \quad \tau = tT^0 \quad (89)$$

Since the oscillator signals are assumed to be periodic, it is possible to represent the port variables $\mathbf{l}(t)$ by periodic Fourier series:

$$\mathbf{l}(t) = \sum_{v=-\infty}^{+\infty} (\mathbf{l}_{rv} + j\mathbf{l}_{iv})e^{j2\pi v\tau} \quad (90)$$

From Eq. (88) we obtain

$$\mathbf{c}'(t) = \sum_{v=-\infty}^{+\infty} \mathbf{V}_v(\mathbf{l}_{rv} + j\mathbf{l}_{iv})e^{j2\pi v\tau} \quad (91)$$

where \mathbf{V}_v is the hybrid matrix of the linear multiport, at the v th harmonic, which can be computed with standard linear network analysis methods. The Fourier series expansion representing the port variables is truncated after the k th element. In this case due to the sampling theorem it is necessary and sufficient that the condition $\mathbf{c}(t) = \mathbf{c}'(t)$ be fulfilled for $2K + 1$ discrete time values within the interval T^0 . We obtain

$$\mathbf{c}(\tau_v) = \mathbf{c}'(\tau_v), \quad \tau_v = \frac{v-1}{2K+2}, \quad v = 1, 2, \dots, 2K+1 \quad (92)$$

The solution of (92) and the periodic boundary condition may be expressed, similar to the solution in Section 4.2, as the solution of a boundary value problem. The state equations of the nonlinear subnetwork are therefore

expanded by $(2K + 1)M$ additional state equations:

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{A}(\mathbf{x})\mathbf{x} + \mathbf{B}(\mathbf{x})\mathbf{w}(\mathbf{x}) + \mathbf{D}(\tau)\mathbf{l}(\tau)T^0 \\ \dot{T}_p &= 0 \\ \dot{L}_0 &= 0 \\ \dot{L}_1 &= 0 \\ &\dots \\ \dot{L}_k &= 0 \end{aligned} \tag{93}$$

The required $n + (2K + 1)m$ boundary conditions are

$$\begin{aligned} \mathbf{c}(\tau_v) - \mathbf{c}'(\tau_v) &= 0, \quad \tau_v = \frac{v-1}{2K+2}, \quad v = 1, 2, \dots, 2K+1 \\ \mathbf{x}(0) - \mathbf{x}(1) &= 0 \end{aligned}$$

Note that the boundary conditions are no longer given only at $\tau=0$ and $\tau=1$, but at $2K+2$ points at $\tau = [v - 1/(2K + 2)]$, $v = 1, \dots, 2K + 2$. Because of the special structure of the boundary value problem, the multiple-shooting algorithm can be adapted in a numerically efficient way [90].

5. NOISE IN OSCILLATORS

5.1. Problems in Microwave Oscillator Noise Analysis

Noise analysis of microwave oscillators is usually based on the assumption that the unperturbed state of the oscillator is almost sinusoidal. This allows the application of a describing function method for characterization of the nonlinear devices in the oscillator [35]. Based on this method, the noise behavior of microwave oscillators has been analyzed by several groups [28,57,58,92]. These methods were applied and extended to special cases [54,62,88]. They methods provided a good qualitative and to some extent also a quantitative description of the oscillator noise behavior. However, the applicability of these methods is restricted to simplified oscillator models, since the accuracy of the method depends on the validity of the approximation of the dynamic behavior of the nonlinear elements by a describing function [58]. Another severe limitation is that the upconversion of the low-frequency noise such as $1/f$ noise cannot be treated by these methods. Kärtner has developed a time domain method for noise analysis of oscillators, based on the solution of the Langevin equations [48,49]. Adding the noise terms to the normal form equations (70) yields

$$\frac{dx}{dt} = f(x, \zeta, y_1, \dots, y_M), \quad x \in \mathbb{R}^N, \zeta \in \mathbb{R}^k \tag{95}$$

The vector ζ describes white-noise sources, and y_1, \dots, y_M represent $f^{-\alpha}$ noise sources. Colored-noise sources may be derived from white-noise sources by inserting linear systems transforming the white-noise sources to colored noise. For considering $f^{-\alpha}$ noise sources infinite-dimen-

sional systems are required. However, as shown in Ref. 49, these infinite-dimensional systems may be treated with analytical formulas, so that $f^{-\alpha}$ noise sources may be treated by low computational effort. Using the perturbation method, the correlation spectra of the phase and amplitude noise due to white-noise sources as well as due to $f^{-\alpha}$ noise sources can be calculated. The method has been applied to bipolar transistor oscillators [48,49] to planar integrated microwave oscillators [34,78], and varactor tunable oscillators [33]. Frequency-domain noise analysis can be performed on the basis of the HB method [5–7]. Starting from the HB equations (71), we obtain a nonlinear system of equations:

$$F(X, \omega, N_T) = 0, \quad X_T \in \mathbb{C}^{n(2k+1)}, N_T \in \mathbb{C}^{r(2k+1)} \tag{96}$$

In this equation X_T is the system state vector summarizing the signal spectra of n signals at a frequency ω close to the fundamental frequency ω_0 and at k harmonics. The subscript “T” denotes that the signals are time-windowed [44,84]. The vector N_T summarized the r noise source spectra at a frequency ω and at k harmonics. The numerical solution of this equation is based on correlation matrix techniques. Combining of time- and frequency-domain techniques is also possible in noise analysis [9]. The phase noise is computed in the time domain. The linear subcircuits are described by noise multiports. This method again exhibits the advantages of the time/frequency-domain method. In Ref. 7 the results of measurements of designed and fabricated integrated oscillators are compared with the numerical simulations based on the methods discussed above. This paper [7] also considers a method to minimize oscillator phase noise by numerical optimization. Based on the computation of the oscillator steady state and spectral behavior in the time domain, single-sideband phase noise is minimized using a method of optimal control problems, a direct collocation algorithm [9,10].

Another essential aspect is the simulation of the startup behavior of oscillators. If the resonator is weakly damped, it is well known that many oscillations to the steady state occur. Although some analytical results are available (see, e.g., Ruzsnyak [85]) where a simplified model of a crystal oscillator is used, the corresponding simulation problem is very complicated [87]. Schmidt-Kreusel published an efficient solution for this problem that is based on the idea that the transient trajectory of a weakly damped oscillator consists of nearly closed trajectories in the state space. If only a few parts of this transient are approximated by periodic solutions, the envelope of the transient behavior can be calculated in a fast manner. This approach is described in detail by Mathis [67]. An alternative approach was published by Brachtendorf and Laur [15] that uses a certain kind of partial differential equations for calculating the envelope.

5.2. Description of Noisy Circuits

In linear noisy circuits we usually have to deal with stationary Gaussian noise signals. Such signals may be characterized completely by their correlation spectra [23].

For a signal $s(t)$ unlimited in time, the average power within the time interval of length $2T$ centered around t is given by

$$\frac{1}{2T} \int_{t-T}^{t+T} |s(t_1)|^2 dt_1 \tag{97}$$

If for large time intervals $2T$ the average power approaches a limit, which is independent from t , the signal $s(t)$ is called *stationary*. The average power $\langle P \rangle$ of a stationary signal can be exactly defined by

$$\langle P \rangle = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^{+T} |s(t)|^2 dt \tag{98}$$

We investigate the more general term

$$c_{ij}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^{+T} s_i(t) s_j^*(t - \tau) dt \tag{99}$$

The function $c_{ij}(\tau)$ is called a *correlation function*. For $i=j$, the function $c_{ii}(\tau)$ is the autocorrelation function of the signal $s_i(t)$ and for $i \neq j$ we have the cross-correlation function $c_{ij}(\tau)$ of the signals $s_i(t)$ and $s_j(t)$. With the time-windowed function $s_T(t)$ of the signal $s(t)$ defined by

$$s_T(t) = \begin{cases} s(t) & \text{for } |t| \leq T \\ 0 & \text{for } |t| > T \end{cases} \tag{100}$$

we can write Eq. (99) in the form

$$c_{ij}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-\infty}^{+\infty} s_{iT}(t) s_{jT}^*(t - \tau) dt \tag{101}$$

The average power $\langle P \rangle$ of the signal $s_i(t)$ is given by

$$\langle P \rangle = c_{ii}(0) \tag{102}$$

We denote the Fourier transform of the time-windowed function $s_{iT}(t)$ with $S_{iT}(f)$:

$$s_{iT}(t) \circ \dots \bullet S_{iT}(f) \tag{103}$$

As mentioned before, the symbol $\circ \dots \bullet$ represents the correspondence between a pair of Fourier transforms. From Eq. (103), we obtain

$$s_{iT}(t) * s_{jT}^*(-t) \circ \dots \bullet S_{iT}(f) S_{jT}^*(f) \tag{104}$$

The symbol $*$ denotes the convolution operation

$$s_1(t) * s_2(t) = \int_{-\infty}^{+\infty} s_1(t_1) s_2(t - t_1) dt_1 \tag{105}$$

The correlation spectrum $C_{ij}(f)$, given by

$$C_{ij}(f) = \lim_{T \rightarrow \infty} \frac{1}{2T} S_{iT}(f) S_{jT}^*(f) \tag{106}$$

is the Fourier transform of the correlation function:

$$c_{ij}(\tau) \circ \dots \bullet C_{ij}(f) \tag{107}$$

$C_{ii}(f)$ with $i=j$ is the autocorrelation spectrum of the signal $s_i(t)$, and $C_{ij}(f)$ with $i \neq j$ is the cross-correlation spectrum of the signals $s_i(t)$ and $s_j(t)$. With the exception of a dimensional factor, $C_{ij}(f)$ is a spectral power density or a power spectrum. Since the autocorrelation function is a real and even function of τ , the autocorrelation spectrum is a real and even function of frequency. The cross-correlation function is complex. Changing the sign of the frequency or interchanging the indices i and j yields the complex conjugate of the correlation function:

$$2C_{ii}(f) \Delta f \tag{108}$$

The factor 2 results from considering both the positive and negative frequency parts. In general for random signals no amplitude spectra exist, whereas power spectra may be calculated also for random signals. For a stationary noise signal $s_{ni}(t)$ the Fourier integral does not exist. However, a correlation function

$$c_{ij}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-\infty}^{+\infty} \langle s_{niT}(t) s_{njT}^*(t - \tau) \rangle dt \tag{109}$$

can be defined, in which the brackets indicate the statistical mean value over signals measured on an ensemble of identical circuits. If the signals $s_{ni}(t)$ and $s_{nj}(t)$ have zero mean value, in general, the mean value of the product $s_{ni}(t) s_{nj}^*(t - \tau)$ approaches 0 with arbitrary order for $\tau \rightarrow \infty$, so that the integral (109) and also its Fourier transform exist. Since the Fourier integral of a time-windowed function exists in general, the correlation spectrum may also be defined by

$$C_{ij}(f) = \lim_{T \rightarrow \infty} \frac{1}{2T} \langle S_{niT}(f) S_{njT}^*(f) \rangle \tag{110}$$

In this case, $T \rightarrow \infty$ has to be carried out after the ensemble averaging. The autocorrelation and cross correlation spectra $C_{ij}(f)$ of the noise sources of a linear network are given by

$$C_{ij}(f) = \lim_{T \rightarrow \infty} \frac{1}{2T} \langle S_{iT}(f) S_{jT}^*(f) \rangle \tag{111}$$

where $S_{iT}(f)$, $S_{jT}(f)$ are the spectra of the time-windowed signals of the noise sources. The correlation spectra $C_{ij}(f)$ can be combined in the correlation matrix

$$C(f) = \begin{bmatrix} C_{11}(f) & C_{12}(f) & \dots & C_{1n}(f) \\ C_{21}(f) & C_{22}(f) & \dots & C_{2n}(f) \\ \vdots & \vdots & & \\ C_{n1}(f) & C_{n2}(f) & \dots & C_{nn}(f) \end{bmatrix} \tag{112}$$

The correlation matrix $C(f)$ can be represented as the product of the column vector

$$\mathbf{S}_T(f) = \begin{bmatrix} S_{1T}(f) \\ \vdots \\ S_{nT}(f) \end{bmatrix} \quad (113)$$

and its Hermitian conjugate row vector

$$\mathbf{S}_T^\dagger(f) = [S_{1T}^*(f) \cdots S_{nT}^*(f)] \quad (114)$$

in matrix notation by

$$\mathbf{C}(f) = \lim_{T \rightarrow \infty} \frac{1}{2T} (\mathbf{S}_T(f) \mathbf{S}_T^\dagger(f)) \quad (115)$$

We now formally use the complex amplitudes $S_{iT}(f)$ in the same way as the amplitudes of deterministic signals. $S_{iT}(f)$ is the spectrum of a time-windowed noise signal. We can measure the noise signal within some finite interval of time, and we may calculate the spectrum of this sample. This specific sample of a noise signal has to be considered as a deterministic signal since we have exact knowledge of its time dependence. The transition from deterministic signals to random signals is done in our description by performing the ensemble average. After performing the ensemble average in the case of random signals, the decomposition of the correlation matrix into a product of a column vector and a row vector will be impossible. For example in the case of a signal vector describing independent random noise sources, the nondiagonal elements will be averaged out to zero and the correlation matrix will be diagonal. In general, the network equations have the following form in matrix notation:

$$\tilde{\mathbf{S}}_T(f) = \mathbf{M}(f) \mathbf{S}_T(f) \quad (116)$$

The coefficient matrix $\mathbf{M}(f)$ combines the complex amplitude vectors $\mathbf{S}_T(f)$ and $\tilde{\mathbf{S}}_T(f)$. Multiplying Eq. (116) from the right with its Hermitian conjugate, we obtain

$$\tilde{\mathbf{S}}_T(f) \tilde{\mathbf{S}}_T^\dagger(f) = \mathbf{M}(f) \mathbf{S}_T(f) \mathbf{S}_T^\dagger(f) \mathbf{M}^\dagger(f) \quad (117)$$

Performing the ensemble average on both sides and subsequently carrying out the transition $T \rightarrow \infty$, we obtain

$$\tilde{\mathbf{C}} = \mathbf{M}(f) \mathbf{C}(f) \mathbf{M}^\dagger(f) \quad (118)$$

This establishes a general rule for deriving equations for the correlation matrices from linear equations for the signal amplitudes. A linear noisy two-port may be characterized by two equivalent noise sources. These noise sources may be located at the input or at the output. If both equivalent noise sources are located at the same port, one noise source must be a voltage source in series with the port and the other source must be a current source in parallel with the port. If one equivalent noise source is assigned to every port, in general we may choose an equivalent current source or an equivalent voltage source at each port.

5.3. Noise in Two-port Oscillators

We analyze the noise behavior of the simple two-port oscillator shown in Fig. 13. The left two-port is the linear frequency-determining feedback two-port. In our example the feedback network of the Meissner oscillator was chosen. The right two-port is the nonlinear amplifying two-port. In our example, all internal noise sources of the linear two-port as well as the nonlinear two-port are summarized in the noise current source $I_{rT}(f)$. This equivalent noise source is obtained in the following way. In the first step, describe the noise properties of the linear feedback two-port by equivalent output noise located at its output and the noise properties of the active two-port by equivalent noise sources located at the input of the active two-port. To extract the noise parameters of the active two-port, we consider the active two-port to be linear. After connecting the output of the feedback two-port to the input of the active two-port, we can contract the four equivalent noise sources into one noise source $I_{rT}(f)$.

For the oscillator circuit depicted in Fig. 13, the following equations are valid:

$$I_{1T}(f) = A_{21}(f) V_{2T}(f) + A_{22}(f) I_{rT}(f) \quad (119)$$

$$I_{2aT}(f) = S(V) V_{1aT}(f) \quad (120)$$

$$V_{1aT}(f) = V_{2T}(f) \quad (121)$$

$$I_{1T}(f) = -I_{2aT}(f) \quad (122)$$

Figure 13. Noisy two-port oscillator.

The variables $I_{1T}(f)$, $V_{2T}(f)$, $V_{1aT}(f)$, and $I_{2aT}(f)$ are the noise current and voltage amplitudes at the ports of the two-ports. To investigate the oscillator noise behavior, we have to consider the nonlinear saturation properties of the active two-port. $A_{21}(f)$ and $A_{22}(f)$ are circuit parameters of the feedback two-port in chain representation. In our simple model we describe the active element by a nonlinear voltage-controlled current source. With the real amplitude V of the oscillator signal at the input of the nonlinear two-port, we describe the relation between input and output noise signals by the amplitude-dependent transconductance $S(V)$. From (119) to (122) we obtain

$$(A_{21}(f) + S(V))V_{2T}(f) + A_{22}(f)I_T^r(f) = 0 \quad (123)$$

The autocorrelation spectra $C^I(f)$ and $C^V(f)$ of the noise current source $I_T^r(f)$ and the voltage current source $V_T^r(f)$ are given by

$$C^I(f) = \lim_{T \rightarrow \infty} \frac{1}{2T} \langle I_T^r(f) I_T^{r*}(f) \rangle \quad (124)$$

$$C^V(f) = \lim_{T \rightarrow \infty} \frac{1}{2T} \langle V_{2T}(f) V_{2T}^*(f) \rangle \quad (125)$$

With (123) we obtain

$$C^V(f) = \frac{|A_{22}(f)|^2}{|A_{21}(f) + S(V)|^2} C^I(f) \quad (126)$$

For the Meissner oscillator the circuit parameters of the linear feedback two-port are given by

$$A_{21}(f) = -G_0 \left(1 + jQ \left(\frac{f}{f_0} - \frac{f_0}{f} \right) \right) \quad (127)$$

$$G_0 = \frac{L_2}{|M|} G \quad (128)$$

$$Q = \frac{2\pi f_0 C}{G} \quad (129)$$

$$A_{22}(f) = -\frac{L_2}{|M|} \quad (130)$$

where M is the mutual inductance of the transformer and L_2 is the inductance of the secondary coil. Substituting into (126), we obtain

$$C^V(f) = \left(\frac{L_2}{|M|} \right)^2 \frac{C^I(f)}{(G_0 - S)^2 + G_0^2 Q^2 \left(\frac{f}{f_0} - \frac{f_0}{f} \right)^2} \quad (131)$$

The power spectral density at the load conductance G is

$$W(f) = 2C^V(f)G \quad (132)$$

and the total power flowing into G is given by

$$\bar{P}_0 = \int_0^{+\infty} C^V(f) G df \quad (133)$$

With

$$\int_{-\infty}^{+\infty} \frac{dx}{a^2 + b^2 \left(x - \frac{1}{x} \right)^2} = \frac{\pi}{ab} \quad (134)$$

we obtain

$$\bar{P}_0 = \pi \frac{f_0 C^I}{Q(G_0 - S)} \quad (135)$$

The frequency deviation Δf from the carrier is given by $\Delta f = f - f_0$. For $\Delta f \ll f_0$ we can approximate

$$\frac{f}{f_0} - \frac{f_0}{f} \doteq 2 \frac{\Delta f}{f_0} \quad (136)$$

To characterize the oscillator noise, we introduce the *noise measure* M_r . The noise measure is the factor by which the power spectral density of a noise source exceeds the thermal noise. The autocorrelation spectrum of the equivalent noise source of a conductance G exhibiting thermal noise at a temperature T is given by $2kTG$. From this definition it follows that

$$M_r = \frac{C^I}{2kTG} \quad (137)$$

From (131), (132), (136), and (137) we obtain the power spectral density of the oscillator:

$$W(f) = \frac{4kTM_r G_0^2}{(G_0 - S)^2 + 4G_0^2 Q^2 \left(\frac{\Delta f}{f_0} \right)^2} \quad (138)$$

From (135) and (137) we obtain the average total power:

$$\bar{P}_0 = \frac{2\pi kTM_r G f_0}{Q(G_0 - S)} \quad (139)$$

We define the spectral width of the oscillator as the ratio of the average power \bar{P}_0 and the power spectral density $W(f_0)$ at the center frequency f_0

$$B = \frac{\bar{P}_0}{W(f_0)} \quad (140)$$

and obtain

$$B = \pi \frac{G_0 - S}{G_0} \frac{|M| f_0}{L_2 Q} \quad (141)$$

In the oscillator without noise, S equals G_0 , whereas in the noisy case $G_0 - S > 0$ is valid. The oscillator amplitude is determined by the nonlinear gain characteristics of the active element. It is only slightly influenced by the noise source. The ratio $G_0/(G_0 - S)$ is determined by the ratio of the saturation power \bar{P}_0 and the injected noise power. Using (139), we can express $G_0 - S$ by the ratio of the

power spectral density of the equivalent noise source and the saturation power of the oscillator and obtain

$$B = \frac{2\pi^2 f_0^2}{Q^2} \left(\frac{|M|}{L_2} \right)^2 \frac{kTM_r}{\bar{P}_0} \quad (142)$$

The spectral width of the oscillator is proportional to the noise measure M_r and proportional to the inverse of the saturation power and to the square of the quality factor Q of the resonant circuit. Low-noise design of oscillators requires a low-noise active element, a high quality factor of the active circuit, and a high saturation power of the oscillator. Since the amplitude of the oscillator is stabilized by the nonlinear saturation behavior of the oscillator, an oscillator exhibits primarily amplitude noise.

5.4. Noise Analysis in Frequency Domain

In the following a frequency-domain perturbation method for simulating the noise behavior of free-running microwave oscillators is presented [7]. The method is based on a piecewise harmonic-balance technique. The single-sideband phase noise of the oscillator is derived from the system equations. The method is limited to neither certain circuit topologies nor certain types of noise sources.

5.4.1. Fluctuations of the State Variables. In the frequency-domain method, noise sources may be considered by extending the nonlinear system of equations (83). Introducing the noise source vector $\mathbf{N}_T(\omega)$, which summarizes the time-windowed spectra of the noise sources the system equations now exhibit the following form:

$$\mathbf{F}(\mathbf{X}_T, \omega, \mathbf{N}_T) \equiv \mathbf{0} \quad (143)$$

The index “T” denotes the time-windowed signal spectra as defined in (103). The vector $\mathbf{N}_T \in \mathbb{C}^{r(2k+1)}$ summarizes the amplitudes at the fundamental frequency ω_0 and at the harmonics up to $k\omega_0$ of a number of r noise sources of arbitrary spectrum. In (143) all harmonics up to k th order, and their fluctuations are considered. This allows us to compute the complete correlation spectrum at the frequency deviation $\omega_m = \omega - \omega_0$. All noise processes, including the upconversion of low-frequency noise, are considered. Since the noise contribution is small compared with the deterministic part of the oscillator signal, the noise contribution may be considered as a first-order perturbation. From (143) we obtain

$$\mathbf{F}(\mathbf{X}_T, \omega, \mathbf{N}_T) + \mathbf{G}(\mathbf{X}_T^0, \omega)\mathbf{N}_T = \mathbf{0} \quad (144)$$

with $\mathbf{G}(\mathbf{X}_T^0, \omega) \in \mathbb{C}^{n(2k+1) \times r(2k+1)}$ and

$$\mathbf{G}(\mathbf{X}_T^0, \omega) \equiv \left. \frac{\partial \mathbf{F}(\mathbf{X}_T, \omega, \mathbf{N}_T)}{\partial \mathbf{N}_T} \right|_{\mathbf{X}_T = \mathbf{X}_T^0, \mathbf{N}_T = \mathbf{0}} \quad (145)$$

The matrix $\mathbf{G}(\mathbf{X}_T^0, \omega)$ describes the coupling of the noise sources \mathbf{N}_T with the system. It is assumed that noise sources effect only a small perturbation of the limit cycle

of the oscillator:

$$\begin{aligned} \mathbf{X}_T(\omega) &= \mathbf{X}_T^0(\omega) + \delta\mathbf{X}_T(\omega); \quad \omega = \omega_0 + \omega_m \\ \|\delta\mathbf{X}_T(\omega)\| &\ll \|\mathbf{X}_T^0(\omega)\|; \quad \omega_m \ll \omega_0 \end{aligned} \quad (146)$$

Therefore the system of nonlinear equations (144) may be linearized in the neighbourhood of the limit cycle, and we obtain

$$\mathbf{J}(\mathbf{X}_T^0, \omega)\delta\mathbf{X}_T + \mathbf{G}(\mathbf{X}_T^0, \omega)\mathbf{N}_T = \mathbf{0} \quad (147)$$

with the Jacobian matrix $\mathbf{J}(\mathbf{X}_T^0, \omega) \in \mathbb{C}^{n(2k+1) \times n(2k+1)}$ of the unperturbed system equations given by

$$\mathbf{J}(\mathbf{X}_T^0, \omega) \equiv \left. \frac{\partial \mathbf{F}(\mathbf{X}_T, \omega, \mathbf{0})}{\partial \mathbf{X}_T} \right|_{\mathbf{X}_T = \mathbf{X}_T^0} \quad (148)$$

This equation describes the perturbation of the oscillator by the noise sources. It includes the mixing of the injected noise signals \mathbf{N}_T with the unperturbed state variables \mathbf{X}_T^0 . From the solution of the linearized system of equations (147), the correlation spectra of the state variables may be computed. A problem arises from the fact that the Jacobian matrix $\mathbf{J}(\mathbf{X}_T^0, \omega_0)$ is singular for the limit cycle of the unperturbed system [4,102]. The linearized perturbed system equations cannot be solved by inversion or by LR decomposition. The lowest eigenvalue of the Jacobian is $\lambda_1 = 0$. A perturbation $\delta\mathbf{X}_T$ corresponding to the eigenvalue 0 of the Jacobian induces a perturbed solution $\mathbf{X}_T^0 + \delta\mathbf{X}_T$, which is again a solution of the system equations (143). The eigenvector corresponding to the eigenvalue $\lambda_1 = 0$ is tangent to the limit cycle. The fluctuations in direction of this eigenvector are the phase fluctuations. The subspace spanned by the other eigenvectors of the Jacobian is the space of the amplitude fluctuations. This subdivision of the eigenvector space of the Jacobian allows a clear and well-defined distinction between phase and amplitude fluctuations.

5.4.2. Solution of the System Equations Including Noise.

The Jacobian is singular at the steady state and for a small frequency deviation f_m of the carrier frequency the deviations of the matrix elements are small and the condition number of the Jacobian remains high [102]. The condition number *cond*, defined by

$$\text{cond}(\mathbf{J}) = \|\mathbf{J}\| \|\mathbf{J}^{-1}\| \quad (149)$$

provides a measure for the numerical error in the solution of a linear system of equations [18,32]. The expression $\|\mathbf{J}\|$ is the matrix norm of the Jacobian \mathbf{J} . The condition number of a matrix may be approximated by the ratio of the largest and the smallest eigenvalues of the matrix [32]. The largest eigenvalue is much larger than the frequency of oscillation f_0 because it is related to the fastest process of the system. The smallest eigenvalue is of the order of the frequency deviation f_m , as we will show later in (167). Therefore the condition number *cond* of the Jacobian is much larger than the ratio of the carrier

frequency to the frequency deviation of interest [50]

$$\text{cond}(\mathbf{J}(\mathbf{X}_T^0, 2\pi(f_0 + f_m))) \gg \frac{f_0}{f_m} \quad (150)$$

This means that the steady state of an oscillator has to be determined to a much higher precision than the inverse of the condition number to achieve a relative error smaller than 1 [18]. Considering a 10-GHz oscillator and a frequency deviation of $f_m = 10$ kHz, for instance, the condition number is much larger than 10^6 . To overcome the numerical problems, the Jacobian is linearized at the carrier frequency with respect to the frequency

$$\mathbf{J}(\mathbf{X}_T^0, \omega) = \mathbf{J}(\mathbf{X}_T^0, \omega_0) + \omega_m \mathbf{J}_\omega(\mathbf{X}_T^0, \omega_0) \quad (151)$$

with the abbreviation

$$\mathbf{J}_\omega(\mathbf{X}_T^0, \omega_0) \equiv \left. \frac{\partial \mathbf{J}(\mathbf{X}_T^0, \omega)}{\partial \omega} \right|_{\omega=\omega_0} \quad (152)$$

An eigenvalue decomposition [32] of the Jacobian with left- and right-sided eigenvectors is used. Thus the complete correlation spectra can be calculated in a numerically stable way. First we want to analyze the unperturbed Jacobian $\mathbf{J}_\omega(\mathbf{X}_T^0, \omega_0)$. The left- and right-sided eigenvectors of the Jacobian are denoted by \mathbf{V}_j^\dagger and \mathbf{W}_i and the eigenvalues with λ_j^V and λ_i^W , respectively.

$$\mathbf{V}_j^\dagger \mathbf{J}(\mathbf{X}_T^0, \omega_0) = \lambda_j^V \mathbf{V}_j^\dagger; \quad \mathbf{V}_j \in \mathbb{C}^{n(2k+1)} \quad (153)$$

$$\mathbf{J}(\mathbf{X}_T^0, \omega_0) \mathbf{W}_i = \lambda_i^W \mathbf{W}_i; \quad \mathbf{W}_i \in \mathbb{C}^{n(2k+1)} \quad (154)$$

The eigenvalues of the Jacobian are equal for a set of left- and right-sided eigenvectors:

$$\lambda_j^V = \lambda_i^W = \lambda_i \quad \text{for } i=j \quad (155)$$

The left- and right-sided eigenvectors satisfy the orthogonality relations [102]:

$$\mathbf{V}_j^\dagger \cdot \mathbf{W}_i = \delta_{ij} \quad \text{with} \quad \delta_{ij} = \begin{cases} 1 & i=j \\ 0 & i \neq j \end{cases} \quad (156)$$

According to these equations, the eigenvector \mathbf{V}_1 is orthogonal to all right-sided eigenvectors \mathbf{W}_i with the exception of \mathbf{W}_1 . The eigenvectors corresponding to the eigenvalue $\lambda_1 = 0$ are denoted with \mathbf{V}_1 and \mathbf{W}_1 . These eigenvectors will be investigated in the following in detail. The eigenvector \mathbf{W}_1 is determined by the steady-state solution [5,8]

$$\mathbf{W}_1 = j\omega_0 \mathbf{K} \mathbf{X}_T^0 \quad (157)$$

where $\mathbf{K} \in \mathbb{R}^{n(2k+1) \times n(2k+1)}$ is a matrix that has only nonvanishing diagonal elements consisting of the number

of the harmonics:

$$\mathbf{K} = \begin{bmatrix} -k & & & & & & \\ & -(k-1) & & & & & \\ & & \ddots & & & & \\ & & & +k & & & \\ & & & & -k & & \\ & \mathbf{0} & & & & \ddots & \\ & & & & & & k \end{bmatrix} \quad (158)$$

Figure 14 illustrates the meaning of the eigenvectors $\mathbf{v}_i(t)$ and $\mathbf{w}_i(t)$ in the time domain. The vector $\mathbf{v}_1(t) \circ \dots \bullet \mathbf{V}_1(f)$ is the tangent vector to the steady-state limit cycle $\mathbf{x}^0(t)$ and $\mathbf{w}_1(t) \circ \dots \bullet \mathbf{W}_1(f)$ is the normal vector defining a plane \mathcal{N} that is mapped onto itself by the unperturbed flux of the linearized set of differential equations (Poincaré map) [49].

The left-sided eigenvector \mathbf{V}_1 is determined via

$$\mathbf{J}^\dagger(\mathbf{X}_T^0, \omega_0) \mathbf{V}_1 = \mathbf{0} \quad (159)$$

which is a linear homogeneous system of equations and can be solved with a standard LU decomposition. The length of the vector \mathbf{V}_1 has to be normalized to satisfy (156):

$$\|\mathbf{V}_1\|_2 = \|\omega_0 \mathbf{K} \mathbf{X}_T^0\|_2^{-1} \quad (160)$$

The eigenvectors \mathbf{W}_i are a complete basis for the state space, and, due to (156), a multiplication of \mathbf{V}_1^\dagger with a vector within the state space is a projection onto the complementary space of the plane \mathcal{N} . This means that the projection operator $\mathbf{W}_1 \mathbf{V}_1^\dagger$ applied to any vector $\mathbf{z} = \sum_{i=1}^n a_i \mathbf{W}_i$ results in a vector with a tangential component a_1 with respect to the limit cycle. So if this projection operator $\mathbf{W}_1 \mathbf{V}_1^\dagger$ is applied to the noise sources in the state space $\mathbf{G}(\mathbf{X}_T^0, \omega) \mathbf{N}_T$, the contributions of the noise sources that cause a phase shift of the unperturbed

Figure 14. Limit cycle in a two-dimensional phase space.

steady state are separated. This will be shown in the following. For a small frequency deviation f_m the deviations of the elements of the Jacobian are small. Therefore the deviations of the eigenvalues and eigenvectors of the Jacobian are small, too [32]:

$$\lambda'_i = \lambda_i + \delta\lambda_i; \quad |\delta\lambda_i| \ll |\lambda_i| \quad (161)$$

$$\mathbf{V}'_j = \mathbf{V}_j + \delta\mathbf{V}_j; \quad \|\delta\mathbf{V}_j\|_2 \ll \|\mathbf{V}_j\|_2 \quad (162)$$

$$\mathbf{W}'_i = \mathbf{W}_i + \delta\mathbf{W}_i; \quad \|\delta\mathbf{W}_i\|_2 \ll \|\mathbf{W}_i\|_2 \quad (163)$$

The eigenvalues and eigenvectors of the perturbed Jacobian $\mathbf{J}'_\omega(\mathbf{X}_T^0, \omega_0)$ are denoted by a prime. It is sufficient to consider the deviations of the eigenvalues and eigenvectors up to the first order in ω_m :

$$\delta\lambda_i = \omega_m \mathbf{V}_i^\dagger \mathbf{J}'_\omega(\mathbf{X}_T^0, \omega_0) \mathbf{W}_i \quad (164)$$

$$\delta\mathbf{W}_i = \sum_{l=1, l \neq i}^{n(2k+1)} \frac{\omega_m}{\lambda_i - \lambda_l} (\mathbf{V}_l^\dagger \mathbf{J}'_\omega(\mathbf{X}_T^0, \omega_0) \mathbf{W}_i) \mathbf{W}_l \quad (165)$$

$$\delta\mathbf{V}_j = \sum_{l=1, l \neq j}^{n(2k+1)} \frac{\omega_m}{\lambda_j - \lambda_l} (\mathbf{V}_j^\dagger \mathbf{J}'_\omega(\mathbf{X}_T^0, \omega_0) \mathbf{W}_l) \mathbf{V}_l \quad (166)$$

The eigenvalue λ'_1 is of special interest since it is identical to the deviation $\delta\lambda_1$ from the lowest eigenvalue $\lambda_1 = 0$ of the unperturbed system. Using (157), we obtain

$$\lambda'_1 = \delta\lambda_1 = 2\pi f_m \mathbf{V}_1^\dagger \mathbf{J}'_\omega(\mathbf{X}_T^0, \omega_0) j2\pi f_0 \mathbf{K} \mathbf{X}_T^0 \quad (167)$$

The smallest eigenvalue of the perturbed Jacobian $\lambda'_1 = \delta\lambda_1$ is therefore of the same order of magnitude as the small frequency deviation ω_m . The inverse $\mathbf{J}'_\omega^{-1}(\mathbf{X}_T^0, \omega_0)$ of the Jacobian is represented by an eigenvalue decomposition with the eigenvalues and left- and right-sided eigenvectors of the Jacobian $\mathbf{J}'_\omega(\mathbf{X}_T^0, \omega_0)$:

$$\mathbf{J}'_\omega^{-1}(\mathbf{X}_T^0, \omega) = \sum_{i=1}^{n(2k+1)} \frac{1}{\lambda'_i} \mathbf{W}'_i \mathbf{V}'_i{}^\dagger \quad (168)$$

This inversion will not be calculated, because of the ill-conditioning of the Jacobian. We derive this equation to calculate the correlation spectrum of the state variable fluctuations. Later on we take into account the special eigenvalue λ'_1 , which causes the bad condition of the matrix and the problems associated with numerical inversion. The state variable fluctuations are given by

$$\delta\mathbf{X}_T = - \sum_{i=1}^{n(2k+1)} \frac{1}{\lambda'_i} \mathbf{W}'_i \mathbf{V}'_i{}^\dagger (\mathbf{G}(\mathbf{X}^0, \omega) \mathbf{N}_T) \quad (169)$$

5.4.3. Correlation Spectrum of the Oscillator Noise. The correlation spectra of the state variables $\mathbf{C}^{\delta X}(f)$ and the

noise sources $\mathbf{C}^N(f)$ are given by

$$\mathbf{C}^{\delta X}(f) = \lim_{T \rightarrow \infty} \frac{1}{2T} (\delta\mathbf{X}_T(f) \delta\mathbf{X}_T^\dagger(f)) \quad (170)$$

$$\mathbf{C}^N(f) = \lim_{T \rightarrow \infty} \frac{1}{2T} (\mathbf{N}_T(f) \mathbf{N}_T^\dagger(f)) \quad (171)$$

where the brackets denote the ensemble average. The correlation spectra of the state variables are derived using (170), (171), and the equation of the state variable fluctuations (169)

$$\begin{aligned} \mathbf{C}^{\delta X}(f) &= \sum_{i=1}^{n(2k+1)} \sum_{j=1}^{n(2k+1)} 1/(\lambda'_i \lambda'_j{}^*) \\ &\times (\mathbf{V}'_i{}^\dagger \mathbf{C}^{GN}(f) \mathbf{V}'_j) \mathbf{W}'_i \mathbf{W}'_j{}^\dagger \end{aligned} \quad (172)$$

with the abbreviation

$$\mathbf{C}^{GN}(f) = \mathbf{G}(\mathbf{X}_T^0, \omega) \mathbf{C}^N(f) \mathbf{G}^\dagger(\mathbf{X}_T^0, \omega) \quad (173)$$

The approximations of (164)–(166) for the eigenvalues and eigenvectors of the perturbed Jacobian are used to derive the correlation spectra of the state variable fluctuations. The term with the major contribution to the correlation spectrum is the term with $i=j=1$ due to the small eigenvalue $\lambda'_1 = \delta\lambda_1$ given in (167). This term denotes, as already described, the phase noise of oscillators. As the perturbation of the eigenvectors $\delta\mathbf{W}_1$ and $\delta\mathbf{V}_1$ are of the order of ω_m and therefore small compared with the unperturbed eigenvectors, they are negligible:

$$\mathbf{C}^{\delta X}(f) = \frac{(\mathbf{V}'_1{}^\dagger \mathbf{C}^{GN}(f) \mathbf{V}'_1) \mathbf{K} \mathbf{X}^0 \mathbf{X}^0{}^\dagger \mathbf{K}}{(2\pi f_m)^2 |\mathbf{V}'_1{}^\dagger \mathbf{J}'_\omega(\mathbf{X}^0, \omega_0) \mathbf{K} \mathbf{X}^0|^2} \quad (174)$$

Because of the special situation of the eigenvalue λ'_1 and the eigenvectors $\delta\mathbf{W}_1$ and $\delta\mathbf{V}_1$, the terms with $i=1$ and $j \neq 1$ or $i \neq 1$ and $j=1$ in (172) denote the amplitude phase correlation spectra. Finally the terms with $i \neq 1$ and $j \neq 1$ in (172) represent amplitude noise. These noise contributions are small compared with the phase noise, due to the larger eigenvalues, and are not taken into account in the following subsections.

5.4.4. Single-Sideband Phase Noise. The single-sideband phase noise $L(f_m)$ is the ratio between the noise power in a sideband of bandwidth 1 Hz at a frequency deviation $f_m = f - f_0$ from the carrier frequency and the total signal power P_s . The single-sideband phase noise $L(f_m)$ is equal for all state variables, and therefore we can choose any state variable x_i to calculate the single-sideband phase noise:

$$L(f_m) = P_{Ni}(f_m) / P_{Si} \quad (175)$$

In order to obtain the single-sideband phase noise at the fundamental frequency, the matrix element corresponding to the i th state variable is chosen that denotes the noise

power at the fundamental frequency. We have to select the element $|X_{i,1}^0|^2$ of the matrix $\mathbf{KX}^0\mathbf{X}^{0\dagger}\mathbf{X}$ and obtain for the noise power $P_{Ni}(f_m)$ in a 1 Hz bandwidth

$$\begin{aligned} P_{Ni}(f_m) &= 2\mathbf{C}^{\delta X}(f_0 + f_m)_{i,1}R_n \\ &= 2 \frac{|X_{i,1}^0|^2 R_n \mathbf{V}_1^\dagger \mathbf{C}^{GN}(f) \mathbf{V}_1}{(2\pi f_m)^2 |\mathbf{V}_1^\dagger \mathbf{J}_\omega(\mathbf{X}^0, \omega_0) \mathbf{KX}^0|^2} \end{aligned} \quad (176)$$

where R_n is a resistance of normalization. The signal power of the fundamental frequency is represented by

$$P_{Si} = 2|X_{i,1}^0|^2 \cdot R_n \quad (177)$$

With the definition of the single-sideband phase noise in (175), we derive an equation for $L(f_m)$ using the approximations of the noise power (176) and the signal power (177):

$$L(f_m) = \frac{1}{(2\pi f_m)^2} \cdot \frac{\mathbf{V}_1^\dagger \mathbf{C}^{GN}(f_0 + f_m) \mathbf{V}_1}{|\mathbf{V}_1^\dagger \mathbf{J}_\omega(\mathbf{X}^0, 2\pi f_0) \mathbf{KX}^0|^2} \quad (178)$$

where \mathbf{V}_1 is the solution of the homogeneous linear system of equations

$$\mathbf{J}^\dagger(\mathbf{U}_T^0, 2\pi f_0) \mathbf{V}_1 = \mathbf{0} \quad (179)$$

which can be obtained very easily with a standard LU decomposition of the Jacobian. The derivative of the Jacobian with respect to the frequency $\mathbf{J}_\omega^\dagger(\mathbf{U}^0, 2\pi f_0)$ can be calculated numerically, as we will show in our example. The denominator of the second term is constant for different frequency deviations and needs to be calculated only once. The numerator consists of the correlation spectrum of the noise sources multiplied by the vector \mathbf{V}_1^\dagger from the left side and by \mathbf{V}_1 from the right side. As we already described, this multiplication is a projection of all noise sources of the state space onto the tangent vector to the steady state. That means that the vector \mathbf{V}_1 selects the contributions of the noise sources that are tangential to the steady state and therefore induce phase noise. The noise sources, $1/f^\alpha$ -noise sources and white-noise sources, and their modulation are taken into account in the correlation matrix \mathbf{C}^{GN} . The correlation spectrum of a $1/f^\alpha$ -noise source decreases at 10α dB per decade, and therefore $L(f_m)$ decreases at $[20 + 10\alpha]$ dB/frequency decade. The single-sideband phase noise decreases at 20 dB per frequency decade due to white-noise sources because the correlation spectra of white-noise sources are constant with respect to the frequency. This method results in a numerically stable calculation of the phase noise of free-running oscillators, where all effects of the noise sources converted with harmonic signals are taken into account.

6. SYNCHRONIZATION OF OSCILLATORS

In the previous sections electronic oscillators without excitations were considered, but even in the early days

of oscillators undesired entrainment phenomena of forced oscillators were described by Möller [75] and others (see van der Pol [99]) around 1920. Although van der Pol mentioned forced oscillations in a 1920 paper, he considered circuits only with positive (differential) resistances. In 1922 Appleton [3] discussed “automatic synchronization” of forced triode oscillators (only another expression for entrainment), and in the following years this subject was studied in more detail (see van der Pol’s review paper [100]), but a sound mathematical basis of entrainment phenomena was not presented until the paper of Andronov and Vitt [2] in 1930, where again the mathematical ideas of Poincaré were used. A modern presentation can be found, for example, in the monograph by Jordan and Smith [47]. In 1945 Tucker [96] emphasized that

the synchronization (or entrainment) of oscillators was originally investigated because of difficulties experienced with early radio transmitters of “pull-in” to adjacent-station frequencies. Since then, however, the properties of oscillators under the influence of injected tones have been utilized in several ways.

He also mentioned ideas from his Ph.D. thesis about applications to carrier telephone systems and Kirschstein’s [53] miscellaneous applications in radio and other applications in communication engineering. Today many of these early applications of entrainment and synchronization of forced oscillators are discussed in the area of so-called phase-locked loops (see, e.g., Stensby [94] for further details and references). Although it seems that phase-locked-loop (PLL) circuits and forced electronic oscillators differ in their circuit structure a mathematical analysis shows similar phenomena in both circuits.

In this section some aspects of entrainment will be illustrated using the forced van der Pol equation (with normalized $\omega_0^2 = 1$)

$$\ddot{x} + \varepsilon(x^2 - 1)\dot{x} + x = \Gamma \cos \omega t \quad (180)$$

where $\varepsilon > 0$. Following Jordan and Smith [47], where van der Pol’s idea is used, we look for responses approximately of the form

$$x(t) = a(t) \cos \omega t + b(t) \sin \omega t \quad (181)$$

where a , b are slowly varying functions. Neglecting \dot{a} , \dot{b} , we obtain after some calculations a system of differential equations for the amplitude functions a and b

$$\begin{aligned} \left(2\omega - \frac{1}{2}\varepsilon ab\right)\dot{a} + \varepsilon\left(1 - \frac{1}{4}a^2 - \frac{3}{4}b^2\right)\dot{b} \\ = \varepsilon\omega a\left(1 - \frac{1}{4}r^2\right) - \Omega b \end{aligned} \quad (182)$$

$$\begin{aligned} -\varepsilon\left(1 - \frac{3}{4}a^2 - \frac{1}{4}b^2\right)\dot{a} + \left(2\omega + \frac{1}{2}\varepsilon ab\right)\dot{b} \\ = \Omega a + \varepsilon\omega b\left(1 - \frac{1}{4}r^2\right) + \Gamma \end{aligned} \quad (183)$$

where $\Gamma^2 = a^2 + b^2$ and $\Omega := \omega^2 - 1$. The periodic solutions with the frequency ω of the “input function” $\Gamma \cos \omega t$ (RHS of 180) correspond the equilibrium points ($\dot{a} = 0, \dot{b} = 0$) of these equations. Using the abbreviations $v = (\omega^2 - 1)/\varepsilon\omega$ (“detuning”) and $\gamma = \Gamma/\varepsilon\omega$, we obtain from the equilibrium equations the following condition for “response” solutions

$$r^2 \left\{ v^2 + \left(1 - \frac{1}{4}r^2 \right)^2 \right\} = \gamma^2 \tag{184}$$

Analysis of this polynomial equation shows that there are one or three real roots (since $r > 0$) depending on the parameter values v and γ . A graphical representation of r^2 in dependence of $|v|$ is called “response diagram,” which can be found, for example, in Jordan and Smith [47]. Based on these equilibrium points, a stability analysis has to be performed. As a conclusion it can be found that for certain values of the parameters v and γ around the frequency $\omega_0^2 = 1$ ($v = 0$) of the “free” oscillator (i.e., zero input function), there is a finite region (“lockin band”) of detunings v where a stable harmonic solution (with frequency ω) exists. This region of frequencies corresponds to the region of entrainment or synchronization. Outside this frequency region there are no stable harmonic solutions with the input frequency ω and in the $a - b$ -plane limit cycles appear. In Fig. 15 a variant of the response diagram is shown using the coordinates r and ω . A first curve subdivides the r, ω plane into the stable and unstable areas, whereas the semicircle above corresponds to the stable solutions of the polynomial equation (184). Moreover, the dashed lines confine the entrainment or synchronization region. These results were published by Andronov and Vitt [2] for the first time. Note that the forced van der Pol equation is nonlinear, and, in contrast to linear differential equations with constant coefficients where general solutions consist of a superposition of “free” and “forced” oscillations, this distinction makes no sense

Figure 15. Response diagram of the van der Pol equation.

although it seems obvious if the frequencies ω_0 and ω are widely separated.

The abovementioned mathematical concept can be applied to discuss some basic aspects of entrainment/synchronization phenomena, but there are other effects (e.g., higher harmonics, subharmonics) where more involved techniques have to be applied. The reader is referred to the monograph of Jordan and Smith [47] for further details. For analysis of PLL circuits with its feedback structure, the monograph by Stensby [94] is very helpful.

Finally, we should mention that there is a close relationship between synchronization and chaotic behavior. This subject is contained in an interesting paper by Tsang et al. [95]. As a conclusion of their discussion, it can be emphasized that each circuit with synchronization properties is a potential candidate of a chaotic system.

7. MISCELLANEOUS PROBLEMS OF OSCILLATOR DESIGN

Besides the design problems discussed above, further problems are essential in the design of oscillators. Some of these problems are mentioned, but the reader is referred to the literature; for instance, the monographs by Parzen [79], Frerking [30], and Kurz and Mathis [59] contain many interesting design aspects. Several monographs are available that consider the design of microwave oscillators [e.g., 101]. We will discuss only some more general aspects of oscillator design. Spurious oscillations: Most spurious oscillations are caused by the parasitic inductances and capacitances in the active devices (e.g., transistors) or the physical layout for the components of the oscillator circuit. A main approach to avoid these oscillations is to introduce of additional damping (e.g., additional resistors). Parasitics that are related to the layout and a rather poor design can be reduced by an experienced designer since general rules to avoid it are not available. In crystal oscillators there is a tendency of spurious signals due to the crystal itself. For studying these effects a more complete model of the crystal with additional resonances (so-called modes) has to be considered [79].

Another effect is self-produced amplitude modulation of high-frequency oscillation; this effect is often denoted as “squegging.” The physical reason of squegging is related to an interaction between the time constant of the bias and coupling circuits and the time constants of the high-frequency tuned circuits of the oscillation part. Squegging occurs more frequently in self-limiting oscillators with low Q values than in crystal oscillators where a high Q is usual. Furthermore a suitable thermal design is necessary, especially if a crystal resonator is chosen. Some hints about this subject can be found in the literature [see, e.g., Kurz and Mathis [59]].

PACKAGING RF DEVICES AND MODULES

Y. C. LEE
 WENGE ZHANG
 BINGZHI SU
 ZHIPING FENG
 K. C. GUPTA
 University of Colorado, Chong-
 IL Park, Kyocera America,
 Inc.

Initially implemented in military radar, microwaves have been used in communication, space, scientific, and commercial applications. The term *microwave* usually refers to the frequency spectrum ranging from 300 MHz to 300 GHz. Strictly speaking, the millimeter-wave (mm-wave) range begins at about 30 GHz; therefore, the term *radiofrequency* (RF) is used, instead of *microwave*, to represent both microwave (300 MHz–30 GHz) and mm-wave (30–300 GHz) frequency spectra.

Radiofrequency (RF) packaging is becoming more and more important because of the significant growth of military and commercial applications in wireless communication and sensing. Packaging strongly affects performance, cost, and reliability; it is a determining factor in application growth. Many RF packaging, issues are the same as those for microelectronic packaging, which are covered in other articles. However, RF packaging has three distinguishing features:

1. Table 1 lists application examples at frequencies ranging from 1 to 100 GHz [1]. There is another long list for frequencies less than 1 GHz. For such a wide spectrum of applications, it is not practical to develop a few “standard” packaging solutions to meet requirements that are usually frequency-dependent.
2. For frequencies higher than 1 GHz, the package strongly affects RF performance. It is a part of the circuit, not just a housing. The package parasitic becomes more critical as frequency increases [2,3].

Table 1. Examples of RF Applications at Frequencies from 1 to 100 GHz

Frequency(GHz)	Applications
1.9–2.1	Personal communication services (PCS)
4–8	Cooperative engagement military communication
5.1–5.3	Supernet band for PCS
12.4–12.7	Direct broadcast satellite (DBS)
20, 44	Military MILSTAR
27.5–30	Local multipoint distribution service (LMDS)
26–40	Military precision guided missiles
60	Wireless communication links
77	Vehicular collision avoidance radar
75–110	Concealed-weapon detection

3. The number of inputs/outputs (I/O) in RF packages is small, for instance, 6 I/Os or 12 I/Os; however, electromagnetic waves must be transmitted in and out with minimum losses.

RF packaging technologies have been driven by military applications; as a result, most packages are semicustom or custom designed for performance, reliability, and small volume manufacturing. With the growth of commercial applications, cost is becoming the predominant factor. As a result, plastic and low-cost ceramics are used for mass production of RF packages for PCS applications at frequencies around 2 GHz. They are being developed for higher frequencies around 5 GHz.

High-volume applications in mm-wave frequencies, for example, 23, 26, 30, 38, 60, and 77 GHz, are to be implemented in the near future. Packaging these RF devices and modules is critical to a successful implementation. Package complexity is increasing substantially in order to support these new commercial systems using microwave and millimeter-wave integrated circuits (MMICs), active antennas, antenna arrays, microelectromechanical systems (MEMSs), substrates with ferroelectric or superconductor or other novel components.

RF packaging technologies are advancing rapidly. This article provides basic knowledge to understand the technology advances. Most packaging issues common to those for microelectronics packaging will not be covered here, and they can be found in other articles. The following sections will focus on unique issues for RF packaging. Representative packages and assembly technologies will be reviewed. Critical consideration of RF performance and reliability will be introduced. The reliability section will cover both thermal management and mechanical integrity. A case study will be presented to illustrate a typical design procedure considering various factors. In addition, computer-aided-design (CAD) issues and advanced packaging concepts will be introduced, to understand future challenges.

1. RF PACKAGES

A typical microwave and mm-wave system is shown in Fig. 1. Signals are generated by an oscillator and transmitted from an antenna driven by an amplifier. The signals are received by another antenna and propagated to a receiver. There are many transmission-line components to interconnect these basic devices. In many cases, the transmission line is a part of the circuits. The trend is to integrate all the devices and components more and more using MMIC and advanced packaging technologies. High integration could eliminate layers of interconnects for cost reduction and performance enhancement.

Figure 2 shows an example of two levels of RF packaging. For a single-chip package, an RF device is connected to a package substrate through wire bonding or flip-chip soldering/bonding. Usually there are transmission lines

Figure 1. A typical microwave or millimeter-wave system consisting of major functional modules and circuits for signal transmitting and receiving. The integration of the oscillator, amplifier, and antenna is for signal transmitting. The integration of the antenna and receiver is for signal receiving. For high-frequency applications, the transmission-line components should be reduced as much as possible for high efficiency.

on the substrate; the lines are connected to the external ports through feedthroughs or vias. The external ports are connected to the next level board assembly. For a multichip RF module, bare-die devices and RF components are connected to a multilayer substrate with transmission lines as interconnects. These single-chip and multichip modules will be briefly reviewed in what follows (see Fig. 2).

1.1. Single-Chip Packages

Figure 3 shows a photo of a typical RF package with various components of a package shown in Fig. 4. The wall of housing is usually made of metal or ceramic. The feedthroughs are gold-coated leads passing through a metal or ceramic wall. With a metal wall, feedthroughs are isolated from the wall by glass. A gold plated Kovar (iron–nickel–cobalt alloy) or CuW (copper–tungsten) base is soldered to the bottom of the package, and a gold-plated Kovar lid is typically attached to the wall with AuSn (gold–tin) solder.

There are many different packaging approaches other than the example given above. Several factors should be addressed before an individual packaging method is chosen [4]:

- Low-loss electrical interconnect with impedance matching
- Dimensional stability and achievable tolerances
- Three-dimensional package characterization with antiresonance housing

Figure 3. Photo of a typical single-chip RF package. Details of the package are described in Fig. 4.

- Electromagnetic shielding
- Efficient thermal management
- Matching of material properties for reliable connections
- System constraints such as size, weight, shape, hermeticity, or the special positioning of the package or modules in the array
- Test and validation
- Overall cost including assembly and rework as well as package manufacturability

With these considerations, a designer can choose a proper packaging solution. A summary of different packages are described below.

1.1.1. Package Materials. RF single-chip packages can be categorized by package material such as metal wall, ceramic wall, glass ceramic, and plastic packages. Their major characteristics are listed in Table 2 qualitatively, and a brief description is given in this section.

1.1.1.1. Metal Wall Package. The metal wall is usually Kovar coated with nickel and gold. Its feedthroughs for output leads are striplines isolated from the wall. Striplines are described later. A good package can be used up to 90 GHz with low insertion loss and excellent isolation. However, thermal performance is poor using Kovar and the cost can be high. Thermal performance can be enhanced substantially with a CuW base plate. To reduce cost, metal injection molding can be used for fabricating the metal housing [5].

Figure 2. Single-chip and multichip RF packages mounted on a board. The single-chip package can be through-hole or surface mount types. The multichip module can be assembled using wire bonding or flip-chip connections; the module can be mounted onto the board using through-hole or surface mount technologies. All the critical elements for the first- and the second-level packaging are shown in the figure.

Figure 4. Structure of an RF package consisting of a wall, feedthroughs, and a baseplate. The baseplate carries the RF device that is connected to RF ports through wire bonding pads and feedthroughs. The metal wall is to provide electrical, thermal, and mechanical protection of the device.

1.1.1.2. Ceramic Wall Package. The ceramic wall is usually made by high-temperature cofired ceramic (HTCC) coated with nickel and gold. The process for HTCC is described in Ref. 6. The feedthrough conductor can be tungsten striplines without additional electrical isolation. A good package can be used up to 60 GHz with low insertion loss and good isolation. The package cost can be lower than that of the metal wall package's, but it may still be high.

1.1.1.3. Glass Ceramic Package. The package material is a compound mixing glass and alumina. It is also called low-temperature cofired ceramic (LTCC) with copper as the conductor. The substrate is ideal for surface mount package and multichip modules. A good package can be used up to 40 GHz with low insertion loss. Its cost is low because the use of copper as the conductor; however, without enhancement, its thermal performance can be poor.

Figure 5 shows a surface-mounted ceramic package with RF vias. The external ports can be designed for leadless chip carrier or ball-grid array (BGA) surface mount technologies. The insertion loss can be high, and the operation frequency is limited to a band between 18 and

Figure 5. A surface mount package with RF vias. At the end of each port, the RF signal passes through the via to solder pad for surface mounting. No lead is needed for better RF performance because of short connections. Surface mount is important to automatic assembly of the package onto a board.

26 GHz. With higher frequencies, the typical $\lambda/4$ length scale is close to length scales of package discontinuities caused by bonding wires or joints, vias, walls, and other elements. To reduce the loss at a selected high-frequency band, the electromagnetic coupling at critical interfaces should be designed to smooth such discontinuities. Figure 6 is a package with coupling designed for 77 GHz.

1.1.1.4. Plastic Package. The plastic package is fabricated by injection molding of a device on a pedestal/lead-frame for die attachment and I/O leads. The package is excellent in manufacturability and ideal for surface-mount technology. However, it is usually used for frequencies less than 10 GHz due to high insertion loss. The manufacturing processes are the same as those for plastic packages used in microelectronics; however, the inductance of bonding wire and leadframe should be evaluated for high-frequency packages. A new premolded plastic package can enhance the performance, which is described later. The cost of a plastic package is low; however, it may not be lower than that of the glass ceramic package if both are designed for reach the same electrical performance.

1.1.1.5. Boards. The single-chip RF packages are generally mounted on a board. The board technologies are very similar to those for RF modules; these technologies are to be described in the next section.

1.2. Multichip Modules

Multichip module (MCM) technologies are being applied to design and manufacture RF modules. It is defined as a substrate of dielectric and conduction layers, on which integrated circuits (“chips”) and passive components (if any) are mounted directly on (or inside) the substrate, without

Table 2. Different Materials for Single-Chip RF Packages

	Metal Wall	Ceramic Wall	Glass Ceramic	Plastic
Features	Broadband	Broadband	Low loss	Low cost
	Low loss	Lower cost than metal wall	Suitable for single-chip and MCM	Suitable for high-volume applications
	Antiresonation	Low loss	Surface mount	Surface mount
Structure		Anticavity resonance	Suitable for high-volume applications	
	Excellent shielding	Good shielding		
	Excellent isolation	Good isolation	Excellent design flexibility	

Figure 6. Structure of an electromagnetic coupling package. The top-layer microstrip line is coupled to the bottom one through the slot on the ground plane. The structure achieves the low insertion loss in a selected high frequency band. Such a specific RF design is important to reduce losses in millimeter-wave applications.

separate packaging for most of the active components. The entire MCM may be placed in a hermetic package much like a large single-chip carrier, or may be directly covered with a sealant material to protect the components from physical damage [7]. A good MCM example is shown in Fig. 7, which is a drawing of a photo taken from Ref. 8. The module consists of components on both sides. The front side has RF multicavities with all the MMICs and a large cavity with low-frequency components, for example, ASICs and discrete components for power supply and distribution. The backside is a nonhermetic area where all the surface mount components are assembled.

Figure 7. Substrate for a mixed multichip module. The frontside consists of low-frequency microelectronics and RF areas. Critical devices are sealed separately to avoid crosstalk. The backside is a nonhermetic area for all low-frequency surface mount components. A multichip module is much more complicated than single-chip packages; it is custom-designed and fabricated to interconnect many devices to reach specific targets on cost, performance, size, weight, or reliability.

Table 3. Advantages and Concerns for Single-Chip and Multichip Packaging

	Single Chip	MCM
Advantages	Each device testing Good yield as module Device to device isolation	Size reduction Lightweight Assembly cost reduction/cycle time reduction
	Hermeticity for individual device	Performance enhancement Reliability enhancement
Concerns	Volume manufactuability Electrical performance as module level	Power reduction Bare-die testing and yield Rework Use of via for RF line DC/RF shielding

The advantages and concerns of MCM and single-chip packaging are listed in Table 3. MCM technologies are emerging as a cost-effective technology for next-generation devices because of their advantages in small size, performance enhancement, better reliability, low power consumption, package cost reduction, and potential overall cost reduction for high-volume applications [9]. It is the predominant approach for mm-waves modules with frequencies higher than 30 GHz. However, its cost can be very high if manufacturing yield is low. With the establishment of MCM manufacturing infrastructure for microelectronics, the manufacturing barrier is being reduced substantially. In addition, sizes of single-chip packages are reduced significantly with chip-scale-package (CSP) technology. These packages for some RF and microelectronic devices can be integrated with other devices to form an MCM. It is anticipated that more MCM-based RF modules will be developed for size, weight, performance, power, or cost advantages in future.

MCMs can be fabricated using thin-film, thick-film, or thick/thin-film technologies. Typical substrate materials important to RF packaging are listed in Table 4 [10,11] for hard and Table 5 [12] for soft substrates.

1.2.1. Alumina/Glass Alumina. Alumina and glass alumina are popular substrates for MCMs. The fabrication of alumina substrate usually employs cofired technology, which includes low-temperature cofired ceramic (LTCC) and high-temperature cofired ceramics (HTCC). LTCC and HTCC are alumina/glass systems that differ in glass content (50% vs. 4%) and firing temperature (850°C vs. 1500°C). The LTCC firing temperature permits the use of silver, gold, and copper as conductors, while HTCC is limited to the use of a higher-melting-point refractory alloy, such as tungsten and molybdenum. LTCC substrates thus have lower sheet resistance but higher dielectric loss tangent. Their mechanical strengths and thermal conductivities are also lower than those of HTCC substrates. To achieve better cost/performance ratio, thin-film MCMs can use a harder alumina substrate, for example, A493, listed in Table 4, which has good RF, mechanical, and thermal

Note: For properties of BeO the reader is referred to *Integrated Active Antennas and Spatial Power Combining* (J. A. Navarro, K. Chang, 1996). Properties of fused quartz, sapphire, and Si are covered in *Materials Handbook for Hybrid Microelectronics* (edited by Joseph Alison King, Artech House, 1988). Properties of gallium arsenide are listed in this table for reference.

properties. With thin-film technologies, low-temperature metals can be used for circuits. If planer passive components are needed, either HTCC or LTCC multilayer ceramic can be used as the substrate for thin film. Details on thin-film, thick-film, and thin/thick film-MCM technologies are given in other articles in this encyclopedia.

With single-layer or multilayer structures, different types of interconnect, for example, stripline, microstrip, and coplanar waveguide, can be used. Thermal conductivities of alumina and glass alumina substrate are usually poor. If needed, thermal performance can be enhanced by the use of metal plates, for example, CuW and Cu–Mo–Cu composites. Alternatively, AlN or BeO can be used.

1.2.2. BeO. Beryllium oxide or beryllia (BeO) is an alternative substrate material with an excellent thermal conductivity of 260 W/m · K. However, it is not widely used because of toxicity of outgasing during substrate fabrication. Also, its CTE is 9 ppm/°C, which is quite different from GaAs's CTE. In addition, BeO cannot be used to fabricate multilayer structures.

1.2.3. AlN. AlN, with a thermal conductivity of 150 W/m · K, is becoming an appealing alternative to alumina. Its coefficient of thermal expansion (CTE) of 4.7 ppm/°C, which is closer to silicon's and GaAs's CTE. It can be used for single-layer and multilayer thin-or thick-film technologies. AlN substrate also utilizes refractory metallizations, firing at 1800°C. AlN powders are currently more expensive than alumina and result in higher substrate cost. In addition, the electrical loss could be high and the thermal conductivity can be degraded substantially, with processing variations.

1.2.4. Polymers. Laminated substrates are being used widely for personal communication systems (PCS) appli-

cations. Their well-established manufacturing infrastructure can be accessed by module designers. The typical substrates can be PTFE, FR4 and polyimide. Their properties are listed in Table 5. Their CTEs are very large and thermal conductivities are poor, so reliability issues should be considered during module design. For low-loss modules, PTFE with different fillers can be used.

In addition to the properties discussed above, another major concern regarding the materials is dimensional stability. RF performance is affected by the variations of dimensions such as the length and the width of a line, the shape of a line's cross section, the spacing among lines, the diameter of a via, surface roughness, and many other geometric parameters. In particular, performance in millimeter-wave modules is strongly dependent on dimensional stability. For these applications, HTCC, LTCC, and plastic packages might not be good choices; their structural shrinkage or expansion could cause performance degradation. Rigorous process control is needed to limit the dimensional change during manufacturing. Or, thin-film packages could be used. Even for the thin-film interconnects, tight process control or new processing techniques may be a needed. For example, reactive-ion etching (RIE) instead of a wet etching process may be used to fabricate a precise structure for superior performance [7].

1.3. Assembly Technologies

The first-level (device-to-package) assembly technologies are wire bonding, tape-automated bonding (TAB), and flip-chip soldering or bonding. The second-level (package-to-board) assembly technologies can be through-hole or surface mount. The surface-mounted packages can be leaded or leadless peripheral, ball-grid-array (BGA), chip-scale-package (CSP), or direct chip assembly (DCA). The major challenge to the assembly technology to control its effect on the package performance. Since the unique RF requirements of the second-level packaging are very similar to those of the first-level packaging, only the requirements for the wire bonding, TAB, and flip-chip assembly will be discussed.

1.3.1. Wire Bonding. Wire bonding technology is the earliest and by far the most prevalent technology (>90%) in use today. A typical microwave chip and wire intercon-

nect utilizes 18–25- μm diameter gold wire, which is ball or wedge bonded to gold-plated die and substrate bondpads. The very narrow wires are highly inductive at higher frequencies, and variations in wire length and loop shapes cause performance variations from module to module [13]. Length and impedance control are critical issues.

1.3.2. TAB. Tape-automatic bonding (TAB) technology is commonly utilized in commercial products requiring lightweight, thin packaging. TAB is typically a reel-to-reel process using solid copper tape or copper prepatterned on a polyimide film. The inner leads of the tape are bumped and bonded to the die pads. Finally, the bonded assembly is encapsulated and the outer leads are bonded to a printed wiring board [13]. The coplanar film carrier can be made for TAB RF packaging, which has an insertion loss of less than 0.2 dB/mm without resonance over the frequency range from DC to 30 GHz. The electrical performance of a GaAs MMIC module with coplanar film carrier is almost equal to that of an MMIC measured directly on wafer [14].

1.3.3. Flip-Chip Assemblies. Flip-chip technology provides a direct metallurgical interconnect between die bondpads and the substrate. Solder-bumped die are soldered or bonded directly to the substrate, providing an excellent electrical connection.

The thermal path is through the solder connection to the substrate. In the case of high-power GaAs MMICs, without the use of thermal bumps, this thermal path is usually inadequate for reliable operation [13]. However, flip-chip assembly is becoming more and more important with the following advantages [15–17]:

- Automated assembly
- Compact modules
- Minimum interconnect length
- Low inductance and discontinuity
- Compatibility with coplanar interconnects without the use of thin devices
- Efficient thermal management with the use of thermal bumps

RF packaging is very challenging because of the wide spectrum of operation frequencies and strong packaging effects on RF performance. For example, the number of I/Os is substantially less than those for microelectronics; however, it is still very difficult to switch from wire bonding to flip-chip assembly. Such a switch is a paradigm shift, demanding reconsideration of not only package but also device designs. The microstrip lines on an MMIC should be replaced by coplanar waveguides. More important, placement of high-power dissipation MESFETs or other devices should be close to the flip-chip joints. Trade-off considerations on RF performance and reliability must be taken into account before any package design. These two issues are to be discussed in the following sections.

2. PERFORMANCE OF RF PACKAGES

At microwave and higher frequencies, packaging can affect the RF performance of circuit significantly. RF parameters of the package are frequency-dependent. Insertion loss, return loss, package resonance frequency, and crosstalk caused by electromagnetic coupling are measures of RF performance. As frequency increases, packaging can become the limiting factor of electrical performance by degrading signal propagation, or by contributing to structural configuration that fosters cavity resonances or that propagates waveguide modes.

2.1. Single-Chip RF Package

Even though RF performance of multichip modules (discussed later) is superior [3] to that of single-chip package to some extent, the single-chip package is still useful due to several reasons [3]:

1. Electrical response of a packaged device is more reproducible and defined. Bondwire and mounting techniques affecting RF characteristics can be defined.
2. Die performance can be tested and validated.
3. Each package can be designed for machine handling.
4. Packages assembled are usually reworkable.

2.1.1. RF Structure of the Package. Figure 8 illustrates typical RF components for a single-chip package. An RF/MMIC chip (die) may be a single device or an integrated circuit consisting of several devices. The chip is bonded to pads on the substrate by using wire/ribbon bonding of flip-chip bonding technology. Transmission lines on the package substrate carry the signal in or out of the chip. Microstrip lines or coplanar waveguides (CPWs) can be used. Bias and control signal lines are also fabricated on

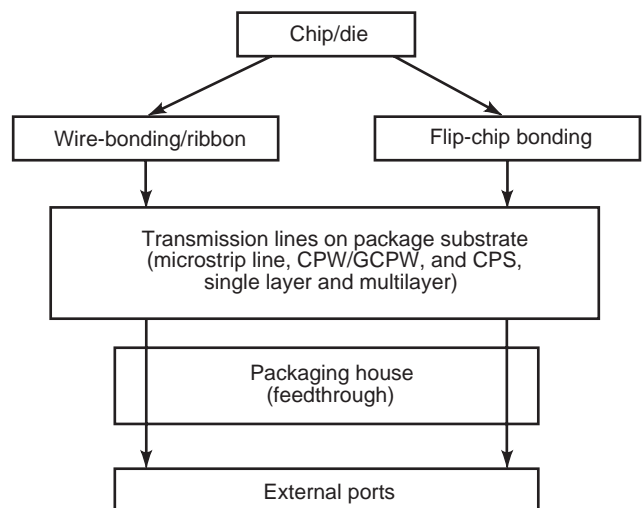

Figure 8. Block diagram of RF components for a general single-chip RF package. Each block represents a critical package element that affects the RF performance of a packaged RF device.

the package substrate. The package substrate can be either single-layer or multilayer. For a multilayer substrate, vertical vias are needed to carry the signal or DC power through different layers. The substrate is enclosed in the metal or ceramic housing with external ports. Feedthroughs are needed to carry the RF and other signals in and out through the package housing. A stripline structure is a common choice for these feedthroughs. External ports can be miniature coaxial connectors, through-hole leads, or solder joints for the next level packaging (see Fig. 2).

2.1.2. Bondwire and Flip-Chip Interconnect. Bondwires/ribbons and flip-chip interconnects provide electrical connections between a chip and a substrate. Figure 9 shows the comparison of effect of wire bond length and flip-chip interconnects on insertion and return losses. The insertion loss (S_{21}) in two-port RF circuits is found by driving port 1 with an incident wave of unit amplitude, and measuring the transmitted wave voltage amplitude, coming out of port 2, when port 2 is terminated in matched load to avoid reflection. The return loss (S_{11}) is, similar to the insertion loss, the ratio of the amplitude of the wave reflected from port 1 to the incident wave voltage amplitude to port 1 when port 2 is terminated in matched load. The return loss (S_{11}) and insertion loss (S_{21}) are widely used in RF engineering as measures of RF performance. As observed in Fig. 9, the flip-chip interconnect typically results in better performance, particularly for frequencies higher than 4 GHz [7]. Most of the discussions in the literature concentrate on S_{21} effects. However, to ensure a minimum amount of standing waves in the assembly and, hence, the most uniform behavior across a wide range of frequencies, S_{11} should be less than -20 dB across the entire passband of

interest. Here again, wire bonds of all lengths perform poorly in comparison with flip-chip interconnects for frequency above a few hundred megahertz.

2.1.2.1. Bondwire or Ribbons. Wire bonding is the most widely used method of connecting a chip to a package. A typical bondwire is around $300 \mu\text{m}$ long and $200 \mu\text{m}$ high. This length includes a margin of error due to (1) the height difference between the chip and the substrate, (2) chip contact pads' locations, and (3) an extra length needed to avoid a mechanical failure during thermal cycling. The inductance of the wire length may degrade the electrical performance of the RF chip. Wire bond inductance can be calculated using the following formula (18)

$$L_s = 5l \left[\ln \left(\frac{2l}{p} \right) - \frac{3}{4} \right]$$

where L_s is the self-inductance with the unit of nH, l is the length of the wire in inches, and p is the diameter of the wire in inches. Figure 10 shows calculated return loss and insertion loss of bondwire and bond ribbon interconnect versus normalized wire length L/λ_0 (19). An interconnect with a return loss better than -10 dB requires bondwires not longer than $0.033\lambda_0$, which is only $100 \mu\text{m}$ at 94 GHz. Bond ribbon has better performance; the limit on the length in this case is $0.063\lambda_0$ for -10 dB return loss (19).

2.1.2.2. Flip-Chip Interconnects. The use of CPW line on the chip and the substrate is the key step that allows applying flip-chip as an alternative interconnect technique for RF systems. In CPW, the ground conductors are on the same plane as the signal strip. Microstrip line is more

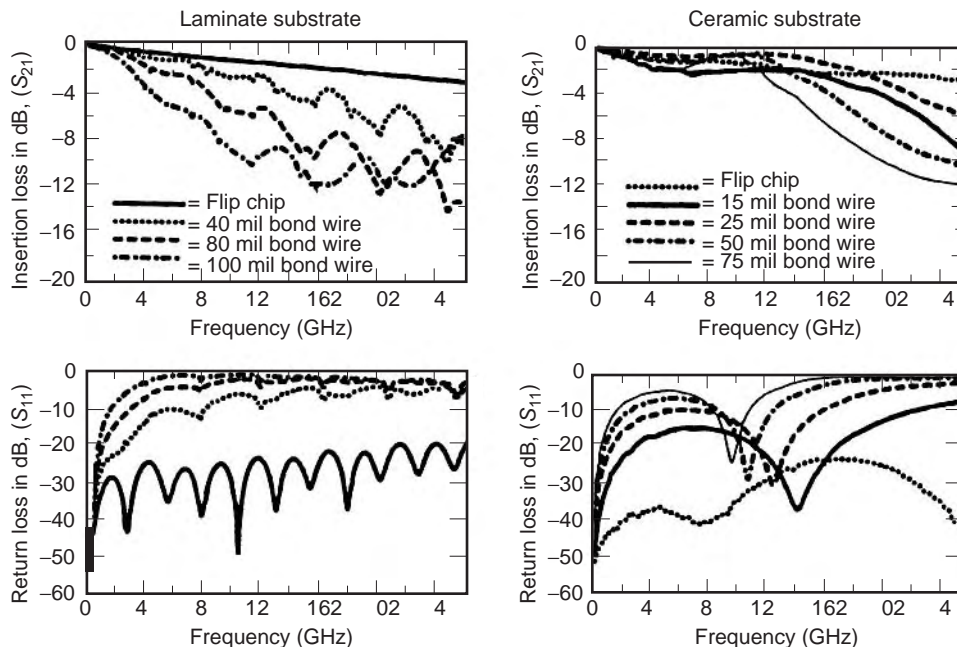

Figure 9. Insertion loss and return loss for flip-chip and bondwire interconnects with RF chips mounted on a laminate or a ceramic substrate. The losses are strongly dependent on the assembly technologies, substrate materials, and operating frequencies. This figure can be used to estimate losses in a typical RF package. (From Ref. 7, © IEEE 1997, reprinted with permission.)

Figure 10. Calculated return and insertion losses of bondwire and bond ribbon interconnect versus normalized wire length L/λ_0 . This figure can be used to estimate the right wire length for desirable losses. (From Ref. 19, © IEEE 1996, reprinted with permission.)

commonly used in RF packages. Therefore, flip-chip interconnects are also used with microstrip. Because the ground conductor and signal strip line are not on the same plane in the microstrip line configuration, vias are needed to connect the ground planes on the chip and package substrate. Therefore, most of the comments in this section are limited to CPW flip-chips. Figure 11 shows the structure of flip-chip interconnect on CPW and microstrip lines. The bump height (50–75 μm) is small compared with the length of bondwire, and the bump diameter (40–150 μm) is larger than that of the bondwire. Therefore, a considerable improvement in the electrical interconnect properties is achieved. The return loss is less than -10 dB at 100 GHz for bump height 70 μm and bump diameter 40 μm [19]. However, chips are flipped so the substrate is very close to the chip. When the fields of the transmission lines on the chip interact with the mounting substrate, the RF performance of the chip can be affected for several reasons: (1) transmission lines on the chip, (2) the gap between the chip and the substrate, (3) the transition into the chip’s transmission lines, (4) chip thickness, (5) transmission lines or other structures on the substrate under chip, and (6) dielectric constants of the chip and the substrate. The change in line impedance for the flipped versus the unflipped cases is larger than 5% for microstrip line on GaAs with width 254 μm and airgap 100 μm [20]. When a CPW is used as the transmission line for MMICs, the fields in the CPW are well confined within the gaps on the CPW and narrower line widths and gaps are possible for a desired line impedance at the expense of higher transmission-line loss. The change in the impedance for CPW on GaAs is less than 0.53% up to 50 GHz with the width 14.2 μm, gap 15.42 μm, and airgap 100 μm [20]. As the airgap between the substrate and the chip is reduced, more field fringes into the substrate, which reduces the line impedance; the optimum airgap is about 100 μm for CPW with width 76.2 μm and gap 50.8 μm [20]. For protecting the chip from the environment and for increasing the connection reliability, an underfill epoxy can be used for flip-chip interconnects. The effect of underfill for RF

Figure 11. (a) Structure of flip-chip interconnect on a coplanar waveguide (CPW) with h_b as the bump height, P_b as the bump pitch, and t_b as the bump diameter. Three solder bumps are needed for one RF and two ground connections. (b) Structure of flip-chip interconnect on a microstrip line. A single solder bump is needed for the RF connection. (From Ref. 19, © IEEE 1996, reprinted with permission.)

performance of chips has been reported [16,17,21]. A lumped-element model of flip-chip joint is available [22].

2.1.3. Transmission Lines on Package Substrates. Microstrip line is widely used for MMICs and MCMs, but recently the CPW and coplanar strip (CPS) have been shown to be appealing alternatives. A brief discussion about microstrip line, CPW, and CPS is given below. Detail descriptions of these transmission lines are available in other articles in this encyclopedia.

2.1.3.1. Microstrip Line. The microstrip line is the most commonly used transmission line for MMICs; it is formed by a strip conductor of a width of W and thickness t , situated on the topside of a planar dielectric substrate and a ground conductor (see Fig. 12).

Given the dimensions of the microstrip line, the characteristic impedance can be calculated as [23].

$$Z_0 = \frac{60}{\sqrt{\epsilon_e}} \ln \left(\frac{8d}{W} + \frac{W}{4d} \right) \text{ for } 1 \geq W/d$$

$$= \frac{120\pi}{\sqrt{\epsilon_e} [W/d + 1.393 + 0.667 \ln(W/d + 1.444)]}$$

for $W/d \geq 1$

Figure 12. Geometry of a microstrip line with d as the substrate height, W as the width of the conducting strip, and ϵ_r as the relative dielectric constant of the substrate. The impedance of the line is determined by these three parameters.

where W is the width of the strip in microstrip line, d is the thickness of substrate, and ϵ_e is the effective dielectric constant of a microstrip line, which is given approximately by

$$\epsilon_e = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \frac{1}{\sqrt{1 + 12d/W}}$$

where ϵ_r is the dielectric constant of the substrate.

Given characteristic impedance Z_0 and dielectric constant ϵ_r , the W/d ratio can be found as

$$\begin{aligned} \frac{W}{d} &= \frac{8e^A}{e^{2A} - 2} \text{ for } W/d < 2 \\ &= \frac{2}{\pi} \left[B - 1 - \ln(2B - 1) + \frac{\epsilon_r - 1}{2\epsilon_r} \right. \\ &\quad \left. \times \left(\ln(B - 1) + 0.39 - \frac{0.61}{\epsilon_r} \right) \right] \\ &\text{for } W/d > 2 \end{aligned}$$

where

$$\begin{aligned} A &= \frac{Z_0}{60} \sqrt{\frac{\epsilon_r + 1}{2}} + \frac{\epsilon_r - 1}{\epsilon_r + 1} \left(0.23 + \frac{0.11}{\epsilon_r} \right) \\ \text{and } B &= \frac{377\pi}{2Z_0\sqrt{\epsilon_r}} \end{aligned}$$

Microstrip line is used for frequencies below 60 GHz with impedance ranging from 15 to 120 Ω [24]. Because the ground plane is usually fabricated on the backside of the chip or the component, it is necessary to fabricate via holes to connect ground bonding pads and the backside. Such via processing is expensive and susceptible to thermal mismatch-induced stresses.

2.1.3.2. CPW. The structure of a coplanar waveguide (CPW) is shown in Fig. 13. It consists of a signal conductor placed between two ground planes. All the three conductors are deposited on one side of a dielectric substrate. The dominant mode on a CPW is quasi-TEM at low frequencies [25]. For an ideal case, when the ground planes are very wide relative to the slot spacing S and the dielectric substrate is much thicker than S , the characteristics of the CPW can be determined by conformal mapping techniques [25]. The capacitance of the CPW is given by [25]

$$C = 4\epsilon_0 \frac{(\epsilon_r + 1)}{2} \frac{K(\kappa)}{K'(\kappa)}$$

where $K(\kappa)$ and $K'(\kappa) = K(\kappa')$ are the complete elliptical integrals of the first kind. The modulus $\kappa = S/(S + 2W)$ with gap S and width of signal conductor strip W . Consequently, the characteristic impedance is given by

$$Z_0 = \frac{120\pi K'(\kappa)}{\sqrt{\epsilon_e} K(\kappa)}$$

where ϵ_e is the effective dielectric constant for the CPW ($= (\epsilon_r + 1)/2$). Design equations for CPW with general dimensions are complex and available in Ref. 25, Section 2.1.4. Since the CPW is used in circuits with a higher integration density, attention has been paid to the effect of the distance between the top metal and CPW substrate and of the finite width of conductors on the line parameters [26].

The principal advantages of CPW are [27]: (1) easier construction using thicker substrates without via holes; (2) good grounding for integrated active devices; (3) compatibility with flip-chip assembly technology; (4) less radiation at discontinuities, low conductor loss in some cases, and less dispersion as compared with the microstrip line; and (5) reduced coupling between different lines in

Figure 13. Structure of a CPW transmission line with W as the width of the center conducting strip and S as the spacing between the grounding plane and the center strip. The impedance of the line is determined by these two parameters and the effective dielectric constant of the substrate.

the same metallization layer [28]. One of major problems with CPW is that a balanced coupled-slotline mode can be excited at nonsymmetric discontinuities. This mode can be avoided by incorporating grounding straps between the ground planes, using either airbridges or underpasses [27]. Number and optimum placing of ground straps are issues of design.

2.1.3.3. Coplanar Strips. A coplanar strip (CPS) transmission line consists of a pair of strip conductors of width W and separated by a narrow slot of width S on a dielectric substrate, as shown in Fig. 14 [29]. As a balanced transmission line, it is ideally suited to balanced mixers and push-pull amplifiers. CPS has several advantages over conventional microstrip line and CPW [29]. It facilitates shunting as well as series mounting of active and passive devices and eliminates the need for wraparound/via holes, which introduce additional parasitic elements. In short, CPS has all the advantages of CPW. In addition, CPS makes efficient use of the wafer area, so the die size per circuit function is small. This results in lower cost and larger number of circuit functions for a given die size. Also, CPS propagation parameters are independent of the substrate thickness beyond a certain critical thickness that simplifies heatsinking and circuit packaging. CPS does not require grounding, which is an appealing feature for high-density interconnects. However, the lack of design information has severely restricted its use. More important, transitions from CPS to microstrip/CPW in real applications are very difficult because CPS is a balanced line without a ground plane.

2.1.3.4. Multilayer Substrate. A multilayer substrate consists of thin dielectric layers and metal conductors formed on a wafer surface. These metal transmission lines and ground planes are connected through vertical via holes. Using multiple dielectric and metal layers, it is possible to get an increased flexibility in circuit layouts, reduce the package size, get more flexible means of interconnect, and maintain low cost. Since the ground plane is used between the signal layers, the crosstalk among the signal lines is reduced. A typical multilayer substrate with microstrip lines and striplines (discussed later) is shown in Fig. 15 [30]. Analysis methods for mul-

Figure 14. Structure of coplanar strip (CPS) transmission line with W as the width of each strip, S as the spacing between the strips, and d as the thickness of the dielectric substrate.

Figure 15. A typical multilayer substrate using microstrip lines and striplines as transmission lines. The substrate is used to interconnect RF packages or bare devices. (From Ref. 30, © ASME 1997, reprinted with permission.)

tilayer substrates can be found in Ref. 31. Additional discussions about the multilayer substrate will be presented later.

2.1.3.5. Crosstalk. When frequency increases, the signal energy is not confined to the transmission lines, but gets coupled from one line to others, including the DC powerlines. Coupling generally occurs in an unintended manner. The energy can be coupled to undesired propagating modes in the complicated waveguide structure formed by the package. This can result in spurious resonances in the package housing. A signal that is unintentionally coupled to the neighboring lines is called *crosstalk*, a term derived from telephone networks, where faint conversations might be heard from other lines.

Crosstalk actually arises from both the distributed capacitive and the inductive couplings of approximately equal magnitudes [32]. Although it may be easier to visualize the electric field of mutual capacitance between adjacent lines, it should be recognized that there is also a corresponding magnetic field coupling between the adjacent lines. When signal energy travels in one direction on the primary line, the portion of the signal coupled into the adjacent line travels in both directions. The magnetic coupling is important to understand the difference between the capacitive and inductive crosstalk at the two ends of a coupled line. The mutual capacitance coupling is in phase with the signal on the primary line at both ends. However, the inductively coupled lines are essentially the primary and secondary of a transformer due to mutual inductance coupling, although both sides of this transformer have only a single “turn”. Therefore, the two ends of the induc-

tively coupled secondary have opposite signal polarities [6]. Practical circuits often consist of numerous lines, which may be in proximity. Hence the space between lines should be considered for design of microstrip, CPW, or other interconnects in a package. A typical method for reducing spurious coupling is to restrict the routing of conductor lines on adjacent layers to orthogonal directions, so that signals cross only at 90° angles and the coupling is minimized. Also, in the multilayer structure the dielectric layers should be optimized in order to minimize coupling between the lines [33]. Grounded isolation lines, which convert the microstrip line into coplanar waveguide with finite size strips, can be used to reduced the coupling between lines in the same layer [26,34].

2.1.4. Housings for RF Packages. RF chips are generally enclosed in a package housing which is metallized on walls to shield the chips from outside EM fields. Because the package housing is almost completely metallized, it can be considered to be a rectangular metal waveguide cavity. Signal energy can be coupled to propagating modes in the complicated waveguide structure. Such a coupling may result in a resonance in the package with undesirable consequences such as power loss, poor isolation, and circuit instabilities. Therefore, package electrical performance is not only associated with the transmission-line design and functions of chips, but also affected by package housing geometry and intrinsic material properties [4].

The resonance frequencies of the TE_{mnl} or TM_{mnl} modes in a rectangular enclosure without a dielectric substrate is given by [23]

$$f_{mnl} = \frac{c}{2\pi} \sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2 + \left(\frac{l\pi}{d}\right)^2}$$

where *c* is the velocity of light and *a*, *b*, and *d* are the dimensions of the cavity in *x*, *y*, and *z* directions, respectively. If *b* < *a* < *d*, the TE₁₀₁ model will be the dominant resonant mode with the lowest resonance frequency *f*₁₀₁. In RF packages, to improve end-to-end isolation and raise cavity resonance frequencies, a large cavity is divided into some subcavities, with partition walls surface-mounted to the substrate and grounded with a row of vias [35]. For example, an empty package housing of 27.94 × 53.85 mm has a resonance frequency of about 6.0 GHz. But the resonance frequency of the 27.94 × 14.22 mm empty housing is approximately 11.8 GHz. When a dielectric substrate is inserted in the package cavity, the resonance frequency of the cavity is modified. If the substrate is placed in contact with the bottomwall of the package and has a thickness much smaller than the height of the package, the modified resonance frequency *f*_r is given by [36]

$$f_r = f_{101} \left[1 - \frac{d}{b} \left(\frac{\epsilon_r - 1}{\epsilon_r} \right) \right]^{1/2}$$

where *f*₁₀₁ is the resonance frequency for TE₁₀₁ mode, *d* is the thickness of the substrate, *b* is the cavity height, and *ε*_r is the dielectric constant of the substrate. In the formulas above, the effect of chips, imperfect cavity endwall (for

feedthroughs), and interconnections and passive circuits on the substrate on the resonance frequencies have not been considered. A full-wave simulation is needed to accurately predict the resonance frequencies of a package [35].

2.1.5. Feedthroughs/Ports in Housing. A design requirement of feedthroughs, which bring the signals through a package sidewall to external ports, is to provide controlled RF impedance and minimize the DC/RF losses. A stripline is used where a planar strip penetrates the dielectric-filled hole in the metal wall. Given the desired characteristic impedance of the stripline, spacing between the ground planes *b*, and dielectric constant *ε*_r, the ratio of the strip width *W* to the spacing *b* (see Fig. 16b) is given as [23]

$$\frac{W}{b} = \frac{30\pi}{\sqrt{\epsilon_r} Z_0} - 0.441 \text{ for } \sqrt{\epsilon_r} Z_0 < 120$$

$$\frac{W}{b} = 0.85 - \sqrt{1.041 - \frac{30\pi}{\sqrt{\epsilon_r} Z_0}} \text{ for } \sqrt{\epsilon_r} Z_0 > 120$$

Figure 16. (a) Typical microstrip–stripline–microstrip feedthroughs. There are two different transitions to connect different linewidths. The tapered transition has lower losses than those with the sharp transition. A typical configuration for the transition consists of the metal housing and the cofired feedthrough. (b) Cross-section of a stripline commonly used for a feedthrough. (From Ref. 2, © Artech House 1989, reprinted with permission.)

Different microstrip–stripline–microstrip feedthroughs are shown in Fig. 16a. Loss properties of the ceramic substrate and physical dimensions of the feedthrough structure could attenuate the high-frequency signal as it travels along the feedthrough. Microstrip–stripline–microstrip feedthroughs behave like lowpass filters. The cut-off frequency is determined by the physical, geometric, and material properties of the structure [2,4]. Coaxial feedthroughs can also be used for RF packages [2].

2.2. RF Multichip Module (MCM) Packages

2.2.1. Types of MCMs for RF Circuits. Multichip modules are substrates of dielectric and conducting layers, on which integrated circuits (“chips”) and passive components (if any) are mounted directly on (or inside) the substrates, without separate packaging of each of the active components. That is, the chips are mounted “bare” onto the MCMs, which then provide the required power and ground, as well as all the signal interconnects and the electrical interface to the external environment. There are three kinds of MCMs:

1. Laminate MCMs (MCM-Ls) are manufactured through the lamination of sheet layers of organic dielectrics. These MCMs exhibit very low line losses up to relatively high frequencies because the lines are thick and wide; however, the vias are typical quite tall and also much wider than the lines, thus causing substantial impedance discontinuities and signal reflections for frequency components above 500 MHz.
2. Ceramic MCMs (MCM-Cs) are manufactured by stacking unfired layers of ceramic dielectric, onto which liquid metal lines are silk-screened using a metal ink process. The individual inked layers are then aligned, pressed together, and “cofired” at 800–900°C, or 1500°C to 1600°C into a solid planar structure. Vias in these MCMs are also tall and wide,

resulting in substantial impedance discontinuities and signal reflection for frequencies above 500 MHz.

3. Deposited MCMs (MCM-D) are manufactured through the deposition of organic or inorganic dielectrics onto a silicon or alumina support substrate. After each dielectric layer is deposited, one of several techniques is used to pattern metal lines as well as metal “vias,” which penetrate the dielectric layer to connect adjacent metal layers [7]. The chips are then mounted on the upper surface using wire bonding/TAB or flip-chip bonding technology. In MCM-D, line cross sections are smaller than those in MCM-C or MCM-L. The small cross section results in higher resistive line losses. However, the via heights are quite small, and the via cross sections are comparable to the linewidths, resulting in low levels of impedance discontinuity and signal reflections compared with the MCM-Ls and MCM-Cs.

2.2.2. Design Consideration

2.2.2.1. Multilayer Structure/Via for MCM. A multilayer structure is generally needed for an MCM. It is similar to the multilayer substrate for a single-chip package. Because there are more chips on a substrate, the multilayer substrate for an MCM is more complex than that for a single-chip package. Table 6 lists suggested number of layers for different design restrictions [7]. A large number of layers is not desirable because of manufacturing difficulty; four layers are typically used. Vias, interconnects between layers, are lossy (particularly at high frequency) and difficult to model accurately.

2.2.2.2. Power/Ground Noise. Power/ground noise becomes important when circuits are more complex and there are more circuit signal planes sharing one ground plane. A comprehensive understanding of this noise is being developed [37–39]. The noise is not a set of random fluctuations caused directly by the state switching of the

Table 6. Number of Layers versus Design Restrictions

Number of Metal Layers	Design Restrictions	Suggested Layer Assignments
1		
2	Digital systems up to 25–50 MHz; analog microwave designs using microstrip interconnects with no crossovers	1 routing/attach; 1 shared power/ground plane
3	Digital system up to 50 MHz with split-plane power delivery; analog microwave designs using microstrip interconnects	2 routing; 1 shared power/ground plane
4	Digital system up to 1 GHz; analog microwave system requiring microstrip and stripline interconnect.	2 routing; 1 shared power; 1 ground plane
5	Digital system up to 2.5 GHz; most analog microwave systems	2 routing; 1 shared power; 2 ground plane
6	Digital system up to 10–12 GHz; analog microwave systems up to 12–16 GHz	2 routing; 2 shared power; 2 ground plane
7	All digital and all analog or mixed signal designs are feasible	2 routing; 1 routing/attach; 1 power plane; 2 ground planes; 1 integrated small capacitor and/or embedded resistor layer
8	All digital and all analog or mixed signal designs are feasible	2 routing; 1 routing/attach; 2 power plane; 2 ground planes; 1 integrated small capacitor and/or embedded resistor layer

(From Ref. 7, © IEEE 1997, reprinted with permission.)

digital chips; but a complex resonance behavior of an essentially high Q circuit with a very large number of resonant modes, which are pumped by harmonic components in the state switching currents [37].

Many proposed next-generation analog or mixed-signal systems have been demonstrated to be exceptionally sensitive to noise in their power and ground planes [38]. These resonances must be characterized for a complete understanding of this phenomenon. Further, suppression of the resonant modes, at least within the signal passband of interest, is required [38,39].

2.3. EMC/EMI Considerations for RF Packages

Electromagnetic compatibility (EMC) and electromagnetic interference (EMI) issues have been studied for some time. However, only very simple models to characterize EMC/EMI have been proposed [40,41]. The conduction and radiation emission and susceptibility models are still at the component level, and need to be improved to reach the complexity level of real-world problems. The amount of EMI generated by a digital processor is directly related to the edge rates of the signals, the system clock rate, the total amount of switching current, and the size and shielding effectiveness of the device or system. Due to the complexity of an actual processor system, a combined deterministic and statistical approach is necessary to address these problems [7].

3. RELIABILITY

There are two issues related to RF package reliability. One is thermal management to control the temperatures of RF devices. The other is mechanical integrity to ensure reliable connections among different interfaces and low stresses in RF devices. Most thermal and mechanical considerations are the same as those for microelectronic packaging. However, there are unique requirements for RF packaging. These requirements are described in the following sections.

3.1. Thermal Management

Major thermal management challenges for RF packaging are associated with power MESFETs for transmitters. The unique requirements arise because of a very high heat flux.

- At high-frequency operations, power dissipation is high. A single GaAs FET (field-effect transistor) is capable of delivering a CW (continuous-wave) power output of 15 W at 10 GHz. When a few of these FETs are used along with other parts, this problem is compounded. For higher frequencies in the mm-wave spectrum, the combination of high-frequency and poor efficiency make thermal management a top packaging problem to solve. Heat flux higher than 300 W/cm^2 is not unusual [42], which is an order of magnitude higher than a high-power microprocessor's heat flux level.

- Thermal solutions have to meet constraints demanded by the selection of materials and structures for low-loss RF performance, reliable mechanical integrity, and cost. As shown in Tables 4 and 5, AlN has a high thermal conductivity but also high loss tangent and cost. In most cases, designers are not allowed to choose a high thermal conductivity material just for efficient heat removal.
- An RF device's electrical linearity and efficiency can strongly depend on its junction temperature. In some cases it is necessary to control the temperatures within a range rather than below an upper limit [43,44].
- GaAs, the major RF device material, is a poor thermal conductor. Its thermal conductivity of $50 \text{ W/m} \cdot \text{K}$ (at room temperature) is low and can be even lower at high temperatures. For example, at 150°C , GaAs's thermal conductivity can be as low as $31 \text{ W/m} \cdot \text{K}$ [43]. With low-conductivity GaAs, the power dissipated from the FET cannot be spread effectively. As a result, the heat flux to be removed is close to FET level rather than "chip" level, as usually assumed for silicon-based microelectronic chips with the thermal conductivity around $150 \text{ W/m} \cdot \text{K}$ at room temperature. In fact, wire bonded GaAs chips should be thinned, in order to use conductive material to spread the heat from FET directly to the package.

Heat conduction, convection, and radiation are three typical heat transfer mechanisms. For RF packages, heat conduction and convection are usually considered. To analyze the detail temperature distributions in a package, numerical computation is necessary. However, simple analytical solutions can provide a quick estimation to gain an insight into a thermal problem to be solved. A few useful formulas are to be described below.

For one-dimensional (1D) heat conduction through a component, for example, a plate, the thermal resistance is

$$R = \frac{L}{kA}$$

where L is the length of the component, A is the cross-sectional area of the component, and k is the heat conductivity of the component.

Similarly, for 1D analysis, the thermal resistance corresponding to heat convection can be expressed as

$$R = \frac{1}{hA}$$

where A is the surface area subject to heat convection, and h is convection heat transfer coefficient. Typically, h can be assumed to be around $5 \text{ W}/(\text{m}^2 \cdot \text{K})$ for natural air cooling and $20 \text{ W}/(\text{m}^2 \cdot \text{K})$ for forced air cooling in a desktop personal computer (PC) environment.

When different 1D components are thermally connected, a resistor network can be established to estimate their overall thermal performance. However, when two 1D components with different cross sections are connected, an additional thermal resistance, constriction resistance, needs to be considered. For instance, the additional ther-

mal resistance for a circular heat source in contact with a heat spreader is

$$R = \frac{1}{2\sqrt{\pi rk}}$$

where k is the thermal conductivity of the thermal spreader, and r is the radius of the circular heat source. Examples of how to use these formulas to estimate thermal performance will be presented in Section 4.

3.1.1. Plastic Packaging with Die Attachment. As stated by Pavio et al. [45], a plastic package enables source-to-ground assembly with semiconductor die. Thus, this arrangement supports the direct attachment of a transistor to the package heatsink (or actually a heat spreader). For the lower-power devices (1–2 W), the use of circuit board without additional heat spreading may be adequate. With increasing power levels, other options must be investigated. Figure 17 shows a die bonding to a conductive heat-sink, for example, a Cu slug [42]. Solder has to be used for thermally conductive die attachment, and the copper should be used for efficient heat spreading.

3.1.2. Ceramic Packaging with Die Attachment. Ceramics usually have a higher thermal conductivity compared with plastics and, in some conditions, can be directly used as heatsink. If the heat flux is very high, a more conductive heat spreader may be needed. For example, an AlN heat spreader can be inserted between a thinned GaAs chip and an alumina substrate, as shown in Fig. 18. More details on different materials for such heat spreading are to be discussed later on.

3.1.3. Flip-Chip Package. Flip-chip assembly is well known for its difficulty in removing heat from the chip. In fact, if the RF device is designed properly, the flip-chip assembly is thermally better than the wire bonded assembly. As shown by Gupta [42], the GaAs MESFET chips typically have a central active area of interdigitated source–gate–drain structures (Fig. 19), at which steady-state heat dissipation densities of up to 300 W/cm² are encountered. The prevalent interconnect/package scheme for these power amplifier chips involves die bonding to a

Figure 18. A high-conductivity AlN heat spreader used between thinned GaAs chip and alumina substrate to reduce thermal resistance. The AlN heat spreader has higher thermal conductivity and larger area than those of GaAs chip. Its insertion between the thinned GaAs and alumina reduces the thermal resistance between the heatsource and heatsink.

conductive heatsink, for example, a Cu slug (see Fig. 17). In order to remove intense heat through the die-bonded GaAs chip, additional care needs to be taken, due to the poor thermal conductivity of GaAs. In order to extract heat divergently through the back of the power amplifier chip to the Cu pedestal on which it is die-bonded, the die has to be thinned considerably (e.g., 50 μm) by back-grinding and chemical etching. Due to the brittleness of GaAs, this additional operation may involve yield loss after wafer fabrication.

Flip-chip interconnect is an alternative to the back-grinding of a GaAs chip. Because the active area of the GaAs chip is around the surface of the chip, flip-chip bumps can be used to directly remove the heat. In some conditions, where the power dissipated in the device is so high that the flip-chip bump may be not sufficient to remove the heat, a thermal bump has to be introduced to help remove the heat (Fig. 19). With a high-thermal-

Figure 17. A typical packaging method for GaAs power amplifier chips using die bond to heatsink and gold–gold wire bond. The heat sink connected to the copper (Cu) pedestal is used to extract heat divergently through the back of the power amplifier. (From Ref. 42, © IEEE 1989, reprinted with permission.)

Figure 19. A gold-plated thermal bump on source fingers of a power amplifier. The thermal bump with high thermal conductivity is located close to the heatsource and is directly connected to a heatsink. This bump greatly reduces the thermal resistance between the heat source and heat sink. (From Ref. 42 © IEEE 1989, reprinted with permission.)

conductivity thermal bump (usually made by gold or silver), the thermal resistance from the GaAs chip to the heatsink substrate could be minimized.

3.2. Mechanical Integrity

Compared with microelectronic packaging, the mechanical integrity issues of RF packaging have the following unique features:

- The length scale of thermal mismatch is smaller. Typical sizes of RF chips and packages are smaller than those of microelectronic chips and packages. Therefore, thermal induced stresses/strains could be small.
- For efficient thermal management, mechanically poor materials have to be used for die attachment. For example, they may be highly conductive materials, such as solder, epoxy with added metal, or glass with added metal. In addition, any delamination could degrade heat conduction and increase temperature gradient across the die attachment. The increase could worsen the delamination and destroy the RF device.
- Mechanical solutions have to meet constraints demanded by the selection of materials and structures for low-loss RF performance, efficient thermal management, and cost. For example, underfill epoxy can enhance the fatigue life of flip-chip assembly using Duroid as the substrate [17]. However, the epoxy could degrade the RF performance with additional losses. If these losses are not acceptable, an alumina substrate needs to be used for reliable assembly without the underfill epoxy.
- GaAs is the main RF device with poor mechanical properties; it is brittle and susceptible to cracking. With its poor thermal conductivity, a large temperature gradient in the device can result from high power dissipation and damage the device.

RF packages have different mechanical characteristics, as mentioned above. However, the tradeoff design techniques are the same as those for microelectronic packaging. Delamination and fatigue are main concerns. These problems are well covered elsewhere, so only solder joint fatigue will be described briefly. Most discussions will focus on die cracking problem closely related to GaAs devices. The die cracking can occur at a die edge, at a via, and at a notch or a flaw due to stress concentration.

3.2.1. Solder Joint Fatigue. For a typical flip-chip assembly, the fatigue life of the solder joints is a major reliability concern. To estimate the solder fatigue life, numerical computation using finite-element methods (FEM) is necessary. However, some simple formulas can be used to illustrate the fatigue problem and to quickly estimate the fatigue life. The Coffin–Manson relationship is popularly used to estimate the fatigue life of a solder joint in a flip-chip assembly with different thermal expan-

sions of the chip and the substrate. It is expressed by

$$N_f = \frac{1}{2} \left(\frac{\Delta\gamma}{2\varepsilon_f} \right)^{-1/C}$$

where N_f is the fatigue life of the solder joint in terms of number of thermal cycles, $\Delta\gamma$ is total shear strain range, ε_f is fatigue ductility coefficient (which is the maximum strain resulting in a failure in one cycle; it is approximately 0.325 for Sn/Pb eutectic solder), and C is fatigue ductility exponent (which is 0.442 for the eutectic solder). The shear strain range caused by mismatch of thermal expansions of the chip and the substrate can be estimated by

$$\Delta\gamma = \frac{L(\alpha_1 - \alpha_2)\Delta T}{h_C}$$

where L is the distance between the solder joint and the neutral point of the assembly, α_1 is the CTE (coefficient of thermal expansion) of the substrate, α_2 is the CTE of the chip, and h_C is the height of the solder joint.

From these formulas, it is clear that solder fatigue problem is caused by the mismatch between chip's and substrate's thermal expansions during thermal cycling with temperature changes. To avoid the reliability problem, there are typically three design approaches: (1) to choose a substrate with CTE matched to that of the chip, (2) to control the distance from the solder joint to the neutral position, or (3) to increase solder joint height. More details of the solder fatigue will be illustrated in the section entitled Case Study.

3.2.2. Cracking at a Die Edge. Solder is commonly used in RF die attachment because of its high thermal conductivity. Since the CTEs of die, solder, and substrate/heat-sink are different, during thermal cycling, there is a large stress at the edge of the die. This stress, together with the imperfection of the die edge (caused by cutting), may result in a chip crack. Typically, there are vertical and horizontal cracks at the die edge. Vertical die cracks propagate under tensile stress and horizontal die cracks propagate under shear stresses at the edge. Horizontal edge cracks, developed from die-cutting damage, may propagate from the corner of the die to active chip elements and induce device failure. Or, it may propagate horizontally, causing the die to lift. Although die fracture is mainly governed by the size, shape, and defect locations in the die, voids in the attachment material or in the die-attach interface may also result in die fracture hyperverturing the thermal and stress transfer mechanisms [46]. Lee and Matija-sevic [47] developed a technique to produce void-free bonding between GaAs dice and alumina substrate using Au–Sn eutectic solder alloy, which reduced the possibility of chip crack greatly.

3.2.3. Cracking at a Via. For the die attachment using solder, the capillary action causes the vias to fill with molten solder during reflow. Due to the thermal expansion mismatch between the Si/GaAs chip and solder, the chip

may crack around vias during thermal cycling. The propagation of the crack could gradually damage the electrical performance of the device. Pavio [48] studied via cracking in a GaAs chip. The factors affecting the cracking are via size and shape. The problem can be eliminated by controlling the amount of solder which penetrates the via. A critical process window must be developed for each alloy to minimize the amount of solder filling the via, while maintaining sufficient coverage of solder die attachment for efficient thermal management. In addition, a small-size via can reduce the crack potential.

3.2.4. Cracking at a Notch or a Flaw on the Chip. Another cause for die cracking is the notches or the flaws on a chip. The fracture strength of brittle materials is dependent on several factors, the most important of which is the effect of stress concentration on notches and flaws. It is known from fracture mechanics that actual strengths for brittle materials will range $\frac{1}{10} - \frac{1}{1000}$ of that predicted theoretically, because flaws act as stress concentrators. Fractures occur because a crack (flaw) propagates due to the decrease in stored elastic energy associated with crack extension, exceeding the increase in surface energy associated with the formation of new surface. The flaws on the chip are caused by wafer slicing and thinning, which can reduce the mechanical strength of the Si/GaAs chip. Hawkins et al. [49] and Vidano et al. [50] studied the fracture strength of Si and GaAs chip, respectively. They showed that mechanical thinning followed by chemical thinning (etching) can improve chip strength, because the size and population of flaws were reduced by the chemical thinning.

Notches are different from flaws. Notches are features of the design. For example, a sharp angle exists between any two bonded plates with different sizes. The sharp angle would cause stress concentration that could result in crack initiation in a brittle plate.

3.2.5. Crack Prediction. Cracking is a major concern when it comes to ensuring a RF package's mechanical integrity. Unfortunately, there is lack of knowledge of how to control this problem using a quantitative analysis. To characterize cracks initiated from flaws, the stress-intensity approach can be used. For the flaw shown in Fig. 20 the stress intensity factor is $K_0 = \sigma\sqrt{\pi a}$ [51].

For a notch as a designed feature, however, there is no well-established approach. Dunn et al. developed a new approach to characterize stress intensities in a notch for microelectromechanical systems (MEMS) [52]. Such an approach may be useful to understand cracks induced by stress concentration around a notch. In their study, they combined modeling, analysis, and experimental results to establish the crack criteria for a notch. They used the stress intensity factor K to study crack initiation. Cracks initiate for a given notch configuration when the stress intensity factor reaches a critical level K_{cr} . They found K_{cr} to be similar for a given notch angle and material regardless of other geometric factors. Their method may be used to predict crack initiation at flaws or notches.

Figure 20. Plate of length $2h$, width $2b$, containing a central crack of length $2a$. Tensile stress σ acts in longitudinal direction and results in a stress intensity factor around the crack tip to be $K_0 = \sigma\sqrt{\pi a}$. When the stress intensity factor is higher than its critical value due to high stresses, the crack would propagate and break the plate.

4. CASE STUDY

This study illustrates a typical design procedure with a few key considerations for a RF package. The calculations are carried out using simple analytical solutions to get qualitative guidelines. Numerical computations may be needed for any quantitative designs.

4.1. Problem Definition

Figure 21 shows a flip-chip assembly with a GaAs chip soldered onto an alumina substrate. A metal wall encloses the assembly. CPW or microstrip lines can be used as the transmission lines on the substrate. Feedthrough is the transition from the substrate to the next level interconnects; it can be microstrip–stripline–microstrip or CPW–stripline–CPW. For CPW, there are three solder joints on each end of chip-to-substrate connection (see Fig. 11a). For a microstrip line, there would be a single solder joint at

Figure 21. RF single chip package used in the case study. GaAs chip is flip-chip bonded on an alumina substrate with 6 solder joints for the case with a CPW and 2 solder joints for the case with a microstrip line. Feedthrough as shown is a microstrip–stripline–microstrip transition for RF signals. RF, thermal, and mechanical analyses are carried out in the case study to design the package.

each end (see Fig. 11b). All the critical dimensions and material properties taken from Table 3 are listed below.

- Cavity enclosing the flip-chip package—the size is $a \times b \times d = 14.4 \times 6 \times 24$ mm, where a , b , and d are housing dimensions in the x , y , and z directions, respectively.
- GaAs chip—thermal conductivity $k_{\text{chip}} = 48 \text{ W/m} \cdot ^\circ\text{C}$, CTE (coefficient of thermal mismatch) $\alpha_{\text{chip}} = 6.1 \times 10^{-6} \text{ mm/mm} \cdot ^\circ\text{C}$, and size $L_{\text{chip}} \times W_{\text{chip}} \times t_{\text{chip}} = 4.7 \times 1.13 \times 0.625$ mm.
- Ceramic substrate: $k_{\text{substrate}} = 20 \text{ W/m} \cdot ^\circ\text{C}$, $\alpha_{\text{substrate}} = 6.9 \text{ mm/mm} \cdot ^\circ\text{C}$, $L_{\text{substrate}} \times W_{\text{substrate}} \times t_{\text{substrate}} = 14.4 \times 24 \times 0.625$ mm, dielectric constant $\epsilon_r = 9.8$.
- Flip-chip solder joint: $k_{\text{joint}} = 53 \text{ W/m} \cdot ^\circ\text{C}$, height $H_{\text{joint}} = 75 \mu\text{m}$, diameter of the circular pad $d_{\text{pad}} = 150 \mu\text{m}$ (radius $r = d_{\text{pad}}/2 = 75 \mu\text{m}$), center-to-center distance of solder joints $p_x = 4$ mm and $p_z = 0.46$ mm.
- Air: $k_{\text{air}} = 0.03 \text{ W/m} \cdot ^\circ\text{C}$.

A complete analysis would be very complicated since many packaging effects are coupled. RF, thermal, and mechanical designs are to be studied only to address the following questions:

- What are the RF losses of the interconnects for operating frequencies below 10 GHz?
- What is the lowest resonance frequency of the housing?
- What is the feedthrough design for smooth transition?
- What would be the junction temperature for the GaAs chip dissipating 0.8 W with the substrate cooled by air with the convection heat transfer coefficient $h_{\text{conv}} = 20 \text{ W/m}^2 \cdot ^\circ\text{C}$ and $T_{\text{air}} = 25^\circ\text{C}$?
- What would be the fatigue life of the solder joints under thermal cycling from -25 to 125°C ?

4.2. RF Design

4.2.1. Losses in Interconnect. From Fig. 9, the losses can be estimated for a CPW and its associated flip-chip

solder joints. Using the same figure, the return loss is found to be less than 30 dB up to 8 GHz and the insertion loss could be found to be less than 1 dB. Such a loss is negligible if the GaAs chip has an amplifier with 10 dB gain.

4.2.2. Resonance Frequency of the Housing. The resonance frequency of the package housing can be calculated approximately by considering it as a rectangular waveguide cavity without a dielectric substrate. If dimensions shown in Fig. 22 are $b < a < d$, the dominant resonant mode (with lowest resonance frequency) is TE_{101} . Its corresponding resonance frequency can be calculated using the following formula taken from [23]. For the dimensions $a = 14.4$ mm, $b = 6.0$ mm, and $d = 24$ mm, the resonance frequency for the lowest TE_{101} mode is about 12.1 GHz, which is calculated as

$$f_{mnl} = \frac{c}{2\pi} \sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2 + \left(\frac{l\pi}{d}\right)^2}$$

$$f_{101} = \frac{3 \times 10^8}{2 \times 3.1416} \sqrt{\left(\frac{3.1416}{14.4 \times 10^{-3}}\right)^2 + \left(\frac{3.1416}{24.0 \times 10^{-3}}\right)^2}$$

$$= 12.1(\text{GHz})$$

where c is the speed of light and m, n, l are mode integers (1, 0, 1 for f_{101}).

However, with a dielectric substrate material located at the bottom of the housing, the resonance frequency should be modified. In this case, dielectric material is alumina with $\epsilon_r = 9.8$ and thickness $t_{\text{substrate}} = 0.625$ mm, the resonance frequency should be modified to be 11.5 GHz, which is calculated by using the following formula taken from [36]

$$f_r = f_c \left[1 - \frac{t_{\text{substrate}}}{b} \left(\frac{\epsilon_r - 1}{\epsilon_r} \right) \right]^{1/2}$$

$$= f_{101} \left[1 - \frac{0.625}{6} \left(\frac{9.8 - 1}{9.8} \right) \right]^{1/2} = 11.5(\text{GHz})$$

Figure 22. Premolded plastic package to increase applicable frequency. This package is different from typical injection-molded plastic packages with bondwires in air to control inductance variations. Bondwires are moved during the injection molding process; such movements are eliminated by the use of the premolded packages.

where f_{101} is the frequency without the dielectric effect; b is the height of the cavity in y direction (see Fig. 21).

The dielectric substrate reduces the resonance frequency from 12.1 to 11.5 GHz. In addition, the GaAs chip might cause another effect on the frequency. In this case, the chip is small compared with the housing, so the effect could be negligible. However, if the effect should be considered, for example, in the case of a multichip module, a full-wave simulation would have been conducted.

4.2.3. Feedthrough Design. A microstrip line is to be studied for this design consideration since it is the base transmission line for a feedthrough. For a CPW, it can be designed as a CPW–stripline–CPW transition [4] or CPW–shielded CPW–CPW transition [53]. A full-wave simulation is needed for CPW feedthrough structure design [53]. A common feedthrough for a microstrip line is for the transition from a 50- Ω microstrip line to a 50- Ω stripline as shown in Fig. 16. To design a 50- Ω microstrip line on the alumina substrate with thickness $t_{\text{substrate}} = 0.625$ mm and ϵ_r of 9.8, the width of the strip (W) can be calculated using a formula for $W/d < 2$ [23]

$$W = t_{\text{substrate}} \frac{8e^A}{e^{2A} - 2}$$

where

$$A = \frac{Z_0}{60} \sqrt{\frac{\epsilon_r + 1}{2}} + \frac{\epsilon_r - 1}{\epsilon_r + 1} \left(0.23 + \frac{0.11}{\epsilon_r} \right)$$

Hence, for this case

$$A = \frac{50}{60} \sqrt{\frac{9.8 + 1}{2}} + \frac{9.8 - 1}{9.8 + 1} \times \left(0.23 + \frac{0.11}{9.8} \right) = 2.13$$

$$W = 0.625 \times \frac{8 \times e^{2.13}}{e^{2 \times 2.13} - 2} = 0.61(\text{mm})$$

To design a 50- Ω stripline on the alumina substrate with the spacing between two ground planes $t_{\text{strip}} = 2t_{\text{substrate}} = 1.25$ mm and $\epsilon_r = 9.8$, the width of the strip (W) can be calculated as follows [23]:

For $\epsilon_r Z_0 > 120$

$$x = \frac{30\pi}{\sqrt{\epsilon_r} Z_0} - 0.441 = 0.16$$

$$W = t_{\text{strip}} \times (0.25 - \sqrt{0.6 - x}) = 0.23(\text{mm})$$

There is a clear mismatch between the width of the microstrip line (0.61 mm) and that of the stripline (0.23 mm). Typically, a taper section is used to connect these two transmission lines to decrease the return loss. The insertion loss of a typical feedthrough (a single microstrip–stripline–microstrip transition) can be less than 0.1 dB up to 20 GHz [4].

These three RF design considerations on interconnect losses, resonance frequency, and feedthrough are very critical to RF packaging. In addition, there are many other concerns that were discussed above. More general design methods are available in the literature [2,54–56].

4.3. Thermal Design

There are two approaches for thermal design. The simplest approach assumes no temperature gradients inside the GaAs chip. The substrate is cooled by air through convection heat transfer at the bottom surface; therefore, the main thermal path is from the chip to the bottom of the substrate through the solder joints. Its thermal resistance can be estimated using formulas described in the section on reliability/thermal management.

The thermal resistance of each solder joint is

$$R_{\text{joint}} = \frac{H_{\text{joint}}}{\pi r^2 k_{\text{joint}}}$$

For six joints, the thermal resistance is

$$\begin{aligned} R_{\text{joints}} &= \frac{1}{6} R_{\text{joint}} = \frac{H_{\text{joint}}}{6\pi r^2 k_{\text{joint}}} \\ &= \frac{75 \times 10^{-6}}{6\pi(75 \times 10^{-6})^2 \times 53} \\ &= 13(^{\circ}\text{C}/\text{W}) \end{aligned}$$

The thermal resistance of the air between the chip and the substrate is

$$\begin{aligned} R_{\text{air}} &= \frac{H_{\text{joint}}}{(L_{\text{chip}} W_{\text{chip}} - 6\pi r^2) k_{\text{air}}} \\ &= \frac{75 \times 10^{-6}}{(4.7 \times 10^{-3} \times 1.13 \times 10^{-3} - 6\pi(75 \times 10^{-6})^2) \times 0.03} \\ &= 480(^{\circ}\text{C}/\text{W}) \end{aligned}$$

The thermal resistance of the substrate (as a heat spreader) is

$$\begin{aligned} R_{\text{substrate}} &= R_{\text{constriction}} + R_{\text{conduction}} + R_{\text{convection}} \\ &= \frac{1}{6} \frac{1}{2\sqrt{\pi} k_{\text{substrate}}} + \frac{t_{\text{substrate}}}{L_{\text{substrate}} W_{\text{substrate}} k_{\text{substrate}}} \\ &\quad + \frac{1}{h_{\text{conv}} L_{\text{substrate}} W_{\text{substrate}}} \\ &= \frac{1}{12\sqrt{\pi} \times 75 \times 10^{-6} \times 20} \\ &\quad + \frac{0.625 \times 10^{-3}}{14.4 \times 10^{-3} \times 24 \times 10^{-3} \times 20} \\ &\quad + \frac{1}{20 \times 14.4 \times 10^{-3} \times 24 \times 10^{-3}} \\ &= 31 + 0.09 + 145 \\ &\approx 176(^{\circ}\text{C}/\text{W}) \end{aligned}$$

So the total thermal resistance is

$$\begin{aligned}
 R_{\text{total}} &= \frac{1}{\frac{1}{R_{\text{joints}}} + \frac{1}{R_{\text{air}}}} + R_{\text{substrate}} \\
 &= \frac{1}{\frac{1}{13} + \frac{1}{480}} + 176 \\
 &= 12.7 + 176 \\
 &\approx 189(^{\circ}\text{C/W})
 \end{aligned}$$

With GaAs chip power dissipation at $Q = 0.8\text{ W}$

$$\begin{aligned}
 T &= QR_{\text{total}} + T_{\text{air}} \\
 &= 0.8 \times 189 + 25 \\
 &= 176(^{\circ}\text{C})
 \end{aligned}$$

The chip temperature is estimated to be 176°C with the air temperature at 25°C . This temperature is too high to be acceptable. To reduce the temperature, it is important to understand the roles of major thermal elements. The thermal resistance across the airgap (480°C/W) is very large compared with the resistance through the solder joint (13°C/W). For a GaAs chip without temperature gradients, that is, with no heat conduction across the chip, the conduction through the airgap could be overlooked. On the other hand, the convection heat transfer results in a 145°C/W thermal resistance; it plays the dominant role for thermal design. The $20\text{ W}/(\text{m}^2 \cdot ^{\circ}\text{C})$ is a typical convection heat transfer coefficient for an air cooling system in a desktop personal computer (PC) environment. This value can be changed by using a heatsink, a different fan, or even different cooling medium such as liquid. If a small heatsink is added to double the surface area, it would reduce the chip temperature from 176°C to only 118°C , which may be acceptable for some applications. If this temperature is not acceptable or $T_{\text{air}} = 25^{\circ}\text{C}$ is not a good assumption because of higher inlet air temperature, additional thermal enhancement is needed. The enhancement can be accomplished by using a high-thermal-conductivity substrate to reduce the spreading resistance from 31°C/W to a lower value. Or, the convection can be further increased with more powerful air cooling or even liquid cooling.

The assumption of the chip without temperature gradients is reasonable for silicon chips; however, it may be unrealistic for a GaAs chip with a poor thermal conductivity. Let us calculate additional thermal resistance across the chip to understand this consideration. Assume the heatsource is a line source dissipating at the center of the chip; the additional thermal resistance from the chip center to the solder joints can be roughly calculated as

$$\begin{aligned}
 R_{\text{chip}} &= \frac{1}{4} \frac{p_x/2}{t_{\text{chip}}(W_{\text{chip}}/2)k_{\text{chip}}} \\
 &= \frac{4 \times 10^{-3}/2}{4 \times 0.625 \times 10^{-3} \times (1.13/2) \times 10^{-3} \times 48} \\
 &= 30(^{\circ}\text{C/W})
 \end{aligned}$$

where $P_x/2$ and $W_{\text{chip}}/2$ are for a quarter of the chip. The thickness t_{chip} of the GaAs is used to calculate the area for heat conduction. The $\frac{1}{4}$ is to convert the thermal resistance across a quarter of the chip into that across the entire chip. This additional thermal resistance is very large; it is the same as the spreading resistance in the substrate.

The corresponding total thermal resistance becomes

$$\begin{aligned}
 R_{\text{total}} &= 189 + 30 \\
 &= 219(^{\circ}\text{C/W})
 \end{aligned}$$

The highest temperature in the chip becomes

$$\begin{aligned}
 T &= QR_{\text{total}} + T_{\text{air}} \\
 &= 0.8 \times 219 + 25 \\
 &= 200(^{\circ}\text{C})
 \end{aligned}$$

The junction temperature increases 24°C if poor GaAs conduction is considered. Of course, the abovementioned different enhancement schemes have to be adopted to reduce the junction temperature.

This simple calculation illustrates a key challenge to thermal design in RF packaging. GaAs is a poor thermal conductor, and concentrated heatsources in GaAs could cause a major thermal problem if they are located far from solder joints.

The calculation also shows how difficult it is to estimate an accurate junction temperature using one-dimensional formulas for a three-dimensional configuration. Sometimes, contributions of important thermal elements might be neglected by wrong assumptions. Numerical simulation is always preferred if accuracy is crucial.

4.4. Reliability Design

The formulas

$$\Delta\gamma = \frac{L(\alpha_1 - \alpha_2)\Delta T}{h_C}$$

and

$$N_f = \frac{1}{2} \left(\frac{\Delta\gamma}{2\varepsilon_{f'}} \right)^{1/C}$$

are typically used to estimate the fatigue life of the flip-chip solder joints under thermal cycling. The life is strongly affected by the longest distance from the solder joints to the chip center (L), the mismatch between the chip's and the substrate's coefficients of thermal expansion ($\alpha_1 - \alpha_2$), and the temperature change (ΔT) during thermal cycling. With the dimensions and properties given and the temperature changing from -25°C to 125°C , the shear strain is

$$\begin{aligned}
 \Delta\gamma &= \frac{\sqrt{\left(\frac{P_x}{2}\right)^2 + \left(\frac{P_y}{2}\right)^2} (\alpha_{\text{substrate}} - \alpha_{\text{chip}})\Delta T}{H_{\text{joint}}} \\
 &= \frac{\sqrt{2^2 + 0.23^2} \times 10^{-3} \times (6.9 - 6.1) \times 10^{-6} \times [125 - (-25)]}{75 \times 10^{-6}} \\
 &= 0.0032
 \end{aligned}$$

The corresponding fatigue life the solder joint is

$$N_f = \frac{1}{2} \left(\frac{\Delta\gamma}{2\varepsilon_f} \right)^{1/C} = 0.5 \left(\frac{0.0032}{2 \times 0.325} \right)^{1/0.442} \\ = 8.3 \times 10^4 (\text{cycles})$$

The fatigue life, that is, number of thermal cycles, is very high because of the very small mismatch between the chip and the substrate. However, it should be noted that the formula used might not be valid for the case studied. The formula is derived for a flip-chip assembly dominated by a global mismatch caused by a large CTE difference between the chip and the substrate. With a very small global mismatch of $6.9 - 6.1 = 0.8 \times 10^{-6} \text{ mm/mm} \cdot ^\circ\text{C}$ in this assembly, the local mismatch between the solder and the GaAs chip may become the main failure cause. Unfortunately, there is no simple formula to estimate the fatigue life in a case strongly affected by a local mismatch. Numerical analysis is needed [57].

Although the 3.5×10^5 cycles predicted might not be accurate, the fatigue life is expected to be very high because of the very small global mismatch. If the substrate is changed to a polymer one, for example, Duroid (CTE = $14 \text{ mm/mm} \cdot ^\circ\text{C}$), the global mismatch is large and would reduce the fatigue life substantially. Under the same temperature range, the fatigue life with this large global mismatch can be estimated as follows. The shear strain is

$$\Delta\gamma = \frac{\sqrt{\left(\frac{P_x}{2}\right)^2 + \left(\frac{P_y}{2}\right)^2} (\alpha_{\text{substrate}} - \alpha_{\text{chip}}) \Delta T}{H_{\text{joint}}} \\ = \frac{\sqrt{2^2 + 0.23^2} \times 10^{-3} \times (14 - 6.1) \times 10^{-6} \times [125 - (-25)]}{75 \times 10^{-6}} \\ = 0.032$$

The corresponding fatigue life of the joint is

$$N_f = \frac{1}{2} \left(\frac{\Delta\gamma}{2\varepsilon_f} \right)^{1/C} = 0.5 \left(\frac{0.032}{2 \times 0.325} \right)^{1/0.442} \\ = 450 (\text{cycles})$$

The fatigue life is reduced substantially, and underfill epoxy might be used to enhance its reliability. However, underfill epoxy would affect RF performance, due to the change of the effective dielectric constants of the surrounding materials. A RF design is needed to identify potential problems for this use. A good tradeoff analysis can be found in Ref. 57.

The calculations were carried out using simple analytical solutions to review the basic design considerations. It is clear that qualitative guidelines could be obtained quickly. However, it is also clearly indicated that there are limitations of the formulas used. For a quantitative design, the designer must have a good background to select the right formulas for the estimation. Unfortunately, RF packaging involves many multidisciplinary consider-

ations; it is very unusual to train a designer with such a background. Advanced CAD tool integrating RF, thermal, mechanical, and other considerations is critical to the design of RF package.

5. CAD ISSUES FOR RF PACKAGING

Two outstanding CAD issues in RF package design need to be addressed fully and resolved in the near future. The first one is the integration of the design of RF circuits with the design of the package used for housing the circuit. Design tools for RF and microwave circuits have now reached a level of professional maturity. However, the CAD tools for millimeter-wave circuit design [58] have yet to arrive at a similar level of maturity. Even for RF and microwave frequencies, at the current state of the art, different approaches are used for simulation of circuits and for packages in which these circuits are housed. Network analysis-based software packages like Microwave Design System (MDS from HP) and Super Compact (from Compact Software Division of Ansoft Corp.) are used for circuit analysis. On the other hand, frequency-domain and time-domain electromagnetic simulation (EM) techniques (like HFSS and Momentum from HP, Em from Sonnet Software, Strata from Ansoft, and I3D from Zealand Software) are available for characterization of electronic packages at RF, microwave, and millimeter-wave frequencies. None of these approaches is, by itself, applicable for incorporating the effect of packages on performance of RF circuits, for designing of interconnects in the package assembly, or for design of passive embedded circuit functions in packages with multilayered dielectric substrates. Obviously, the network analysis approach, as such, cannot be applied to the RF package design; and three-dimensional field simulation approaches are not practical for analysis of complete RF circuit-package combinations because of impractical excessive computer memory and time requirements.

Two different approaches could possibly be used (and are being developed) for concurrent or integrated design of RF circuits and packages. The first one is based on network modeling of package effects [56,59–61]. In this approach, the significant effects of the package on circuit performance are modeled in terms of equivalent network representations. Rigorous electromagnetic analysis (or approximate field analysis based evaluations) is used for these equivalent network model derivations. These equivalent network models are then used in RF network simulators for design of RF circuits incorporating the effect of package on circuit performance. An alternative to the equivalent network model is the derivation of artificial neural network (ANN) models for packages, trained by EM simulation of the package, that could be coupled to RF circuit design software tools. Use of ANN modeling has been successfully carried out for incorporating difficult-to-model circuit components in microwave design [62,63], but so far it has not been implemented for incorporating the effect of packages in RF circuit design. It is expected that the network or ANN modeling of package effects will be

developed to a level appropriate for RF circuit designers to use it with commercially available RF circuit CAD tools.

The second approach for concurrent RF package and circuit design consists of using EM field simulators for package design and network simulators for circuit design (as is done separately now!) but linking the two simulators so that the design process can be carried out in an integrated manner. There have been some attempts [62–64] for interlinking diverse kinds of simulation tools. However, more of these have been directed toward analysis and design of integrated circuit–antenna modules. Design of integrated circuit–antenna modules is computationally similar to integrated package–circuit design. Just as package design needs to be based on EM field analysis (in contrast to the circuit design, which is based on network analysis), the design of antennas also needs EM field analysis. Thus the computational techniques developed for concurrent circuit–antenna design [65] are conceptually applicable to integrated circuit–package design also.

The second issue in the design of RF packages is the need for integration of thermal and mechanical design considerations with the electrical design of packages. Incorporation of thermal vias in RF circuit chips can affect the RF performance. Shape and dimensions of flip-chip bumps in RF circuit affect both the mechanical reliability and RF performance (because of the inductance introduced by flip-chip bumps). Use of underfill epoxy in flip-chip modules can change the characteristic impedances and insertion losses of transmission lines of RF chips. These are a few of the examples illustrating how mechanical, thermal, and electrical issues can be interrelated in the design of RF packages. Thus the CAD of RF packages calls for some sort of functional integration of electrical, thermal, and mechanical design tools.

CAD of RF packages is a developing area of research and commercial implementation. We can look forward to the arrival of these CAD tools in the near future.

6. ADVANCED PACKAGING CONCEPTS

Trends in packaging may be described in categories based on combinations of power and frequency. Table 7 describes eight such regions from low RF/low power (A1) to millimeter-wave/high power (D2). These regions of applications will be used to discuss different advanced packaging concepts. New materials include high thermal conductivity and low-loss materials. New packaging approaches include premolded plastic package, packages with passive components, and flip-chip assembly. In addition,

Table 7. Application Regions for RF Packaging

Frequency Range	Low RF 100– 800 MHz	High RF 800 MHz– 2 GHz	Microwave 2–30 GHz	Millimeter- Wave 30– 100 GHz
Power low (mW–10 W)	A1	B1	C1	D1
Power high (>10 W)	A2	B2	C2	D2

more challenging packaging technologies are being driven by new applications using active antennas, antenna arrays, RF photonics, RF microelectromechanical systems (MEMS), superconductors, and ferroelectric materials.

6.1. New Materials

6.1.1. High-Thermal-Conductivity Materials. There are instances where, although the total dissipation power requirement is low, devices have a heat concentrated area requiring local heat to be removed from a device surface. Thus aluminum nitride submounts with a surface mount configuration might be suitable in this area. An AlN grade with lower conductivity around 75 W/m · K can be used.

In the areas of high-power device packaging, thermal management is the predominant issue. The current heat-sinking materials have thermal conductivities between 150 W/m · K (for AlN, CuW, and CuMoCu) to 350 W/m · K (for Cu). Several studies are being pursued to investigate the development of diamondlike materials. Pure diamond has a thermal conductivity higher than 1000 W/m · K. An alternative is to develop cost-effective solutions using composite materials. Composites with thermal conductivities over 400 W/m · K are desirable.

6.1.2. Low-Loss Materials. Transmission loss α_{total} in high-frequency regions such as C1, D1, C2, and D2 is

$$\alpha_{\text{total}} = \alpha_r + \alpha_c + \alpha_d$$

where α_r is radiation loss dependent on package structure, α_c is conductor loss proportional to the length and inversely proportional to the square root of electrical conductivity, and α_d is dielectric loss proportional to loss tangent ($\tan \delta$). These loss components in packages become an issue in higher frequency regions such as C1 and D1 if the conducting path is long.

Materials development is required for ultra-low-loss tangent ceramics and plastics that are compatible with highly conductive line materials. Use of magnetic coupling to transfer electrical energy through dielectric materials without a conductive path can be used in the low-loss package solution in very-high-frequency regions such as C1, D1, C2, and D2.

6.2. New Packaging Approaches

6.2.1. Premolded Plastic Package. Currently, the plastic mold package is used in low-power regions at lower frequency (A1 and B1 regions). There are many attempts to increase the applicable frequency upward to the C1 region. Major issues in this area include wire bond inductance and control of the inductance. Thus the wire bonds must be in air, and this requires that a premold type of plastic should be used in this area, since it can create the necessary cavity structure in the package construction. An example of a premolded plastic package is shown in Fig. 22.

6.2.2. Flip-Chip Assembly. Various flip-chip applications are being developed, and flip-chip packaging is beginning to be utilized on the lower-power side. However,

Figure 23. RF package with inductor and capacitor components integrated in a substrate. Such planar discrete components would reduce packaging costs. A large number of inductors and capacitors are commonly used as discrete components for RF modules. A high-density integration and batch processing of such planar components could result in a significant cost reduction.

high-power applications demand new solutions. The flip-chip configuration has the disadvantage of taking heat out of the back side since heat dissipation is very limited through the solder-ball-bonded face. Without a proper design, thermal resistance could be very high. In addition, devices have to be redesigned. See Section 3.1.3 or Ref. 66 for details.

6.2.3. Package with Passive Components. For some RF packaging, the future trend is in integration of passive devices into the package. In regions A1 and B1 there are many functional integration schemes being used, such as integration of impedance matching and use of L , R , and C filter functions within the package. The impedance-matching approach can reduce cost of the MMIC by fabricating matching circuits on the package instead of the MMIC. In some cases, the integration of passive components shown in Fig. 23 into the package could be easier and more cost-effective than integration into the active device.

6.3. New Applications

6.3.1. Active Antenna. As shown in Fig. 1, transmission lines interconnecting different RF devices are the limiting factors for RF performance. The trend for C1–D2 applications is to remove these lines by integrating RF devices and antennas into one active antenna. Figure 24 shows an

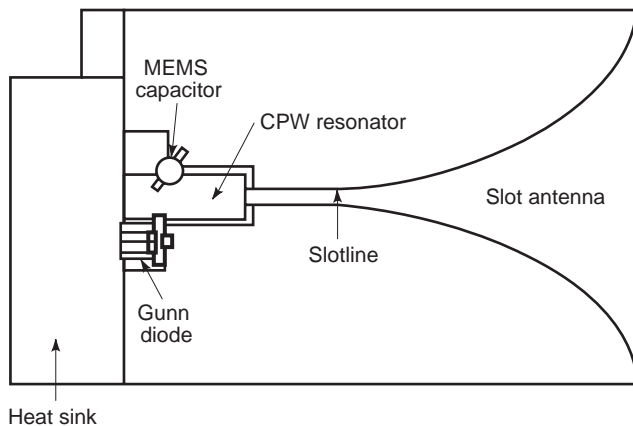

Figure 24. A tapered slot active antenna tuned by a variable capacitor. The device, transmission lines and antenna are integrated into a single module for high efficiency. The MEMS-based tunable capacitor could replace the varactor reported in Ref. 10 in order to enhance the quality factor (Q).

active slot antenna modified from a design taken from Ref. 10. The package itself is the active antenna, requiring integrated considerations of antenna, electrical, thermal, and mechanical designs.

6.3.2. Antenna Arrays. For applications in D1 and D2, device efficiency is very poor, so power combining using a resonant antenna array is necessary. Figure 25 shows a design similar to a quasioptical oscillator with frequency modulation obtained by a varactor array [67]. In addition to power combining, new functionality can be created by manipulating phases of waves [68]. Thousands of antenna elements are needed to achieve desirable functionality. The RF module is very complex and demands advanced MCM technologies.

6.3.3. RF Photonics. Another emerging area of integration is combination of optical and RF functions in devices and packages. RF characteristics of optoelectronic packages have already been identified as the major performance factors for gigahertz bandwidth. In addition, RF transceivers/optical transceivers can be integrated to form different module combinations for efficient transition between optical to wireless communication. Novel packaging concepts are being developed to accommodate this new challenging area.

Figure 25. Quasioptical oscillator with frequency modulation. This is an example to use an antenna array to enhance power transmission efficiency. The power transmission through grid resonance is an effective approach for power combining.

Figure 26. RF ON/OFF switches using MEMS. The capacitance ratio between the air dielectric layer and the silicon nitride layer could reach 100. The switching is controlled by electrostatic forces. In addition to ON/OFF switches, more complex MEMSs can be designed and fabricated for tunable capacitors, inductors, and multiway switches. MEMS technologies can also be used to fabricate precise RF circuits and packages.

6.3.4. RF Microelectromechanical Systems (MEMSs).

MEMSs can be used to fabricate low-loss switches, high- Q tunable capacitor, integrated high- Q inductors, and microscale vibrating mechanical resonators [69–71]. Through μm - or nm -level mechanical movements surrounded by air, the low-loss dielectric material, high- Q components could be designed and fabricated for applications in regions from C1–D2. Figure 26 shows RF switches using a thin diaphragm [1,69]. In the mm-wave region, RF performance is very sensitive to μm -level movements. Such sensitivity used to be a major manufacturing problem. Using an MEMS, however, the sensitivity could be tuned for frequency-agile electronics [70]. RF MEMSs are going to have an impact on low-cost, high- Q , frequency/phase-adaptable filters, circulators, conformal and phased-array antennas, oscillators, and phase shifters. For RF packaging involving MEMSs, new problems need to be overcome. For example, flip-chip assembly is the best approach to integrate MEMS with other RF devices and circuits; however, the silicon substrate used to fabricate MEMS has to be removed to achieve desirable RF performance [72].

Another interesting application of MEMS is the fabrication of RF circuits by silicon-based micromachining [73,74]. In this application, bulk silicon can be used to fabricate waveguide like circuit elements that simultaneously provide circuit function and package enclosures for MMIC and discrete components. Since silicon has good thermal conductivity, such structures are suitable for power devices. In addition, since air-filled cavities may be used to implement high- Q circuit elements, it is possible to fabricate many such circuits/packages out of an 8-inch (203 mm) wafer. This silicon-based micromachining technology is important to manufacture low-cost, precision circuits/packages for millimeter-wave applications.

6.3.5. Superconductor and Ferroelectric Materials. For very-high- Q modules, superconductor and ferroelectric new materials can be used. The high-temperature superconductor makes it possible to build low-loss structure and the ferroelectric gives a voltage variable dielectric [75]. The mixture of $\text{Ba}_{0.08}\text{Sr}_{0.92}\text{TiO}_3$ (BST) has shown to have both the desired large dielectric constant, for example, 17,000, and a large decrease in the dielectric constant, for example, 17,000 reduced to 6000, with an applied field of 25 kV/cm at 77 K. BST can be integrated with the superconductor $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ (YBCO), because of the lattice match and chemical compatibility. The combinations have been used in a voltage-tunable oscillator, a phase shifter, and a voltage-tunable phase-array antenna system. In addition to typical issues for high- Q modules, the new materials and the new operation temperature at 77 K will demand very advanced RF packaging solutions.

7. SUMMARY

RF packaging is critical to the growth of applications of microwave and mm-wave modules and systems. The number of I/Os of RF packaging is not high; major packaging challenges result from two unique features:

1. Wide spectrum of operation frequencies ranging from kHz to hundreds of GHz
2. Packaging being a part of circuitry with strong effects on RF performance

This article reviews different RF single-chip and multichip packages, with an emphasis on their requirements that differed from those for microelectronics. It also discusses basic issues related to RF performance and package reliability in thermal management and mechanical integrity. To meet development needs, advanced packaging concepts are being created using new approaches and new materials. In addition, more challenging packaging technologies are being driven by new applications using active antenna, antenna arrays, RF photonics, RF microelectromechanical systems, superconductor, and ferroelectric materials.

 Kowloon, Hong Kong SAR,
 China

1. PARALLEL COMPUTING

Parallel computing can be performed with either shared- or distributed-memory multiprocessors [1,2]. Figures 1a and 1b show the schematic diagrams for shared-memory multiprocessor (SMMP) and distributed-memory multiprocessor (DMMP) architectures, respectively. In shared-memory multiprocessors, the architecture consists of a number of identical processors sharing a global main memory. The parallel processes are thread-controllable. Each runs on a separate processor and shares memory with other threads in the framework. The OpenMP [3] is a more recent application program interface (API) for writing multithreaded applications in shared-memory multiprocessor architecture. In distributed-memory multiprocessors, the architecture consists of a number of processors with individual memory that are interconnected via a communication network. The parallel processes run on separate processors and use message passing to communicate with each other. The MPI (message-passing interface) [4,5] and PVM (parallel virtual machine) [6] are the most popular message-passing libraries for programmers to write message-passing programs. As parallel computing has become more popular, many useful parallel packages suitable for science and engineering applications can now be downloaded freely from the Internet. The Fast

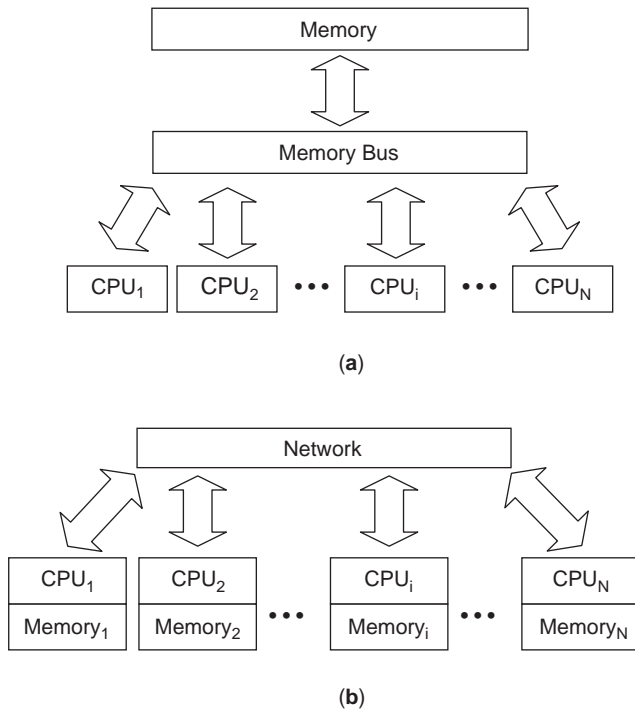

Figure 1. (a) Shared-memory multiprocessor architecture; (b) distributed-memory multiprocessor architecture.

Fourier Transform in the West (FFTW) [7] is one of these packages.

In this article, we will discuss some parallel algorithms and programming clues suitable for large-scale electromagnetic simulations in which the numbers of unknowns are too large for typical desktop computing. Readers are also referred to the work of Velamparambil et al. [8] for large-scale parallel computing. All the parallel computing techniques presented here are based on our experiences with self-built Beowulf clusters [9,10]. It is believed that these techniques are also applicable to other science and engineering applications. This article is outlined as follows. We will first describe the principle of parallel computing and the architecture of the Beowulf cluster in the City University of Hong Kong. Readers can then appreciate the cost-effectiveness of the Beowulf cluster, which is perhaps the easiest parallel computing platform that one can build by oneself. We will also discuss parallel implementation of commonly used computational techniques such as the finite-difference time-domain (FDTD) method [11] and the method of moments (MoM) [12]. Manipulations of full matrix as well as sparse matrix calculations will be described.

1.1. Principle of Parallel Computing

Regardless of the computing architecture, the principle of parallel computing is to decompose the large computational domain into smaller subdomains. Tasks in each subdomain are performed independently with minimum intercommunication among them. Each processing unit in the parallel computing platform will be tasked to

manipulate the computation for the corresponding identified domain. Results may need to be exchanged among processors via a message-passing library and API during the computation. There are two levels of parallelism: hardware-level parallelism and software-level parallelism.

1.1.1. Hardware-level Parallelism. Parallelism at this level is implemented by breaking down the load among multiple hardware components of the same category. Parallelism is attained by having the computational work done by these hardware components in parallel, and thus can achieve a higher computing performance. There are two types of hardware-level parallelism: fine-grained and coarse-grained parallelism. Fine-grained parallelism is achieved by performing the computing task with either one or multiple CPUs, while coarse-grained parallelism is achieved by a collection of systems. Hardware-level parallelism can further be classified by several sublevels, including the following:

- *CPU-Level Parallelism.* Multiple CPUs within the same machine to have computation work done in parallel.
- *Memory System Parallelism.* Instead of accessing the same memory pool through the same memory bus at the same time, memory access can be distributed by dividing the memory pool into independent memory blocks. The memory blocks and CPUs are connected through a crossbar memory access switch. Each memory access to different pieces of data can go through distinct access paths without interfering with memory access activities in the same system.
- *Input-Output Parallelism.* Usually input/output (I/O) channels and devices are bottlenecks in computational tasks, especially those with large data volume. Using multiple I/O channels and devices to serve the same I/O requests in parallel can increase throughput of data access.
- *System level parallelism.* This is a higher-level parallelism compared with the aforementioned parallelism categories. Computational tasks are decomposed into smaller, independent subtasks. Multiple nodes coordinate to work on independent subtasks in parallel. Linux clusters such as the Beowulf are included in this category.

1.1.2. Software-Level Parallelism. Software-level parallelization is one of the core parts of parallel computing. It features the ability to break up a problem into independent, self-contained parts that are solved by different hardware. Algorithms that can be parallelized can result in substantial speedup in execution. Problem domains of a serial nature (e.g., graphical user interface that waits for user input), or with more overhead than performance gain after parallelization, are unsuitable for parallelization. Whether a problem can be parallelized depends on whether we can take advantage of the following parallel application features:

- *Granularity.* —a measure of the size of problem fragments that can be accomplished independently without communicating with other fragments in the same problem domain
- *Data dependence.* —the data availability among problem fragments when some fragments have to wait for data available only from the remaining fragments
- *Control dependency.* —the data availability among problem fragments when some fragments have to wait for results of control conditions (e.g., execution of an expression that returns a true or false) available only from the remaining fragments

1.2. Schemes

There are various ways to construct a parallel computing platform; each has a different level of parallelism and thus limitation. However, there are two major streams in the development of parallel computing platform.

- *Shared-Memory Multiprocessor. (SMMP).* In this architecture, processors have equal access to the memory address space. There are multiple processors that access a shared-memory pool through a common memory access channel, usually via a bus or crossbar switch. Processors within the same machine communicate with each other through shared address space.
- *Distributed-Memory Multiprocessor. (DMMP).* In this architecture, each processor has its own memory module. Processors access their own memories and communicate with each other through message passing. Usually such a system is constructed from multiple systems, connected through high-speed network equipment. Processors access memory area in the corresponding machine and communicate with processors on other machines through high-speed networks.

In the SMMP model, various processors can reference the same variables and memory just as the single processor machine can. However, the system has to maintain the shared data integrity. In a DMMP model, the memory modules reside on separate machines, where they can be accessed. There is no data integrity issue among machines. The tasks of distributing data to various machines and reassembling the result collected from each machine are handled by software implementation. This requirement also adds communication complexity to the implementation, which does not exist in shared-memory multiprocessors [13]. On the other hand, well-designed distributed-memory multiprocessor software has better scalability for adding more machines [14]. Compared with the DMMP model, the SMMP model requires much more effort to scale up in both the hardware and software paradigms.

1.3. Beowulf Cluster

The Beowulf cluster is a distributed memory multiprocessor architecture. It usually consists of one server node and one or more client nodes connected together via Ethernet

or some other networks. Users access resources in the cluster by connecting to a single node while the rest of the cluster nodes are inaccessible from the outside world. Machines used in a cluster can be of identical models (a homogeneous cluster) or of different models (a heterogeneous cluster). It is commonly built by using commodity hardware components. Essential components include standard Ethernet adapters, Ethernet switches, and a personal computer (PC) that is capable of running a free operation system such as Linux. There is substantial benefit in price: performance ratio for Beowulf clusters compared to those traditional expensive supercomputers, at the expense of efforts in system management and software parallelization.

1.4. Cluster in CityU

In the Wireless Communications Research Center of CityU, parallel computing platforms are built by harnessing personal computers interconnected by a central network, forming a Beowulf cluster to solve large-scale electromagnetic problems. This kind of Beowulf architecture is well suited for scaling and is easy to implement with standardized programming models and without paying fees for an operating system.

1.4.1. Cluster Configuration. Figure 2 shows one of the Beowulf clusters in CityU. The schematic configuration is shown in Fig. 3. The cluster configuration consists of

- *1 Server Node.* —Intel Pentium IV 2.0GHz CPU, 1.5 GB (gigabyte) RAM, 36 GB Ultra 160 SCSI (small-computer system interface) hot-swap hard disk for RAID (redundant array of independent or inexpensive disks) 1 and 90 GB Ultra 160 SCSI hot-swap hard disk for RAID 5 storage disk, and sets of 3Com 3C905C 100 TX network interface cards
- *24 cluster nodes.* —dual Intel Pentium III 1GHz CPU, 2GB RAM, 18GB Ultra 160 SCSI hot-swap

Figure 2. Fourth generation of Beowulf Linux cluster in Wireless Communications Research Center, City University of Hong Kong.

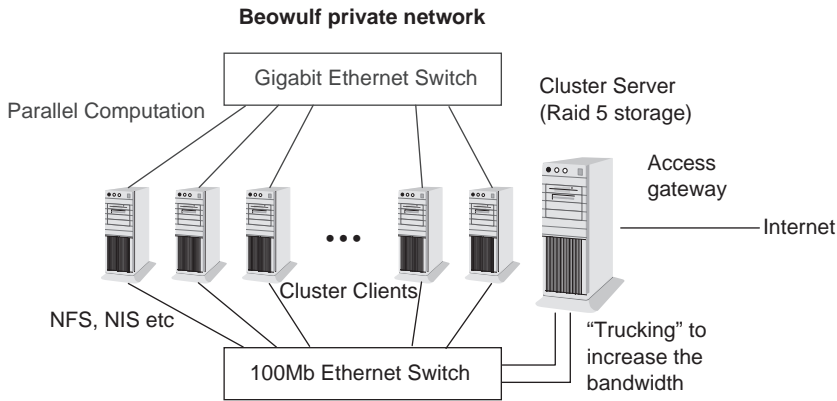

Figure 3. Schematic diagram illustrating configuration of a Beowulf Linux cluster.

hard disk, 1 set of 3Com 3C905C 100 TX network interface cards, and 1 set of 3Com 996B 1000TX Gigabit Fast Ethernet network interface cards

- *2 Ethernet switches.* —3Com Superstack 3 Switch 4924 24-port Gigabit Fast Ethernet network switch and 3Com Superstack 3 switch 4300 48-port Ethernet network switch
- *Cluster node operating system.* —RedHat Linux 8.0
- *Software packages*
 - Message-passing interface (MPI) [15]
 - Fast Fourier Transform West (FFTW) [7]
 - Basic linear algebra subprograms (BLASs) [16]
 - Linear algebra package* (LINPACK) [17]
 - Miscellaneous scientific and engineering software packages
 - Administrative and system monitoring software packages such as Cheops [18]

1.4.2. Design considerations. The server provides cluster-wide services, including Network File Services (NFS) for user home directories and common program depository, plus Network Information Services (NIS) for user information, and so on to all the client nodes. All the cluster nodes are connected through private gigabit and 100-Mb (megabit) Ethernet switches. Traffic among cluster nodes goes through the private network while the cluster is accessible through only one of the cluster nodes connected to Internet. The benefit of using private network is twofold:

- Network loading is incurred by interprocess communication and file access of the parallel applications running on the cluster. Performance of parallel applications running on other systems on the public network may be affected if such network loading is not isolated from the public network.
- Since only one cluster node is Internet-accessible, it is much easier to enforce the security of this single machine, rendering the cluster less vulnerable to network attacks. Furthermore, network protocols with low security level, such as NFS and NIS, are

protected against eavesdropping as they all go through the private network connection.

To further improve performance of inter-process communication and file access across the network, each cluster node possesses more than one network interface. The server node has three 100-Mb Ethernet network interfaces. One interface is used for Internet access to the cluster. The remaining two interfaces are used to access the private network through the 100-Mb Ethernet switch. They are bounded together to form a virtual network interface. This “trunking” method is adopted to double the communication bandwidth. Each client node has one Gigabit Ethernet card and one 100-Mb Ethernet card. All the client nodes are connected to the Gigabit Ethernet switch for interprocess communication of parallel computation applications. The 100-Mb Ethernet switch is used to connect the clients and server to provide NIS, NFS, and other services. In this way, two different network switches manage tasks related to parallel computation, I/O, and other file systems separately, and hence a more efficient and stable parallel computing platform can be achieved. To provide centralized storage for user data and application programs to be shared among all cluster nodes, a disk storage system is bundled with the server node. The storage system is configured as a “RAID 5” system, with which the storage system will continue to operate even after failure of any single hard disk. This configuration provides a secure and reliable way to protect the data and the system information, and avoids the storage system becoming a single point of failure for the entire cluster.

The cluster architecture deployment also provides (1) *high availability*—the cluster continues to operate regardless of single- or multiclient cluster node failure (hardware can be replaced without affecting the rest of the cluster) and (2) *upgradability*—new hardware and operating systems can be introduced into the cluster gradually by adding additional nodes, without making drastic changes to the entire cluster environment.

We now have some basic ideas about the parallel computing and components needed to build the parallel computing platform. In the following section, we will discuss some general parallel algorithms.

2. PARALLEL ALGORITHMS

In this section, we discuss several parallel algorithms and their implementations for the FDTD method and MoM on Beowulf PC clusters. Manipulations of full matrix as well as sparse matrix calculations are described.

2.1. Finite-Difference Time-Domain (FDTD) Method

The FDTD method was proposed by Kane Yee in 1966 [11]. It is one of the most popular simulation techniques in computational electromagnetics. It has broad applications, including electronic packaging, antennas and radiation, waveguiding structures, nonlinear problems in transmission lines with active devices, and other electromagnetic problems.

2.1.1. Theory of FDTD. Consider a free-space region that does not have either electric or magnetic current sources. The time-dependent Maxwell equation can be written as

$$\nabla \times \vec{E} = -\mu \frac{\partial \vec{H}}{\partial t} \quad (1)$$

$$\nabla \times \vec{H} = \sigma \vec{E} + \varepsilon \frac{\partial \vec{E}}{\partial t} \quad (2)$$

where \vec{E} and \vec{H} are the electric field and magnetic field, respectively. The magnetic permeability is denoted by μ , the electric permittivity by ε , and the electric conductivity by σ . In Cartesian coordinates, we can decompose the vector components of the curl operators in (1) and (2) as the following system of six coupled scalar equations:

$$\frac{\partial H_x}{\partial t} = \frac{1}{\mu} \left(\frac{\partial E_y}{\partial z} - \frac{\partial E_z}{\partial y} \right) \quad (3a)$$

$$\frac{\partial H_y}{\partial t} = \frac{1}{\mu} \left(\frac{\partial E_z}{\partial x} - \frac{\partial E_x}{\partial z} \right) \quad (3b)$$

$$\frac{\partial H_z}{\partial t} = \frac{1}{\mu} \left(\frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial x} \right) \quad (3c)$$

$$\frac{\partial E_x}{\partial t} = \frac{1}{\varepsilon} \left(\frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} - \sigma E_x \right) \quad (4a)$$

$$\frac{\partial E_y}{\partial t} = \frac{1}{\varepsilon} \left(\frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} - \sigma E_y \right) \quad (4b)$$

$$\frac{\partial E_z}{\partial t} = \frac{1}{\varepsilon} \left(\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} - \sigma E_z \right) \quad (4c)$$

These six coupled partial-differential equations form the basis of the FDTD algorithm for general three-dimensional electromagnetic interactions. The Maxwell equations are discretized in a finite-difference timestepping manner by means of the Yee grid. The geometric position of the electric and magnetic field vector components in a unit Yee space lattice is shown in Fig. 4.

Figure 4. The Yee lattice.

If the space point in Yee's grid is uniform, we can define a gridpoint in the solution region as

$$(i, j, k) = (i \Delta x, j \Delta y, k \Delta z) \quad (5)$$

where Δx , Δy , and Δz are the spatial increments in x , y , and z directions, respectively. On the basis of this notation, any function F of space and time can be discretized as follows:

$$F^n(i, j, k) = F(i \Delta x, j \Delta y, k \Delta z, n \Delta t) \quad (6)$$

We adopt the central-difference approximation for both temporal and spatial derivatives with the second-order accuracy. Then the corresponding derivatives of function F can be expressed as follows:

$$\frac{\partial F^n(i, j, k)}{\partial x} = \frac{F^n(i + \frac{1}{2}, j, k) - F^n(i - \frac{1}{2}, j, k)}{\Delta x} + O((\Delta x)^2) \quad (7)$$

$$\frac{\partial F^n(i, j, k)}{\partial t} = \frac{F^{n+(1/2)}(i, j, k) - F^{n-(1/2)}(i, j, k)}{\Delta t} + O((\Delta t)^2) \quad (8)$$

With the notation in (7) and (8), we can express the components in (4a) as follows:

$$\frac{\partial E_x}{\partial t} \approx \frac{E_x^{n+1}(i, j, k) - E_x^n(i, j, k)}{\Delta t}, (n + \frac{1}{2}, i, j, k) \quad (9)$$

$$\frac{\partial H_z}{\partial y} \approx \frac{H_z^{n+(1/2)}(i, j + \frac{1}{2}, k) - H_z^{n+(1/2)}(i, j - \frac{1}{2}, k)}{\Delta y}, \quad (10)$$

$$(n + \frac{1}{2}, i, j, k)$$

$$\frac{\partial H_y}{\partial z} \approx \frac{H_y^{n+(1/2)}(i, j, k + \frac{1}{2}) - H_y^{n+(1/2)}(i, j, k - \frac{1}{2})}{\Delta z}, \quad (11)$$

$$(n + \frac{1}{2}, i, j, k)$$

$$\sigma E_x \approx \frac{E_x^{n+1}(i, j, k) + E_x^n(i, j, k)}{2}, \quad (12)$$

$$(n + \frac{1}{2}, i, j, k)$$

Thus

$$E_x^{n+1}\left(i + \frac{1}{2}, j, k\right) = \frac{\left(1 - \frac{\sigma \Delta t}{2\varepsilon}\right)}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} E_x^n\left(i + \frac{1}{2}, j, k\right) + \frac{\frac{\Delta t}{\varepsilon}}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} \times \left[\frac{H_z^{n+(1/2)}\left(i + \frac{1}{2}, j + \frac{1}{2}, k\right) - H_z^{n+(1/2)}\left(i + \frac{1}{2}, j - \frac{1}{2}, k\right)}{\Delta y} \right] - \frac{\frac{\Delta t}{\varepsilon}}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} \left[\frac{H_y^{n+(1/2)}\left(i + \frac{1}{2}, j, k + \frac{1}{2}\right) - H_y^{n+(1/2)}\left(i + \frac{1}{2}, j, k - \frac{1}{2}\right)}{\Delta z} \right] \quad (13a)$$

The y and z components of the electric field can be expressed as follows:

$$E_y^{n+1}\left(i, j + \frac{1}{2}, k\right) = \frac{\left(1 - \frac{\sigma \Delta t}{2\varepsilon}\right)}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} E_y^n\left(i, j + \frac{1}{2}, k\right) + \frac{\frac{\Delta t}{\varepsilon}}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} \times \left[\frac{H_x^{n+(1/2)}\left(i, j + \frac{1}{2}, k + \frac{1}{2}\right) - H_x^{n+(1/2)}\left(i, j + \frac{1}{2}, k - \frac{1}{2}\right)}{\Delta z} \right] - \frac{\frac{\Delta t}{\varepsilon}}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} \left[\frac{H_z^{n+(1/2)}\left(i + \frac{1}{2}, j + \frac{1}{2}, k\right) - H_z^{n+(1/2)}\left(i - \frac{1}{2}, j + \frac{1}{2}, k\right)}{\Delta x} \right] \quad (13b)$$

$$E_z^{n+1}\left(i, j, k + \frac{1}{2}\right) = \frac{\left(1 - \frac{\sigma \Delta t}{2\varepsilon}\right)}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} E_z^n\left(i, j, k + \frac{1}{2}\right) + \frac{\frac{\Delta t}{\varepsilon}}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} \times \left[\frac{H_y^{n+(1/2)}\left(i + \frac{1}{2}, j, k + \frac{1}{2}\right) - H_y^{n+(1/2)}\left(i - \frac{1}{2}, j, k + \frac{1}{2}\right)}{\Delta x} \right] - \frac{\frac{\Delta t}{\varepsilon}}{\left(1 + \frac{\sigma \Delta t}{2\varepsilon}\right)} \left[\frac{H_x^{n+(1/2)}\left(i, j + \frac{1}{2}, k + \frac{1}{2}\right) - H_x^{n+(1/2)}\left(i, j - \frac{1}{2}, k + \frac{1}{2}\right)}{\Delta y} \right] \quad (13c)$$

Similarly, the vector components of the magnetic field can be expressed as follows:

$$H_x^{n+(1/2)}\left(i, j + \frac{1}{2}, k + \frac{1}{2}\right) = H_x^{n+(1/2)}\left(i, j + \frac{1}{2}, k + \frac{1}{2}\right) + \frac{\Delta t}{\mu} \left[\frac{E_y^n\left(i, j + \frac{1}{2}, k + 1\right) - E_y^n\left(i, j + \frac{1}{2}, k\right)}{\Delta z} \right] - \frac{\Delta t}{\mu} \left[\frac{E_z^n\left(i, j + 1, k + \frac{1}{2}\right) - E_z^n\left(i, j, k + \frac{1}{2}\right)}{\Delta y} \right] \quad (14a)$$

$$H_y^{n+(1/2)}\left(i + \frac{1}{2}, j, k + \frac{1}{2}\right) = H_y^{n+(1/2)}\left(i + \frac{1}{2}, j, k + \frac{1}{2}\right) + \frac{\Delta t}{\mu} \left[\frac{E_z^n\left(i + 1, j, k + \frac{1}{2}\right) - E_z^n\left(i, j, k + \frac{1}{2}\right)}{\Delta x} \right] - \frac{\Delta t}{\mu} \left[\frac{E_x^n\left(i + \frac{1}{2}, j, k + 1\right) - E_x^n\left(i + \frac{1}{2}, j, k\right)}{\Delta z} \right] \quad (14b)$$

$$H_z^{n+(1/2)}\left(i + \frac{1}{2}, j + \frac{1}{2}, k\right) = H_z^{n+(1/2)}\left(i + \frac{1}{2}, j + \frac{1}{2}, k\right) + \frac{\Delta t}{\mu} \left[\frac{E_x^n\left(i + \frac{1}{2}, j + 1, k\right) - E_x^n\left(i + \frac{1}{2}, j, k\right)}{\Delta y} \right] - \frac{\Delta t}{\mu} \left[\frac{E_y^n\left(i + 1, j + \frac{1}{2}, k\right) - E_y^n\left(i, j + \frac{1}{2}, k\right)}{\Delta x} \right] \quad (14c)$$

It is noted from (13) and (14) that both electric field and magnetic field could be updated from the previous E and H fields. Following the timestepping expressions in (13) and (14), we can calculate the corresponding fields step by step. Many geometries of interest are defined in “open” regions where the spatial domain of the computed field is unbounded in one or more coordinate directions. Because of the finite size in computer memory, the finite-difference grid has to be truncated. Therefore, we need to define not only the field computation domain in a finite size that should be large enough to enclose the structure of interest but also a suitable boundary condition such that the simulation is capable of extending the outer perimeter to infinity and ensuring that the reflections of outgoing waves are minimized. Such artificial boundaries described by the mathematical expressions are known as the absorbing boundary conditions (ABCs). The most commonly used ABC includes Mur ABC [19] and perfectly matched layered ABC [20].

To ensure the stability and accuracy of FDTD computation, the size of Yee cell are typically $\frac{1}{10}$ th– $\frac{1}{20}$ th of the wavelength corresponding to the highest frequency of interest, and then the timestep must satisfy the following stability condition [21]

$$\Delta t \leq \frac{1}{c_{\max} \times \sqrt{\frac{1}{\Delta x^2} + \frac{1}{\Delta y^2} + \frac{1}{\Delta z^2}}} \quad (15)$$

where Δt is the timestep and c_{\max} is the maximum light velocity; Δx , Δy , and Δz are the size of the FDTD cube in x , y , and z directions, respectively.

The algorithm of FDTD calculation is shown in Fig. 5. The process of updating the magnetic and electric fields is the most time-consuming part of the calculation. This problem can be solved by means of parallel computing as discussed in the following subsection.

2.1.2. Parallel Implementation of FDTD. Although FDTD is a powerful tool for the analysis of time-domain problems and nonlinear problem with active devices, it requires a huge amount of computer memory and long computation time. This limits the use of FDTD in large-scale problems. In this subsection, we discuss how to implement the parallel computation of FDTD. The main idea is to decompose the single FDTD computation domain into several smaller domains. Each node in the Beowulf PC cluster will manipulate each of these domains and compute its corresponding electric and magnetic fields. The exchange of data occurs only at the interface of two different domains, and thus little communication time is required.

Figure 6 illustrates the concept of the FDTD domain decomposition and the mechanism of field exchange. Only three nodes in the parallel computing platform are used for illustrative purposes. As we can see in the figure, the FDTD computation domain is spatially decomposed into three regions of regular gridpoints along the z axis. Each node manipulates the computation for the corresponding region. On the basis of the FDTD algorithm, we need to update the E and H fields in each timestep. These E and H

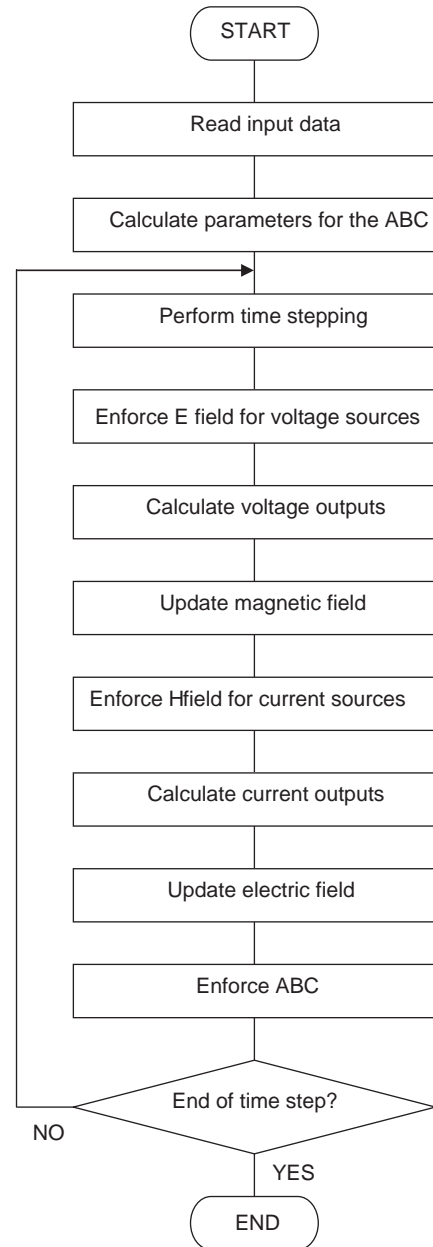

Figure 5. FDTD algorithm.

fields are computed with the corresponding adjacent neighboring E and H fields. Owing to the domain decomposition, some of the required E and H fields are not stored in the same computing node. They are calculated and stored in the adjacent node. When using the ABC, the first or last node needs to exchange E or H fields in either upper or lower slices of its domain only. The node in the center needs to exchange the calculated E and H fields in both upper and lower slices of its domain to its adjacent node for updating E and H fields in each timestep. Such field exchange process is handled by calling the message-passing interface (MPI) library. Referring to Fig. 6, we can see that the H_y field is used for updating the E_x field in each timestep. For the subdomain in node 1, the lower edge of the H_y field is missing. The upper slice of the H_y

Figure 6. Domain decomposition by three computing nodes.

field in node 2's subdomain is needed to transfer the field information to node 1 for updating the E_x field. Similarly, the lower slice of the E_x field in node 1's subdomain will transfer the information to node 2 for updating the H_y field in each timestep.

To generalize the mechanism, Fig. 7 is a pictorial representation of the domain decomposition and field exchange mechanism. Assuming that M computing nodes are used, the FDTD computation domain is decomposed into M subdomains, equal or nearly equal in size, along the z -axis. The corresponding subdomain, which is rectangular in shape, and nonoverlapping, is computed completely independently of other nodes in the parallel computing platform. After the decomposition, only three

types of domain need to be handled separately: the first, center, and last regions, respectively, as shown in Fig. 7b. The field exchange mechanism for these three different regions are shown in Figs. 8, 9, and 10 respectively. In such an exchange mechanism, Eqs. (13) and (14) are used to update the E and H fields, respectively. The parallel-implemented FDTD codes for handling different regions are shown in Figs. 11 and 12. The data communication among all nodes is by means of using message-passing interface (MPI) library. To update the magnetic fields and electric fields in each timestep, MPI library calls such as `MPI_SEND` and `MPI_RECEIVE` are used. `MPI_SEND` and `MPI_RECEIVE` perform basic data communications (i.e., send and receive) among the nodes.

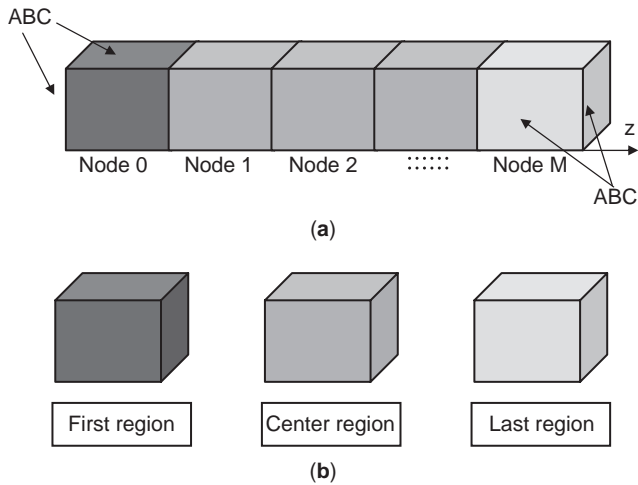

Figure 7. (a) Pictorial representation of domain decomposition into M nodes; (b) three types of region after domain decomposition. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

As an example, we will now analyze the active integrated antennas using parallel-implemented FDTD code.

2.1.3. Numerical Results (FDTD). Active integrated antennas have many military and commercial applications such as spatial or quasioptical power-combining arrays, phased arrays, and wireless communication systems. Since an active integrated antenna is a nonlinear antenna and operates with large-signal oscillations, it is difficult to predict the electromagnetic characteristics such as its stable oscillation modes and operating frequency. In this subsection, FDTD method is used to analyze the active integrated antenna problem [22–24]. The layout of an active integrated antenna array is shown in Fig. 13. The components of the active integrated antenna consist of Gunn diodes, radiating patches, two-stage $\lambda/4$ transformers, open tuning stubs, and adjacent coupling lines. Figure 14 shows the circuit model of the Gunn diode, and the equations of the Gunn diode operation [24,25] are also shown in Eqs. (16)–(20) and (22)

$$\frac{\epsilon}{\Delta t} E_z^{n+1}(i_s, j_s, k) = \frac{\epsilon}{\Delta t} E_z^n(i_s, j_s, k) + L[H_x, H_y] - \frac{I_d^{n+(1/2)}}{\Delta x \Delta y} \quad (16)$$

Figure 8. Pictorial representation for updating E field (red-colored bar) and H field (blue-colored bar) in the center region for each timestep in FDTD calculation. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

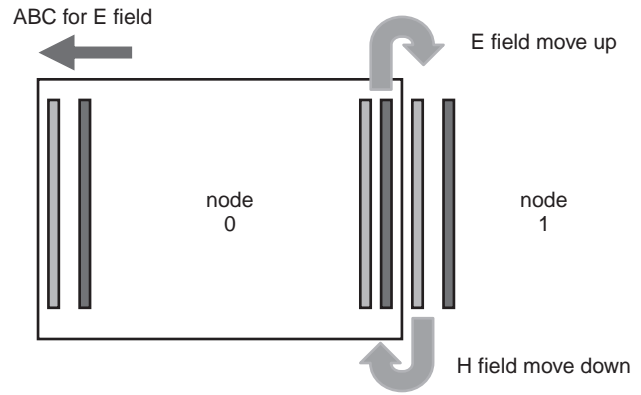

Figure 9. Pictorial representation for updating E field (red-colored bar) and H field (blue-colored bar) in the first region for each timestep in FDTD calculation. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

$$I_d^{n+(1/2)} = -I_d^{n-(1/2)} + \frac{2(V_s^n + V_z^n)}{R} \quad (17)$$

$$V_s^{n+1} = V_s^n - \frac{I_d^{n+(1/2)} + F(V_s^n)}{\frac{C}{\Delta t} + \frac{F'(V_s^n)}{2}} \quad (18)$$

$$V_z^n = \sum_{k=1}^3 E_z(i_s, j_s, k) \Delta z \quad (19)$$

$$F(V_s) = -G_1 V_s + G_3 V_s^3 \quad (20)$$

$$L[H_x, H_y] = \frac{H_x^{n+(1/2)}(i_s, j_s - 1, k) - H_x^{n+(1/2)}(i_s, j_s, k)}{\Delta y} + \frac{H_y^{n+(1/2)}(i_s, j_s, k) - H_y^{n+(1/2)}(i_s - 1, j_s, k)}{\Delta x} \quad (21)$$

where $G_1 = 0.0252 \Omega^{-1}$ and $G_3 = 0.0265 \Omega^{-1} V^{-2}$. The capacitance C is 0.2 pF, and the series resistance R is 1.0 Ω ; $F'(V_s)$ is a derivative of $F(V_s)$.

Figure 11. Parallel-implemented FDTD code to handle center region of the computation domain.

There is a narrow gap between two coupling lines. By short-circuiting the gap with a conductor and a resistor, respectively, the odd and even radiating mode can be obtained [26]. In order to reduce the CPU time, parallel-implemented FDTD code is used in the analysis. The simulation is performed on the Beowulf cluster depicted in Section 1.4. The active integrated antenna with four units operates at 12.4 GHz. The size of the computation domain $N_x \times N_y \times N_z$ is $235 \times 109 \times 16$ cells. The size of

each cell in the x , y , and z directions are 0.372, 0.392, and 0.392 mm, respectively. The narrow gap between coupling lines is connected with a 100- Ω resistor for providing an even radiating mode. The simulation is with Mur ABC. Figure 15 shows the voltage across the Gunn diodes. We can see that the voltages in the four units are in phase. The electric field component E_z at the dielectric-air interface at two different time instants are shown in Figs. 16 and 17, respectively. Figure 16 shows the in-phase

Figure 11. (Continued).

behavior; Fig. 17 shows even radiating mode moment with different timestep.

We examine the parallel code with a different number of nodes in terms of speedup factor, efficiency, computation time, and time saving. Table 1 shows the overall performance of the parallel code with 30,000 timesteps. From the table, we can see that the computing time is reduced rapidly when the number of computing nodes is increased. The rate of change in CPU time with the number of computing nodes is shown in Fig. 18. Figure 19 shows the speedup factor of different number of nodes used. As we can see from the figure, the speedup factor is directly proportional to the number of computing nodes, as expected. For the ideal situation, it is expected that the speedup factor will be M , if M computing nodes are used.

However, that is not the case in practice. For example, as shown in the Figs. 18 and 19, the speedup factor is about 21 if 24 computing nodes are used. The discrepancy is due to the time spent for data communication among nodes for updating the E and H fields. The efficiency can reach almost 100% with the use of two or four computing nodes as indicated in Fig. 20. With a smaller number of nodes, the subdomain will be larger and the time for data communication among the nodes relatively shorter when compared to the remaining computation since most of the CPU time is spent computing the E and H fields. This is why the efficiency can be higher if a smaller number of nodes are used. However, when a smaller number of computing nodes are used, the speedup factor will be relatively low, as shown in Fig. 19. The saving in CPU

Figure 12. Parallel-implemented FDTD code to handle first and last regions of the computation domain.

with a different number of computing nodes is shown in Fig. 21. It is obvious that the saving in CPU time is greater when the number of computing nodes increases.

2.1.4. FDTD Method with SPICE for Analyzing Electric Circuit. In the analysis of electric circuits, commercial software such as SPICE is commonly used. It is one of the most popular software packages for electric circuit analysis in both frequency and time domains. It provides a large number of models for complex electronic devices and libraries [27]. Many researchers have focused on combining the FDTD method with SPICE [28,29]. The FDTD method with SPICE (FDTD-SPICE) is one of the most powerful tools for analyzing integrated circuits, active antennas, and electromagnetic interference (EMI) problems. In this subsection, we will show the application of FDTD in circuit analysis by merging the FDTD method with SPICE. However, SPICE cannot directly merge FDTD domain because the input-output differences. In SPICE, the input and the output are voltage (V) and current (I), respectively. On the other hand, in FDTD, the input and the output are the electric field (E) and magnetic field (H), respectively. To solve this difficulty, we

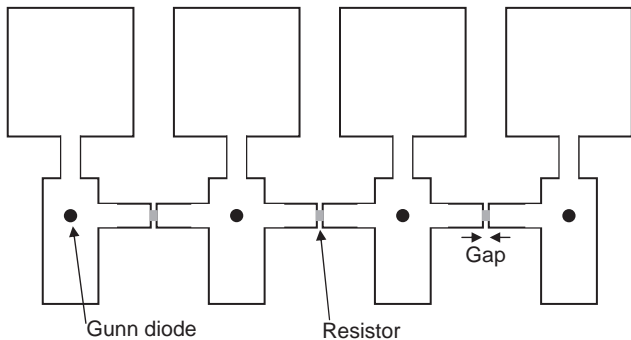

Figure 13. Layout of active integrated antenna.

Figure 14. Circuit model of Gunn diode.

use the equivalent SPICE circuit as shown in Fig. 22. It is expressed by means of Ampere’s law, and the total current I is expressed in the following equation

$$C \frac{dV}{dt} + I(V) = I \tag{22}$$

where $I(V)$ is the current source, C is capacitance of an FDTD cell, and V is the voltage across the lumped element. At each timestep of updating the electric field in the FDTD computation, the information of $I(V)$ and C will be sent to SPICE for solving the lumped element, and then SPICE will send back the voltage of the lumped element to the FDTD module.

Figures 23 and 24 show the FDTD model and the layout of the simplified VHF amplifier circuit [30], respectively. The FDTD cell size is $d_x = d_y = d_z = 1$ mm and the relative dielectric constant is unity. The total number of timesteps in the calculation is 30,000. The impedances of the microstrip lines are 47.9Ω , and the two lines are separated by $2\frac{1}{2}$ times the width of the microstrip. The voltages at the input to the lumped transistor circuit and across the output resistor are shown in Fig. 25. The simulation results of FDTD-SPICE give good agreement with that of SPICE alone. The minimal difference between FDTD-SPICE and SPICE simulation is due to the separation between the microstrip line and parasitic coupling.

2.1.5. Matrix Manipulation of FDTD. If we cast the FDTD operation into matrix-vector manipulation, it is not difficult to see that each field-updating step requires matrix-vector multiplications and that the matrices are sparse ones as the field at an FDTD node is affected only by the nearby fields. This is one of the key characteristics of the partial-differential equation (PDE) approach. On the other hand, another popular tool in computational electromagnetics is the integral equation method in which the integral equation is cast into a matrix equation via the use of MoM. In contrast to the PDE approach, the resulting matrix is a full one. Parallel computing strategies are effective tactics in handling full-matrix solutions, particularly when the matrix size is large. Although the MoM matrix is denser than the FDTD matrix, it is often much smaller in size.

Figure 15. Stable voltage across Gunn diodes. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

In the following subsection, we will discuss two different scenarios when dealing with full-matrix solutions. In the first scenario a direct matrix inversion scheme is tractable. When the available computer memory resources are exhausted, we need to solve the full-matrix equation iteratively.

2.2. Method of Moments (MOM)

2.2.1. Introduction. The integral equation solver such as the method of moments (MoM) can be used to analyze many electromagnetic field problems, including those appearing in printed circuits and microstrip antennas.

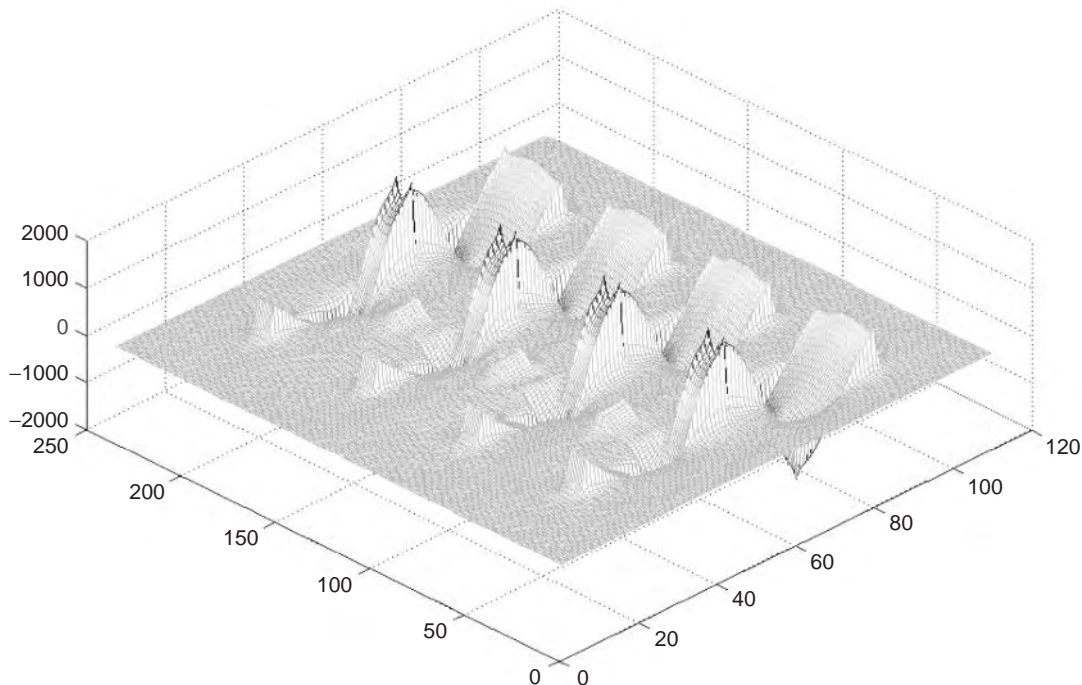

Figure 16. Electric field component E_z at dielectric-air interface. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

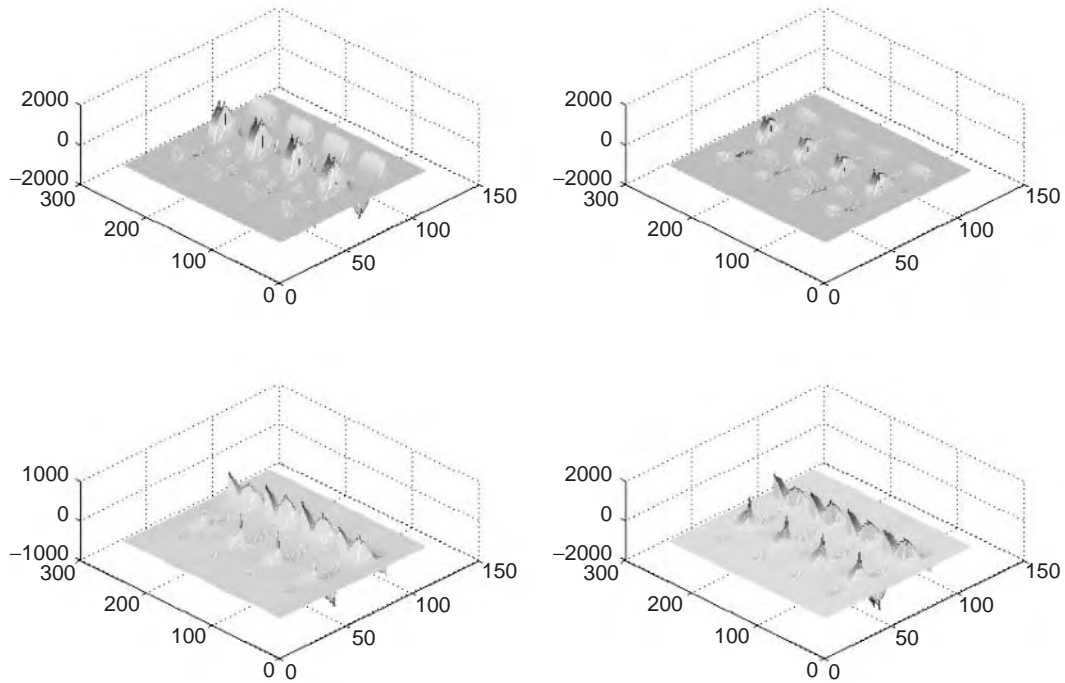

Figure 17. Electric field component E_z at dielectric–air interface at a different timestep. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

For these problems, the mixed potential integral equation (MPIE) formulation is often used. The MPIE is expressed as follows

$$\vec{E}^{\text{inc}} = j\omega\vec{A} + \nabla\phi \tag{23}$$

where \vec{E}^{inc} is the incident electric field and \vec{A} and ϕ are the vector and scalar potentials, respectively. The potentials can be expressed in terms of the unknown surface current density and the corresponding spatial domain Green

Table 1. Overall Performance of Parallel FDTD Code

Number of PCs	CPU Time (s)	CPU Time (min)	Speedup Factor	Efficiency (%)	Time Saving (%)
1	17382	289.7	1.0	100.0	0
2	8612	143.5	2.0	100.0	50.5
4	4323	72.1	4.0	100.0	75.1
8	2223	37.1	7.8	97.5	87.2
12	1525	25.4	11.4	95.0	91.2
16	1170	19.5	14.9	93.1	93.3
20	963	16.1	18.0	90.0	94.5
24	809	13.5	21.5	89.6	95.3

Figure 18. CPU time (s) with using different numbers of PCs.

Figure 19. Speedup factor with different numbers of PCs.

functions as follows:

$$\vec{A}(\vec{r}) = \int_S dS' \vec{G}_a(\vec{r}, \vec{r}') \cdot \vec{J}(\vec{r}') \tag{24}$$

$$\phi(\vec{r}) = \int_S dS' \vec{G}_q(\vec{r}, \vec{r}') \nabla' \cdot \vec{J}(\vec{r}') \tag{25}$$

Applying different basis functions to the MPIE in conjunction with weighting functions, the matrix equation is obtained as

$$[Z]\{J\} = \{E^i\} \tag{26}$$

where $[Z]$ is the impedance matrix, $\{J\}$ is the unknown current vector, and $\{E^i\}$ is the known excitation vector. One of the commonly used basis functions is the Rao–Wilton–Glisson (RWG) basis function [31]. This matrix equation is a linear matrix equation, and direct matrix

inversion or an iterative method can be used to solve for the solution, depending on the available computer memory.

To demonstrate the effectiveness of parallel computing in solving large-scale electromagnetic problems, we consider the analysis of the microstrip reflectarray antenna and densely packed microstrip interconnects. The resulting matrix equation is extremely large in size, and it is difficult to solve by a direct matrix inversion method in a single computer due to the large computer memory requirement and extensive CPU time. To solve this problem, we implement parallel algorithms to solve the matrix equation on a parallel computing platform. The idea of the parallel algorithm is to divide the large matrix into several smaller portions. Each portion of the matrix is stored in its corresponding computing node, and therefore the memory burden can be alleviated. Each node computes only its portion of the matrix, and the overall CPU time is also reduced. The parallel algorithm is also im-

Figure 20. Efficiency with different numbers of PCs.

Figure 21. Time saving with different numbers of PCs.

plemented in matrix–vector multiplication form to speed up the computing time in the iterative solver. In the following subsection, we will discuss solving the matrix equation with both the Gaussian elimination method and *LU* decomposition. The parallel versions of the Gaussian elimination method and *LU* decomposition [32,33] are also considered. Then, we concentrate on discussing the parallel version matrix–vector multiplication [32,33] for iterative solutions. Finally, the sparse matrix canonical grid method [34], which is a fast solver, will be presented.

2.2.2. Methods for Solving a System of Linear Equations. The matrix equation representing the MPIE shown in (26) can be written as follows:

$$\begin{bmatrix} Z_{11} & Z_{12} & \cdots & Z_{1N} \\ Z_{21} & Z_{22} & \cdots & Z_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ Z_{N1} & Z_{N2} & \cdots & Z_{NN} \end{bmatrix} \begin{bmatrix} J_1 \\ J_2 \\ \vdots \\ J_N \end{bmatrix} = \begin{bmatrix} E_1^i \\ E_2^i \\ \vdots \\ E_N^i \end{bmatrix} \quad (27)$$

In the following text, we will discuss full-matrix inversion methods for solving this linear matrix equation. Before we present their parallelized counterparts (Section 2.2.3), we will first concentrate on the conventional im-

plementation of the Gaussian elimination (Section 2.2.1) and *LU* decomposition (Section 2.2.2) methods.

2.2.2.1. Gaussian Elimination. There are two basic stages in the Gaussian elimination method. The first stage is to reduce the matrix into an upper triangular matrix. The form of the upper triangular matrix and its respective equations are shown as follows:

$$\begin{bmatrix} 1 & Z_{12}^{(1)} & \cdots & Z_{1N}^{(1)} \\ 0 & 1 & \cdots & Z_{2N}^{(2)} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{bmatrix} \begin{bmatrix} J_1 \\ J_2 \\ \vdots \\ J_N \end{bmatrix} = \begin{bmatrix} E_1^{i(1)} \\ E_2^{i(2)} \\ \vdots \\ E_N^{i(N)} \end{bmatrix} \quad (28)$$

$$Z_{kj}^{(k)} = \frac{Z_{kj}^{(k-1)}}{Z_{kk}^{(k-1)}} \quad (29)$$

$$Z_{ij}^{(k)} = Z_{ij}^{(k-1)} - Z_{ik}^{(k-1)} \times Z_{kj}^{(k)} \quad (30)$$

$$E_k^{i(k)} = \frac{E_k^{i(k-1)}}{Z_{kk}^{(k-1)}} \quad (31)$$

$$E_i^{i(k)} = E_i^{i(k-1)} - Z_{ik}^{(k-1)} \times E_k^{i(k)} \quad (32)$$

We rewrite (28) as

$$[U]\{J\} = \{\zeta^i\} \quad (33)$$

Figure 22. Equivalent SPICE circuit.

where $[U]$ is the upper triangular matrix and k is the iteration step. In matrix $[U]$, the diagonal entries are equal to 1 and all the coefficients of the lower triangular matrix $[L]$ are set to 0. In the second stage, we apply the backsubstitution procedure to obtain the unknown currents $\{J\}$. The sequential Gaussian elimination algorithm is shown in Fig. 26. There are three nested loops. The outer loop is the iteration step and is controlled by the k variable. The remaining two loops are used to perform the Gaussian elimination calculation in each iteration step. After all the iteration steps, the backsubstitution extracts the solution $\{J\}$. The counter i of the loop is reversed and starts from N to 1. It is decreased by 1 in each looped step.

Figure 27 shows the sequential Gaussian elimination algorithm in detail. In the iteration $k = 1$, the first row of the matrix and E_1^i are divided by Z_{11} and the calculations

$$\begin{aligned} Z_{4j}^{(4)} &= Z_{4j}^{(3)} / Z_{44}^{(3)} \leftarrow \begin{bmatrix} 1 & z_{12}^{(1)} & z_{13}^{(1)} & z_{14}^{(1)} & E_1^{i(1)} \\ 0 & 1 & z_{23}^{(2)} & z_{24}^{(2)} & E_2^{i(2)} \\ 0 & 0 & 1 & z_{34}^{(3)} & E_3^{i(3)} \\ 0 & 0 & 0 & 1 & E_4^{i(4)} \end{bmatrix} \rightarrow E_4^{i(4)} = E_4^{i(3)} / Z_{44}^{(3)} \end{aligned}$$

Figure 27. Flow of Gaussian elimination computation.

in (29) and (31) are performed. The quantity Z_{11} is set to 1 after the end of the first-row computation, and other rows in the matrix are then computed by (30). All the remaining entries in the first column are set to 0. The right hand side of (33), $\{E^i\}$, except E_1^i , is computed according to (32). In the iteration $k = 2$, the computation is similar to the iteration $k = 1$, but the first row and column remain unchanged at this moment. According to (29) and (31), the second row of the matrix and E_2^i are divided by Z_{22} . The third row and below are computed by (30) and (32), and all the remaining entries in the second column are set to 0.

Similar procedures are performed in the next iteration step, following the same iteration algorithm.

2.2.2.2. LU Decomposition. The *LU* decomposition method is similar to the Gaussian elimination method. There are three steps for solving the matrix equation in *LU* decomposition method:

1. *LU* factorization: $[Z] = [L][U]$
2. Forward substitution: $[L]\{y\} = \{E^i\}$
3. Backward substitution: $[U]\{J\} = \{y\}$

The Gaussian elimination method combines steps 1 and 2. Therefore, we can delete lines 6, 7, 13, and 14 in Fig. 26, and thus variables i and j are interchanged. The algorithm for the *LU* decomposition method is subsequently obtained after these modifications. The corresponding computer algorithm is shown in Fig. 28. The required equations in *LU* decomposition method are

$$Z_{ik}^{(k)} = \frac{Z_{ik}^{(k-1)}}{Z_{kk}^{(k-1)}} \tag{34}$$

$$Z_{ij}^{(k)} = Z_{ij}^{(k-1)} - Z_{ik}^{(k)} * Z_{kj}^{(k-1)} \tag{35}$$

The LU decomposition implementation is shown in Fig. 29. In the iteration $k=1$, the first row remains unchanged. The first column is computed by (34). Other matrix coefficients are computed by (35). In the iteration $k=2$, the first row, second row, and first column are fixed. The second column is computed by (34), and the other matrix coefficients are computed by (35). In the next iteration, the computation repeats the procedure of iteration $k=2$. The total number of iteration is $N-1$. After all the iteration steps are computed, the new matrix appears as (36) when N is set to 4 to simplify our discussion:

$$\begin{bmatrix} Z_{11} & Z_{12} & Z_{13} & Z_{14} \\ Z_{21}^{(1)} & Z_{22}^{(1)} & Z_{23}^{(1)} & Z_{24}^{(1)} \\ Z_{31}^{(1)} & Z_{32}^{(2)} & Z_{33}^{(2)} & Z_{34}^{(2)} \\ Z_{41}^{(1)} & Z_{42}^{(2)} & Z_{43}^{(3)} & Z_{44}^{(3)} \end{bmatrix} \quad (36)$$

This matrix stores $[L]$ and $[U]$ matrices. The matrix can be separated into two matrices:

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ Z_{21}^{(1)} & 1 & 0 & 0 \\ Z_{31}^{(1)} & Z_{32}^{(2)} & 1 & 0 \\ Z_{41}^{(1)} & Z_{42}^{(2)} & Z_{43}^{(3)} & 1 \end{bmatrix}$$

Lower triangle matrix

$$\begin{bmatrix} Z_{11} & Z_{12} & Z_{13} & Z_{14} \\ 0 & Z_{22}^{(1)} & Z_{23}^{(1)} & Z_{24}^{(1)} \\ 0 & 0 & Z_{33}^{(2)} & Z_{34}^{(2)} \\ 0 & 0 & 0 & Z_{44}^{(3)} \end{bmatrix}$$

Upper triangle matrix

We apply the forward substitution with the lower triangular matrix to find $\{y\}$ and then the backward substitution for extracting the solution.

2.2.3. Parallel Gaussian Elimination Method. The Gaussian elimination method implemented with a parallel algorithm is discussed in this subsection. We assume that four computing nodes are used. The matrix is separated into several portions with several rows of the original matrix in each portion. Each node stores its portion of the matrix as shown in Fig. 30.

In the iteration $k=1$, node 1 computes the assigned row partitioned matrix. At that time, other nodes are idle and wait for the results in node 1. Data communication among all nodes is required after node 1 finishes its computation. Other nodes can now begin to compute the computation for the iteration $k=1$. In the iteration $k=2$, node 1 is idle and does not participate in any computation

```

Figure 28. Algorithm of LU decomposition.

and data communication. First, only node 2 computes the assigned row partitioned matrix. Other nodes are idle and wait for receiving results from node 2. Other nodes begin their computations after the data communication. In the iteration $k=3$ and $k=4$, the computation procedures are similar to the iteration $k=1$ and $k=2$ but the computation for iteration $k=4$ does not include any data communication. The parallel Gaussian elimination algorithm is slightly different from the sequential algorithm depicted in Fig. 26 and it is shown in Fig. 31.

2.2.4. Pipelined Parallel Gaussian Elimination. The parallel Gaussian elimination version mentioned above can reduce the memory requirement and computing time. However, the efficiency is not high because three nodes remain idle and continue to wait for one of the nodes to finish its computation during each iteration step. In order to enhance the computation efficiency, an asynchronous parallel version of the Gaussian elimination called *pipelined parallel Gaussian elimination* is used. The weakness of the synchronous parallel Gaussian elimination is that each node starts its computation after the previous node completes its computation. In contrast, each iteration k of the computation can be taken at the same time in the pipelined parallel Gaussian elimination and, thus, can further reduce the computing time. The procedure of the method is detailed in Fig. 32.

In Figs. 32b–32e, node 1 computes its partition. Other nodes are idle until node 1 finishes the first iteration. The row data will be sent to node 2 from node 1, but at that time other nodes are also idle. The received row data will be stored and passed to node 3. Similarly, other nodes store and pass the received data to the next node, namely, node 4. Node 2 starts its computation after passing the

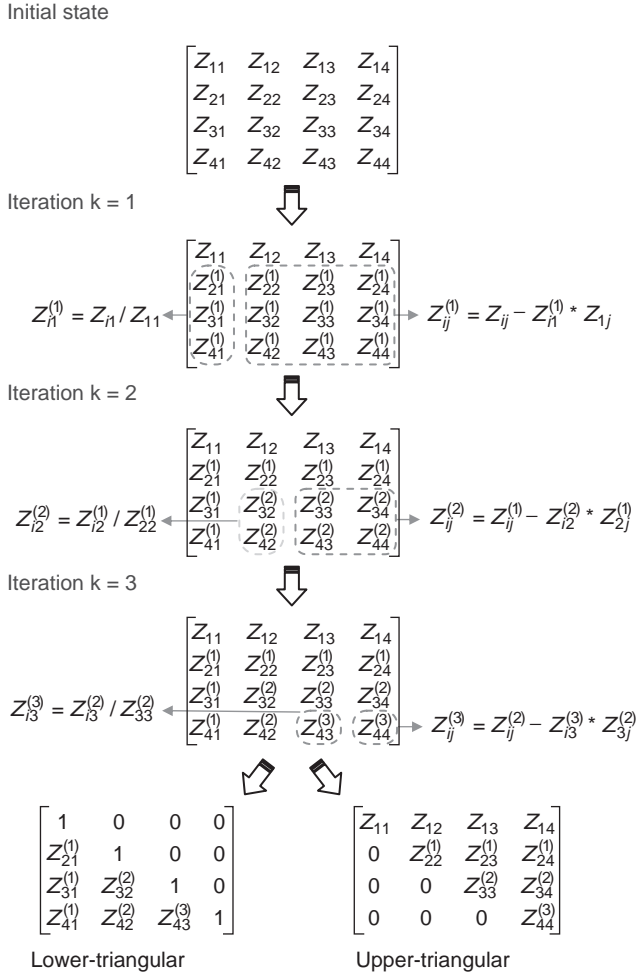

Figure 29. Flow of LU decomposition.

row data. Other nodes repeat similar procedure. In Fig. 32f, node 2 completes the computation of iteration $k=1$ and starts the computation of iteration $k=2$. At the same time, node 3 starts the computation of iteration $k=1$. Two iteration computations appear at the same time. In addition, node 4 passes the row data of iteration $k=1$. In Fig. 32g, data communication between nodes 2 and 3 appears after nodes 2 and 3 finish their respective iteration computation. Node 4 then starts the computation of iteration $k=1$. In Fig. 32h, node 4 completes the computation of the iteration and receives the row data of iteration $k=2$. Node 5 starts the computation of iteration $k=1$. In Fig. 32i, node 3 starts the computation of iteration $k=2$ and nodes 4 and 5 perform data communication. The iteration procedures continue until the upper triangular matrix is obtained by the pipelined parallel implementation as shown in Fig. 32q. The pipelined parallel algorithm is shown in Fig. 33.

The implementation of the parallel version of LU decomposition is slightly different from the parallel version of the Gaussian elimination. As we can see in Figs. 27 and 29, the computation of Gaussian elimination starts from the row of matrix $[Z]$. Both matrices $[Z]$

and $[E]$ are needed to involve in the calculation. On the other hand, the computation of LU decomposition starts from the column of matrix $[Z]$. Only matrix $[Z]$ is involved in the calculation. Therefore, a similar parallel LU decomposition algorithm as discussed above can be formulated using a modified-form parallel Gaussian elimination algorithm.

2.2.5. Numerical Results (Gaussian Elimination/ LU Decomposition). In this subsection, we will show the numerical results of implementing the Gaussian elimination and LU decomposition. Both results from sequential and parallel codes will be shown to illustrate the effectiveness of parallel computing. All the computations are performed on the parallel computing platform, which consists of 24 nodes of Pentium III 1-GHz processors. Figure 34 shows the CPU time for solving a full matrix with the Gaussian elimination. Results from the parallel Gaussian elimination and pipelined parallel Gaussian elimination methods as discussed in the previous subsection are also shown in the figure for comparison. As we can see from the figure, the CPU time for the sequential method radically increases when increasing the matrix size. On the other hand, both parallel methods can greatly reduce the CPU time. Figure 35 shows the speedup factors with both parallel methods versus the matrix size. We can see that the pipelined parallel Gaussian elimination method is higher in efficiency compared with the parallel Gaussian elimination method. The CPU times with the LU decomposition computation, including sequential, parallel, and pipelined parallel methods, are shown in Fig. 36. Similar to the results shown in Fig. 34, both parallel methods can essentially reduce the CPU time when dealing with a large matrix size. Again, the pipelined parallel LU decomposition method shows higher efficiency compared with the parallel LU decomposition method as shown in Fig. 37. We can see from Figs. 35 and 37 that the speedup factor is greater those that of the computing nodes used. This may be due to the loop overheads in sequential algorithms and insufficient cache size in the single computing node [35].

2.2.6. Matrix-Vector Multiplication. The parallel matrix-vector multiplication is introduced in this subsection. The sequential matrix-vector multiplication algorithm is to perform the calculation of $[Z]\{a\} = \{b\}$. Each of solution $\{b^i\}$ is equal to the dot product of row i of the matrix $[Z]$ with the column vector $\{J\}$. The sequential implementation is shown in Fig. 38. In the parallel matrix-vector multiplication algorithm, matrix $[Z]$ can be partitioned by either rows or by columns. The choice of partitioning by rows or columns mainly depends on the programming language used. For instance, since the arrays in C language are stored in row-major order, array elements in each row will store contiguously in memory. Thus, it is appropriate to choose partitioning by rows if C programming language is used. On the other hand, since the arrays in FORTRAN language are stored in column-major order, it is appropriate to choose partitioning by column if FORTRAN language is used. Both partitioning methods can distribute the required memory of storing the matrix

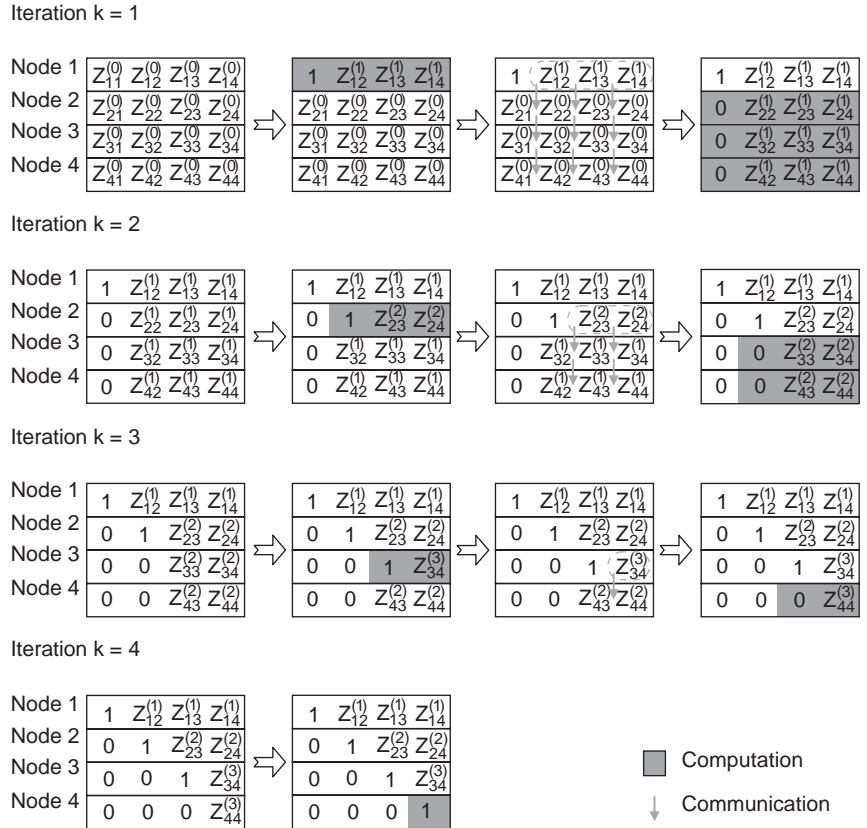

Figure 30. Workflow of parallel Gaussian elimination.

among the nodes. Therefore, the computation time can be shortened with the handling of a partitioned matrix in each node.

Suppose we adopt the row partitioning parallel algorithm to be implemented on an M -node parallel platform. Matrix $[Z]$ is partitioned into M portions of $[Z]$ by rows, and each portion is stored in its corresponding node. However, the whole vector $\{a\}$ is needed in each node as shown in Fig. 39. This should not be a problem as its size is only a small fraction of that of the partitioned portion of matrix $[Z]$. In the matrix-vector multiplication, each node computes only its portion of $[Z]$ and stores its results in $\{b^i\}$. For instance, node 1 computes only the result b_1^i and b_2^i . Similarly, entries in $\{b^i\}$ correspond to the row number of the partitioned matrix are computed in other nodes. However, as each node only computes a portion of $\{b^i\}$, the result is not complete. In order to compile the complete result of $\{b^i\}$ in each node, data communication among all nodes is required. We can use the callable MPI library MPI_ALLGATHER to collect the result $\{b^i\}$ from each node and broadcast the properly arranged $\{b^i\}$ to all nodes. The algorithm is shown in Fig. 40. If other nodes need the corresponding result of $\{b^i\}$ in each node, we can instead use the callable MPI library MPI_GATHER [5] in data communication. In that case, only node 0, the master node, gets the result of the entire $\{b^i\}$. The second partition method is the parallel column partition algorithm as shown in Fig. 41. Matrix $[Z]$ is partitioned by column, and the vector $\{a\}$ is partitioned by row. The result $\{b^i\}$ in

each node is obtained by matrix-vector multiplication. However, the result $\{b^i\}$ in each node is not complete as only some columns are involved in the matrix-vector multiplication. Therefore, we need to gather all $\{b^i\}$ in each node, sum them individually during the data communication, and broadcast the correct results $\{b^i\}$ to all nodes. In that case, we can use the callable MPI library MPI_ALLREDUCE. The algorithm is shown in Fig. 42. Similarly, the callable MPI library MPI_REDUCE can be applied instead in the data communication if the partial result of $\{b^i\}$ does not have to be distributed to all nodes.

2.2.6.1. Sparse Matrix Canonical Grid (SMCG) Method.

In the previous subsection, we discussed the parallel version of the matrix-vector multiplication. However, each node also requires a large memory to store its respective rows or columns of the matrix. In this subsection, we introduce another method, called the *sparse matrix canonical grid* (SMCG) method [36,37], to reduce the memory requirement and maintain speedy computation. The basic idea is the decomposition of the impedance matrix, which is divided into two parts: near interaction and far interaction. The near-interaction part corresponds to a sparse matrix, while that of the far interaction corresponds to a dense matrix. The sparse matrix-vector multiplication part is carried out in the conventional manner. In contrast, the dense matrix-vector multiplication part is computed efficiently using the fast Fourier transforms (FFTs).

Figure 31. Algorithm for parallel Gaussian elimination method.

In the SMCG method [36,37], the impedance matrix can be represented as the sum of the strong neighborhood interactions sparse matrix $[Z^S]$ and the weak far-interaction dense matrix $[Z^W]$ as

$$[Z] = [Z^S] + [Z^W] \quad (37)$$

Figure 43 shows the relationship of the strong neighborhood interactions and weak far interactions.

Through Taylor expansion of the Green functions about uniformly spaced canonical gridpoints overlying the triangular discretization (see Fig. 44), we need to compute the Green function between the two centroids (x_i, y_i) and (x_j, y_j) of two interacting triangles. The Green function can be evaluated by either direct or indirect computation. The indirect Green function between the centroids of two interacting triangles includes three parts. The first part is from the point (x_j, y_j) to its nearest gridpoint (x_{j0}, y_{j0}) . The second and third parts are from gridpoint (x_{j0}, y_{j0}) to another gridpoint (x_{i0}, y_{i0}) and from (x_{i0}, y_{i0}) to (x_i, y_i) . This indirect computation corresponds to Taylor series expansion about the canonical gridpoints at (x_{j0}, y_{j0}) and (x_{i0}, y_{i0}) as shown in Fig. 44. The appropriate Green function can

be written as

$$\begin{aligned}
 G(\rho_{ij}) &= \sum_{m_1} \sum_{n_1} \sum_{m_2} \sum_{n_2} \frac{x_{d_i}^{m_1} y_{d_i}^{n_1} x_{d_j}^{m_2} y_{d_j}^{n_2}}{m_1! n_1! m_2! n_2!} \\
 &\times \frac{\partial^{m_1+m_2}}{\partial x_{i0}^{m_1+m_2}} \frac{\partial^{n_1+n_2}}{\partial y_{i0}^{n_1+n_2}} G(\sqrt{x_{d_{ij}}^2 + y_{d_{ij}}^2})
 \end{aligned} \quad (38)$$

where $x_{d_{ij}} = x_{i0} - x_{j0}$ and $y_{d_{ij}} = y_{i0} - y_{j0}$. It is not difficult to see that $G(\sqrt{x_{d_{ij}}^2 + y_{d_{ij}}^2})$ and its derivatives are translationally invariant. Consequently, (37) can be written as

$$\begin{aligned}
 \{[Z^S] + [Z^W]\}[I] &= \left\{ [Z^S] + \sum_{i=0}^k [Z^W_i] \right\} [I] \\
 &= [V]
 \end{aligned} \quad (39)$$

where k is the total number of terms in the expansion. We can solve Eq. (39) by an iteration method. The iterative solution is expedited by applying parallel computing

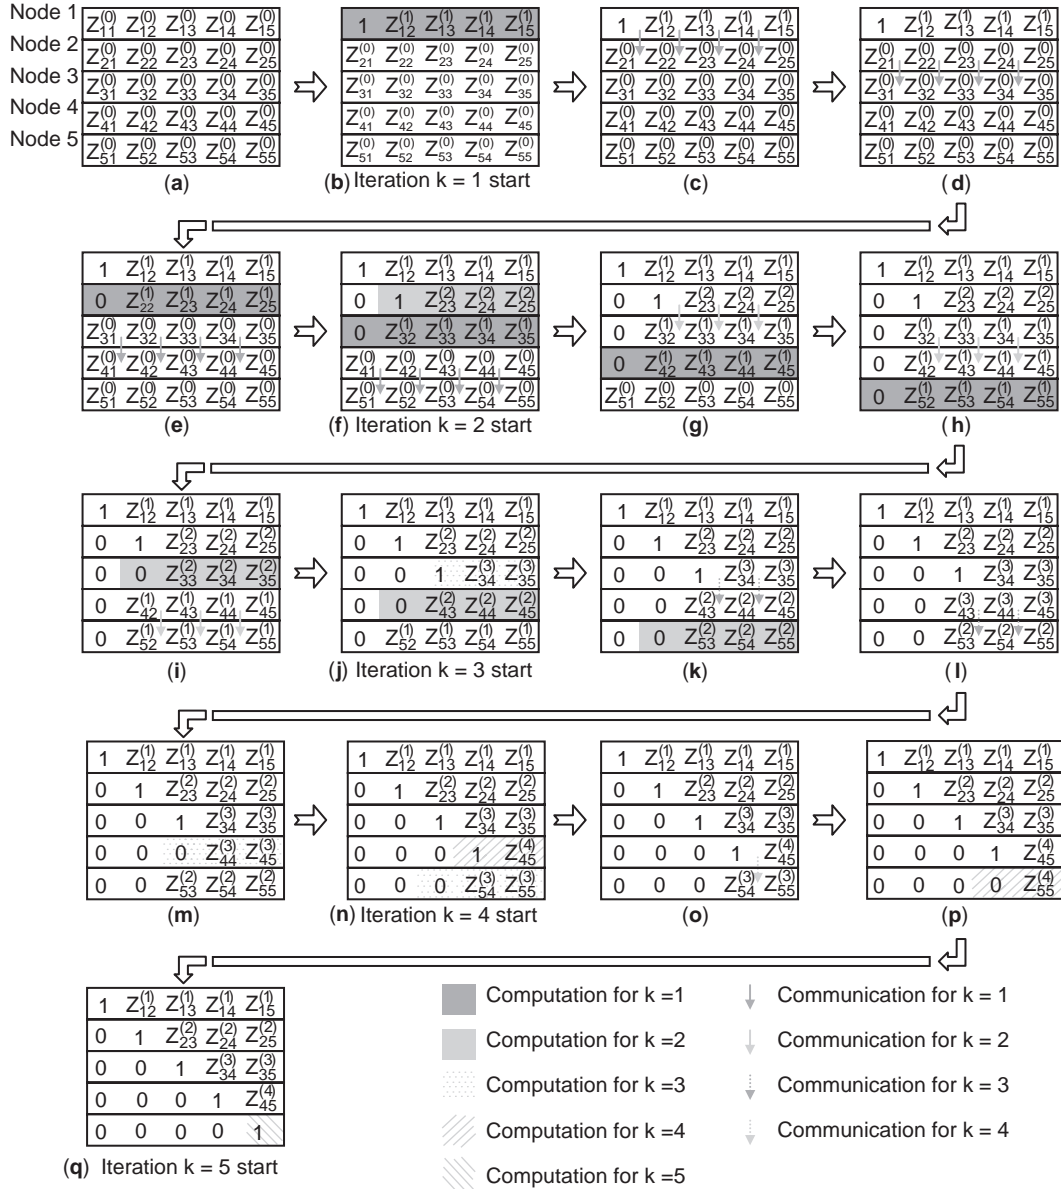

Figure 32. Workflow of pipelined parallel Gaussian elimination method.

techniques in the matrix–vector multiplication between $[Z]$ and the current vector in the n th iteration $[I_n]$. The first-order and higher-order solutions in the iterative procedure are defined as follows:

$$\{[Z^s] + [Z_0^w]\}I_1 = V \tag{40}$$

$$\{[Z^s] + [Z_0^w]\}I_{n+1} = V - \left\{ \sum_{i=1}^k [Z_i^w] \right\} I_n \tag{41}$$

From (41), more terms in the expansion series of $[Z^w]$ can be relocated to the left-hand side of the matrix equation to reduce the CPU time. Each order is solved by the biconjugate gradient (BCG) iterative solver [38].

The closed-form expressions of the spatial domain Green function [39] can be obtained by using the fast

Hankel transform (FHT) algorithm [40] and matrix pencil method [41]. Such closed-form expressions make the Taylor’s series expansion solvable analytically. Because of the translationally invariant kernels in the expanded Green functions, the weak matrix vector multiplication in the iterative procedure can be efficiently performed via the fast Fourier transforms. The matrix–vector multiplication corresponding to the far-interaction contributions can be written as

$$\begin{aligned} [Z^w][I_n] &= \left\{ \sum_{i=0}^K [Z_i^w] \right\} [I_n] \\ &= \left\{ \sum_{i=0}^K [T_i][G_i][T_{s_i}] \right\} [I_n] \end{aligned} \tag{42}$$

Figure 33. Algorithm for pipelined parallel Gaussian elimination method.

where the diagonal matrix $[T_s]$ corresponds to a premultiplication, while the other diagonal matrix $[T_t]$ corresponds to a postmultiplication. Note that the premultiplication corresponds to shifting the centroids of the basis triangles to their nearest gridpoints. The multiplication of the block-Toeplitz matrix corresponds to the inclusion of all

the interactions among the uniformly spaced canonical gridpoints. The final postmultiplication corresponds to translating the interactions at the gridpoints back to the centroids of the testing triangles. The multiplication with the block-Toeplitz matrix $[G_i]$ can then be performed via the FFT. It should be noted that some of the matrix-vector multiplications corresponding to the weak interactions are moved to the right-hand side of (39) to reduce the number of FFT operations in the iterative solution.

2.2.6.2. Parallel Version of the SMCG Method. The parallel code is implemented on the Beowulf parallel computer. The parallel code is written with the message-passing interface (MPI) [5] and the MPI version of the Fast Fourier Transform in West FFTW [7] is employed to perform the FFTs. The matrix is divided into subsections according to the number of computing nodes used. Figure 45 is a pictorial representation of the matrix decomposition. Note that N_{grid} represents the number of Cartesian canonical grid nodes used in the SMCG method and M the computing nodes used.

In regard to the sparse matrix-vector multiplication, the first advantage is that only a portion of the sparse

matrix is stored in each computing node. Therefore, parallel computing can solve the problem with a huge number of unknowns. The other advantage is that each computing node computes only a portion of the sparse matrix and thus can reduce CPU time.

In computing the dense matrix–vector multiplication, we use FFTs to perform matrix–vector multiplication with block–Toeplitz matrix $[G_i]$ as in (42). The block Toeplitz matrix involves $2N_{\text{grid}} \times 2N_{\text{grid}}$ array elements, where N_{grid} is the number of gridpoints in x and y axes. We use

FFT_w to compute the convolution between $[G_i]$ and the product of the diagonal matrix $[T_{s_i}]$ and $\{I_n\}$; therefore the matrix $[G_i]$ can be partitioned into M portions. Because of the distribution of $[G_i]$, each computing node handles only the corresponding elements of diagonal matrices $[T_s]$ and $[T_t]$ in the calculation of the matrix operation $[T_t][G_i][T_x]$. As a result, both CPU time and memory requirement can be reduced. However, if one of the nodes contains substantially larger amount of elements than other nodes, this node will reduce the overall speed of the computation.

2.2.6.3. Numerical results (MOM/SM/CG). In this subsection, we show two electromagnetic problems with implementation of the SMCG method. One is the densely packed interconnect problem, and the other one is the planar microstrip reflectarray. First, we discuss the densely packed interconnects using SMCG [37]. Figure 46 shows the top view of 12 densely curved microstrip lines. The microstrip structure contains a dielectric substrate backed by a ground plane. The thickness of the dielectric substrate is 1 mm, and the dielectric constant ϵ_r is 12.6. The length of each line is 6.2 mm, and the width is 0.3 mm. The canonical grid is set at $\Delta x = \Delta y = 0.1$ mm, which is about 30 points per linear dielectric wavelength. The first

and last lines are excited in our example. The amplitude of current density for each microstrip lines is shown in Fig. 47. From the figure, the mutual coupling effects and induced current on each line are observed. In this example

Figure 43. Near and far interactions.

Figure 44. Canonical grid for Taylor series expansion.

with 8136 unknowns, 16 PCs each with a Pentium II 450-MHz processor and 256 MB of RAM are used. It takes about 5 min to complete the computation. The convergence of the biconjugate gradient method (BCGM) for each order is shown in Fig. 48. The convergence of percentage error is shown in Fig. 49.

Another microstrip problem with a large number of unknowns is also studied. The geometry and current distribution are shown in Fig. 50. There are 35,410 unknowns in this problem. The thickness and dielectric constant of the substrate are $h = 1$ mm and $\epsilon_r = 12.6$. The operation frequency is 30 GHz. The horizontal and vertical dimensions are 6.1 mm. Since the width of separation between adjacent small sections and the width of the hole are only 0.1 mm, the canonical grid is set at $\Delta x = \Delta y = 0.05$ mm. This structure is excited in the middle of the left-hand side. The parallel code is implemented in the parallel computer platform with eight Pentium II 600-MHz processors. The total CPU time for this problem is

Figure 45. Pictorial representation of decomposition of block-Toeplitz matrix in SMCG method.

15.89 min. When the same code is run on the Beowulf with eight Pentium III 1-GHz processors, the total CPU time is reduced to 6.11 min. When 16 1-GHz processors are used, the total CPU time is 4.09 min.

Another example of using the SMCG method is the analysis of planar microstrip reflectarray. The reflectarray consists of 1117 dipoles printed on a Duroid 2.5 substrate, as described in Ref. 40. The design frequency is 24 GHz. The unit cell dimensions T_x and T_y are both equal to $0.4 \lambda_0$. It should be pointed out that the actual spacings of the

Figure 46. Geometry and discretization of microstrip lines. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

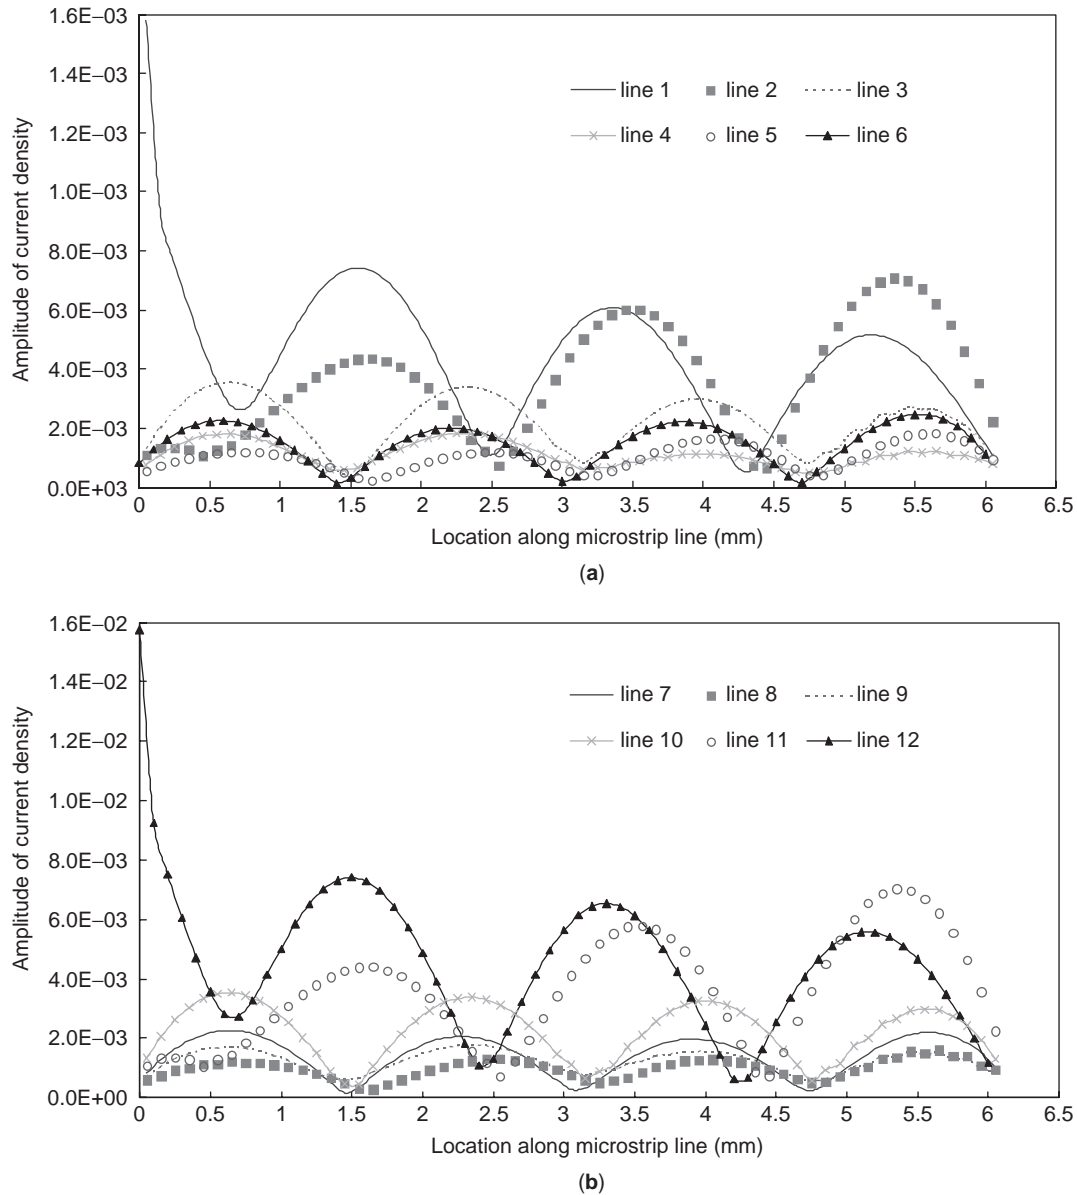

Figure 47. (a) Current distributions on microstrip lines 1–6; (b) current distributions on microstrip lines 7–12. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

canonical grid Δx and Δy are not necessarily equal. The dielectric constant and the thickness of the dielectric substrate are 2.5 and 0.76 mm, respectively. The layout of this dipole reflectarray is shown in Fig. 51. A rectangular horn with an aperture size of 10.7×4.3 mm is used to excite the reflectarray. The horn is located at $x_h = -216$ mm, $y_h = 0$ mm, $z_h = 160$ mm, as shown in Fig. 52. With eight nodes of dual Intel Pentium III 1-GHz processor and 23,676 unknowns, the computation time with the SMCG method for different number of discretization grids is shown in Table 2. The convergence of the BCGM for each order is shown in Table 3. As we can see from the tables, an increase in the number of canonical gridpoints also increases the computational time needed to perform the FFTs and hence leads to a longer total solution time.

The strong sparse matrix $[Z^s]$ in (37) is computed directly if the interactions are within the region $N_{near}\Delta x \times N_{near}\Delta y$. The convergence behaviors of each order of the SMCG method using 512×512 grids are shown in Fig. 53. The simulated radiation patterns in the $y-z$ plane are plotted in Fig. 54 with indistinguishable results using different canonical grid sizes. The experimental result, reported in Ref. 42, is also plotted in the same figure for comparison, and it is evident that the simulation and measured results compare well with each other.

Another reflectarray antenna consisting of 1117 square patches has been designed, fabricated, and measured. The design frequency was 28 GHz, and T_x and T_y were equal to $0.4 \lambda_0$. The dielectric constant and the thickness of the dielectric substrate were 2.94 and 0.76 mm, respectively. A

rectangular feed horn with an aperture of 23.64×17.3 mm was offset-located to provide the necessary excitation. Although not shown here, the radiation pattern of the feed horn was measured to ensure that it radiates an adequate level of power when illuminating the reflect-

array. The mainbeam scan angle at -3 dB level is about $\pm 22^\circ$; hence the angles θ_1 and θ_2 in Fig. 52 should fall within the 22° limit. The location of the feed horn was chosen to be $x_h = -216$ mm, $y_h = 0$ mm, and $z_h = 160$ mm, so that the θ_1 and θ_2 angles were approximately 18° . The layout of a 1117-square-patch reflectarray is shown in Fig. 55. The measurement was performed with an NSI near-field measurement system.

With eight nodes of dual Intel Pentium III 1 GHz and 59,880 unknowns, the computational time with SMCG implemented on a 512×512 grid is approximately 121.7 min. The number of zeroth- and higher-order iterations needed are 1650, 308, and 99, respectively. The simulated and measured far-field patterns of a 1117-square-patch microstrip reflectarray in y - z plane are shown in Fig. 56. As we can see from the figure, there is a sharp mainbeam in the center, as desired. Although the first sidelobe of the pattern is not clearly observed in the measured result, the trend of the simulated peak location matches well with the measured result. The convergence behaviors of each order of the SMCG method using 512×512 grids are shown in Fig. 57.

As we can see from the examples above, the SMCG method implemented on parallel computers can efficiently handle and solve any large electromagnetic problem with a large number of unknowns.

Table 3. Convergence of the BCGM for Each Order

3. SUMMARY

In this article, we discuss some parallel algorithms and programming clues for solving large-scale electromagnetic problems on the Beowulf PC cluster. Parallel implementation of commonly used computational techniques such as FDTD and MoM methods are discussed in detail. Manipulation of FDTD calculation is one of the key characteristics of the PDE approach. In contrast to the PDE approach, the resulting matrix in MoM calculation is a full one. Several methods for solving a full-matrix solution are discussed. When the available computer memory resources are exhausted, we need to solve the full-matrix equation iteratively. We also discuss the SMCG method to reduce the memory requirement and maintain speedy computation of matrix-vector multiplication. Numerical examples presented are drawn from various applications of computational electromagnetics, and they are successfully solved by means of parallel computing, using various algorithms presented in this article.

1. INTRODUCTION

Advances in digital and microwave electronics have resulted in increasing operating frequencies, reduction in circuit size, and the concomitant increase in circuit complexity. Design of microwave circuits and systems requires understanding the proximity interactions between components, effects of radiation, ohmic loss, and other properties, which are strongly dependent on the physical geometry, and cannot be predicted by circuit-theoretic approaches. Increasingly, full-wave electromagnetic (EM) simulation techniques, which calculate the EM field within and around the circuit, are being used in the analysis of high-speed digital circuits and microwave and millimeter-wave integrated circuits (MMICs). Commonly used simulation methods include the method of moments (MoM) [1], the finite-element method (FEM) [2], the finite-difference time-domain (FDTD) method [3], and the transmission-line matrix method [4]. Commercial software based on these methods is available to the microwave engineer. EM simulation, however, is typically computation-intensive and therefore finds use predominantly in microwave circuit analysis. It has attracted somewhat limited attention to the design and optimization of microwave circuits. Therefore, it is desirable to investigate means of improving the efficiency of full-wave methods so that they become more suitable to performing complex design-oriented tasks demanded by the increasing circuit complexity in the microwave industry.

It is instructive to conceptually understand how circuit parameters are calculated using full-wave methods in order to realize reasons for their limited use in design. In all these methods, the circuit parameters, such as admittance parameters of a matching transformer, are determined from the currents and voltages derived from the EM field within the circuit domain. In MoM, the surface of the circuit or scattering object (e.g., a microstrip antenna) is discretized into polygonal patch elements and the currents on these elements are determined by solving an

integrodifferential equation for the EM field on the surface. By using appropriate piecewise-approximate representation of the current within each patch, and forming moments involving pairwise current–field interactions between all the patches, a system of matrix equations is obtained that relates the patch currents to the impressed voltage or field. The matrix is dense (in fact *full*) because all the near-field and far-field interactions between the patch currents are accounted for. The currents are computed by solving such a linear system. Therefore, in design applications involving MoM simulations, one solves a large linear system of equations at *each design step* for the surface currents on the scattering object.

In FEM, a three-dimensional (3D) circuit region is divided into volume elements such as tetrahedra, and an energy functional, in the form of an integrodifferential operator equation, is formulated on the vector field components. Minimization of the functional determines the values of the field components within the region of interest. The unknown field is approximated by a polynomial function within each volumetric cell, and the Rayleigh–Ritz procedure is applied to minimize the functional, resulting in a system of linear equations. Although the procedure produces a sparse matrix because only the interactions between nearest neighbors need to be accounted for, FEM involves discretization of the volume around the circuit region all the way up to an artificial terminating boundary called the *absorbing boundary*. Thus, in design applications, FEM requires the solution of a large system of linear equations for the EM field in an entire 3D grid surrounding the object.

The FDTD method, first formulated by Yee [5], involves expressing Maxwell’s equations in finite difference form in an entire 3D spacetime lattice encompassing the scattering object, which is terminated in an absorbing boundary for open-region problems. The finite difference approximations are iteratively updated at each timestep for each spatial lattice point using an *explicit* method such as the marching-on-time or leapfrog algorithm. The spatial and temporal sampling increments are selected according to the Courant stability condition necessary (but not sufficient) for stability of the time-marching algorithm. Time-marching iterations are terminated when the desired steady-state response is observed. A major drawback of the FDTD method is that it is highly computer-intensive and suffers from lack of accuracy due to dispersion and other roundoff errors that accumulate in time and space. Therefore, unlike MoM and FEM, which have been coupled with optimization algorithms [6,7], the FDTD method has been used only in the analysis phase. Efforts to improve the accuracy and reduce the computational requirements have received significant attention more recently, and one such effort, related to extrapolation of time sequences, will be discussed in Section 2.

The TLM method exploits the relationship between EM field quantities in a computational volume and voltages and currents on equivalent transmission lines to solve boundary value problems applicable to microwave circuits. Equivalent transmission-line equations for the transverse electromagnetic (TEM) mode are derived from Maxwell’s equations and boundary conditions of the

problem. The TEM modal equations for voltage and current are expressed in finite difference form on a timespace lattice of transmission lines, terminated as necessary by an absorbing load, a short circuit, or an open circuit. Specific lattice points are excited by voltage or current pulses, and pulse propagation through the lattice is evaluated iteratively until a suitable convergence criterion is satisfied. The TLM method has a number of similarities with the FDTD method and thus suffers from the same drawbacks alluded to earlier.

From the summary above, it is evident that EM simulation methods are in general of limited value in microwave design unless their computational efficiencies can be improved. As a means to achieve this goal, it is desirable to investigate independent “signal” models, which accurately represent the circuit parameters of interest in the design space spanned by the full-wave simulation, and can be constructed from a limited number of EM simulations. Within this space, one can then utilize the model for computing the frequency response at each design iteration, thus minimizing the need for intensive computer simulations. This article focuses on the development and validation of such signal models.

We present techniques for modeling time-domain signatures in Section 2 and those applicable to frequency-domain data in Section 3. The emphasis is on practical implementation of the algorithms, rather than the underlying theory. The latter has been published in signal processing and control systems literature, and applicable references are cited throughout the article. Sufficient implementation details are included to enable the reader to generate computer programs for the algorithms with minimal effort. Microwave circuit and antenna examples are presented for both time- and frequency-domain models to illustrate the effectiveness of the proposed algorithms and to validate them. Important conclusions on the algorithms and their implementation are summarized in Section 4.

2. TIME-DOMAIN MODEL

The EM response of any scattering object can be conveniently represented as a sum of complex sinusoids whose amplitude and phase are closely related to parameters of interest (e.g., complex propagation constants on a transmission line and their modal response). This feature has been applied to signal modeling in EM with some success, particularly in time-domain methods such as the FDTD method. Signal processing techniques have been widely used to estimate microwave circuit parameters from time-domain EM simulations [8–13], and to characterize the system response from transient data extracted from simulations or measurements [14–17]. Important circuit parameters, such as quality factor of microstrip antennas [8], resonant frequencies of dielectric resonators [10], characteristic impedance and propagation constant of waveguides [12], and *S*-parameters of discontinuities [13], have been computed using these methods. In this section, we review how the complex exponential signal model can be constructed from a short time-varying data sequence computed by the FDTD method, and extrapolate

this model three- or fourfold to fill the remainder of the sequence [13]. Since the FDTD simulation is used for a relatively short time window compared to overall length of the final time signature, utilization of the signal model in the FDTD method improves its computational efficiency considerably. Although the signal model is demonstrated with the FDTD method because of its popularity in time-domain EM simulations, the model can be used to process the data generated by any time-domain simulation (see Ref. 18 for model-based extrapolation of time-domain MoM data), as well as measured data.

The FDTD technique is well-established as a versatile analytical tool for solving EM problems associated with characterizing scattering and radiation from microwave structures. However, it is also recognized that for accurate characterization of the underlying scattering modes of even relatively simple structures, very long time sequences (TSs) need to be computed. FDTD simulations are highly computation-intensive, and generation of these long TSs can be prohibitively expensive. The problem becomes particularly acute for high- Q structures with energy storage features such as cavities and cavity-backed apertures, which tend to manifest relatively long decay times requiring thousands of timesteps. The number of timesteps n_{\max} that are computed also increases with the maximum electrical size of the structure. Depending on the excitation and the structure being analyzed, in three dimensions, $n_{\max} \propto N^\beta$, where N is the number of volumetric grid cells used to model the structure and $\beta < 1$ [3]. As an example, for a box that measures $5\lambda \times 5\lambda \times 10\lambda$ at the highest operating frequency and divided into $50 \times 50 \times 100$ cubical cells (10 cells per wavelength), assuming that it takes the equivalent of five round-trip traverses across the maximum diagonal dimension of the box to achieve steady state, we estimate $n_{\max} = 2450$ and $\beta = 0.63$. A timestep $\Delta t = \Delta/2c$, where Δ is the space step and c is the speed of light, is used in the calculation above. Although n_{\max} appears to be relatively small, total simulation time can still be quite large, as the execution time for one temporal iteration over the whole object increases linearly with the number of spatial cells.

Several researchers have attempted to model time-domain EM data as the impulse response (IR) of an autoregressive moving-average (ARMA) transfer function [9–13]. The ARMA model involves both poles and zeros of the transfer function whereas the simpler AR model involves only poles [19–21]. In order to avoid long computation times and the associated cost, the ARMA or AR model of the TS is constructed from short “early” data records. The estimated (or trained) “model” is then used to predict the remainder of the TS by extrapolation.

Determination of ARMA parameters via IR fitting is a deterministic nonlinear optimization problem [21]. In EM literature, Prony’s method (PM) and its variations have played a dominant role in the “late time” extrapolation [8–12]. This is due primarily to the fact that PM approximates the true nonlinear modeling problem of minimizing the fitting error (FE), and converts it into a simpler linear estimation problem. In fact, it is shown in this section that PM actually optimizes an equation error (EE), which is a linearized approximation of the true nonlinear FE. As a

consequence, Prony’s approach suffers from certain drawbacks. Since it attempts to minimize an approximated error between the IR model and the simulated TD data, it tends to overmodel the system to achieve a close fit to the data. In fact, when there are deep nulls in the frequency domain magnitude spectra, significantly high model orders are needed to achieve a close fit. Furthermore, overmodeling may lead to instability, as demonstrated by simulated results in the sequel below.

The underlying assumption for system identification using PM (or linear predictor, stochastic AR/ARMA modeling, or similar approaches) is that the measured output TS can be characterized well as the response of a linear time invariant (LTI) system, represented by a ratio of polynomials. Figure 1 shows a typical input–output scenario of an unknown system to be modeled. System modeling using the output response of such a rational system can be categorized into two distinct classes, stochastic or deterministic, as summarized next:

- *Stochastic or Random Process.* In this case, usually only the output $y(n)$ is available for identification purposes. The input process $x(n)$ is either unavailable or cannot be measured, and is usually assumed to be “white noise” within the bandwidth of interest. Traditional stochastic modeling techniques assume that the process $y(n)$ is stationary and make use of its second-order statistics or autocovariance values to estimate the denominator and/or the numerator parameters of the unknown LTI system. A large class of “spectrum estimation” techniques belong to this category [19,20]. Interestingly, this inherent “random process” assumption has been made often, albeit implicitly, in extracting the poles of EM systems from transient response using Prony’s method [10,14,15], and the generalized pencil of functions (GPoF) method [16,17,22–24]. GPoF method utilizes certain properties of data and covariance matrices formed with the system response, whose generalized eigenvalues yield the poles.
- *Deterministic Process.* In this case, both the input excitation as well as the output sequence of the system are either known or can be measured [21]. The most common example is to estimate the system parameters from the output IR sequence [25–37]. The more general case, when both input and output sequences are directly used to estimate the unknown system parameters, is known as system identification, and has also received considerable attention [38–42]. Example applications of this deterministic approach to EM problems may be found in the literature [43–47].

Figure 1. Rational transfer function system with input and output [13] (© IEEE 2001).

In modeling EM time-domain data, considerable research has focused on stochastic spectrum estimation based techniques [9,11,43–47]. As noted above, these methods implicitly assume the system input to be unknown white-noise sequence. However, limited attention has been given to deterministic IR modeling approaches. This is rather surprising, given that a known excitation sequence is used in EM analysis, which clearly implies that modeling the EM TS belongs more appropriately to the *deterministic* category. For example, in the FDTD analysis of EM scattering phenomena, a narrow Gaussian pulse is used as the input sequence. Since the pulse is sufficiently narrow in width, its bandwidth is much wider than the system bandwidth. Hence, the input can be essentially considered as an impulse, and the response can be categorized as a (deterministic) IR. Thus, the white noise input implicitly assumed in spectrum estimation-based techniques is neither necessary nor appropriate for FDTD signal modeling. We will show that a properly chosen deterministic model of the data represents time evolution of the FDTD signal more accurately, and leads to smaller model orders, than classical stochastic approaches.

There are other fundamental limitations in using stochastic spectrum estimation approaches for modeling EM signatures. It is well established that in spectrum estimation, AR parameter estimation is a linear problem (as in Prony-type algorithms) whereas estimating the MA part is a highly nonlinear optimization problem [19,20]. This perhaps explains why AR modeling has been the most common choice in EM literature. However, since AR models represent purely all-pole systems, they are known to be primarily effective for modeling “peaky” spectra, that is, systems with dominant poles. On the other hand, the response of microwave circuits such as filters and resonators often has deep nulls in the frequency domain. Clearly, the transfer functions of such structures must contain dominant zeros, which cannot be modeled well with poles *only*. In the absence of zeros in the assumed model, the pure AR approaches attempt to synthesize the nulls using significantly large numbers of poles away from the unit circle, leading to very high model orders [9,11,43–47]. Furthermore, the fundamental objective of modeling any unknown system is to seek the true underlying model fit with minimum possible number of parameters or model order (“principle of parsimony”). From that perspective, even if a large-order AR model can achieve a reasonably good fit, it does not necessarily produce the most efficient model characterization of an unknown system.

In general, in order to match a mixed spectrum containing both peaks and nulls, ARMA models are better suited than AR models [19–21]. We demonstrate in this article that if an appropriate *deterministic* ARMA model is assumed, and the model parameters are estimated by minimization of the true (nonlinear) IR model-fitting error (not the linearized “equation error” used in previous approaches), very close approximations to the measured TS can be achieved with significantly low model orders. It is interesting to note that unlike the stochastic spectrum estimation approaches, the numerator (MA) estimation problem in the deterministic case is *linear* whereas the

denominator (AR) estimation problem is *nonlinear* [21,36]. However, it has been shown [36] that the two problems can be decoupled without affecting the optimality properties of the true error criterion. The decoupling leads to two subproblems of reduced complexities. This approach, termed as the *decoupled optimal method* (OM), has been applied to model and extrapolate FDTD TSs [13], and will be described later.

In the representation of FDTD signals, we note that the TSs are highly oversampled because of the small sampling period necessitated by Courant’s stability condition. Hence, prior to modeling, the TSs need to be decimated by some decimation factor (DF). We have developed a frequency-domain approach for determining DFs that is based on acceptable level of aliasing caused by decimation [13]. The proposed approach is practically useful as it relies only on the “early” part of the FDTD TS to determine the DF. This approach will be illustrated with examples in Section 2.4.

This section on time-domain modeling is organized as follows. In Section 2.1, the EM time sequence model is defined and the modeling problem is stated. In Section 2.2, a few important “deterministic” model estimation approaches, applicable to FDTD sequences, are briefly reviewed. In Section 2.3, the decoupled optimal method for signal modeling is outlined, focusing on algorithm implementation rather than its theory. We also describe a practically useful data-driven criterion for model order selection. The effectiveness of the proposed approach is demonstrated in Section 2.4 with simulation results on high- Q structures such as a lowpass filter with sharp cut-off characteristics and a patch antenna.

2.1. Problem Statement

A general complex exponential model of the electromagnetic TD signal can be defined as the IR of an LTI system

$$h(n) = y(n) \triangleq \sum_{k=1}^p \alpha_k e^{(\sigma_k + j\omega_k)n\Delta t + j\phi_k}, \quad (1)$$

$$n = 0, 1, \dots, (N - 1)$$

where α_k , σ_k , ω_k , and ϕ_k denote the real amplitude, damping factor, frequency, and initial phase, respectively, of the k th exponential, and Δt is the sampling period. However, the time sequences generated by EM simulations are always real; that is, the exponentials occur in complex conjugate pairs. Consequently, these sequences can be represented as

$$h(n) \triangleq \sum_{k=1}^{p/2} \alpha_k e^{n\Delta t\sigma_k} \cos(\omega_k n\Delta t + \phi_k), \quad (2)$$

$$n = 0, 1, \dots, (N - 1)$$

Note that p has been assumed to be even without any loss of generality. If p is odd or if any frequency $\omega_k = 0$, there would be real components representing pure decay without any oscillation. Taking z transform on both sides of (1),

we obtain

$$H(z) = \sum_{k=1}^p \frac{A_k}{(1 - d_k z^{-1})} \quad (3)$$

where $A_k \triangleq \alpha_k e^{j\phi_k}$ denotes complex amplitudes and $d_k \triangleq \sigma_k + j\omega_k$. After summation of the p terms in the right-hand side, we obtain the transfer function (TF)

$$H(z) = \frac{a_0 + a_1 z^{-1} + \dots + a_{p-1} z^{-(p-1)}}{1 + b_1 z^{-1} + \dots + b_p z^{-p}} \triangleq \frac{N(z)}{D(z)} \quad (4)$$

where the coefficient of z^0 term in the denominator has been assumed to be unity. Note that the coefficients in this TF are real because all A_k and d_k occur in conjugate pairs. It is also noted that the TF in (4) represents a special case of a more general ARMA TF, given by

$$H(z) = \frac{a_0 + a_1 z^{-1} + \dots + a_{q-1} z^{-(q-1)} + a_q z^{-q}}{1 + b_1 z^{-1} + \dots + b_{p-1} z^{-(p-1)} + b_p z^{-p}} \quad (5)$$

where p and q denote the number of poles and zeros, respectively, and can have any arbitrary integer values, in general. When $p = q + 1$, the special ARMA TF in (4) is also known as “strictly proper” and classical Prony’s model belongs to this category. Another important special case is the purely autoregressive (AR) TF with $q = 0$. The transfer function $H(z)$ in (5) can be written equivalently in terms of its IR sequence as

$$H(z) = h(0) + h(1)z^{-1} + \dots + h(k)z^{-k} + \dots \quad (6)$$

which is aptly referred to as the *infinite impulse response* (IIR) TF. Stacking the first N significant samples of $H(z)$:

$$\mathbf{h} \triangleq [h(0) \quad h(1) \quad \dots \quad h(N-1)]^T \quad (7)$$

Next, let the vector containing the N samples of the simulated FDTD-TS (i.e., impulse response) be denoted as

$$\mathbf{h}_d \triangleq [h_d(0) \quad h_d(1) \quad \dots \quad h_d(N-1)]^T \quad (8)$$

According to Steiglitz [26], given a desired IR \mathbf{h}_d , “the ideal problem” of optimal estimation of the parameters a_i and b_i can be represented by the following model fitting error minimization

$$\begin{aligned} \min_{\mathbf{a}, \mathbf{b}} \|\mathbf{e}\|^2 &\triangleq \min_{\mathbf{a}, \mathbf{b}} \sum_{i=0}^{N-1} \left[h_d(i) - \left\{ \frac{N(z)}{D(z)} \right\} \delta(i) \right]^2 \\ &\triangleq \min_{\mathbf{a}, \mathbf{b}} \|\mathbf{h}_d - \mathbf{h}\|^2 \end{aligned} \quad (9)$$

where

$$\begin{aligned} \delta(i) &= \begin{cases} 1, & i = 0 \\ 0, & i \neq 0 \end{cases} \\ \mathbf{e} &\triangleq \mathbf{h}_d - \mathbf{h} \\ \mathbf{a} &\triangleq [a_0 \quad a_1 \quad \dots \quad a_q]^T \\ \mathbf{b} &\triangleq [1 \quad b_1 \quad \dots \quad b_p]^T \end{aligned} \quad (10)$$

The notation $\{N(z)/D(z)\}\delta(i)$, denotes the i th output when a “system” represented by $N(z)/D(z)$ is driven by the input $\delta(i)$. The estimation of the model parameters in (9) is known to be nonlinear in \mathbf{b} , and standard nonlinear optimization algorithms have been suggested [29–32]. Unlike these suboptimal methods, the decoupled OM presented in Ref. 13 does not modify the error criterion or the least-squares minimization of the nonlinear FE defined in (9). This optimal approach is general and has no restrictions on the numbers of poles and zeros, unlike other closely related methods [27,34,35], which are valid only for strictly proper TFs. In order to motivate the proposed approach, some of the important developments in deterministic system identification are briefly outlined next.

2.2. Overview of Deterministic System Identification

Over the last several decades, identification of unknown discrete-time linear systems received considerable attention [25–42]. Linear system modeling can be broadly categorized into two classes: nonparametric and parametric. Classical nonparametric models can be applied to IR sequence (e.g., the EM time sequence), frequency response, power spectral density (PSD) or periodogram, autocorrelation sequence, characteristic function, and other signals [19–21,48,49]. The major drawback of classical nonparametric models is that, more often than not, these representations are theoretically infinite in extent.

Parametric models such as rational transfer functions, exponential models and state space representations overcome the infinite-dimensionality problem of nonparametric models by parsimonious representation of systems in terms of a finite number of coefficients. The pole-zero or rational transfer function model is perhaps the most effective and practical representation of systems, and has been widely applied in the EM literature. Research on parameter estimation of rational transfer functions has evolved in four major directions. The first among the following four approaches listed below deals with modeling “random” processes, whereas the later three deal with “deterministic” scenarios:

1. In statistical and modern spectrum estimation literature, unknown systems, or rather their PSDs, are modeled using ARMA model identification methods [19,20]. The system parameters are estimated from the observed output data record only. Since the input to such systems cannot be observed, it is assumed as white noise for modeling convenience.

2. In control systems, the input and output signals of a plant are usually measurable. Hence, the system parameters are estimated from the known input/output record [38–42].
3. In digital filter design, the ideal filter specifications are given in the frequency domain in terms of the magnitude and phase responses in the passbands and stopbands, and classical methods are used for approximating IIR (or ARMA) filters, such as Butterworth, Chebyshev, and elliptic [21,48,49]. For arbitrary or nonclassical frequency-domain specifications, least-squares matching leads to general nonlinear optimization algorithms [29–31].
4. In data modeling, the least-squares fit between measured or simulated data and the desired IR is required. In this case, it becomes more appropriate to fit the data directly to the IR output of the rational transfer function model.

The FDTD modeling problem addressed in this work belongs to category 4 listed above. However, the time-domain algorithms for case 2 above may be appropriate if the Gaussian “input” pulse sequence is considered. Case 3 may also be applicable when frequency-domain simulated data characterize the unknown system (such as in FDFD and the finite-element methods). Hybrid algorithms combining any two or more of the three deterministic categories also appear feasible. Important theoretical developments leading to decoupled OM for rational model fitting are described next.

2.2.1. Kalman’s Method. In an early work on rational transfer function identification, Kalman suggested the solution of the following linear problem [40]:

$$\min_{\mathbf{a}, \mathbf{b}} \sum_{i=0}^{N-1} [\{D(z)\}h_d(i) - \{N(z)\}\delta(i)]^2 \quad (11)$$

The advantage of this modified error criterion is that it can be easily minimized in the least-squares sense with respect to the unknown coefficients in \mathbf{a} and \mathbf{b} , by solving a set of simultaneous linear equations. Apart from its simplicity, this approach is not known to possess any optimality property.

2.2.2. Prony-Based Methods. Prony’s work [50] was perhaps the first to recognize that the exponentials ($e^{j\omega k}$ terms) in (1) are the p roots of the polynomial $D(z)$ in (5). Making use of this fact, Prony converted the “nonlinear” problem of frequency (or “periodicity”) estimation into a “linear” problem of coefficient estimation. However, this was accomplished by bypassing the ideal model fitting error criterion in (9) and instead, an “equation error” is minimized. Using (4), we obtain

$$H(z)D(z) = N(z) \quad (12)$$

The LHS clearly represents a convolution operation. Hence, by equating the coefficients of same powers of z^{-1}

on both sides of (12), we obtain

$$\sum_{i=0}^p b_i h(k-i) = a_k \quad \text{for } k=0, 1, \dots, (p-1) \quad (13)$$

$$\sum_{i=0}^p b_i h(k-i) = 0 \quad \text{for } k=p, p+1, \dots \quad (14)$$

These equalities hold only if there is no error in modeling and the model parameters are exact. Otherwise, we get modeling or “equation errors” from (14):

$$e_{\text{eq}}(k) \triangleq \sum_{i=0}^p b_i h_d(k-i) \quad \text{for } k=p, p+1, \dots \quad (15)$$

In PM, the b_i coefficients are found by minimizing the squared sum of these equation errors:

$$\begin{aligned} \min_{\mathbf{b}} \sum_{k=p}^{N-1} e_{\text{eq}}^2(k) &\triangleq \min_{\mathbf{b}} \sum_{k=p}^{N-1} \sum_{i=0}^p b_i h_d(k-i) \\ &\equiv \min_{\mathbf{b}} \sum_{k=p}^{N-1} [\{D(z)\}h_d(k)]^2 \end{aligned} \quad (16)$$

Using matrix–vector representation, the equation error vector can be expressed as

$$\begin{aligned} \mathbf{e}_{\text{eq}} &\triangleq \begin{bmatrix} e_{\text{eq}}(p) \\ e_{\text{eq}}(p+1) \\ \vdots \\ e_{\text{eq}}(N-1) \end{bmatrix} \\ &\triangleq \begin{bmatrix} h_d(p) & h_d(p-1) & \cdots & \cdots & h_d(0) \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ h_d(N-1) & h_d(N-2) & \cdots & \cdots & h_d(N-p-1) \end{bmatrix} \times \mathbf{b} \\ &\triangleq \mathbf{H}_2^p \mathbf{b} \end{aligned} \quad (17)$$

The minimization of the norm of this vector is also known as the “covariance method” of linear prediction [20,21]. The coefficients \mathbf{b} obtained by minimization of this criterion do not minimize the “ideal” FE criterion defined in (9), and hence these estimates are not optimum in that sense. There are two types of ARMA model identification techniques based on the denominator produced by PM, namely, Shank’s or Burrus–Parks methods.

2.2.2.1. Shanks’ Method. This is a two-step approach where the denominator coefficients are first estimated by

minimizing the equation error in (16) to form $\hat{D}(z)$ and then the numerator coefficients are found by minimizing the following modified fitting error norm [25]:

$$\min_{\mathbf{a}} \sum_{i=0}^{N-1} \left[h_d(i) - \left\{ \frac{N(z)}{\hat{D}(z)} \right\} \delta(i) \right]^2 \quad (18)$$

Note that the estimation of \mathbf{a} in (18) is a linear problem.

2.2.2.2. Burrus–Parks Method. This is also a two-step method closely related to Shank’s work [33]. The difference is only in the way the numerator coefficients are estimated. The denominator is found exactly in the same manner as Prony’s in (16). To obtain the numerator, the first q error samples are set to zeros, with the “best” available estimates used for the first q samples of $h_d(n)$. The elements of \mathbf{a} are then found from

$$a_k = \sum_{i=0}^k \hat{b}_i h_d(k-i) \quad (19)$$

It may be noted that the Matlab Signal Processing Toolbox uses this particular approach to estimate the numerator for its version of PM, and that subroutine function is called *prony*.

2.2.3. The Steiglitz–McBride Iterative Prefiltering Method. The “linear” methods described above completely modify the true criterion in (9) and minimize entirely different error criteria. In contrast, this approach attempts to remain within the framework of the original criterion in (9). In this method, an initial estimate $\hat{D}(z)$ of the denominator coefficients is first found by either Kalman’s method (11) or Shanks’ first step (16). Then the following modified fitting error criterion is optimized iteratively [41]:

$$\min_{\mathbf{a}, \mathbf{b}} \sum_{i=0}^{N-1} \left[\left\{ \frac{D(z)}{\hat{D}(z)} \right\} h_d(i) - \left\{ \frac{N(z)}{\hat{D}(z)} \right\} \delta(i) \right]^2 \quad (20)$$

The estimate $\hat{D}(z)$ obtained at the i th iteration step is used as prefilter for obtaining the estimates at the next iteration step. Note that (20) closely approximates (9) and both are exactly same if $D(z) = \hat{D}(z)$. But using (20), the unknown parameters in \mathbf{a} and \mathbf{b} can be estimated by solving a set of simultaneous linear equations. Further details on this method and its application in AR and ARMA model-based filter design may be found in Ref. 21.

2.3. Decoupled Optimal Method

The goal of this approach can be summarized as follows. Given a simulated (or measured) EM time sequence (8), estimate the coefficients of the numerator and denominator polynomials of the unknown rational transfer function (5) by minimizing the true IR model-fitting error [see Eq. (9)] in the least-squares sense. The approach presented below attempts to solve this multidimensional,

nonlinear optimization problem, as posed in (9), by optimizing with respect to the denominator and numerator coefficients.

As given by (9), the direct formulation reveals coupling between the numerator and denominator estimation problems. Shaw [36] showed that the joint FE optimization problem defined in (9) can be theoretically *decoupled* into two subproblems of *reduced* computational complexities. The approach, known as decoupled optimal method, is applicable to identification of rational models with *arbitrary* numbers of poles (p) and zeros (q). It has been shown that the nonlinear denominator subproblem possesses a weighted-quadratic structure that can be utilized to formulate an efficient *iterative* minimization algorithm. Unlike Steiglitz–McBride’s work, no iterations are needed to find the optimal numerator, which is estimated in a single step using a linear least-squares approach. The decoupled subcriteria of OM are known to possess *global optimality* properties [36]. A brief outline of OM follows, with details of implementation included in the Appendix at the end of this article.

It has been shown [36] that the nonlinear denominator criterion of OM has the following equivalent forms:

$$\begin{aligned} \min_{\mathbf{a}, \mathbf{b}} \|\mathbf{e}_{\text{OM}}(\mathbf{a}, \mathbf{b})\|^2 &\equiv \min_{\mathbf{b}} \|\mathbf{e}(\mathbf{b})\|^2 \\ &\triangleq \min_{\mathbf{b}} \|\mathbf{B}(\mathbf{B}^T \mathbf{B})^{-1} \mathbf{B}^T \mathbf{h}_d\|^2 \\ &= \min_{\mathbf{b}} \|\mathbf{h}_d^T \mathbf{B}(\mathbf{B}^T \mathbf{B})^{-1} \mathbf{B}^T \mathbf{h}_d\|^2 \\ &= \min_{\mathbf{b}} \mathbf{b}^T \mathbf{H}_2^T (\mathbf{B}^T \mathbf{B})^{-1} \mathbf{H}_2 \mathbf{b} \end{aligned} \quad (21)$$

where

$$\mathbf{B} \triangleq \begin{bmatrix} b_{q+1} & b_{q+2} & \cdots & b_p & \cdots & 0 \\ b_q & b_{q+1} & \cdots & b_{p-1} & \vdots & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & b_p \\ 1 & b_1 & \cdots & \cdots & \cdots & b_{p-1} \\ 0 & 1 & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots & b_1 & \cdots & \cdots \\ \cdots & \cdots & \cdots & 1 & \cdots & \cdots \\ 0 & 0 & \cdots & \cdots & \cdots & b_1 \\ 0 & 0 & \cdots & 0 & \cdots & 1 \end{bmatrix} \quad (22)$$

$\in \mathbf{R}^{N \times (N-q-1)}$

$$\mathbf{H}_2 \triangleq \begin{bmatrix} h_d(q+1) & h_d(q) & \cdots & h_d(0) & 0 & \cdots & 0 \\ h_d(q+2) & h_d(q+1) & \cdots & h_d(1) & h_d(0) & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ h_d(p) & h_d(p-1) & \cdots & \cdots & \cdots & \cdots & h_d(0) \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ h_d(N-1) & h_d(N-2) & \cdots & \cdots & \cdots & \cdots & h_d(N-p-1) \end{bmatrix} \quad (23)$$

where $\mathbf{H}_2 \in \mathbf{R}^{(N-q-1) \times (p+1)}$. Note that, in deriving (21), no linearization approximation had been introduced at the outset. The criterion in (21) is nonlinear in \mathbf{b} but possesses a weighted-quadratic structure, where the weight matrix, $(\mathbf{B}^T \mathbf{B})^{-1}$ depends on the unknown parameters in \mathbf{b} . An iterative minimization scheme for this criterion has been developed [36], and the steps are summarized next.

2.3.1. Denominator Estimation. The nonlinear criterion for estimating the *denominator* in (21) is optimized in two steps.

Step 1: Initial Estimate of OM and Its Relation to Prony's. The initial estimate of \mathbf{b} is found by first setting $\mathbf{b} = [1 \ 0 \ 0 \ \cdots \ 0]^T$ to avoid the trivial solution. This is exactly equivalent to setting the “prefilter” matrix $(\mathbf{B}^T \mathbf{B})^{-1} = \mathbf{I}_{(N-q-1)}$ in (21). This modification or linearization leads to the following “equation error” (EE) criterion

$$\begin{aligned} \min_{\mathbf{b}} \|\mathbf{e}_{\text{eq}}(\mathbf{b})\|^2 &\triangleq \min_{\mathbf{b}} \|\mathbf{h}_d^T \mathbf{B} \mathbf{B}^T \mathbf{h}_d\|^2 \\ &= \min_{\mathbf{b}} \mathbf{b}^T \mathbf{H}_2^T \mathbf{H}_2 \mathbf{b} \end{aligned} \quad (24)$$

where the EE vector is defined as

$$\mathbf{e}_{\text{eq}}(\mathbf{b}) \triangleq \mathbf{B}^T \mathbf{h}_d = \mathbf{H}_2 \mathbf{b} \quad (25)$$

Interestingly, when $p = q + 1$, this equation error becomes

$$\begin{aligned} \mathbf{e}_{\text{eq}}^p(\mathbf{b}) &\triangleq \begin{bmatrix} h_d(p) & h_d(p-1) & \cdots & \cdots & h_d(0) \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ h_d(N-1) & h_d(N-2) & \cdots & \cdots & h_d(N-p-1) \end{bmatrix} \\ &= \mathbf{H}_2^p \mathbf{b} \end{aligned} \quad (26)$$

Minimization of this error is exactly equivalent to the standard Prony method as well as the “covariance method” of AR modeling [19–21], both of which are commonly used in the EM literature. Note that \mathbf{H}_2^p in (26) is identical to the “data matrix” for Prony’s estimator in (17). Since the Prony’s estimator is a linearized special case of OM and, in fact, provides the initial estimate for OM iterations, it is fair to argue that OM would always outperform Prony-based methods. OM iteratively minimizes the modeling

error further to obtain a better fit. This will be demonstrated by the simulation examples later in this section.

Step 2: Phase 1 Iterations. Once the initial estimate of \mathbf{b} is available, the following criterion is iteratively optimized by utilizing the estimate obtained at the l th (previous) iteration to update the estimate at the $(l+1)$ th (present) iteration:

$$\min_{\mathbf{b}} \mathbf{b}^T \mathbf{H}_2^T (\mathbf{B}^{T(l)} \mathbf{B}^{(l)})^{-1} \mathbf{H}_2 \mathbf{b} \quad (27)$$

Details of this optimization are given in the Appendix.

2.3.2. Numerator Estimation. At convergence of the OM iterations, the optimum \mathbf{b}^o is used to find the minimized error as

$$\mathbf{e}_o \triangleq \mathbf{B}_o (\mathbf{B}_o^T \mathbf{B}_o)^{-1} \mathbf{B}_o^T \mathbf{h}_d \quad (28)$$

Using the optimal error, the “cleaned up” or optimum IR is found from

$$\mathbf{h}^o = \mathbf{h}_d - \mathbf{e}_o(\mathbf{b}) \quad (29)$$

The first q elements of this optimum IR are used for calculating the optimum \mathbf{a}^o as

$$a_k^o = \sum_{i=0}^k \hat{b}_i^* h^*(i-k), \quad k = 0, 1, \dots, q \quad (30)$$

Equations (27) and (30) are the two key formulas for estimating the coefficients of the denominator and numerator polynomials, respectively, of the unknown TF.

The decoupled estimation of \mathbf{a} and \mathbf{b} in OM belongs to a special class of nonlinear optimization problems that have been studied extensively by numerical analysts [51]. It has been shown [51] that in a non-linear error criterion, if some of the unknown variables are linearly related to the error and the other variables are nonlinearly related, and if these variables appear in a separable form, as in this case, then the two decoupled estimators in (27) and (30) are the *globally optimum estimators* for both sets of variables.

2.3.3. Computational Complexity. The major computational load of the algorithm is in performing the iterative refinement in (27), where, at each iteration step, one needs to invert an $(N-q-1) \times (N-q-1)$ matrix $(\mathbf{B}^T \mathbf{B})$. It may appear that this inversion should require $O[(N-q-1)^3]$ operations. However, $(\mathbf{B}^T \mathbf{B})$ is a symmetric banded Toeplitz matrix and many efficient algorithms are available for inverting such matrices [34,52,53]. Specifically, it has been shown that inversion of such banded Toeplitz matrices requires only operations of $O[N]$ [52]. Furthermore, numerical experimentation reveals that the iterations converge fairly quickly (5–10 iterations maximum).

2.3.4. Model-order Selection. As in any modeling problem, selection of the order of the underlying system is a critical issue. The difference between the desired and modeled signal, as defined in (9), is a combination of model mismatch error, measurement error and noise. If this error is Gaussian-distributed, then the minimization of the criterion in (9), as performed by OM, is the maximum-likelihood estimator (MLE) for this problem. In case of MLE, the Akaike information criterion (AIC) or minimum description-length (MDL) criterion are often used for order determination. However, it has been shown [54] that MDL is a consistent estimator of order, whereas AIC is inconsistent and that AIC often overestimates the model order. Hence, we propose to use MDL for order determination in combination with OM.

For the general ARMA (p, q) process, MDL is given by [54–56]

$$\begin{aligned} \text{MDL}(p, q) &= N \ln \sigma(p, q) + (p + q) \ln N; \quad p = 1, 2, 3, \dots, \\ q &= 0, 1, 2, \dots \end{aligned} \quad (31)$$

where N is the number of IR samples used and $\sigma(p, q)$ is the minimized error power as defined in (9) for a particular choice of p and q . According to [54–56], the optimal p and q correspond to the minimum value of $\text{MDL}(p, q)$. However, for Prony's case, $q = p - 1$ and the optimal p can be determined according to the minimum of

$$\text{MDL}(p) = N \ln \sigma(p) + (2p - 1) \ln N; \quad p = 1, 2, 3, \dots \quad (32)$$

These equations will be used in our simulations for comparing equivalent orders of OM and Prony's approaches. It may be noted that the first term in the MDL criterion is proportional to the error power that tends to diminish as p is increased, whereas the second term is a "penalty factor" that penalizes higher choice of p . As p is increased, $\text{MDL}(p)$ diminishes initially with the error. However, when p goes beyond the "true" model order, the second term dominates and pushes the value of $\text{MDL}(p)$ back up again. Hence, ideally, the plot of MDL is bowl-shaped and the optimum orders correspond to the bottom of the bowl.

2.4. Simulation Examples

In this section, we present results from Ref. 13 on modeling and extrapolation of FDTD simulated data for a microstrip lowpass filter and a microstrip patch antenna, comparing the performance of various algorithms, such as Prony's method, OM and AR modeling, in terms of model fidelity and accuracy. We also estimate the model order for each algorithm using the MDL criterion.

2.4.1. Lowpass Filter. In this section, the performance of OM is compared with that of a standard Prony-based algorithm provided with the Matlab signal processing toolbox. The FDTD-TS (time sequence) used for these simulations is shown in Fig. 2. This time-signature is sampled at the output port of a microstrip two-port lowpass filter

Figure 2. The raw FDTD time sequence of a microstrip lowpass filter [13] (© IEEE 2001).

(see Fig. 7 in Ref. 57 for the geometry). Both ports have a characteristic impedance of 50 Ω .

2.4.1.1. Determination of Decimation Factor (DF). The raw simulation is run with $\Delta t = 0.441$ ps, and hence, the total frequency range is $F = 1/\Delta t = 2267.6$ GHz. Clearly, the signal is oversampled and needs to be decimated because only 40 GHz (20 GHz on either side) is of interest for comparison with the measurements in Ref. 57. With appropriate decimation of the TS, the data processing required for modeling can be reduced considerably, and the effective model order will also be lower. However, the DF needs to be selected carefully so as not to cause any undesirable aliasing resulting from the decimation operation. The magnitude response of the filter shown in Fig. 3 indicates that in order to limit the aliasing below -50 dB, the one-sided bandwidth of the decimated signal cannot be less than 50 GHz. Hence, to limit aliasing effect to less than -50 dB, the filter TS can be safely decimated by a ratio of 22:1. Conservatively, we have chosen a DF of 10:1. The magnitude response in Fig. 3 validates that the DF choice of 10:1 is quite adequate for preserving the signal information, and will keep the alias level below -60 dB. In order to obtain the frequency domain plot in Fig. 3, only the *early-time* computed response (the first 2000 samples) were used, with sufficient zero padding as necessary for a smooth spectrum. This a priori selection of the DF before computing the entire TS presents a minor overhead to the FDTD simulation time, and is practically useful.

The FDTD simulation of the filter is terminated after 2000 timesteps (in contrast to 8000 in the original paper [57]). The first 1000 time samples, which correspond to transient data, are not considered in the signal processing; the samples between 1001 to 2000 are used for estimating the model. The selected 1000 samples are decimated by a factor of 10:1 to obtain the 100 modeling samples. Figure 4 shows the comparison of IR fit between an ARMA (6,5) model (sixth-order OM), and the standard Prony result (also sixth-order) for the decimated sequence. The corre-

Figure 3. Frequency spectrum magnitude of the reflected signal for a lowpass filter [13] (© IEEE 2001).

sponding 1000-sample window of the raw FDTD-computed TS is also included in Fig. 4. While the ARMA model shows excellent agreement with the original raw data, Prony's model tracks the time signature rather poorly. The sixth-order model thus established has been used to extrapolate the TS from 2000 to 8000 (i.e., late-time data are extrapolated from an early-time model). Although not shown, excellent comparison between ARMA model and the reference solution in Ref. 57 has been observed for the entire TS of 8000 samples. The *entire* TS of 8000 samples is then Fourier-transformed to generate the frequency response. The prediction performance in the frequency-domain insertion loss S_{21} of the filter is shown in Fig. 5. The solid line corresponds to the measurements reported in Ref. 57, the dashed line to the sixth-order OM, and the dotted-dashed line to the sixth-order Prony. The measured data is in good agreement with the Fourier Spectrum of the original FDTD reference Signal of 8000 timesteps [57]. The results of direct FDTD analysis using

Figure 4. Comparison of the ARMA (6,5) model response for a lowpass filter using OM (dashed line), and Prony's method (dashed-dotted line), with the decimated FDTD reference solution (solid line) [13] (© IEEE 2001).

Figure 5. Comparison of frequency-domain insertion loss (S_{21}) for a lowpass filter, computed using extrapolated time sequences [13], with the measurements from Ref. 57 (© IEEE 2001).

only the initial 2000 timesteps are also included in Fig. 5 (dotted line) for comparison. Good corroboration between the spectrum of direct (truncated) FDTD sequence and the extrapolated model is not surprising given that the most significant spectral content is contained in the first 2000 temporal samples. Therefore, one could argue that good corroboration of FDTD-computed data with the measurements for the filter can be obtained by computing only 2000 samples and zero padding up to 8000. However, if we reduce the sample size to 1500, thereby discarding more of the significant spectral content, the discrepancy between spectra of truncated and extrapolated data increases, especially near the critical band in the vicinity of the notch [13].

The filter under consideration is a notch lowpass filter, designed with a notch frequency at 7.5 GHz and attenuation of -40 dB. The return loss S_{11} , also computed for both OM and Prony's models, is compared with the measurements from [57] in Fig. 6. It is observed that for the same

Figure 6. Comparison of frequency-domain return loss (S_{11}) for a lowpass filter, computed using extrapolated time sequences [13], with the measurements from Ref. 57 (© IEEE 2001).

Figure 7. Comparison of a lowpass filter's model-fitting error for Prony's method with the error for OM [13] (© IEEE 2001).

low model order ($p=6$), OM outperforms the standard Prony model by a significant margin, and corroborates very well with the measurements. Again, it is observed that a truncated sequence of the initial 2000 samples predicts the return loss to the same accuracy as the extrapolated FDTD sequence, albeit with a 200 MHz shift in the resonant frequency at 15 GHz.

The IR fitting error defined in (9) was calculated for both methods with the model orders (p) ranging from 1 to 24, and the results are shown in Fig. 7. The figure shows that in order to obtain corroboration to the same degree of accuracy as achieved by OM with $p=6$ (-22 dB or better), the Prony's model order would have to be increased to $p=20$, as reported in Ref. 9. Figure 7 further suggests that the discrepancy between OM and Prony's model tends to diminish at higher model orders.

It may be noted that since PM does not minimize the true FE for the denominator, it needs extra poles to account for the notches in the frequency response. However, one needs to be careful about selecting too high an order because such "overmodeling" may lead to instability. This is depicted in Fig. 8, where the maximum pole radii in the case of PM are plotted for p ranging from 1 to 40. This figure clearly shows that at high orders, the largest pole radius pushes towards—and even exceeds—unity, which will render the estimated transfer function unstable. Standard stabilization approach by means of flipping the unstable poles inside the unit circle would not affect the magnitude response. However, such stabilization would alter the phase characteristics, the optimized impulse response, as well as the model fitting error, none of which may be desirable in practice.

That low values of p may be quite appropriate for this problem is further validated by the MDL criterion. Using the fitting errors shown in Fig. 7, the MDL(p) values were calculated for both OM and Prony's method at increasing orders, and the results are shown in Fig. 9. The figure indicates that in the case of OM, the values of MDL(6) and MDL(8) are about the same, and hence, the choice of $p=6$ for OM is justified.

Figure 8. Maximum pole radius with increasing model order using Prony's method [13] (© IEEE 2001).

In summary, OM appears to be computationally more efficient, and gives better accuracy than Prony's method for FDTD data processing. For higher- Q and electrically large structures, the computational savings are expected to be much higher than for the filter studied.

2.4.1.2. Comparison with Pure AR Model. We note that the Matlab function *prony*, used for the comparisons given above actually produces ARMA models. This is because *prony* uses the Burrus–Parks version of Prony's method [33], where both the numerator and the denominator of the TF are estimated linearly. Hence, the Prony's results reported above are superior to what would otherwise be obtained if pure AR models had been used instead, as in Refs. 11 and 47, where no zeros at all are used to account for the notches. To illustrate this point, the fitting errors at different model orders are compared in Fig. 10 for pure AR models, ARMA and the Matlab function *prony*. Clearly, for

Figure 9. MDL criterion with increasing model order using OM and Prony's method on a lowpass filter [13] (© IEEE 2001).

Figure 10. Comparison of model-fitting error for pure AR model with the error for Prony's method and that for OM [13] (© IEEE 2001).

the range of low orders depicted in Fig. 10, the performance of the AR models is poorer than either of the other two approaches. In fact, in order to obtain equivalent fit with the AR model for the same accuracy as the sixth-order OM, much longer training sequences and much higher filter orders need to be used [11,47].

2.4.2. Patch Antenna. Next, we consider modeling the field of a microstrip-line-fed patch antenna whose geometry is depicted in Fig. 3 of Ref. 57. The excitation is a Gaussian pulse of the same temporal parameters as indicated in Ref. 57. The raw simulation is run for 8000 timesteps ($\Delta t = 0.441$ ps) and produces the reference TS. The initial 1500 samples are discarded for transients and the samples between 1501 and 3000 are used for estimating the model. In this case also, the frequency range prior to decimation is $F = 1/\Delta t = 2267.6$ GHz. The magnitude spectrum of the reflected signal at the input port using the first 3000 samples is shown in Fig. 11. It indicates that in order

Figure 11. Frequency spectrum magnitude of the reflected signal for the patch antenna [13] (© IEEE 2001).

to limit aliasing to less than -50 dB, the one-sided bandwidth of the decimated signal in this case must be at least 45 GHz. Hence, this signal can be safely decimated by up to about 25:1 without any significant distortion due to aliasing. On the basis of this analysis, the signal was decimated with a ratio of 15:1. This structure has a narrower bandwidth and higher Q than does the filter example considered earlier.

Figure 12 compares the decimated reflected signal at the input port of the antenna with the ones produced by an ARMA (7,6) model (seventh-order OM) and the standard Prony method (also of seventh order). The models thus produced were then used to extrapolate the TS from 3000–8000 timesteps. The initial TS of transients between 1–1500 was added back. Because the antenna has a relatively high Q , it is reasonable to expect some compromise in accuracy between modeled and FDTD-computed TSs *with the low orders used*. However, even with $p = 7$, OM captures the details of the dominant early-time response very closely, and maintains a fairly good temporal corroboration overall. Prony's method, on the other hand, performs poorly for $p = 7$. The model fitting error is plotted as a function of the model order in Fig. 13. In order to obtain the same accuracy as the seventh-order OM, Prony's model would require an order of about 18. The MDL values for both methods are compared in Fig. 14, and once again, we clearly show that $p = 7$ is the optimal choice for OM in this case. Using the same late-time extrapolation approach as pursued for the filter, the frequency-domain return loss S_{11} of the patch antenna is computed for both OM and Prony's models, and compared in Fig. 15 with the measurements or equivalently, the spectrum of the original FDTD sequence of 8000 timesteps, reported in Ref. 57. It is observed that for the same order ($p = 7$), OM clearly outperforms Prony's in this case also, and corroborates quite well with measurements.

For comparison, we have also included in Fig. 15, the return loss computed from a truncated TS of the first 3000 timesteps. Although the discrepancy between the result in

Figure 12. Comparison of the ARMA (7,6) model response for the patch antenna using OM (dashed line) and Prony's method (dashed-dotted line), with the decimated FDTD reference solution (solid line) [13] (© IEEE 2001).

Figure 13. Comparison of the patch antenna's model-fitting error for Prony's method with the error for OM [13] (© IEEE 2001).

Ref. 57 (8000 steps) and the truncated TS appears to be negligible, it is emphasized that because of strong resonance, the tail for the patch antenna does not decay as rapidly as it does for the filter. Also, because of radiation, the pulse loses energy and experiences dispersion as it travels along the patch. These effects do not seem to influence the lower-frequency resonances as much as the high-frequency ones. To illustrate this, in Fig. 16 we have plotted return loss computed from both the truncated FDTD-TS (3000 timesteps) and the sequence used in Ref. 57 (8000 timesteps), over an extended frequency range. The discrepancy between the two results increases significantly above 41 GHz.

3. FREQUENCY-DOMAIN MODEL

In the previous section we described a robust technique for computing the poles and zeros of the ARMA transfer function in (5) by nonlinear optimization of the decoupled

Figure 14. MDL criterion with increasing model order using OM and Prony's method on a patch antenna [13] (© IEEE 2001).

Figure 15. Comparison of frequency-domain return loss (S_{11}) for a patch antenna, computed using extrapolated time sequences [13], with measurements from Ref. 57 (© IEEE 2001).

denominator estimation problem followed by a least-squares solution of the numerator problem. Although nonlinear ARMA methods achieve a given model accuracy with lower model orders than do linear parameter estimation methods, their implementation is inherently complex, and the optimization can become impractical when many iterations are required for convergence. This becomes an issue, for example, in time-domain simulations when the transients established after the incoming wave first strikes the object decay slowly, and perhaps need to be partially included in the model. Another such example, where the transient tail decays very slowly, is the simulation of modes in a large, highly resonant cavity. Besides increasing the number of iterations needed for convergence of the nonlinear estimation methods, inclusion of transient data in the complex exponential model makes the amplitudes *time-de-*

Figure 16. Comparison of frequency-domain return loss (S_{11}) for a patch antenna, computed using OM extrapolation on a truncated FDTD time sequence of 3000 timesteps [13], with the reference computation in Ref. 57 that employs 8000 timesteps (© IEEE 2001).

pendent. Well-established model-based parameter estimation techniques such as Prony's method, the generalized pencil-of-functions method, and OM do not allow for time- or frequency-dependent amplitudes. However, discarding transients in the simulation neglects important physics pertinent to the early-time response, namely, establishing the natural response of the object, which depends only on the object's geometric and physical features. As an example, consider the time-domain reflection from a dielectric slab. If the interaction with the back end of the slab is ignored for the moment (e.g., for a thick slab), the reflection coefficient is completely determined from the interaction between the incident pulse and the slab's front end. Ignoring the first few time samples in the reflected signal is tantamount to not capturing this interaction, and leads to a very erroneous estimate of the reflection coefficient. In this section, we present a robust state space method (SSM) to solve the underlying estimation problem of modeling frequency-domain (FD) signature from a circuit, antenna, or scatterer, in terms of complex exponentials. The amplitudes in the model have decay or growth constants that vary with frequency, and thus permit inclusion of the entire signal in model construction. The model parameters are estimated using concepts from linear system theory without any need for iterative solution. The signal model and its estimation using the SSM are shown to be stable and computationally efficient.

SSM has been introduced by Piou et al. for radar signal processing [58], and is based on linear estimation of all the model parameters. SSM signal processing is a subset of general techniques used to model the EM scattering of an object in the frequency domain in terms of scattering centers. These techniques, including multiple signal classification (MUSIC) [59] and estimation of signal parameters via rotational invariance techniques (ESPRIT) [60], have been used in radar signal processing for understanding scattering mechanisms, tracking, and target feature extraction. They are referred to as *superresolution* techniques because the resulting radar images potentially have better resolution than do conventional Fourier transform techniques. In contrast to MUSIC and ESPRIT, state space signal modeling provides an alternative representation of a rational transfer function that is popular in linear system and control theory. SSM seeks to achieve superresolution in the frequency domain by coherently processing wideband EM data, simulated or measured. The complex exponential terms in the model are interpreted in terms of *scattering centers*, whose amplitudes and time delay (or *range*) are made frequency-dependent to capture the dynamic wideband behavior of the scattering mechanism. The exponential model is cast in terms of a system of difference equations, and state space techniques are employed to solve for the model parameters (decay/growth constants and range) by determining the complex eigenvalues of the system's open-loop state matrix, constructed from the data samples. The modal amplitudes are subsequently obtained from a least-squares solution. Determination of the complex eigenvalues and their modal amplitudes allows one to compute the frequency response of isolated scattering centers on the object, such as the reflection from the frontface of the

dielectric slab alluded to earlier. Unlike previous signal modeling approaches, no part of the signal under consideration is discarded, and therefore the proposed SSM provides a robust state space model in lieu of full-wave simulation for microwave circuit synthesis.

The motivation of this study comes from the seminal work of Carl Baum who proposed the singularity expansion method (SEM) in 1976 [61]. SEM permits description of the distributed parameter problems of electromagnetics by the same pole-zero representations used in the analysis and synthesis of lumped circuits and linear control systems. SSM captures the essence of SEM by applying well-established control system theory to compute the poles and zeros of the rational transfer function that corresponds to the exponential signal model. As shown in Refs. 58 and 62, this algorithm performs robustly even in a low signal-to-noise-ratio (SNR) environment, and therefore, it can also be applied to extract physical parameters, such as dielectric constant, from *measured* data. The proposed approach is also expected to perform better than the existing time-domain extrapolation methods [e.g., 9,13] with respect to model order, stability, and fidelity. Unlike these methods, transients can be considered in the model, potentially capturing important physical phenomena neglected therein. For brevity, however, we restrict ourselves to frequency-domain modeling in this article, although the method is equally applicable for processing time-domain data.

This section on frequency-domain signal models is organized as follows. In Section 3.1, the state-space signal model is introduced. The next subsection presents solution of the difference equation that describes the model in terms of an ARMA transfer function. An alternative input-output description of the model in terms of state space representation is discussed in Section 3.3, and the system parameters are derived in Section 3.4. This method is applied to two practical problems in Section 3.5: (1) determination of dielectric constant of a lossy slab by isolating the leading-edge reflection and (2) isolation of creeping-wave modes by decomposition of the total EM-simulated field scattered by a dielectric-coated cylinder. The latter problem is relevant to calculation of mutual coupling in conformal antenna arrays.

3.1. Signal Model

In this subsection, we review the data sequence $y(k)$ that constitutes N uniformly spaced frequency samples, each represented as a sum of M complex sinusoids (or point scatterers) corrupted by white Gaussian noise $w(k)$. Over a given bandwidth, the signal measurements at these N frequencies can be modeled as

$$y(k) = \sum_{i=1}^M a_i p_i^k + w(k); \quad k = 1, \dots, N \quad (33)$$

where a_i refers to the amplitude of the i th scattering center and the complex pole p_i is given by

$$p_i = \exp \left[-\Delta f \left(\alpha_i + j \frac{4\pi}{c} R_i \right) \right] \quad (34)$$

where a_i , α_i , and R_i denote the amplitude, decay/growth parameter, and the range, respectively, associated with the i th scattering center. The parameter c refers to the speed of light, and Δf is the sampling interval. The range may alternatively be written in terms of the time delay τ_i to the i th scattering center as $\tau_i = (2R_i)/c$. In this article, the primary interest is in estimating the parameters embedded in the data sequence $y(k)$. The state space method presented in Refs. 58 and 62 provides an efficient computation of the decay/growth and range parameters from the eigenvalues of an open-loop matrix (see Section 3.3). Once these parameters are accurately estimated, the amplitudes a_i can readily be derived from the state space matrices using least-squares fit based on a modal decomposition method [58]. The state space formulation may be seen as an input–output relationship between the noise $w(k)$ and the data sequence $y(k)$. The best way to derive the state space matrices is to rewrite (33) as a difference equation and study its transfer function. The next subsection presents the difference equation that best describes the input–output relationship between $y(k)$ and $w(k)$, and the subsequent subsections summarize the derivation of the state-space matrices that allow for computation of the model parameters.

3.2. Transfer Function of the ARMA Model

The input–output relationship for the general ARMA transfer function describing the model in (33) is characterized by the difference equation

$$y(k) = \sum_{i=1}^m d_i y(k-i) + \sum_{j=1}^q b_j w(k-j) + b_0 w(k) \quad (35)$$

where $w(k)$ and $y(k)$ are the input and output, respectively. The transfer function $H(z)$ of the system described by (35) may be defined as

$$H(z) = \frac{Y(z)}{W(z)} = \frac{B_0(z)}{A_0(z)} \quad (36)$$

where

$$A_0(z) = 1 - \sum_{i=1}^m d_i z^{-i} \quad (37)$$

and

$$B_0(z) = b_0 + \sum_{j=1}^q b_j z^{-j} \quad (38)$$

The roots of the polynomial $A_0(z)$ are the poles of the system, whereas the roots of $B_0(z)$ determine the zeros. An interesting and popular special case of the ARMA model in (35) is the AR model, described by the input–output relationship

$$y(k) = \sum_{i=1}^m d_i y(k-i) + b_0 w(k) \quad (39)$$

The transfer function of the AR model is therefore given by

$$H(z) = \frac{b_0}{A_0(z)} \quad (40)$$

with $A_0(z)$ defined by (37). As the AR model is a special case of ARMA, the state space representation will be carried out on the ARMA model unless specified otherwise. In the next subsection, we present the state-space method for the ARMA model.

3.3. State Space Representation

The input–output description of the model in (33) is given alternatively by the difference equations

$$x(k+1) = Ax(k) + Bw(k) \quad (41)$$

$$y(k) = Cx(k) + w(k) \quad (42)$$

where $x(k) \in \mathcal{R}^{M \times 1}$ is the state, $A \in \mathcal{C}^{M \times M}$ is the system matrix, and $B \in \mathcal{C}^{M \times 1}$ and $C \in \mathcal{C}^{1 \times M}$ are constant matrices. The transfer function of the state space formulation is obtained by taking the z -transform of Eqs. (41) and (42), and evaluating the ratio $Y(z)$ to $W(z)$ as follows:

$$X(z) = (zI - A)^{-1}BW(z) \quad (43)$$

$$Y(z) = CX(z) + W(z) \quad (44)$$

where I is an identity matrix. Inserting (43) in (44), we obtain

$$Y(z) = C(zI - A)^{-1}BW(z) + W(z) \quad (45)$$

Thus

$$H(z) = C(zI - A)^{-1}B + 1 \quad (46)$$

Equation (46) shows that the ARMA model for a discrete-time process $y(k)$ in state space notation is related to the transfer function such that the poles of the model [i.e., the roots of the polynomial $A_0(z)$ in (37)] are the eigenvalues of the open-loop matrix A . Furthermore, the zeros [i.e., the roots of $B_0(z)$ in (38)] are the eigenvalues of the matrix $(A - BC)$. Next, we present a procedure to estimate the triplet (A, B, C) from a given data vector.

3.4. State Space Identification

Let the impulse response of the ARMA model be represented by (46). To identify the state space matrices (A, B, C) from the impulse response, we expand the matrix $(zI - A)^{-1}$ into an infinite series:

$$(zI - A)^{-1} = Iz^{-1} + Az^{-2} + A^2z^{-3} + \dots \quad (47)$$

Inserting (47) into (46) yields

$$Y(z) = 1 + CBz^{-1} + CABz^{-2} + CA^2Bz^{-3} + \dots \quad (48)$$

By invoking the definition of the z -transform, (48) may be written as

$$Y(z) = y(0) + y(1)z^{-1} + y(2)z^{-2} + y(3)z^{-3} \quad (49)$$

By comparing coefficients of the z^{-k} terms in Eqs. (48) and (49), we obtain the following sequence:

$$\begin{aligned} y(0) &= 1, \quad y(1) = CB, \\ y(2) &= CAB, \quad \dots \quad y(k) = CA^{k-1}B, \quad \dots \end{aligned} \quad (50)$$

Thus, the relationship between the impulse response of the model and the state space parameters for any positive k is defined by

$$y(k) = CA^{k-1}B \quad (51)$$

If we form a Hankel matrix H from the data samples, given by

$$H \triangleq \begin{bmatrix} y(1) & y(2) & y(3) & \dots \\ y(2) & y(3) & y(4) & \dots \\ y(3) & y(4) & y(5) & \dots \\ \vdots & \vdots & \vdots & \vdots \end{bmatrix} \quad (52)$$

then (51) indicates that H can be factored as

$$H = \begin{bmatrix} C \\ CA \\ CA^2 \\ \vdots \end{bmatrix} [B \quad AB \quad A^2B \quad \dots] \triangleq \Omega \Gamma \quad (53)$$

where, borrowing from linear system theory, Ω and Γ are known as *observability* and *controllability* matrices [63]. It is important to note that despite the infinite dimensions of H defined by (52), for a finite order filter of length M [see (33)], Ω and Γ can be truncated to M rows and M columns, respectively. Consequently H has finite rank $r \leq M$. For a given set of measurements the Hankel matrix H is, of course, always finite. In this case H may be considered to be an operator constructed from a set of measurements $y(k)$ that maps the past input vector w_- to the future output y_+ . In the remainder of this subsection, we present a method to compute the Hankel matrix and derive the state space matrices from a finite set of samples.

Let a set of measurements be defined by

$$y = [y(1) \quad y(2) \quad y(3) \quad \dots \quad y(N)] \quad (54)$$

and suppose that we want to derive the corresponding state space matrices. The first step in computing the triplet (A, B, C) is to form the matrix H from the available data

samples

$$H = \begin{bmatrix} y(1) & y(2) & \dots & y(L) \\ y(2) & y(3) & \dots & y(L+1) \\ \vdots & \vdots & \vdots & \vdots \\ y(N-L+1) & y(N-L+2) & \dots & y(N) \end{bmatrix} \quad (55)$$

where the parameter L denotes the correlation window, and it is heuristically chosen to be $L = \lfloor N/2 \rfloor$, with the brackets denoting the smallest integer less than or equal to the inserted quantity. The Hankel matrix given in (55) may be partitioned into signal and noise subspaces via a singular-value decomposition (SVD). Computing the SVD of H and rearranging its singular values σ_i in decreasing order yields

$$H = [U_{\text{sn}} \quad U_{\text{n}}] \begin{bmatrix} \Sigma_{\text{sn}} & 0 \\ 0 & \Sigma_{\text{n}} \end{bmatrix} \begin{bmatrix} V_{\text{sn}}^* \\ V_{\text{n}}^* \end{bmatrix} \quad (56)$$

In (56), the subscripts “sn” and “n” denote the signal and noise subspaces, respectively, and the superscript * refers to conjugate transpose. The matrices U_{sn} and U_{n} are the signal and noise components, respectively, of the left unitary matrix, V_{sn} and V_{n} are the signal and noise components, respectively, of the right unitary matrix, Σ_{sn} and Σ_{n} denote diagonal matrices, with the signal and noise singular values of H arranged in decreasing order along their main diagonals. For a given SNR, the appropriate threshold may be defined to discard the lowest-order singular values. To increase the accuracy of the state space matrices, the Hankel matrix H may be truncated by suppressing the noise singular values and their associated unitary matrix components. It is well known that an M -rank matrix that best approximates (56) in the spectral norm sense is obtained by retaining only the dominant components [58]:

$$\tilde{H} = U_{\text{sn}} \Sigma_{\text{sn}} V_{\text{sn}}^* \quad (57)$$

By using the balanced coordinate method proposed in Ref. 64, (57) may be further written as [also see (53)]

$$\tilde{H} = \tilde{\Omega} \tilde{\Gamma} \quad (58)$$

where the observability and controllability matrices are calculated as

$$\tilde{\Omega} = U_{\text{sn}} \Sigma_{\text{sn}}^{1/2} \quad \text{and} \quad \tilde{\Gamma} = \Sigma_{\text{sn}}^{1/2} V_{\text{sn}}^* \quad (59)$$

respectively. Then, the matrix $A \in \mathcal{C}^{M \times M}$ can be obtained either from $\tilde{\Omega}$ or $\tilde{\Gamma}$. If the derivation of A is based on the observability matrix, the following equation holds:

$$A = (\tilde{\Omega}_{-r1}^* \tilde{\Omega}_{-r1})^{-1} \tilde{\Omega}_{-r1}^* \tilde{\Omega}_{-r1} \quad (60)$$

The matrices $\tilde{\Omega}_{-r1}$ and $\tilde{\Omega}_{-r1}^*$ in (60) are obtained by deleting the first $\tilde{\Omega}$ and last rows ($r1$ and $r1$), respectively, of

$\tilde{\Omega}$. The state space matrix (or vector) C may next be computed from the observability matrix defined in (53):

$$C = \tilde{\Omega}(1, :) \quad (61)$$

In other words, vector C is given by the first row of $\tilde{\Omega}$. Likewise, the vector B may be computed as the first column of the controllability matrix defined in (53):

$$B = \tilde{\Gamma}(:, 1) \quad (62)$$

If the eigenvalues of A are assumed to be distinct, one has

$$\lambda\{A\} = \{\lambda_1, \lambda_2, \dots, \lambda_M\} \quad (63)$$

It is well known from spectral estimation theory [58] that the eigenvalues (λ_i) carry decay/growth and range information about the scattering object's features; magnitude and phase of the eigenvalues are related to α_i and R_i by

$$\alpha_i = -\frac{\log|\lambda_i|}{\Delta f} \quad \text{and} \quad R_i = -\frac{c\phi_i}{4\pi\Delta f} \quad (64)$$

respectively. In (64), Δf is the sampling frequency and ϕ_i refers to the phase of the eigenvalue λ_i . The amplitudes α_i ($i = 1, \dots, M$) are easily obtained from a least-squares fit to the data using the model in (33) with the parameters calculated in (64) [58].

3.5. Simulation Examples

3.5.1. Synthetic Noisy Data. We consider synthetic data involving four point scatterers, corrupted by complex white Gaussian noise $w(k)$ with variance σ_n defined by the peak signal-to-noise ratio

$$\text{SNR} = 20 \log \frac{\sigma_{\text{sn}}}{\sigma_n} \quad (65)$$

where σ_{sn} denotes the signal variance. The synthetic data are generated using Eq. (33) over the frequency range 3–10 GHz, with a sampling rate of 20.057 MHz. The SNR is 40 dB, and the signal parameters for the data are depicted in Table 1.

To test the effectiveness of the SSM algorithm in the presence of noise, we performed 200 independent trials using these signal parameters with SNR = 40 dB for each run. For each trial, the focus is on a segment of the data with 101 samples in the frequency range 5.5–7.5 GHz. To estimate the signal parameters, the Akaike information criterion (AIC) [65] is used to identify the number of scat-

tering centers (or model order). For each trial, the AIC detects the four signals embedded in the dataset that are estimated by the SSM. The average estimates of the signal parameters over the 200 trials is given in Table 2, showing good corroboration with the original data. The model thus constructed using the SSM with synthetic data over the 5.5–7.5 GHz frequency band is then extrapolated in both forward and backward directions to cover the entire frequency range 3–10 GHz. Excellent agreement is observed between both of the extrapolated models and the “truth” dataset for the complex amplitudes [known as I (in-phase) and Q (quadrature) channels in radar signal processing] over the extended frequency range. The pertinent plots, omitted here for brevity, may be found in Ref. 58.

Next, the same simulation was repeated, decreasing the SNR to 20 dB, and performing 200 trials as stated above. In each trial, AIC detects the four signals that are used to generate the dataset, and SSM estimates their complex amplitudes. The SSM algorithm filters a great deal of noise; therefore, we expect reasonably good corroboration between the estimates and the “truth” data even at this moderately low SNR. Indeed, Table 3 depicts such agreement for all the four scattering centers. The model thus constructed with synthetic data over the 5.5–7.5 GHz frequency band is then extrapolated in both forward and backward directions to cover the entire frequency range 3–10 GHz. Excellent agreement is observed between both of the extrapolated models and the “truth” dataset over the extended frequency range. Pertinent comparison plots may be found in Ref. 58.

3.5.2. Reflection from a Dielectric Slab. The reflection from a 15-mm-thick lossy slab with dielectric constant $\epsilon_r = (5, -0.01)$ is considered next, and it is shown that the response of the frontface of the slab can be isolated from the composite response using the SSM. The “truth” data consists of the Fresnel reflection coefficient for the slab, calculated at normal incidence over the 2–18 GHz frequency band. The dataset is Fourier transformed to obtain the composite response shown in Fig. 17. The transform employs distance to the scatterer (or range) instead of time, and this operation is also known as *pulse compression* or *range processing* [66]. Because the phase reference is at the front face, the pulse with peak at zero range is the first reflection off the slab front, the second pulse is the reflection off the backface, the third pulse is the rereflection off the front, and so on.

Next, a 20th-order state space AR model [see (33)] is computed from the simulated reflection data, and a single pole located at (1,0), with amplitude of 0.382 and phase π radians, is determined to have zero range. Thus, using only this pole in the AR transfer function, one can isolate the front face response of the slab. Figure 18 displays the frequency response of the isolated pulse along with that of the complete model, which is obtained by coherent addition of the response from all 20 poles. The interference between incident and reflected waves, causing the nulls at half-wavelength intervals, is evident. Although not shown, frequency response of the complete model coincides with the “truth” data. Because the leading reflection is isolated, the reflection coefficient of this pulse is the

Table 1. Signal Parameters for Synthetic Data

Scattering Center	Decay/Growth (α)		Time Delay (τ)		Amplitude ($ a $)	
	Estimates	% Error	Estimates	% Error	Estimates	% Error
1	-0.9118×10^{-9}	1.22	1.98×10^{-9}	1.0	0.997	0.3
2	-0.2084×10^{-9}	9.71	5.8×10^{-9}	3.33	1.03	3.0
3	-0.3318×10^{-9}	7.83	1.0×10^{-8}	0	0.995	0.5
4	0.51×10^{-16}	4.1	13.8×10^{-9}	1.43	1.0	0

same as that of the half-space problem. In other words, the ability to compute using the SSM the responses of different reflected pulses, isolated in range, provides a feature akin to time-domain gating in vector network analyzer measurements, *albeit* with simulated data. This feature has many applications, including determination of physical parameters from simulated (or measured) data. As an example, using the constant amplitude of S_{11} for the isolated pulse from Fig. 18 (with a phase of π), the slab's dielectric constant can be determined as

$$\epsilon_r = \left(\frac{1 - S_{11}}{1 + S_{11}} \right)^2 \quad (66)$$

This equation yields $\epsilon_r = 5 - j0.01$ *exactly*. Once the dielectric constant is known, using the distance d_{12} between the first two peaks in Fig. 17, the slab thickness can be determined as $d = d_{12} / \sqrt{\text{Re}(\epsilon_r)} = 34 / \sqrt{5} = 15.2$ mm, an error of 1.3%.

Next, the analysis shows how the proposed SSM algorithm works for moderately thin slabs when the resolution between the first two peaks in Fig. 17 becomes difficult. For example, when d is reduced to 5 mm, one obtains the range response in Fig. 19, which clearly shows impending merging of the two peaks. Because the first peak can still be isolated, this should result in an accurate dielectric constant. Indeed, the state-space AR model produces a pole with amplitude 0.384 and phase π at zero range, yielding the correct permittivity, thus illustrating qualitatively that the model is not sensitive to thickness variations within the extent of a range cell.

3.5.3. Coupling in a Conformal Array. Microstrip arrays conformal to cylindrically shaped substrates are important in radar and communication applications. Microstrip lines on such substrates serve to feed signal to the radiating elements, and are also used in baluns or couplers for matching the elements. Therefore, examining the modal

propagation on the surface of a cylindrical substrate can be useful. A primary source of coupling between the elements is azimuthal (or creeping) surface waves propagating along helical paths [67], which are not easily resolvable from the radiating space wave. Unlike the planar microstrip counterpart, the cylindrical surface waves do not exhibit pronounced resonance, and difficulty in their detection in the presence of noise is compounded by the fact that their amplitude is much smaller than that of the space wave. An example is the well-known Mie scattering from a sphere, in which the dominant creeping wave is 30 dB below the specularly reflected wave; subsequent creeping waves are considerably weaker. Therefore, isolation of creeping waves provides a challenging test for the SSM algorithm.

This article applies the superresolution SSM to resolve the creeping waves along the surface of a finite-length cylindrical microstrip substrate. Since the modal propagation characteristics are independent of the excitation, without loss of generality, we consider an incident plane wave, and compute the surface currents over a wide frequency band using the body-of-revolution method of moments (MoM) [68]. The radiated field is calculated from the currents as a function of incident angle and frequency. The data for specific angles, such as the specular aspect, contain, in addition to the space wave, the contribution from creeping waves launched at different locations on the substrate. Because the algorithm maps the origin of the creeping waves on the scatterer, one can ascertain in a practical situation not only the interelement coupling but also the source of such coupling. We believe that such an algorithm has significant potential for array optimization.

We consider a cylindrical substrate with a perfect electrically conducting (PEC) core of radius 10 mm, coated with a 4-mm-thick dielectric layer ($\epsilon_r = 3 - j0.6$). Figure 20 depicts the geometry along with schematic position of two conformal microstrip dipole elements, one active (A) and the other passive (P). The radiated field, observed broadside to the cylinder over the 2–12 GHz bandwidth, consists

Table 3. Average Estimates of Signal Parameters over 200 Trials (SNR = 20 dB)

Figure 17. Range response of the reflection coefficient for a 15-mm-thick slab.

of two components: (1) the space wave directly reaching the field point from the active element and (2) the surface (creeping) wave that radiates as it traverses around the cylinder surface. The strength of the creeping wave is proportional to the coupling between the elements. The frequency-domain field data in the principal plane $\theta = 90^\circ$ are Fourier-transformed to obtain the composite response shown in Fig. 21. The first peak denotes the space wave, and the next one, about 35 dB lower, denotes the creeping wave. The range separation between the two peaks equals the arc length between the active and passive elements. The phase reference (zero range) is along the cylinder axis. Thus, the creeping wave originates from a fictitious line source on the opposite end of the cylinder at a range of 0.21 m (or one diameter), as one would expect from physical optics.

Figure 18. Frequency response of an isolated frontface reflection. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 19. Range response of the reflection coefficient for a 5-mm-thick slab.

A 30th-order state space AR model [see (33)] is applied to the frequency-domain data, and the two wave spectra are extracted from the MoM data. The frequency response of the complete model is obtained by coherent addition of the response contributed by all the poles. Figure 22 depicts excellent corroboration between the model response and the original MoM data. The ripple up to 7.5 GHz is due to the interference between the space wave and the creeping wave in the direction of maximum radiation. As we shall show next, the latter cuts off around 7.5 GHz. An advantage of using range processing with SSM is the direct relation between range and pole locations. Thus, one may isolate a given mode (pulse) by simply adding contributions of only those poles that are associated with the range window of that pulse. By coherently summing the responses of only three poles whose range is centered on the creeping wave peak, we obtain the isolated response (model) shown in Fig. 23. For comparison, Fig. 23 also depicts an analytical solution derived in Ref. 67 by appealing to angularly propagating wave representation. Good agreement between the two at such low amplitude levels indicates the robustness, as well as the accuracy, of the SSM algorithm. In accord with Ref. 67, the creeping wave exhibits a high-frequency cutoff around 7 GHz, where it extinguishes and becomes trapped in the dielectric layer

Figure 20. Radiating elements on a cylindrical substrate.

Figure 21. Range response for the radiated field.

(numerical cutoff is arbitrarily defined as the frequency at which the signal ≤ -30 dB). The trapped wave bounces back and forth internal to the layer, similar to a guided mode, and leaks outside tangentially on the surface as a result of curvature. Figure 23 indicates that the coupling between the elements can be neglected at the higher frequencies. The creeping-wave propagation constants and their modal amplitudes have also been calculated, giving considerable physical insight into the coupling. Calculation of these modal parameters will be discussed next.

3.5.3.1. Modal Propagation Constants. Because the exact path of the isolated creeping wave along the substrate surface can be determined from geometric considerations and the range plot, one can compute the attenuation and phase constants (or the complex propagation constant) of the mode using the SSM model. By computing the complex amplitude of the tangential field along the path using the SSM, the attenuation and phase constants have been ob-

Figure 22. Frequency response comparison for the total field. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 23. Comparison of the extracted creeping-wave response with the analytical solution in Ref. 67. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

tained as functions of frequency, and are plotted in Figs. 24 and 25 for the transverse electric (TE) and transverse magnetic (TM) modes, respectively. The TM modal field is extracted from the MoM simulation with horizontally polarized (or parallel to the cylinder axis) plane-wave incidence. The TE field corresponds to vertical polarization. It is noted that although the modes on a finite-length cylindrical microstrip substrate are hybrid in general, the TE-TM mode coupling can be neglected for broadside radiation, because the creeping-wave surface path has very small helicity.

As the creeping wave propagates, it attenuates by shedding energy tangentially because of curvature. The attenuation constant of the TE mode remains relatively constant until about 7.5 GHz and then increases rapidly with frequency, resulting in the trapped mode referred to earlier. Beyond the creeping-wave cutoff, there is very lit-

Figure 24. Creeping-wave attenuation and phase constants for the dominant TE mode. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 25. Creeping-wave attenuation and phase constants for the dominant TM mode. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

tle curvature-induced leakage, or in antenna terms, there is negligible interelement coupling due to the surface wave. From the phase constant plot, it is observed that dispersion exists at higher frequencies. The form of the attenuation curve, including the cutoff frequency, is in good agreement with the analytical results from Ref. 67. The relative variation of the amplitude over 10 GHz bandwidth is smaller for the TM mode than for the TE mode, and the TM mode does not exhibit high-frequency rolloff. Comparing the attenuation curves in Figs. 24 and 25, we conclude that the TE field is much stronger than the TM field. The TM field of the creeping wave is polarized tangentially to the cylinder surface, and becomes quite small for thin dielectric layers. In the limit of a PEC cylinder, this field should vanish.

4. CONCLUSIONS

We have presented signal models to represent EM signatures in both time and frequency domains. Time-domain data generated by FDTD simulations and frequency-domain data generated by the method of moments have been used to illustrate the effectiveness of the models. Various signal modeling approaches, including Prony's method, decoupled optimal method, and the state space spectral method, have been reviewed for their applicability to EM problems.

A classical ARMA identification technique has been described to model FDTD time sequences for resonant structures. The major focus of the discussion has been to demonstrate that, given a computed FDTD sequence, corresponding to an unknown transfer function with *arbitrary* number of poles and zeros, it is possible to obtain accurate match in time and frequency domains with relatively low model orders. It is shown that the multidimensional nonlinear optimization problem can be decoupled into two separate problems with reduced dimensionality, one of which is linear and the other, nonlinear. The inherent mathematical structure of the nonlinear denominator problem is utilized to design an efficient iterative compu-

tational algorithm for estimating the model from moderately early-time sequences. The simulation examples pertaining to a lowpass filter with sharp cutoff and a high-Q patch antenna demonstrate that low model orders are adequate to model the TSs of resonant structures.

A new method has been presented to model frequency-domain EM-simulated fields using a state space approach derived from control theory. The eigenvalues of the system matrix provide range and amplitude information of the field parameter, which allows for isolation of desired responses in the EM signature via pulse compression and spectral decomposition. This superresolution state space modeling approach has been applied to model and isolate modal EM responses from composite field data. Examples are presented to prove that the method can extract correct "design" parameters from the model, such as dielectric constant and mutual coupling. The proposed method is applicable to microwave circuit synthesis and optimization, where the state space model can potentially reduce the parameter domain and obviate the need for intensive EM simulations at each design iteration. The method has been applied to isolate the creeping-wave modes ensuing from wave propagation external to a cylindrical microstrip substrate. Amplitude variation along the creeping-wave ray path on the cylinder surface is used to calculate attenuation and phase constants of the dominant mode. The method has been validated by good corroboration between computed modal field and analytical data.

5. APPENDIX: COMPUTATIONAL ALGORITHM FOR OM

The criterion in (27) is nonlinear in \mathbf{b} and hence cannot be minimized directly. But instead of using standard nonlinear optimization techniques, the inherent mathematical structure of the criterion will be utilized to develop an iterative computational algorithm. The final form of the error vector in (27) is rewritten as

$$\begin{aligned}
 \mathbf{e}(\mathbf{b}) &= \mathbf{B}(\mathbf{B}^T \mathbf{B})^{-1} \mathbf{B}^T \mathbf{h}_d \\
 &\triangleq \mathbf{W} \mathbf{B}^T \mathbf{h}_d \\
 &= \mathbf{W} \mathbf{H}_2^p \mathbf{b} \\
 &= \mathbf{W}[\mathbf{g} : \mathbf{G}] \mathbf{b} \\
 &= \mathbf{W} \mathbf{g} + \mathbf{W} \mathbf{G} \hat{\mathbf{b}}
 \end{aligned} \tag{A.1}$$

where $\mathbf{W} \triangleq \mathbf{B}(\mathbf{B}^T \mathbf{B})^{-1}$, and \mathbf{H}_2^P is the Prony's data matrix defined in (17). If the matrix \mathbf{W} is treated as independent of $\hat{\mathbf{b}}$, one can minimize $\|\mathbf{e}(\mathbf{b})\|^2$ with respect to $\hat{\mathbf{b}}$ and obtain

$$\begin{aligned} \hat{\mathbf{b}} &= -(\mathbf{W}\mathbf{G})^\# \mathbf{W}\mathbf{g} \\ &= -(\mathbf{G}^T \mathbf{W}^T \mathbf{W}\mathbf{G})^{-1} \mathbf{G}^T \mathbf{W}^T \mathbf{W}\mathbf{g} \end{aligned} \quad (\text{A.2})$$

However, since \mathbf{W} does depend on the elements in $\hat{\mathbf{b}}$, it can be computed iteratively. At the $(i+1)$ th iteration, $\mathbf{W}^{(i)}$ is formed using the estimate of \mathbf{b} found in the i th iteration. This leads to the following iterative algorithm for computing \mathbf{b}^{i+1}

$$\mathbf{b}^{(i+1)} = \begin{bmatrix} 1 \\ \dots\dots\dots \\ -[\mathbf{X}^{(i)} \mathbf{G}]^{-1} [\mathbf{X}^{(i)}] \mathbf{g} \end{bmatrix} \quad (\text{A.3})$$

where

$$\begin{aligned} \mathbf{X}^{(i)} &\triangleq \mathbf{G}^T \mathbf{W}^{T(i)} \mathbf{W}^{(i)} \\ &= \mathbf{G}^T (\mathbf{B}^{T(i)} \mathbf{B}^{(i)})^{-1} \end{aligned} \quad (\text{A.4})$$

The iterations are continued until $\|\mathbf{b}_{i+1}^{i+1} - \mathbf{b}_i^i\|^2 < \delta$, where δ is an arbitrarily small number. It must be noted here that the iterations in (A.3) may not always converge to the absolute minimum of the error criterion in (9), and hence the estimated \mathbf{b} may not be the optimum one. This is because in (A.3) the variability of \mathbf{W} with respect to \mathbf{b} had been ignored while minimizing $\|\mathbf{e}(\mathbf{b})\|^2$. To achieve the optimum, the gradient of the complete expression of $\|\mathbf{e}(\mathbf{b})\|^2$ must be set to zero. If desired, this can be done in a second phase of the algorithm, which may be found in Ref. 36. However, the simulation examples in this article indicate that the first phase of iterations using (A.3) is adequate in bringing the estimate very close to the optimum. Once the estimates of \mathbf{b} converge, \mathbf{a} is computed by following the steps in (28)–(30).

Gainesville, Florida

1. INTRODUCTION

Passivation layers are deposited over the entire top surface of Si or compound semiconductor wafers to form an insulating protective coating for the semiconductor. This procedure guards against environmental contamination that might lead to increased surface leakage currents, and also against mechanical damage during assembly and packaging. Some of the desirable properties of passivation-layer materials include good scratch protection of the underlying interconnect metallurgy, impermeability to moisture and alkali (Na^+ , K^+) ions, low stress ($<5 \times 10^8 \text{ dyn/cm}^2$, preferably compressive), conformal step coverage, and etchability with excellent uniformity and adhesion [1]. While thicker passivation layers would normally be desirable because of the improved mechanical protection they afford, there is generally an upper limit to the thickness in order to avoid cracking. The primary inorganic dielectric passivation films are SiO_2 and SiN_x , while polyimides and epoxy resins are used for low-cost polymer encapsulation. The thermal stability requirements are obviously lower for final passivation coatings than for interlevel dielectrics.

Patterns are formed in the passivation-layer material by either wet (for phosphosilicate glasses) or dry (for SiN_x or polymers) etching to enable electrical contact to the completed circuit. The area of these contact pads is sufficiently large ($100 \times 100 \mu\text{m}^2$) that wet etching is acceptable [2].

2. TYPES OF PASSIVATION LAYER

2.1. Phosphorous-Doped SiO_2 [Phosphosilicate Glass (PSG)]

The addition of P (2–6 at%) to SiO_2 reduces film stresses and improves the barrier properties for minimizing alkali and metallic ion contamination. If higher P contents are used, corrosion of the underlying metal may occur if moisture enters the circuit package; this results from reaction of moisture with PSG to form phosphoric acid (H_3PO_4). Electrochemical corrosion of Al interconnects will eventually lead to metallization failure.

These films are generally deposited by low-temperature chemical vapor deposition (CVD) (either at atmospheric pressure, at low pressure, or by plasma enhancement) with addition of phosphine (PH_3) to the gas flow to form P_2O_5 that is incorporated to form the PSG. The reactions are $\text{SiH}_4 + \text{O}_2 \rightarrow \text{SiO}_2 + 2\text{H}_2$; $4\text{PH}_3 + 5\text{O}_2 \rightarrow 2\text{P}_2\text{O}_5 + 6\text{H}_2$. Atmospheric-pressure CVD PSG has improved step coverage relative to undoped CVD SiO_2 [3]. The PSG may be flowed at temperatures $\geq 1000^\circ\text{C}$ to planarize the surface topography, although this is seldom done for passivation layers; only for interconnect isolation layers. The phosphorus content is controlled by the $\text{SiH}_4 : \text{PH}_3$ ratio in the gas flow. We emphasize that we

are dealing with films deposited from the gas phase, and not with the direct thermal oxidation of Si in either dry O_2 ($\text{Si} + \text{O}_2 \rightarrow \text{SiO}_2$) or steam ($\text{Si} + 2\text{H}_2\text{O} \rightarrow \text{SiO}_2 + 2\text{H}_2$), which is employed for the high-quality gate oxides in metal oxide semiconductor (MOS) devices. Oxides grown by thermal means range in thickness from 6 nm (tunneling oxides), 4–20 nm (gate oxide), 50–300 nm (capacitor dielectrics), 200–500 nm (mask oxide, surface passivation oxide), to 300–1000 nm (field oxide).

2.2. Silicon Nitride

Stoichiometric silicon nitride has the formula Si_3N_4 , but films deposited by plasma-enhanced CVD (PECVD) tend to contain large quantities of hydrogen (10–30 at%) and to be nonstoichiometric, and are thus collectively referred to as SiN_x . It is common as a passivation-layer material because of its scratch resistance and impermeability to moisture and alkali ions. In the case where it is deposited over Al metallization, the process temperature must be kept low, and PECVD is preferred [4]. These films generally have a relatively high compressive stress, which can lead to cracking or enhanced void formation in Al interconnects. There are three main applications for silicon nitride in VLSI technology: as a gate dielectric in metal nitride oxide semiconductor (MNOS) transistors, as a mask for selective oxidation of silicon, and as a final passivation layer for ICs. When used for the first two applications the silicon nitride is deposited by low-pressure CVD at 700–900°C through the reaction $3\text{SiCl}_2\text{H}_2 + 4\text{NH}_3 \rightarrow \text{Si}_3\text{N}_4 + 6\text{HCl} + 6\text{H}_2$. The dielectric strength of this material is generally $\sim 10^7 \text{ V/cm}$ with tensile stress $< 2 \times 10^{10} \text{ dyn/cm}^2$. The thermal stability is excellent, and usually only one IR band (at $\sim 870 \text{ cm}^{-1}$ due to Si = N bonds) is present. For passivation applications, the deposition is performed at 200–400°C through the reaction $\text{SiH}_4 + \text{NH}_3$ (or N_2) $\rightarrow \text{Si}_x\text{N}_y\text{H}_z + \text{H}_2$. The dielectric strength of this material is $\sim 6 \times 10^6 \text{ V/cm}$ with compressive stress $< 10^{10} \text{ dyn/cm}^2$. The thermal stability is variable, and two bands (due to Si = N at $\sim 870 \text{ cm}^{-1}$ and Si = Hat 2187 cm^{-1}) dominate the IR spectrum. The large hydrogen concentration may be detrimental, leading to threshold voltage shifts in devices and acceleration of hot-electron aging effects in MOS transistors. Lower hydrogen concentrations may be obtained when SiH_4/N_2 mixtures rather than SiH_4/NH_3 mixtures are employed in PECVD [5].

2.3. Silicon Oxynitrides

These are formed by reacting SiH_4 with N_2O and NH_3 mixtures, leading to $\text{SiO}_x\text{N}_y(\text{H}_z)$. These have alkali ion and moisture barrier properties similar to those of silicon nitride and are less permeable to these entities than are oxides. The stress of these films is intermediate between that of atmospheric-pressure CVD oxides (tensile) and plasma-deposited oxides and nitrides (compressive), and can be tailored by optimizing the deposition conditions. Typically PECVD oxynitride layers contain about half the hydrogen concentration found in PECVD nitrides.

Bilayers consisting of an initial PECVD oxide followed by PECVD nitride are becoming increasingly popular. The presence of the oxide reduces mechanical stress and

hydrogen content of the passivation layer, while the nitride overcoating provides a barrier for moisture and alkali ions. The dielectric films may then be coated with a polyimide for cushioning during loading of the individual die.

3. INTERLEVEL DIELECTRICS AND POLYIMIDES

Since individual transistors must be wired together with other circuit elements (resistors, inductors, capacitors) to complete the integrated circuit, connections between devices are critically important. Interconnections between devices are generally formed by covering the entire surface of the wafer, then masking the lines to be retained and etching away all the metal not being used. In connection of a die to external circuitry, the metallization on the Si surface terminates in a relatively large area referred to as a *bonding pad*, to which a wire can easily be attached. There are several requirements for an ideal metallization scheme, including low resistance, good adhesion, and ohmicity on Si. Aluminum is the most common metal employed, and gold is also used in some situations. Al and Cr adhere very well to SiO₂, especially if sintered at $\geq 300^\circ\text{C}$ to balance bonding [6].

The wiring delay may be the determining factor in the overall speed of a circuit, and therefore much attention is paid to the design of multiple wiring planes to minimize interconnect length. The multilayered metallization is isolated by interlevel dielectric layers, and a final passivation film is employed for environmental protection. In a metal oxide semiconductor transistor (MOSFET), for example, the total effective capacitance and resistance of the device at the gate and interconnect level produce an RC time constant τ_{RC} of [7]

$$\tau_{RC} = \frac{\rho}{t} = \frac{L^2 E_{ox}}{t_{ox}} \quad (1)$$

where ρ is the resistivity of the interconnect material, L its length, t its thickness, and E_{ox} and t_{ox} are the permittivity and thickness of the oxide that separates the interconnect from the semiconductor. Since the interconnect length increases with circuit complexity, multilevel designs must be employed to maintain circuit speed (schematic shown in Fig. 1).

On the basis of Eq. (1), we would ideally want a low dielectric constant insulation that was also as thick as possible. There are, however, many reasons why film thickness must be limited: (1) the metal levels are connected by holes etched into the intervening dielectric insulators, and to ensure metal continuity through these via holes, the overlying metal would also have to be made thicker (step coverage), and the intralevel capacitance would increase; and (2) it is difficult to etch high-aspect-ratio vias because of limitations in mask robustness and also in lithographic resolution in the type of thick resists needed to act as a mask for deep dielectric etching. This generally necessitates the use of bilevel or trilevel mask schemes, involving a thick imaging resist, a thin transfer layer, and a thick planarizing resist or polyimide. This adds considerably to process complexity, however.

Figure 1. Simplified cross section of a three-level metal interconnect scheme on a metal oxide semiconductor transistor (after Ref. 7).

In addition to a low dielectric constant, it is desirable that the interlevel dielectrics have high breakdown strength ($\sim 10^7$ V/cm), high resistivity ($> 10^{12} \Omega \cdot \text{cm}$), low compressive stress, good adhesion, and impermeability to moisture and alkali ions.

3.1. Polyimides

These have reasonable thermal stability and lower dielectric constant (2.9–3.7) than do inorganic dielectrics such as SiO₂ (3.8–4.2) or Si₃N_{7,4}. They planarize underlying topography, but many polyimides absorb moisture on exposure to air, which in general increases the effective dielectric constant and semiconductor surface leakage. This is a major drawback, and it has been addressed by use of bilayer structures in which an inorganic dielectric is placed over the polyimide. However, this adds process complexity and may not gain much in terms of reducing the effective dielectric constant [8].

Polyimides generally have low stress and good step coverage, and deposition is by spin coating, which makes the process inexpensive, even though the polyimides themselves may be relatively expensive. As with photoresists, the prepolymer is applied to the wafer, and curing at elevated temperature is necessary to convert the precursor into the polyimide. Since the adhesion of polyimides to Al is poor, an adhesion promoter or thin layer of a material such as Cr is necessary to improve bonding to the metal. Moreover, moisture or outgassing from the polyimide may deform the metal overlayers.

Two further drawbacks are the lower thermal conductivity compared to inorganic dielectrics and the inferior resistivity and breakdown voltage of polyimides. Dry etching to form via holes is readily accomplished with O₂-based plasma chemistries.

3.2. Inorganic Insulators

Inorganic insulators in common use are based on undoped or B- or-P-doped SiO₂, or Si₃N₄ (or SiN_xH₄) or silicon oxynitrides, as discussed earlier. Spin-on glasses (SOGs) have good gap-filling/planarizing capabilities and are low-cost.

The most common form is siloxane SOG, a partially hydrolyzed mixture of tetrafunctional siloxane oligomer. While their gap-filling qualities are well established, alternative technologies such as low-pressure CVD with high-density plasmas or tetraethoxysilane (TEOS)/silane processes are attractive at small dimensions and high aspect ratios. Since many of the new materials being investigated are not strictly glasses, but dielectrics, they are referred to as *spin-on dielectrics* (SODs). Spin-on insulators are most commonly applied in processing of memory chips, which are more cost-sensitive and have a more suitable dense regular array geometry relative to logic chips [9].

The SOG films are typically sandwiched between two oxide layers which are usually $\sim 1000 \text{ \AA}$ thick; SOG is $\sim 3000 \text{ \AA}$ thick. If the top layer is subsequently chemically, mechanically (chemicomechanically) polished (CMP) for planarization, it is generally at least 1 \mu m thick, that is, as thick as the tallest underlying feature. This combination of gap filling with low dielectric constant spin-on glass, followed by CMP, is a promising technology for global planarization even at very small critical dimensions ($\leq 0.25 \text{ \mu m}$).

An area receiving a lot of attention is the issue of via poisoning, which occurs when the sidewall of an SOG feature is damaged during plasma ashing. When the SOG is damaged in this fashion, it can readily absorb moisture, which can outgas when the metal is in place and poison the via by leading to formation of metal oxides. These produce high via resistance. Excessive temperature ($> 500^\circ\text{C}$) as well as plasma exposure will cause a hydroscopic surface on an organic SOG, and the plasma ashing may lead to the presence of carbonaceous residues, which also create high via resistance.

Some newer organic, low-dielectric constant materials are formed to exhibit much improved moisture-generating characteristics, and a number of methods have been employed to eliminate via poisoning in conventional materials. These include Ar plasma exposure, ion-beam and electron-beam curing, and implantation of species such as As in order to produce a thin skin of silicatelike material on the sidewall that is impervious to moisture.

Low-dielectric-constant materials as replacements for polyimides or SiO_2 and Si_3N_4 are an avenue to improve chip speed and avoid crosstalk between adjacent metal lines [10]. The dielectric constant of PECVD SiO_2 (~ 4.2) can be reduced to around 3.5 by adding small amounts of fluorine. Poly arylene ethers have a dissociation constant of $K < 3$, while nanoporous silica (often classified as nanofoams and xerogels) have values under 2. A variety of low- K spin-on materials are under development. In addition, CVD low- K materials based on amorphous carbon, diamondlike carbon, or methyl silane/hydrogen peroxide, are under development. In most of these materials, direct contact with the metal is not desirable because of stress and hillock growth, and they are generally embedded in an oxide layer sandwich.

Currently the forecast for future trends in dielectric materials calls for K values of < 2.0 by 2004 [11]. These correspond to a capacitance in fF/um of 0.24 for feature sizes of 0.10 um and 6–8 metal layers. In the short term,

fluorinated silicon dioxide (F_xSiO_4) films are of great interest for intermetal dielectrics since they retain many of the properties of SiO_2 while achieving a modest reduction in dielectric constant. Since fluorine is the most electronegative and least polarizable element, incorporation of fluorine reduces the number of polarizable $\text{Si} = \text{OH}$ bonds and thus lowers the dielectric constant. Typical fluorine concentrations in these films range from 2 to 14 at%. The precursors for depositing F_xSiO_4 films are widely available and are inexpensive compared to alternatives such as fluorinated paralyenes. Moreover, the films are easily deposited in existing process tools, facilitating process integration.

A number of different inorganic precursors have been reported for depositing F_xSiO_4 films, including the following chemistries: $\text{Si}(\text{OC}_2\text{H}_5)_4$ with additional of NF_3 , CF_4 or C_2F_6 , SiF_4 with additions of SiH_4 , O_2 or N_2O , and $\text{FSi}(\text{OC}_2\text{H}_5)_3$ with additions of O_2 or H_2O . It is possible to produce stacked films using sequential deposition and a sequence of O_2 , C_2F_6 , and O_2 to form an oxide/fluorinated silicon dioxide/oxide structure. Deposition has been performed with predominantly plasma-enhanced CVD, but atmospheric pressure CVD has also proved effective. High-density plasma deposition appears very promising because simple precursor chemistries of SiH_4 , SiF_4 , and O_2 can be used that contain no carbon that might be incorporated. These films have low hydroxyl bond density and are generally reported to have dielectric constants lower than those of conventional PECVD films.

There is also an optimum fluorine concentration in F_xSiO_y films. While the dielectric constant decreases with increasing fluorine density, for values ≥ 15 at% the films are more susceptible to moisture absorption. This may result from an excessive number of dangling or weakly bound fluorine atoms. The stability of such films can be improved by either increasing the deposition temperature or applying an RF chuck bias to densify the film during deposition. The sandwich-type structures are obviously much more stable with respect to water absorption. The gap-filling ability and planarizability of F_xSiO_4 films appear to very good, with numerous reports of void-free gap filling for a 0.35-um space pattern with an aspect ratio of 3.8. Some authors have found that addition of C_2F_6 to PECVD TEOS films substantially improved the gap-filling characteristics. Other advantages of F_xSiO_4 films include reduced hillock formation in aluminum-alloy interconnections, longer lifetimes under bias stress, and lower Si/SiO_2 interface trap densities.

In summary, fluorinated SiO_2 has dielectric constants in the range 3.0–3.5 and is readily deposited using existing production equipment and relatively straightforward chemistries. The gap-filling properties for $< 0.5 \text{ um}$ feature sizes with aspect to ratio $> 2.3:1$ intermetal spacing is improved by fluorine addition to silicon dioxide.

4. TRENDS IN METALLIZATION

The semiconductor industry has relied on Al metallization from its inception in the early 1960s because it is a well-established, reproducible, low-cost technology. Early on it

was found that the electromigration resistance of Al could be improved by addition of small quantities of copper. However, improved metallization schemes are desirable. Table 1 shows some of the characteristics of the main contenders. Currently the most common scheme for interconnects is Al-based metallurgy embedded in an oxide/nitride dielectric, with refractory metal plugs for via connections. The Al alloys, CVD tungsten for plugs, with typical liners of Ti/W or Ti/TiN are well established and are basically industry standards.

There is extensive development on squeezing additional performance from the standard structures, including diffusion barriers for Al reflow, CVD tungsten for filling contacts or vias, use of CVD for the liner materials instead of physical vapor deposition (especially for $<0.30\text{-}\mu\text{m}$ vias, where coverage is a major challenge), improved Al deposition techniques and use of chemico-mechanical polishing (CMP) for global planarization. While CMP is well established for hard metals such as W and for dielectrics, there is still work to be done in perfecting its use for Al alloys and copper. The role of microstructures and voids in Al lines is critically important, as is the role of stresses on their reliability. New deposition techniques that might allow improved electromigration resistance, stress migration resistance, and improved yields, coupled with new developments in low-dielectric-constant materials, are the key focus.

4.1. Chemical Vapor Deposition of TiN

TiN is important as a liner material in via connections and serves as a nucleation layer to improve adhesion of W in these vias. It also prevents attack by WF_6 during W plug filling. Conformal deposition using the thinnest possible films is desirable in order to reduce interconnect stack thickness and via resistance, since TiN has a resistivity higher than that of any of the other components of the metallization (Ti, Al, and W). Moreover, the barrier properties must be thermally stable during the various thermal cycles encountered in a process sequence.

TiN films deposited by reactive sputtering (physical vapor deposition) generally have inadequate conformality

for $<0.5\text{-}\mu\text{m}$ applications with high aspect ratio. Collimated sputtering may not be able to produce sufficient sidewall coverage, and therefore there is a strong effort to develop CVD TiN [12].

The most common inorganic precursor is TiCl_4 , which is reduced by NH_3 to produce TiN deposition. Deposition temperatures below $\sim 550^\circ\text{C}$ lead to high concentrations of Cl incorporated in the films ($\sim 5\text{ at}\%$), and even at 700°C there may be $\sim 1\text{ at}\%$. The film resistivity increases with decreasing deposition temperature. Typical values of $85\ \mu\Omega\cdot\text{cm}$ are obtained at 700°C , similar to the values obtained by reactive sputtering. The incorporation of Cl is, of course, a potential corrosion issue with Al metallization. Electron Cyclotron Resonance (ECR) CVD can also be employed, but again temperatures above 400°C must be used to minimize Cl incorporation.

Use of metallorganic precursors enables lowering of the deposition temperature below 400°C so that not only the contact level, but also via, metal 2 and even higher layers can be metallized. The main precursor tried has been tetrakis(diethylamido)titanium, $\text{Ti}[\text{N}(\text{CH}_3)_2]_4$. A basic problem with all metalorganic precursors is incorporation of C, usually at the 2–3 at% level, and often poor step coverage. A new approach to overcome this is by thermal decomposition of $\text{Ti}[\text{N}(\text{CH}_3)_2]_4$ followed by an in situ N_2 plasma treatment. This produces excellent conformal coverage even at high aspect ratio with an absence of gas-phase reactions. Contacts consisting of W plugs with 200 Å CVD TiN as a glue layer performed very well using this TiN deposition process. The N_2 plasma treatment improves stability and reduces sensitivity to moisture uptake.

4.2. CVD of Tungsten

Conventional PVD techniques such as sputtering have problems with filling of high-aspect-ratio vias, and thus CVD is being pursued as a solution. The combination of blanket W CVD, followed by etchback is currently the best alternative to sputtered Al. The deposition occurs by the

Table 1. Properties of Potential Interlayer Metals (After ref. 7)

Property	Metal

reduction of WF_6 :

This produces void-free filling of vias at typical pressures of 80 torr. Typical film resistivity is $\geq 10 \mu\Omega \cdot \text{cm}$, several times the bulk value ($5.65 \mu\Omega \cdot \text{cm}$ at 300 K), due to the columnar microstructure that traps fluorine. Reduction of the tungsten hexafluoride with B_2H_6 eliminates fluorine more efficiently than does H_2 alone [13].

CVD tungsten films have poor adhesion to SiO_2 , because of formation of tungsten oxide. This necessitates the use of TiN or TiW liners, which in addition prevent etching of the Si by WF_6 .

It is also possible to achieve selective tungsten CVD, which then eliminates the need for etchback, and for liner materials. The major issues with this technology are damage to the Si via cleaning prior to deposition and nonuniform via hole filling across large-area wafers. Silicon consumption through the reaction

occurs until a self-limiting growth of $\sim 200 \text{ \AA}$ of W is formed. Since WF_6 does not react with SiO_2 readily at low temperatures, it is straightforward to deposit W selectively on patterned wafers. To lower the deposition temperature, SiH_4 reduction is used in place of H_2 reduction.

An alternative to tungsten CVD is to employ Al sputtering and a reflow step. This can be achieved either by high-temperature Al sputtering, in which the vias fill because of the enhanced surface mobility, or by a cold sputter deposition and subsequent high-temperature sputtering. The reflow temperature is reduced from $\sim 480^\circ\text{C}$ for Al/0.5%Cu to as low as 300°C for Al/5%Ge/0.5%Cu, allowing efficient via and contact hole filling at relatively low temperatures using Al reflow sputtering. The filling characteristics of Al into vias is strongly dependent on the underlying film material. Al has poor wettability on SiO_2 , and poly Si, MoSi_2 , or Ti is generally used as a glue layer [14].

For process simplicity it would be desirable to have a single metallurgy for global interconnects, but no one material has the requisite sheet resistance, electromigration resistance, contact resistance to n^+ and p⁺ Si, adherence, step coverage, etchability, corrosion resistance, and availability of uniform, low-defect density deposition techniques. Al meets most of the requirements and hence is the most widely used. Layered metallizations are used, with the conductive layer as the middle layer [15]. The bottom layers are used for adhesion to the oxide and as barriers to Si. In the case of Al, layering with the refractories Ti, TiW, and TiN improved the reliability of the Al metallization, allowing its use to be extended to $0.18\text{-}\mu\text{m}$ critical-dimension devices.

4.3. Effect of Stress

Since Al films are typically deposited at $\sim 200^\circ\text{C}$, with Al plugs at 450°C , cooling to room temperature puts the

Al into tension because of its higher thermal expansion coefficient relative to the Si wafer. These stresses are generally high enough to cause plastic deformation, and stress relief may involve flow of material from the top surface to the bulk of the film. Spatially nonuniform flow may lead to voids that are failure sites during subsequent process steps.

After patterning of the Al, dielectric deposition typically around 400°C is performed, leading to compressive stresses in the Al lines that are larger in wider lines. These stresses may produce hillocks in the Al, which can be suppressed by addition of Cu to the Al alloy. Once the metal lines are encased in dielectric, they develop a uniform hydrostatic tensile stress that may be relieved by formation of voids. The addition of capping layers such as TiW or Ti can suppress these voids.

The basic causes of stress in interconnect structures are [16]

1. Thermal expansion coefficient differences with the Si
2. Deposition under nonequilibrium conditions
3. Changes in chemical composition (e.g., absorption of moisture in silica-based glasses or evolution of hydrogen from nitrides during heating)
4. Solid-state chemical reactions involving volume changes
5. Structural changes such as plastic flow, amorphous-to-crystalline transitions, or relaxation effects
6. Electromigration

The most obvious effects of mechanical stress are cracking of brittle materials, delamination of films, and formation of voids in metal lines.

Figure 2. Simplified process sequence for localized oxidation of Si (after Ref. 1).

Figure 3. Schematic cross section of typical GaN-based high-electron-mobility transistor, showing degradation of current flow by depletion caused by surface traps.

5. ISOLATION TECHNOLOGIES

The two basic methods for device isolation and prevention of crosstalk are junction isolation, in which each active region of a transistor is surrounded by a reverse-biased pn junction, and oxide-based (insulator) technologies [1]. The former is employed for bipolar transistors and the latter for metal oxide semiconductor (MOS) circuits. The individual components of the circuit are interconnected by metal stripes that run across the oxide. Figure 2 shows a schematic of a simple local oxidation of silicon (LOCOS) process, in which a thin pad oxide is thermally grown (20–60 nm) to cushion the transition of stresses between the Si and the subsequently deposited nitride. The latter is generally put down by CVD to a thickness of 100–200 nm, and its purpose is to prevent oxidation, specifically, oxidation mask. The nitride/pad oxide is patterned by dry etching, and a channel-stop implant is performed in the field region. A field oxide is then grown by wet oxidation at $\sim 1000^\circ\text{C}$ for 2–4 h to create a thickness of oxidized Si of 300–1000 nm. There is some lateral oxidation under the edges of the nitride mask that tapers into the pad oxide (the “bird’s beak” encroachment). The nitride mask is then removed by wet etching. This simple process has a number of limitations for submicrometer technologies, including the lateral encroachment of the field oxide into the active device region, redistribution of the implanted

boron, poor surface topology, and width-dependent field oxide thickness. These have been addressed by a number of advanced LOCoS isolation processes and sidewall-masked isolation techniques.

6. PASSIVATION OF COMPOUND SEMICONDUCTORS

For microwave power amplification in satellite links and wireless communication applications, the AlGaIn/GaN high-electron-mobility transistor (HEMT) has emerged as the most promising device. A typical $\text{Al}_{0.3}\text{Ga}_{0.7}\text{N}/\text{GaN}$ HEMT shows a sheet carrier density up to $\sim 1.5 \times 10^{13} \text{ cm}^{-2}$ (roughly an order of magnitude higher than for GaAs HEMTs), a unity current gain frequency (f_T) of 65 GHz, and a maximum oscillation frequency (f_{max}) of 180 GHz. Output powers up to 9.8 W/mm at 8 GHz (power-added efficiency at 47%) have been reported for large periphery GaN HEMTs, while it has also been shown that these devices can achieve low microwave-added noise figures ($\text{NF} = 0.6 \text{ dB}$ at 10 GHz), while maintaining a large breakdown voltage ($> 60 \text{ V}$) and hence a large dynamic range.

One frequently reported problem in these devices is that the RF power obtained is still much lower than expected from the DC characteristics. This problem is manifested by a collapse in drain current or by frequency dispersions in the transconductance and output resistance, leading to severely reduced output power and power-added efficiency. Several mechanisms have been identified as the causes, including the presence of surface states between the gate and the drain that deplete the channel in this region over a time constant long enough to disrupt modulation of the channel charge during large signal operation or of trap states in the buffer layer (Fig. 3, top). Several studies have shown that the use of SiN_x passivation layers can be effective in reducing the effects of surface states. One drawback of typical plasma-enhanced chemical vapor deposited SiN_x is the high hydrogen content, which could migrate into the GaN or the gate metallization. Two alternative candidates for HEMT passivation are MgO and Sc_2O_3 , which are under development as gate dielectrics for GaN. A comparison of the properties of various dielectrics for compound semiconductors is shown in Table 2. In particular, the oxides have larger bandgaps (8 eV for MgO and 6.3 eV for Sc_2O_3) wider than the previously reported Gd_2O_3 (5.3 eV) and smaller

PERIODIC STRUCTURES

MAURIZIO BOZZI
University of Pavia
Pavia, Italy

1. INTRODUCTION

A structure is defined as being “periodic” when it can be obtained as the combination of infinite replicas of a “unit cell” appropriately shifted along translation vectors. According to the number of translation vectors, a periodic structure can be one-, two-, or three-dimensional. In particular, a one-dimensional periodic structure is simply a uniform linear array of identical elements; a two-dimensional periodic structure consists of a planar array of element arranged in a doubly periodic grid; in the case of three-dimensional periodic structure, the elements are arranged in a lattice.

In the real world any structure is limited in space and, therefore, rigorously periodic structures do not exist. Nevertheless, if an array is large enough, most of the inner elements practically “see” an infinite array environment, and for many applications their behavior can be well approximated by the uniform behavior of elements in an infinite periodic structure.

The reason for considering the infinite array model is that this permits a substantial reduction in the analysis computational complexity. In fact, the electromagnetic field inside a uniformly excited periodic structure is the same in any cell (apart from a phase shift), and therefore

FURTHER READING

- J. H. Edgar, ed., *Properties of Group III Nitrides*, Inspector, the Institution of Electrical Engineers, London, 1994.

the analysis of the whole structure can be reduced to an investigation of the unit cell. From the computational perspective, this often means a reduction in computing time and memory requirement roughly proportional to the square or cube of the number of array elements.

Periodic structures are widely used in the microwave and millimeter-wave ranges for a variety of applications in both circuits and antennas. They also find many applications in the infrared and optical regions. They are usually made of metal, dielectric, or a combination of both.

Periodic structures commonly used in the microwave range are described in Section 2, along with their operation principle, applications, and fabrication issues. The basic theory for the study of the propagation of electromagnetic waves in periodic structures is discussed in Section 3, where Floquet's theorem and Brillouin zones are discussed. Finally, Section 4 presents some numerical techniques, widely adopted for the analysis of periodic components operating in the microwave and millimeter-wave regions.

2. OPERATION PRINCIPLES OF PERIODIC STRUCTURES

This section presents some examples of periodic structures, widely used in the microwave and millimeter-wave

ranges. In particular, the geometry, operation principle, most commonly used fabrication techniques and most significant applications of these components are described and discussed at an introductory level.

Five classes of periodic structures are considered: periodically loaded transmission lines and polarizing grids (which are one-dimensional periodic structures), frequency-selective surfaces and quasioptical arrays (which are two-dimensional periodic structures), and metamaterials (which can be one-, two-, or three-dimensional periodic structures, depending on the applications).

2.1. Periodically Loaded Waveguides and Transmission Lines

Waveguides and transmission lines loaded at identical intervals with reactive elements are a simple example of one-dimensional periodic structures (see, e.g., Ref. 1, Chap. 8). The reactive elements adopted in these structures usually consist of metallic diaphragms that close a portion of the cross section of a waveguide or a coaxial line (Fig. 1).

Periodically loaded waveguides and transmission lines have two common properties:

1. They present a discrete set of passbands separated by stopbands, specifically, frequency bands where the elec-

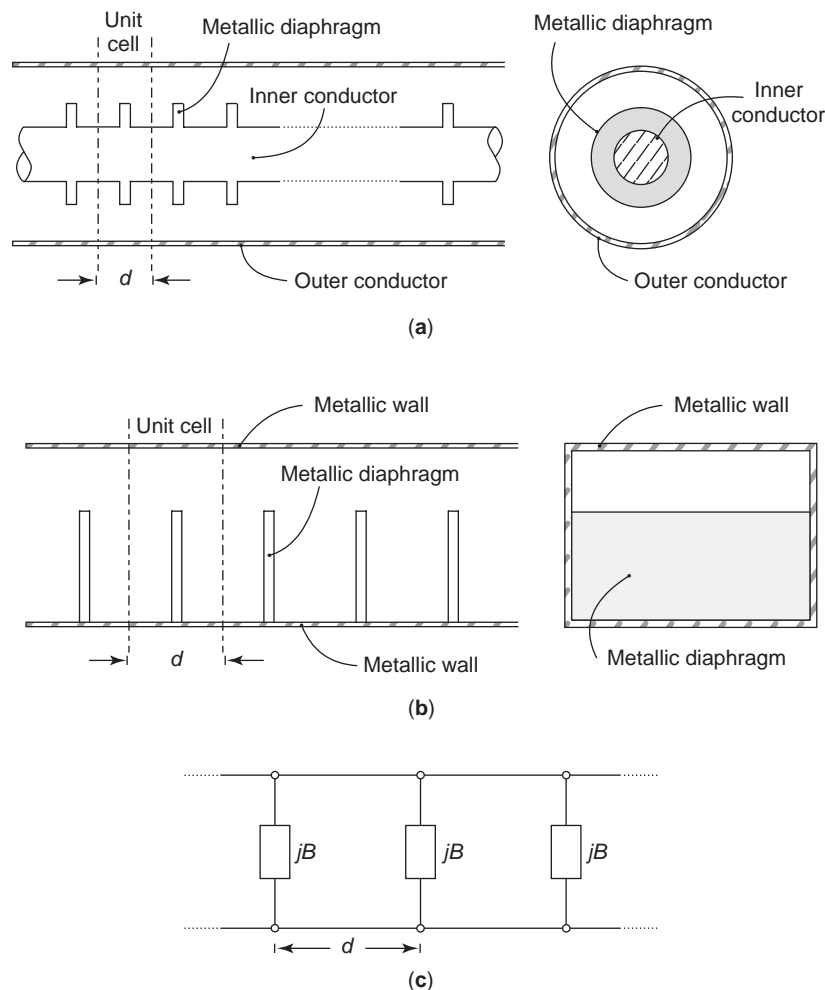

Figure 1. One-dimensional periodic structures: (a) side and front views of a coaxial line periodically loaded with circular diaphragms; (b) side and front views of a rectangular waveguide loaded with capacitive diaphragms; (c) lumped-element equivalent circuit, consisting of a transmission line loaded at intervals d by a lumped susceptance jB .

tromagnetic wave propagates in the structure without attenuation (except for metal losses), separated by frequency bands where the wave is highly attenuated and cannot propagate in the periodic structure. The physical explanation of this behavior can be easily understood by considering the equivalent circuit shown in Fig. 1c, where the periodic structure is modelled as the cascade of transmission-line sections with length d and lumped shunt susceptances jB . At those frequencies where the length d is a half-wavelength (or an integer number of half wavelengths), the transmission-line sections play no role and all susceptances are seen in parallel. Therefore, at these frequencies, the line is practically loaded with an infinite susceptance, and no power flows along the periodic structure. This property of periodically loaded transmission lines is particularly interesting for filtering purposes. To this aim, a tapered transition section is typically used for matching the periodic structure to the input/output transmission line [1]. The matching tapered section consists of a section of periodic structure, where the reactive loads gradually reduce to zero.

2. Periodically loaded transmission lines support the propagation of slow waves: waves with a phase velocity much smaller than the speed of light. This property can be easily understood by considering that the phase velocity of a smooth transmission line is given by

$$v_p = (LC)^{-1/2} \quad (1)$$

where C and L are the capacitance and the inductance per unit length, respectively. If the metallic diaphragm behaves as a lumped capacitance C_0 added at interval d (as shown in Fig. 1), the value of the capacitance per unit length is increased, whereas the inductance per unit length is unchanged. Therefore, the following phase velocity results:

$$v_p = \left[L \left(C + \frac{C_0}{d} \right) \right]^{-1/2} \quad (2)$$

The possibility of supporting slow waves is particularly important in traveling-wave-tube circuits and linear accelerators. In fact, in these applications, the electromagnetic field interacts with an electron beam, whose velocity is often 10–20% of the speed of light. Since an efficient interaction is obtained only when the two velocities are similar, a component able to support a slow wave is required [2].

2.2. Polarizing Grids

Polarizing grids are one-dimensional periodic structures, widely used in antennas and quasi-optical systems, and play an important role in polarization processing systems [3].

The simplest configuration of polarizing grids consists of an array of parallel conductors (round wires or flat strips), with dimension w and spacing g much smaller than the wavelength of the incident wave (Fig. 2a). When they are illuminated by an electromagnetic wave, these

Figure 2. Polarizing grids: (a) inductive grid, consisting of narrow metal strips separated by wide gaps; (b) capacitive grid, consisting of wide metal strips separated by narrow gaps.

grids reflect completely the component of the incident field parallel to the wires, and are transparent for the component of the field perpendicular to the wires. Polarizing grids, operating in the millimeter- and sub-millimeter-wave regions, usually consist of slightly stretched metallic wires supported by a frame. In the microwave region, linear arrays of strips printed on a dielectric substrate are typically preferred.

If the condition that the wire spacing is much smaller than the wavelength is removed, polarizing grids exhibit a frequency-dependent behavior. In particular, at low frequency the component of the incident field parallel to the wires is completely reflected, whereas at high frequency the grid becomes practically transparent. When considering the field component parallel to the wires, the behavior of the grid can be modeled as a shunt inductance, which short-circuits the incident wave at low frequency, and plays no role at high frequency. Therefore, these components are named *inductive grids*.

The complementary structure, termed the *capacitive grid*, consists of a linear array of wide metal strips separated by narrow gaps (Fig. 2b). When considering the field component perpendicular to the gaps, this grid can be modeled as a shunt capacitance; the grid is practically transparent at low frequency, whereas it reflects most of the incident power at high frequency.

2.3. Frequency-Selective Surfaces (FSSs)

Frequency-selective surfaces are planar periodic structures, consisting of either an array of metallic patch elements patterned on a dielectric substrate (*capacitive FSS*; Fig. 3a), or a metallic screen perforated periodically with aperture elements (*inductive FSS*, Fig. 3b [4]). They are illuminated by an incident electromagnetic wave (which is considered planar and uniform in most cases), and their objective is to be transparent at some frequencies, and to reflect the incident wave in the specular direction at other frequencies.

When they are illuminated by a uniform plane wave, capacitive and inductive FSSs exhibit a nearly complementary behavior. At low frequency, the dimension of the array elements is much smaller than the wavelength; therefore, in the case of capacitive FSSs, the printed elements play no role and the periodic structure is practically transparent (apart from the reflection due to the dielectric substrate); conversely, in the case of inductive FSSs, the

Figure 3. Frequency-selective surfaces with arbitrarily shaped elements: (a) capacitive FSS, consisting of a periodic array of metallic patches patterned on a dielectric substrate; (b) inductive FSS, consisting of a thick metallic screen perforated periodically with holes.

apertures are waveguides below cutoff and the structure practically behaves as a solid metallic mirror. When the frequency approaches the first element resonance, capacitive FSSs reflect completely the incident wave, whereas inductive FSSs are practically transparent. At frequencies higher than the first resonance, the reflected and transmitted fields are not a single uniform plane wave, due to the presence of grating lobes (or diffracted orders), which are additional plane waves propagating in different directions.

The frequency response of FSSs is determined mainly by the size and shape of the elements, their periodicity, the thickness and the dielectric permittivity of the substrate (for capacitive FSSs), the thickness of the metallic screen (for inductive FSSs), and the direction of incidence of the uniform plane wave. Different element shapes have been used in the design of FSSs (Fig. 4). In many cases, the elements have canonical shapes (rectangular or circular), due to their easier electromagnetic modeling. On the other hand, more complicated shapes can be adopted to obtain better performance, in terms of stability of the resonance frequency with the incidence angle, low cross-polarization level, large bandwidth, or small band separation. To this aim, the use of crosses, Jerusalem crosses, tripoles, rings and square loops have been proposed [5]. In the case of capacitive FSSs, the resonance frequency also depends on the dielectric permittivity and thickness of the substrate. In particular, for a given shape of the patch, the resonance frequency shifts down when increasing the dielectric permittivity of the substrate, since the dimension of the patch in terms of wavelengths increases.

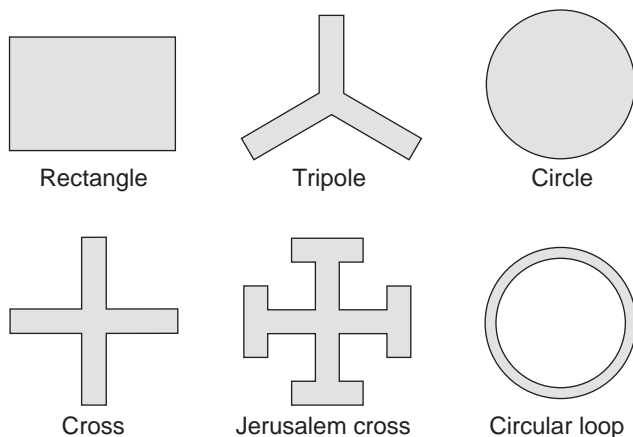

Figure 4. Different element shapes adopted in the design of frequency-selective surfaces.

Various manufacturing techniques can be chosen for the fabrication of FSSs. Capacitive FSSs can be obtained by photolithographic processing, with good accuracy and with no limitation in the element shape. Inductive FSSs operating in the microwave and millimeter-wave ranges are typically manufactured by the milling technique or by drilling, in the case of circular holes. Conversely, the fabrication of inductive FSSs intended for operation in the sub-millimeter-wave range is based mainly on galvanizing growth or laser cutting [6].

FSSs find a number of applications in the microwave and millimeter-wave regions for both scientific and commercial purposes. In the microwave region, FSSs are used as dichroic mirrors in large reflector antennas for radio-astronomy applications [7]. The feeding network of such antennas typically consists of beam-waveguide systems, and the FSS combines the beams generated by two feeds operating at different frequencies (Fig. 5). To this aim, the FSS is practically transparent at one frequency and behaves as a mirror at the other frequency. In this way, two feeds share the same reflector antenna, thus optimizing

Figure 5. Reflector antenna using a frequency-selective surface for combining two feeds operating at different frequencies.

frequency reuse. For this kind of applications, the use of inductive FSSs is mostly preferred, due to lower losses and better power-handling capabilities. Another application of FSSs in the microwave region is the bandpass radome [8]; at the operating frequency the signal passes through the radome with minimum insertion loss, whereas at out-of-band frequencies the signal is reflected. Moreover, FSSs find wide commercial use in the screendoor of microwave ovens; the perforated metal screen reflects completely the microwave energy at 2.45 GHz, while allowing the light to pass through, thus permitting to see the food inside the oven. At higher frequency, FSSs are used as filters in quasi-optical systems, as diplexers, and as dichroic mirrors in laser cavities and in Fabry–Perot interferometers.

2.4. Metamaterials

Metamaterials are a new class of components, which have received a lot of attention since the 1990s for a variety of applications from the microwave to the optical regions [9]. They are based on artificially engineered periodic structures, and their objective is the modification of the electromagnetic properties of materials or the suppression of the electromagnetic wave propagation in certain frequency bands.

It is possible to identify three different classes of metamaterials: electromagnetic bandgap (EBG) structures, artificial magnetic conductors (AMCs), and double-negative (DNG) materials. However, because of the very recent origin of these components, no standard nomenclature is available yet.

EBG structures are periodic arrangements of dielectric and/or metallic elements, where the propagation of electromagnetic waves is inhibited in a certain frequency band. If the propagation is forbidden in all directions and for all polarizations, there is a full bandgap. The behavior of electromagnetic waves in EBG structures is analogous to the propagation of electrons in crystals; in the case of crystals, the periodic arrangement of atoms or molecules determines gaps in the energy band structure, so that electrons are forbidden to propagate with certain energies. Because of this analogy and since many applications were originally proposed in the field of optics, EBG structures are also indicated as photonic crystals (PCs) or photonic bandgap (PBG) structures. After some

discussions, the acronym EBG is becoming the standard term in the microwave community [10].

The idea of EBG structures was first proposed by Yablonoitch in 1987 [11], starting from studies in semiconductor theory. Moreover, Yablonoitch made the first prototype that exhibits a full electromagnetic bandgap in the microwave region [12]. It consists of a modified diamond structure, which is obtained by drilling a dielectric material along three appropriately chosen directions.

Different EBG configurations have been then proposed; they include metallodielectric structures, which are usually applied in the microwave and millimeter-wave ranges, and all-dielectric structures, which are preferred in the optical frequency range. Examples of metallodielectric EBG structures are two-dimensional arrays of metal patches patterned on a grounded dielectric slab. Conversely, an example of a one-dimensional dielectric EBG structure consists of a layered dielectric medium (Fig. 6a). Such structures have been used since long time as high-reflectivity mirrors in the infrared and optical regions: in fact, by choosing the correct thickness of the dielectric layers and their dielectric constants, it is possible to obtain very high reflection at a given frequency. This structure is known as a *Bragg stack*. More recently, two- and three-dimensional dielectric periodic structure have been proposed. In the 2D case, they are planar arrays of cylindrical rods in a square or hexagonal lattice (Fig. 6b), whereas in the 3D case they can be obtained by cross-stacking arrays of dielectric rods (Fig. 6c) and are known as “woodpile” structures [13].

Artificial magnetic conductors (AMCs) are planar periodic structures that reflect an incident plane wave without phase reversal, like a perfect magnetic conductor (i.e., the surface presents an infinite impedance). For this reason, AMCs are also termed *high-impedance surfaces*. AMCs are usually obtained by using metallodielectric planar periodic structures, which also exhibit EBG properties. Therefore, AMC and EBG structures will be discussed jointly here.

An interesting metallodielectric structure that presents EBG and AMC properties was proposed by Sievenpiper [14]. It consists of an array of hexagonal metal patches, patterned on a grounded dielectric substrate according to a triangular grid and connected to the ground plane by metallic vias (Fig. 7). Since the dimensions of the

Figure 6. Examples of dielectric EBG structures: (a) stack of dielectric layers (1D structure); (b) planar array of dielectric rods (2D structure); (c) woodpile structure (3D structure).

Figure 7. EBG structure consisting of an array of metallic mushrooms on a dielectric substrate: (a) top view; (b) side view.

unit cell are much smaller than the wavelength, many electromagnetic properties of this structure can be explained by using an equivalent-circuit model. The equivalent model is a parallel LC circuit, where the capacitance C is due to the gap between the metal patches and the inductance L depends on the loop through the metal vias and the ground plane (Fig. 7b). The impedance Z_p of the parallel LC circuits is given by

$$Z_p = \frac{j\omega L}{1 - \omega^2 LC} \quad (3)$$

where ω is the angular frequency. The value of the impedance is very large in a narrow band around the resonance frequency $\omega_0 = (LC)^{-1/2}$. At frequencies around ω_0 the currents on the surface radiate very efficiently, due to the resonance of the structure, and the structure suppresses the propagation of surface waves, thus exhibiting an EBG behavior. Moreover, at the same frequency, due to the large value of the impedance Z_p , the structure has high surface impedance, and therefore reflects the incident waves without the phase reversal that occurs in the case of conducting plates (AMC behavior).

Another significant metallodielectric EBG structure was proposed by Itoh and is the *uniplanar compact*

photonic bandgap (UCPBG) structure [15]. It is based on a two-dimensional periodic structure, patterned on a grounded dielectric substrate. The unit cell comprises a square patch connected to four thin metal strips with insets, located in the middle of each side of the square (Fig. 8). This structure can also be described as a complementary Jerusalem cross, since the top conducting plane is cut by an array of slots with a Jerusalem cross shape. In this case, the structure is planar, with no need of metal vias connecting the patches to the ground plane, thus resulting in a reduced fabrication complexity. The electromagnetic behavior of the UCPBG structure can be explained by its equivalent lumped-element circuit; also in this case, the equivalent model is a parallel LC circuit, where C represents the fringing capacitance of the gaps between the metal patches and the inductance L originates from the narrow metal strips connecting the patches.

One of the most important applications of EBG structures and AMCs in the microwave range is related to the design of printed antennas with high performance. In fact, standard patch antennas printed on dielectric substrates usually suffer from narrow bandwidth of operation, low gain, and limited radiation efficiency [16]. It is known that patch antennas exhibit good radiation efficiency when the thickness of the substrate is about a quarter-wavelength. With this particular substrate thickness, since the conducting ground plane reflects the incident wave with a phase reversal, the total phase shift of the round trip from the antenna to the ground plane and back to the antenna is equal to 360° (Fig. 9a). Therefore, the reflected wave is in phase with the direct wave, thus resulting in a constructive interference. Conversely, if the substrate thickness is smaller than a quarter-wavelength, the direct wave and the wave reflected by the ground plane

Figure 8. EBG structure consisting of an array of slots with a Jerusalem cross shape: (a) top view; (b) side view.

Figure 9. Patch antennas with EBG structures: (a) standard patch antenna on a thick dielectric substrate; (b) patch antenna surrounded by a periodic structure, which prevents the propagation of surface waves; (c) patch antenna located on a periodic structure, which creates a high-impedance surface (perfect magnetic conductor).

interfere in a destructive way, thus resulting in poor radiation efficiency. Also the antenna bandwidth depends on the substrate thickness, and can be improved by increasing the thickness. In both cases, when using thick substrates and high dielectric permittivity, the antenna couples power to surface waves, and its radiation efficiency deteriorates. Surface waves do not contribute to the primary radiation pattern, and therefore they reduce the radiated power. Moreover, surface waves are diffracted at the edges of the antenna substrate, thus deteriorating the radiation pattern of the antenna by increasing the sidelobes and the backward radiation. The performance of patch antennas can be improved by using an EBG structure, located around the antenna (Fig. 9b). The EBG structure is able to prevent the propagation of surface waves, thus permitting enhancement of the radiation efficiency and improvement of the radiation pattern [17]. Another solution is based on the use of an AMC below the antenna (Fig. 9c). In fact, the AMC is able to reflect the wave coming from the antenna with no phase reversal so that, if the antenna is located very close to the AMC, the direct and the reflected waves add constructively, and this leads to a good radiation efficiency [14]. This solution leads to the use of a substrate thickness much smaller than a quarter-wavelength, which permits substantially relaxation of the issue of the surface waves.

Besides these antenna applications, the use of EBG structures has been proposed for numerous significant applications in microwave circuits, in metallic waveguide, microstrip-line, and coplanar waveguide technologies. The

use of EBG structures has been proposed for implementing novel waveguides able to support a TEM mode [18]. In this waveguide, the top and bottom sides are standard metal layers, and represent an electric wall boundary condition, whereas the lateral sides consists of UCPBG structures, which behave as magnetic walls in a reasonably wide frequency band. The fundamental mode supported by this waveguide propagates with a phase velocity close to the speed of light, and presents TEM properties. The concept of the TEM waveguide was exploited in quasi-optical power amplifiers [19], since the TEM mode exhibits an almost uniform field distribution. In fact, illuminating the quasi-optical array with a uniform power density allows for increasing the overall saturation power of the amplifiers. EBG substrates have also allowed the design of stopband microstrip filters, with a sharp transition from the passband to the stopband [20]. A simple microstrip, located on a dielectric substrate with a periodically etched ground plane, presents a stopband at the frequencies where the periodic structure exhibits a high impedance. In fact, at those frequencies, the microstrip behaves as a narrow metal strip on a magnetic conductor, and this structure is not able to support the fundamental mode of a microstrip. The use of EBG was demonstrated to improve the performance of conductor-backed coplanar waveguides [15]. In fact, these structures suffer from leakage due to the propagation of the parallel-plate mode, which propagates between the ground plane and the upper conductor. By substituting the upper conductor with a UCPBG structure (Fig. 10), the propagation of the parallel-plate mode can be suppressed, thus reducing the losses of the coplanar waveguide mode. Another application of EBG structures is related to active circuits; they have been used to suppress the undesired harmonic frequencies in oscillators, mixers, and power amplifiers [21].

DNG materials are a very recent and promising class of the metamaterials. They include artificial materials that exhibit simultaneously negative real part of the effective electric permittivity and magnetic permeability in a given frequency band. Veselago considered these materials for the first time in the 1960s [22]; he theoretically showed from the Maxwell equations that such media exhibit a

Figure 10. Conductor-backed coplanar waveguide integrated with EBG structure.

negative index of refraction. This means that the direction of the energy flow (Poynting vector) of a plane wave propagating inside the medium is antiparallel with the direction of the wave's phase velocity. In other words, the electric field, the magnetic field, and the propagation vector form a left-handed system, differently from ordinary materials, where they form a right-handed system. Because of these peculiarities, various names have been coined for this type of metamaterial, such as negative-index (of refraction) materials (NIMs), backward-wave (BW) media, and left-handed (LH) materials.

The first experimental verification of a DNG material operating in the microwave regime was reported in 2001 [23]. This artificial material uses an array of split-ring resonators (SRRs) to produce negative magnetic permeability and thin wire elements to produce negative electric permittivity in the same frequency band.

A potential application of DNG materials is the perfect lenses, proposed by Pendry [24]. It is a slab of negative-refractive-index material, which has the power to focus all Fourier components of a two-dimensional image, even those that do not propagate in a radiative manner. These perfect lenses could overcome the limitation of conventional lenses, whose resolution is limited by the wavelength. Another interesting application is based on the idea of subwavelength cavity resonators [25]. In fact, by combining a slab of DNG material and a layer of standard lossless dielectric medium, it is possible to obtain a one-dimensional cavity resonator whose dispersion relation do not depend on the sum of the thicknesses of the two slabs, but depends on the ratio of these thicknesses.

2.5. Quasioptical Arrays

Quasioptical components consist of planar arrays of patch or slot antennas patterned on a semiconductor substrate, monolithically integrated with active or nonlinear devices (Fig. 11). These components have received a lot of attention due to their great potential for applications in the

Figure 11. Quasioptical frequency multiplier, consisting of a planar array integrated with active and/or nonlinear devices; input and output filters (FSSs) are used for unidirectional operation, whereas dielectric slabs are used for input/output matching.

millimeter- and sub-millimeter-wave ranges [26]. At these frequencies, in fact, a technological gap still exists, between the mature technology of waveguide components in the microwave range and the optical technologies in the infrared and optical regions.

Quasioptical components performing a wide range of different operations have been proposed and experimentally verified. Among them, frequency multipliers [27], mixers [28], amplifiers [29], phase shifters [30], and oscillators [31] were proposed.

Quasioptical frequency multipliers (Fig. 11), for instance, are based on Schottky diodes or heterostructure barrier varactors, and use the nonlinear dependence of the junction capacitance versus the applied voltage. In such a way, they are able to convert a portion of the incident power from the fundamental frequency to the upper harmonic (typically second or third harmonic). The shape and size of the antennas where the nonlinear elements are located are designed in such a way, to couple all the incident power to the terminals of the devices and to guarantee their optimal conversion efficiency.

The use of quasioptical structures appears very promising for components and systems operating above 30 GHz. Quasioptics deals with the propagation in free space of electromagnetic beams, which are well collimated and have relatively small dimensions (when measured in wavelengths), transverse to the axis of propagation [3]. Quasioptical propagation is a very interesting method of propagation in the millimeter- and sub-millimeter-wave regions, which permits low power loss over very broad bandwidths. Conversely, traditional waveguide systems (e.g., metallic waveguides, coaxial cables, microstrip lines) present high losses when frequency increases, due to the finite conductivity of metallic conductors and the loss in dielectrics.

A key point of quasioptical components is the concept of power combining [32]. If a single device is limited in power for a specific application, the combination of a large number of identical devices (e.g., tens or hundreds) can easily overcome this limitation. In quasioptical systems, this combination can be easily performed, with no need of beamforming networks. Another significant advantage of these components over single-device structures is that, due to the large number of devices, their performance is subject to a graceful degradation in the case of failure of some devices. Moreover, quasioptical arrays are small and light, and therefore are particularly suitable to space applications. Monolithically integrated components are easier to fabricate than waveguide devices and less expensive in mass production. Finally, quasioptical systems performing complex functions can be realized by simply stacking arrays that perform elementary functions.

3. BASIC THEORY: FLOQUET'S THEOREM AND BRILLOUIN ZONE

This section presents two basic topics of the theory of periodic structures. The first topic is Floquet's theorem (or Bloch's theorem), which permits to determine the solution of the wave equation in a periodic structure. The deriva-

tion of the theorem is performed in the cases of one-dimensional and two-dimensional periodic structures. The second topic is the study of the Brillouin zones, which are very useful in the analysis of the propagation of electromagnetic waves in periodic structures. Some basic definitions are given, and the technique for drawing the Brillouin zones is described.

3.1. Floquet's Theorem

The basic theorem concerning the propagation of waves in a periodic medium was formulated by Gaston Floquet in 1883 [33]. Actually, Floquet's work deals with the solution of a differential equation with periodic coefficients, but perfectly applies to the analysis of 1D periodic structures. The generalization of this theorem for 2D and 3D cases is due to Felix Bloch in 1928 [34], who performed studies mainly in the field of quantum mechanics.

Let us first consider Floquet's theorem in one-dimensional periodic structures (see, e.g., Ref. 1, pp. 569–571). In a structure periodic along the z direction, it is possible to identify a unit cell, defined by two terminal parallel planes at a distance d (e.g., the planes $z=0$ and $z=d$; see Fig. 12). If we consider lossless structures, the fields at the terminal parallel planes have the same amplitude and differ for a phase shift, due to the propagation factor $e^{-\gamma d}$; the term γ is the propagation constant and can be written in the form $\gamma=j\beta$.

Since the choice of the terminal planes of the unit cell is arbitrary, the field in any point of the unit cell differs from the field in the corresponding point of another unit cell for a phase shift, due to the propagation factor $e^{-\gamma nd}$, where nd is the distance between the two cells (where n is an integer number). It results that

$$\begin{aligned}\mathbf{E}(x, y, z + nd) &= e^{-\gamma nd} \mathbf{E}(x, y, z) \\ \mathbf{H}(x, y, z + nd) &= e^{-\gamma nd} \mathbf{H}(x, y, z)\end{aligned}\quad (4)$$

Consequently, the electric and magnetic fields in a periodic structure are in the form

$$\begin{aligned}\mathbf{E}(x, y, z) &= e^{-j\beta z} \mathbf{E}_p(x, y, z) \\ \mathbf{H}(x, y, z) &= e^{-j\beta z} \mathbf{H}_p(x, y, z)\end{aligned}\quad (5)$$

where \mathbf{E}_p and \mathbf{H}_p are periodic functions of z with period d :

$$\begin{aligned}\mathbf{E}_p(x, y, z + nd) &= \mathbf{E}_p(x, y, z) \\ \mathbf{H}_p(x, y, z + nd) &= \mathbf{H}_p(x, y, z)\end{aligned}\quad (6)$$

Figure 12. One-dimensional periodic structure.

Since \mathbf{E}_p is a periodic function, it can be expanded into a Fourier series

$$\mathbf{E}_p(x, y, z) = \sum_{n=-\infty}^{\infty} \mathbf{E}_{pn}(x, y) e^{-j2n\pi z/d} \quad (7)$$

where $\mathbf{E}_{pn}(x, y)$ are vector functions depending on x and y . By multiplying both sides of (7) by $e^{j2m\pi z/d}$, integrating over the unit cell (with z ranging from 0 to d), and exploiting the orthogonality of the exponential functions, we obtain

$$\mathbf{E}_{pn}(x, y) = \frac{1}{d} \int_0^d \mathbf{E}_p(x, y, z) e^{j2n\pi z/d} dz \quad (8)$$

By substituting (7) in (5), and using $\gamma=j\beta$, the electric field in a periodic structure can be expressed as

$$\mathbf{E}(x, y, z) = \sum_{n=-\infty}^{\infty} \mathbf{E}_{pn}(x, y) e^{-j\beta z - j2n\pi z/d} \quad (9)$$

$$= \sum_{n=-\infty}^{\infty} \mathbf{E}_{pn}(x, y) e^{-j\beta_n z} \quad (10)$$

where

$$\beta_n = \beta + \frac{2n\pi}{d} \quad (11)$$

It results that the electric field in a periodic structure can be written as a summation of terms, termed *spatial harmonics* or *Hartree harmonics*. For the n th harmonic, β_n represents the propagation phase constant, and the phase velocity v_{pn} is given by

$$v_{pn} = \frac{\omega}{\beta_n} = \frac{\omega}{\beta + 2n\pi/d} \quad (12)$$

where $\omega=2\pi f$ is the angular frequency. Moreover, the group velocity is given by

$$v_{gn} = \left(\frac{d\beta_n}{d\omega} \right)^{-1} = \left(\frac{d\beta}{d\omega} \right)^{-1} = v_g \quad (13)$$

and therefore does not depend on index n and is the same for all harmonics.

It is noted that both the propagation constant and the phase velocity can be positive or negative, according to the value of the integer number n . This means that in periodic structures some of the harmonics have phase velocity and group velocity opposite in sign [backward waves (BW_s)]. This property is exploited in BW traveling-wave-tube oscillators [2].

Let us now consider Floquet's theorem in two-dimensional periodic structures (see, e.g., Ref. 35, pp. 37–42). In a structure with double periodicity in the xy plane, the periodicity is described by a pair of translation vectors \mathbf{a} and \mathbf{b} . These translation vectors can either be orthogonal

Figure 13. Two-dimensional periodic structure: (a) rectangular grid; (b) skewed grid.

(rectangular grid; Fig. 13a) or form an angle α (skewed grid; Fig. 13b).

The problem of the field representation is somehow similar to the study of metallic rectangular waveguides; in fact, it is convenient to formulate the problem in terms of scalar potentials, which are eigensolutions of the Helmholtz equation. The only difference is the boundary condition, which in this case is a periodicity condition instead of an electric wall condition.

We first consider the case of a rectangular grid (Fig. 13a). The scalar potential $\zeta(x, y, z)$ must satisfy the homogeneous scalar Helmholtz equation

$$\nabla^2 \zeta(x, y, z) + \kappa^2 \zeta(x, y, z) = 0 \tag{14}$$

and the periodicity condition

$$\zeta(x + a, y + b, z) = e^{-j(\psi_x + \psi_y)} \zeta(x, y, z) \tag{15}$$

where a and b represent the amplitude of the translation vectors \mathbf{a} and \mathbf{b} and ψ_x and ψ_y are the inter-element phase shift in the x and y directions, respectively. In the case of a two-dimensional array of elements illuminated by a uniform plane wave, the phase shift depends on the frequency

and the angle of incidence of the plane wave. In particular

$$\begin{aligned} \psi_x &= ka \sin \theta \cos \phi \\ \psi_y &= kb \sin \theta \sin \phi \end{aligned} \tag{16}$$

where (θ, ϕ) is the angle of incidence of the plane wave and k is the wavenumber at the operation frequency.

Similarly to standard waveguides, the behavior in the z direction is such that

$$\zeta(x, y, z) = e^{-\gamma z} \zeta(x, y) \tag{17}$$

where $\gamma = j\beta$ for propagating modes in the case of lossless structures. Therefore, by substituting (17) into (14), the Helmholtz equation is recast as follows

$$\nabla_T^2 \zeta(x, y) + (\kappa^2 - \beta^2) \zeta(x, y) = 0 \tag{18}$$

where ∇_T^2 is the transverse Laplace operator, and the boundary condition is derived directly from (15). By considering that

$$\beta^2 = \kappa^2 - \kappa_x^2 - \kappa_y^2 \tag{19}$$

and applying the technique of separation of variable

$$\zeta(x, y) = f(x)g(y) \tag{20}$$

the Helmholtz equation and its boundary condition can be split into x and y components:

$$\frac{\partial^2}{\partial x^2} f(x) + \kappa_x^2 f(x) = 0, \quad f(x + a) = f(x) e^{-j\psi_x} \tag{21}$$

$$\frac{\partial^2}{\partial y^2} g(y) + \kappa_y^2 g(y) = 0, \quad g(y + b) = g(y) e^{-j\psi_y} \tag{22}$$

Considering first function $f(x)$, a new function $f_p(x)$ is defined as

$$f_p(x) = f(x) e^{j(\psi_x/a)x} \tag{23}$$

It can be easily proved that $f_p(x)$ is a periodic function with period a . In fact

$$\begin{aligned} f_p(x + a) &= f(x + a) e^{j(\psi_x/a)(x+a)} e^{-j\psi_x} \\ &= f(x) e^{j(\psi_x/a)x} = f_p(x) \end{aligned} \tag{24}$$

Since $f_p(x)$ is periodic, it can be expanded into a Fourier series

$$f_p(x) = \sum_{m=-\infty}^{+\infty} f_{pm} e^{-j2m\pi x/a} \tag{25}$$

where f_{pm} are scalar coefficients. By substituting (25) in (23), the expression of function $f(x)$ can be obtained

$$f(x) = \sum_{m=-\infty}^{+\infty} f_{pm} e^{-jk_{xm}x} \quad (26)$$

where

$$\begin{aligned} \kappa_{xm} &= \frac{2m\pi + \psi_x}{a} \\ &= k \sin \theta \cos \phi + \frac{2m\pi}{a} \end{aligned} \quad (27)$$

The same derivation can be applied to function $g(y)$, where we obtain

$$g(y) = \sum_{n=-\infty}^{+\infty} g_{pn} e^{-jk_{yn}y} \quad (28)$$

where

$$\begin{aligned} \kappa_{yn} &= \frac{2n\pi + \psi_y}{b} \\ &= k \sin \theta \sin \phi + \frac{2n\pi}{b} \end{aligned} \quad (29)$$

Therefore, the eigenfunctions $\xi_{mn}(x, y)$ of the Helmholtz equation (18), with the proper normalization, are in the form

$$\xi_{mn}(x, y) = \frac{-j}{\sqrt{ab}} e^{-j(\kappa_{xm}x + \kappa_{yn}y)} \quad (30)$$

and the corresponding eigenvalues are

$$\kappa_{mn} = \sqrt{\kappa_{xm}^2 + \kappa_{yn}^2} \quad (31)$$

Once the eigensolutions of the Helmholtz equation have been determined, an orthonormal set of modal vectors, representing the proper modes of the waveguide with periodicity boundary conditions, can be determined. These modal vectors are termed *Floquet modes*. Similar to standard waveguide modes [36], TE and TM modes can be derived from scalar potentials. These modes propagate in the z direction with a propagation constant γ_{mn} given by

$$\gamma_{mn} = \begin{cases} \sqrt{\kappa_{mn}^2 - k^2} & \text{if } k < \kappa_{mn} \\ j\sqrt{k^2 - \kappa_{mn}^2} & \text{if } k > \kappa_{mn} \end{cases} \quad (32)$$

TM modes (denoted by the superscript prime) have the magnetic modal fields transverse to z ($H'_z = 0$), and their

electric and magnetic modal vectors are

$$\mathbf{E}'_{mn} = -\frac{\nabla_T \xi_{mn}}{\kappa_{mn}} \quad (33)$$

$$\mathbf{H}'_{mn} = -\mathbf{z} \times \frac{\nabla_T \xi_{mn}}{\kappa_{mn}} \quad (34)$$

and the corresponding modal admittance is

$$Y'_{mn} = \frac{jk}{\eta \gamma_{mn}} \quad (35)$$

TE modes (denoted by the superscript double prime) have the electric modal fields transverse to z ($E''_z = 0$), and their electric and magnetic modal vectors are

$$\mathbf{E}''_{mn} = -\frac{\nabla_T \xi_{mn}}{\kappa_{mn}} \times \mathbf{z} \quad (36)$$

$$\mathbf{H}''_{mn} = -\frac{\nabla_T \xi_{mn}}{\kappa_{mn}} \quad (37)$$

and the corresponding modal admittance is

$$Y''_{mn} = \frac{\gamma_{mn}}{j\eta k} \quad (38)$$

In case of $\psi_x = \psi_y = 0$ (e.g., in the case of a two-dimensional array illuminated by a plane wave with normal incidence, $\theta = 0$), the set of modes is not complete, and two additional TEM modes are needed [37]. The electric and magnetic modal vectors of the TEM modes can be derived from scalar potentials, which are the solutions of the Laplace equation with periodic boundary conditions. These modes, denoted by a superscript 0, have both electric and magnetic modal fields transverse to z ($E_z^0 = 0$ and $H_z^0 = 0$), and correspond to the fundamental modes of a rectangular waveguide with two electric walls and two magnetic walls. Their electric and magnetic modal vectors are

$$\mathbf{E}^0_{01} = \frac{\mathbf{x}}{\sqrt{ab}} \quad \mathbf{H}^0_{01} = \frac{\mathbf{y}}{\sqrt{ab}} \quad (39)$$

$$\mathbf{E}^0_{10} = \frac{\mathbf{y}}{\sqrt{ab}} \quad \mathbf{H}^0_{10} = \frac{-\mathbf{x}}{\sqrt{ab}} \quad (40)$$

and the corresponding modal admittance is

$$Y^0_{01} = Y^0_{10} = \frac{1}{\eta} \quad (41)$$

where η is the characteristic impedance of the medium ($\eta_0 = 377 \Omega$ in vacuum).

If translation vectors \mathbf{a} and \mathbf{b} are not orthogonal (i.e., they form an angle α ; Fig. 13b), the grid is not rectangular. In this case, the formulas derived in this section must be slightly modified. In particular, (29) is replaced by

$$\kappa_{yn} = k \sin \theta \sin \phi + \frac{2n\pi}{b \sin \alpha} - \frac{2m\pi}{a \tan \alpha} \quad (42)$$

and in (30), (39), and (40) the term

$$\frac{1}{\sqrt{ab}} \tag{43}$$

is replaced by

$$\frac{1}{\sqrt{ab \sin \alpha}}. \tag{44}$$

3.2. Brillouin Zone

Another important concept in the study of periodic structure is related to the definition of the direct lattice, the reciprocal lattice, and the Brillouin zone.

Let us first consider the study of the propagation characteristics of electromagnetic waves in one-dimensional periodic structures. As stated by the Floquet theorem, the solution of the propagation equation yields propagation constants $\beta_n = \beta + 2n\pi/d$ (with $n = \pm 1, \pm 2, \dots$) in addition to the fundamental mode. This is a direct consequence of the periodic characteristics of the structure. Because of these periodic characteristics, it is sufficient to study the propagation properties of the structure inside one period of the propagation phase constant β . The fundamental interval is usually defined by $-\pi < \beta d < \pi$. This fundamental interval contains all the information on the propagation characteristics of the electromagnetic waves in the periodic structure. All the replicas in other intervals contain redundant information.

The propagation characteristics of the wave in the fundamental interval, also termed the *first Brillouin zone*, are usually shown in the ω - β diagram (Fig. 14). This diagram permits us to identify the frequency bands where the structure exhibits passband behavior and those where it exhibits stopband behavior.

Let us now consider the case of two-dimensional periodic structures. This case is more significant than the one-dimensional case, has the same conceptual difficulties of the three-dimensional case, and is easier to discuss, anyway. Moreover, the two-dimensional case is by far the most

Figure 14. ω - β diagram of a one-dimensional periodic structure.

Figure 15. Direct and reciprocal lattice in a two-dimensional periodic structure.

important for microwave applications. A complete discussion of the three-dimensional case can be found in Ref. 38.

As already stated, a periodic structure can be described in terms of independent translation vectors, say, \mathbf{a} and \mathbf{b} , which form an angle α (Fig. 15). This means that each point of the structure is infinitely repeated at a particular distance, along the direction of the vectors \mathbf{a} and \mathbf{b} . More precisely, a lattice of points (named the Bravais lattice) can be defined

$$\mathbf{r} = l_1 \mathbf{a} + l_2 \mathbf{b} \tag{45}$$

where l_1 and l_2 are integer numbers. The translation vectors \mathbf{a} and \mathbf{b} permit us to define the unit cell of the periodic structure. It is evident that the choice of the vectors \mathbf{a} and \mathbf{b} is not unique. In fact, any linearly independent pair of vectors \mathbf{a}' and \mathbf{b}' , given by

$$\mathbf{a}' = m_1 \mathbf{a} + n_1 \mathbf{b} \tag{46}$$

$$\mathbf{b}' = m_2 \mathbf{a} + n_2 \mathbf{b} \tag{47}$$

where n_1, n_2, m_1 , and m_2 are integers, and $m_1/m_2 \neq n_1/n_2$, is still a satisfactory basis. The most common choice of primitive unit cell is the Wigner-Seitz unit cell, defined as the region of space closer to a particular point rather than to any other point of the Bravais lattice. The vectors \mathbf{a} and \mathbf{b} chosen in this way describe a lattice termed the *direct lattice*.

For each direct lattice it is possible to define a *reciprocal lattice* in the Fourier space. This is particularly important since the solution of many problems related to periodic structures is performed in the Fourier space. The reciprocal lattice is described by the vectors \mathbf{A} and \mathbf{B} , which must satisfy the following requirements:

$$\mathbf{a} \cdot \mathbf{B} = \mathbf{b} \cdot \mathbf{A} = 0 \tag{48}$$

$$\mathbf{a} \cdot \mathbf{A} = \mathbf{b} \cdot \mathbf{B} = 2\pi \tag{49}$$

Therefore, the vectors \mathbf{A} and \mathbf{B} are perpendicular to \mathbf{b} and \mathbf{a} , respectively, and their lengths are chosen in such a way

Figure 16. Graphical construction of Brillouin zones in the case of a square lattice.

that the product of corresponding vectors in the two spaces is 2π .

The Brillouin zones in the case of two-dimensional periodic structures can be obtained through a graphical method (Fig. 16); a point of the reciprocal lattice is chosen as the origin. Then, the construction is accomplished by drawing the perpendicular bisectors of reciprocal lattice vectors joining the origin to the nearest neighbors. The smallest closed polygon formed by these perpendicular bisectors represents the first Brillouin zone. In other words, the first Brillouin zone corresponds to the Wigner-Seitz cell of the reciprocal lattice.

Moving out from the origin, the upper Brillouin zones are sequentially encountered, which become increasingly fragmented. It can be easily seen by inspection that the fragments of the upper Brillouin zones can be mapped directly onto the first Brillouin zone by simple application of the translation vectors of the reciprocal lattice.

The redundancy can be further reduced by exploiting the symmetries. In a square lattice, for instance, the first Brillouin zone can be reduced to one-eighth (Fig. 17a). This smaller region, which contains no redundancy, is termed the *irreducible Brillouin zone*, and is identified by three special points: Γ (with coordinates $k_x = k_y = 0$), X (with coordinates $k_x = \pi/a$ and $k_y = 0$), and M (with coordinates $k_x = k_y = \pi/a$).

In the hexagonal lattice, the irreducible Brillouin zone is one-sixth of the first Brillouin zone (Fig. 17b). In this case, the three special points are Γ (with coordinates $k_x = k_y = 0$), M [with coordinates $k_x = 0$ and $k_y = 2\pi/(\sqrt{3}a)$], and K [with coordinates $k_x = 2\pi/(3a)$ and $k_y = 2\pi/(\sqrt{3}a)$].

Therefore, the analysis of the passband–stopband characteristics of a two-dimensional periodic structure can be performed by considering all the propagation constants in the irreducible Brillouin zone. In practice, since the band extremes of almost all the periodic structures occur at the boundary of the irreducible Brillouin zone, it is conventional to consider only the values of the propagation constant corresponding to the boundary of the irreducible Brillouin zone [39].

4. NUMERICAL TECHNIQUES FOR THE ANALYSIS OF PERIODIC STRUCTURES

The analysis of periodic structures applies to the solution of two basic modeling problems: (1) calculation of the reflected and transmitted fields, when the periodic structure is illuminated by a uniform plane wave with a given incidence angle; and (2) determination of the mode spectrum supported by the periodic structure, which is a discrete set of either propagating or leaky waves.

Analysis of these structures is usually performed under the periodicity approximation. By applying Floquet's theorem, the analysis of the complete structure reduces to investigation of the unit cell of the periodic structure, with the appropriate boundary conditions. Whichever numerical method is adopted for the analysis, this permits significant reduction of computing time.

Many numerical techniques have been developed for modeling of periodic structures. The equivalent-circuit model, discussed for certain cases in Section 2, is typically used only for a preliminary investigation, and is not accurate enough for a reliable modeling of the structure. Numerical techniques such as the integral equation method (IEM), the finite-element method (FEM), and the finite-difference time-domain (FDTD) method have been applied to the analysis of periodic structures, as well as a number of hybrid approaches, which are combinations of the aforementioned methods.

In this section, the most common numerical techniques adopted for the analysis of periodic transmission lines, frequency-selective surfaces, and electromagnetic band-gap structures are presented and briefly discussed.

4.1. Analysis of Periodic Transmission Lines

The study of the mode propagation is the basic problem in the analysis of one-dimensional periodic transmission lines. The aim of this study is the determination of the dispersion diagram, which represents the mode propagation constants versus frequency. In the case of a periodically loaded transmission line or waveguide (Fig. 1), the propagation characteristics of the modal fields can be obtained by using the \mathcal{ABCD} matrix [1].

Let us consider, as an example, a rectangular waveguide, periodically loaded with capacitive irises, whose unit cell is shown in Fig. 18a. The electric and magnetic fields on the ports of the unit cell, located at the terminal cross sections of the input and output waveguides, are expressed as a combination of N modes of the rectangular waveguide

$$\mathbf{E}_1 = \sum_{i=1}^N V_{1,i} \mathbf{e}_i \quad \mathbf{H}_1 = \sum_{i=1}^N I_{1,i} \mathbf{h}_i \quad (50)$$

$$\mathbf{E}_2 = \sum_{i=1}^N V_{2,i} \mathbf{e}_i \quad \mathbf{H}_2 = \sum_{i=1}^N I_{2,i} \mathbf{h}_i \quad (51)$$

where \mathbf{e}_i and \mathbf{h}_i are the electric and magnetic modal vectors of the rectangular waveguide, respectively, and $V_{p,i}$ and $I_{p,i}$ are the modal voltages and currents on the ports ($p = 1, 2$). The unit cell can be characterized through the \mathcal{ABCD} matrix, which relates the modal voltages and currents on the ports (Fig. 18b)

$$\begin{bmatrix} V_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} \mathcal{A} & \mathcal{B} \\ \mathcal{C} & \mathcal{D} \end{bmatrix} \begin{bmatrix} V_2 \\ -I_2 \end{bmatrix} \quad (52)$$

where V_p and I_p are column vectors containing $V_{p,i}$ and $I_{p,i}$. The dispersion diagram is obtained, frequency by frequency, by imposing the periodicity of electric and magnetic fields at the ports of the unit cell. This leads to the following relation between modal voltages and currents at the ports

$$\begin{bmatrix} V_1 \\ I_1 \end{bmatrix} = e^{\gamma d} \begin{bmatrix} V_2 \\ -I_2 \end{bmatrix} \quad (53)$$

where d is the length of the unit cell (Fig. 18) and $\gamma = \alpha + j\beta$. Relation (53) is a phase shift condition when $\alpha = 0$ and an attenuation condition when $\beta = 0$. By combining (52) and (53), the following eigenvalue problem is obtained:

$$\begin{bmatrix} \mathcal{A} & \mathcal{B} \\ \mathcal{C} & \mathcal{D} \end{bmatrix} \begin{bmatrix} V_2 \\ -I_2 \end{bmatrix} = e^{\gamma d} \begin{bmatrix} V_2 \\ -I_2 \end{bmatrix} \quad (54)$$

For a given frequency, the eigenvalues of (54) give the propagation constant γ of the modes. The corresponding eigenvectors give the values of $V_{2,i}$ and $I_{2,i}$, representing the weight coefficients of the electric and magnetic fields at port 2 in terms of the modes of the rectangular waveguide.

Determination of the \mathcal{ABCD} matrix can be performed in different ways. Full-wave methods typically used for modeling waveguide components can be adopted for analysis of the unit cell. Approximated solution can also be found by using lumped-element modeling of the capacitive irises, as discussed by Collin [1].

4.2. Analysis of Frequency-Selective Surfaces

The aim of frequency-selective surface analysis is the determination of their scattering properties versus the frequency. In most cases, the analysis of FSSs is performed under the approximation of an infinite periodic array, illuminated by a uniform plane wave incident at a given angle. Under these hypotheses, the unit cell of the FSS is considered, and the analysis yields the reflection and transmission coefficients for the TE and TM fundamental Floquet modes.

A widely used approach for the analysis of FSSs is the integral equation method, which can be applied to both capacitive and inductive FSSs. Even if only capacitive FSSs are considered in this paragraph, the same approach can be applied to the analysis of inductive FSSs. The IEM is based on the formulation of an electric field integral equation, which is then solved by the method of moments (MoM) [4, Chap. 2]. Let us consider the unit cell of a capacitive FSS, consisting of a thin metallic patch printed on a dielectric substrate (Fig. 19). The transverse-to- z component of the scattered electric field is expressed in the

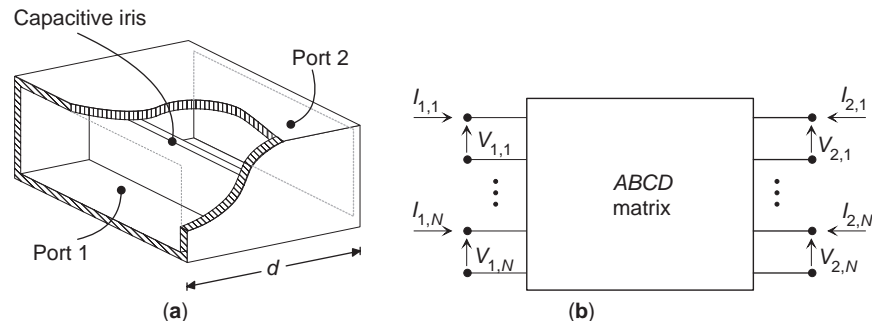

Figure 18. Unit cell of a waveguide periodically loaded with capacitive irises: (a) geometry of the unit cell considered in the analysis; (b) corresponding modeling through the \mathcal{ABCD} matrix.

Figure 19. Unit cell of a capacitive frequency-selective surface.

form of a Green's integral

$$\begin{aligned} \mathbf{E}_{\text{scat}}^{\text{T}}(x, y, z) \\ = \int_S \underline{\mathbf{G}}(x, y, z, x', y', z') \cdot \mathbf{J}(x', y', z') dS' \end{aligned} \quad (55)$$

where \mathbf{J} is an unknown electric current density on the metallic patch, S is the surface of the patch, and $\underline{\mathbf{G}}$ is a dyadic Green function given by

$$\begin{aligned} \underline{\mathbf{G}}(x, y, z, x', y', z') \\ = \sum_{m,n} V_{mn}(z, z') \mathbf{E}_{mn}(x, y) \mathbf{E}_{mn}^*(x', y') \end{aligned} \quad (56)$$

where \mathbf{E}_{mn} denotes the transverse electric modal vector of the (m, n) th Floquet mode (TE, TM, or TEM), the asterisk denotes the complex conjugate, and function V_{mn} is determined by considering the equivalent modal transmission lines for the layered medium in the periodic cell. In the case of a metal patch located at the interface $z=0$, $V_{mn}(0, 0)$ represents the parallel of the impedance of the (m, n) th Floquet mode seen from $z=0$, looking toward the positive and to the negative directions of the z axis. By imposing the electric wall condition on the patch

$$\mathbf{E}_{\text{inc}}^{\text{T}}(x, y, 0) + \mathbf{E}_{\text{scat}}^{\text{T}}(x, y, 0) = 0 \text{ on } S \quad (57)$$

where $\mathbf{E}_{\text{inc}}^{\text{T}}$ is the transverse-to- z component of the electric field of the incident plane wave, and substituting (55) into (57), the following integral equation is obtained:

$$\begin{aligned} \mathbf{E}_{\text{inc}}^{\text{T}}(x, y, 0) \\ + \int_S \underline{\mathbf{G}}(x, y, 0, x', y', 0) \cdot \mathbf{J}(x', y', 0) dS' = 0 \text{ on } S \end{aligned} \quad (58)$$

The solution of (58) is obtained through MoM, which permits us to transform the integral equation into an algebraic matrix problem. By representing the unknown

current density \mathbf{J} as a combination of N vector basis functions \mathbf{f}_j

$$\mathbf{J}(x', y', 0) = \sum_{j=1}^N x_j \mathbf{f}_j(x', y') \quad (59)$$

and using the same set of functions as test functions, a matrix problem is obtained

$$[\mathbf{A}][\mathbf{X}] = [\mathbf{B}] \quad (60)$$

where matrices $[\mathbf{A}]$ and $[\mathbf{B}]$ have dimension $N \times N$ and $N \times 1$, respectively, and their entries are given by

$$A_{ij} = \sum_{m,n} V_{mn}(0, 0) \int_S \mathbf{f}_i(x, y) \cdot \mathbf{E}_{mn}(x, y) dS \quad (61)$$

$$\times \int_S \mathbf{f}_j(x', y') \cdot \mathbf{E}_{mn}^*(x', y') dS'$$

$$B_i = \int_S \mathbf{f}_i(x, y) \cdot \mathbf{E}_{\text{inc}}^{\text{T}}(x, y) dS \quad (62)$$

and $[\mathbf{X}]$ is the column vector of the unknown coefficients x_j . The solution of problem (60) is performed frequency by frequency and yields the unknown coefficients x_j , which are used in (59) to calculate the current density \mathbf{J} . Once \mathbf{J} is known, the transmission and reflection coefficients can be determined [4].

In the application of IEM, the choice of a suitable set of basis/test functions is a key point in the implementation of the algorithm, and has a significant impact on its performance. In fact, the dimension of matrix problem (60) is equal to the number N of basis functions used to represent \mathbf{J} , and the computing time for the solution of a matrix system increases with the square of the order of the matrix (N^2). Many authors have used subdomain basis functions (e.g., rooftops), which are piecewise linear functions defined on a small rectangular or triangular portion of S [4]. Rooftops have an analytical expression, are suited to analytically calculate the coupling integrals between basis functions and Floquet modal vectors appearing in (61), but usually a large number of rooftops are required to reach the convergence, and this leads to large matrix problems. Another possibility is the use of entire-domain basis functions, which are defined on the whole surface of patch S and satisfy the same boundary condition of \mathbf{J} on the boundary of S (i.e., they are tangential to the boundary). A set of "general-purpose" entire-domain basis functions comprises the electric modal vectors of a waveguide with a cross section S and with magnetic wall boundary condition. The use of these functions leads to more efficient algorithms, but these modal vectors are known analytically only for few canonical shapes of the cross section (e.g., rectangular and circular). Specialized entire-domain basis functions have been developed for a number of commonly used shapes (e.g., cross, tripole, and Jerusalem cross) [5],

but they are not flexible and need a customized implementation for each different patch shape. In the case of completely arbitrary shape of S , the entire-domain functions must be numerically calculated, and this requires the solution of the Helmholtz equation in S with Dirichlet or Neumann boundary conditions. Among the possible approaches, the use of the boundary integral–resonant mode expansion (BIRME) method [37,40] and FEM [41] have been recently proposed.

The efficiency of the IEM can be enhanced by improving the convergence of the series used to represent the Green function reported in (56). In fact, the basic formulation in terms of a series of Floquet modal vectors exhibits a rather slow convergence, and some hundreds of modes are typically needed. Even if the number of terms of the series is not related to the dimension of matrix $[A]$, the convergence rate of the Green function impacts the filling time of $[A]$, as evident from (61). Several methods have been proposed for accelerating the convergence of the series of the periodic Green function, based on the Ewald transformation [42], the Poisson summation formula [43], and the Shanks transformation [44].

In the case of FSSs with a complicate geometry (Fig. 20), the use of the IEM becomes unpractical, due to the problem of finding a proper expression of the Green function and a suitable set of basis functions. More flexible codes can be implemented by using the finite-element method [45,46] and the finite-difference time-domain method [47].

In FEM, the electromagnetic problem is formulated in terms of a functional, which must be minimized to find the electric and magnetic fields in the structure. The problem is solved by meshing the whole investigation volume with triangular prismatic elements, and expressing the electric field in terms of a set of edge-based expansion functions [46]. Since the scattering from FSSs is an open problem and the FEM problem must be solved in a limited domain,

Figure 20. Unit cell of a frequency-selective surface with complicated geometry.

the investigation volume must be truncated by imposing a suitable set of boundary conditions (Fig. 20). In particular, the truncation in the x – y plane is performed by exploiting the periodicity of the structure, which turns into a phase shift relation between the fields on the opposite walls of the unit cell. On the top and bottom walls along the z direction, the domain must be truncated by imposing the radiation condition. To this aim, a possible approach is based on the perfectly matched layer (PML), a layer of artificial material that can be placed in close proximity to the FSS and can be used to absorb the scattered field [45]. Instead of using the PML, another approach consists in closing the top and bottom walls with an integral equation, resulting in a hybrid finite-element/boundary integral method [46]. The integral equation permits us to impose a rigorous boundary condition (instead of the approximate radiation condition obtained with the PML), but the resulting matrix is both partially sparse and partially dense, whereas the FEM/PML originates fully sparse matrices.

In the FDTD method [47], FSS analysis is performed by subsequent iterations in the time domain, until a steady-state is reached. The frequency response of the FSS is then obtained through a Fourier transform. Similar to the FEM, also in this case the fields must be evaluated in the whole volume of the domain, and therefore a truncation is required. The truncation in the x – y plane is performed by exploiting the periodicity of the FSS. Since the analysis is performed in the time domain, the phase shift condition turns into a time-delay condition. The truncation on the top and bottom walls along the z direction can be performed by using the absorbing boundary conditions (ABC), which simulates a radiation condition like the aforementioned PML.

With respect to the IEM, both FEM and FDTD method permit to analyze a much wider class of FSSs. Nevertheless, in the IEM the unknowns are defined only on the metallizations, whereas in both the FEM and the FDTD method volume meshing is required, resulting in a large number of unknowns. Consequently, FEM and FDTD method typically pay their flexibility with a significantly longer computing time and larger memory allocation requirements.

4.3. Analysis of Electromagnetic Bandgap Structures

The analysis of electromagnetic bandgap structures should provide two kinds of information. On the one hand, the mode spectrum of the electromagnetic waves which can propagate in the periodic structure must be determined; on the other hand, the phase of the reflection coefficient of the structure under plane-wave illumination needs to be calculated. The second problem is similar to the calculation of the frequency response of FSSs, and can be solved in the same way. Conversely, the techniques for determining the characteristics of the wave propagation are described in this section.

Most of the techniques used for the analysis of FSSs can be adapted to the calculation of the mode spectrum of EBG structures, but there is a substantial difference between the two analyses; whereas in the calculation of the

plane-wave response of FSSs the fields inside the structure are enforced by the incident plane wave, in the determination of the mode spectrum of EBG structures there are no incident fields, and therefore the analysis leads to an eigenvalue problem.

The IEM, already introduced for the calculation of the transmission and reflection properties of FSSs, can also be adopted for determining the bandgap characteristics of metallodielectric EBG structures (Figs. 7 and 8). In the case of FSSs, the boundary conditions are determined by the incident plane wave; for a given frequency and direction of incidence of the plane wave, the interelement phase shift can be calculated through (16). Conversely, in the case of EBG structures, the boundary conditions are enforced by the propagation constant of the mode propagating in the periodic structure. In practice, calculation of the dispersion diagram of EBG structures is performed by choosing a propagation constant (k_x, k_y) , which occurs at the boundary of the irreducible Brillouin zone (see Section 3), and searching the corresponding frequencies, which satisfy the fields equations and the boundary conditions in the unit cell [48]. For a given propagation constant (k_x, k_y) and frequency f , the IEM leads to the following matrix problem

$$[A][X] = [0] \quad (63)$$

where matrix $[A]$ is defined in (61), $[X]$ is the column vector of the unknown coefficients x_i used to represent the unknown current density \mathbf{J} , and $[0]$ is a column vector with the same dimension as $[X]$. Problem (63) has a non-trivial solution only if the determinant of matrix $[A]$ vanishes. In this case, the pair of the propagation constant (k_x, k_y) and the frequency f determine a point on the dispersion diagram. Since matrix $[A]$ depends on both the propagation constant and the frequency, and it is not possible to separate the two dependencies, an iteration is needed to find the dispersion diagram; for a given value of the propagation constant, the frequency is varied to search for the zeros of the determinant of $[A]$. This procedure is repeated for any value of the propagation constant that belongs to the boundary of the irreducible Brillouin zone.

When EBG structures with complicated geometry are considered (like a fully three-dimensional structure), the IEM method can still be applied. In this case, however, a volume integral equation is required, which can be solved by MoM [49]. This leads to large, fully dense matrix problems, which are typically computationally inefficient.

The FEM approach has been used for the modeling of EBG components [50,51]. Its formulation is similar to the one described in the case of FSSs. In order to truncate the analysis domain, both the PML and the integral equation have been adopted. Besides the advantages and disadvantages already discussed for the two truncation approaches, there is a further important difference in this case. In fact, the FEM/PML approach permits to determine the bandgap properties of the structure through the solution of a single-eigenvalue problem for each value of the propagation constant, with no need of a

frequency loop [51]. Conversely, when using the FEM in conjunction with the integral equation, the matrix equation must be repeatedly solved, in order to search for the desired frequency [50], similar to the case of the IEM.

Finite-difference methods have also been proposed in both the time and frequency domains (FDTD [52] and FDFD [53], respectively). Application of the FDTD method to the analysis of EBG structures [52] is similar to the approach described for modeling of FSSs, and the Fourier transform of the steady-state solution yields a peak at those frequencies that are close to the frequency of an eigenmode. The finite-difference methods provide high flexibility in the geometry of the components, but are usually very time-consuming.

Acknowledgment

PERMITTIVITY AND MEASUREMENTS

V. KOMAROV

1. INTRODUCTION

Propagation of electromagnetic (EM) waves in radio frequency (RF) and microwave systems is described mathematically by Maxwell's equations with corresponding boundary conditions. Dielectric properties of lossless and lossy materials influence EM field distribution. For a better understanding of the physical processes associated with various RF and microwave devices, it is necessary to know the dielectric properties of media that interact with EM waves. For telecommunication and radar devices, variations of complex dielectric permittivity (referring to the dielectric property) over a wide frequency range are important. For RF and microwave applicators intended for thermal treatments of different materials at ISM (industrial, scientific, medical) frequencies, one needs to study temperature and moisture content dependencies of the permittivity of the treated materials.

Many techniques have been developed for the measurement of material permittivity. Some general descriptions of those methods are provided in the literature [1–4]. The measurement results for diverse dielectric media are compiled in the literature [5–7].

The objective of this article is to provide a brief description of basic physical theory for the measurement of permittivity associated with three popular experimental methods and to review the permittivities for different materials. Most of these data are taken from the literature, but some of permittivity data were measured in Biological Systems Engineering Department of Washington State University. The measurements were conducted by means of open-ended coaxial probe method with commercial instrumentation.

2. THEORY OF PERMITTIVITY

Permittivity is a quantity used to describe dielectric properties that influence reflection of electromagnetic waves at interfaces and the attenuation of wave energy within materials. In frequency domain, the complex relative permittivity ϵ^* of a material to that of free space can be expressed in the following form:

$$\epsilon^* = \epsilon' - j\epsilon'' \quad (1)$$

The real part ϵ' is referred to as the *dielectric constant* and represents stored energy when the material is exposed to an electric field, while the dielectric loss factor ϵ'' , which is the imaginary part, influences energy absorption and attenuation, and $j = \sqrt{-1}$. One more important parameter used in EM theory is a tangent of loss angle: $\tan \delta_e = \epsilon''/\epsilon'$. Mechanisms that contribute to the dielectric loss in heterogeneous mixtures include polar, electronic, atomic, and Maxwell–Wagner responses [7]. At RF and microwave frequencies of practical importance and currently used for applications in material processing (RF 1–50 MHz and microwave frequencies of 915 and 2450 MHz), ionic conduction and dipole rotation are dominant loss mechanisms [8]:

$$\epsilon'' = \epsilon''_d + \epsilon''_\sigma = \epsilon''_d + \frac{\sigma}{\epsilon_0 \omega} \quad (2)$$

where subscripts “d” and “ σ ” stand for contributions due to dipole rotation and ionic conduction, respectively; σ is the ionic conductivity in S/m of a material, ω is the angular frequency in rad/s, and ϵ_0 is the permittivity of free space or vacuum (8.854×10^{-12} F/m). Dielectric lossy materials convert electric energy at RF and microwave frequencies into heat. The increase in temperature (ΔT) of a material can be calculated from [9]

$$\rho C_p \frac{\Delta T}{\Delta t} = 5.563 \times 10^{-11} f E^2 \epsilon'' \quad (3)$$

where C_p is the specific heat of the material in $\text{J kg}^{-1} \text{ }^\circ\text{C}^{-1}$, ρ is the density of the material in kg/m^3 , E is the electric field intensity in V/m, f is the frequency in Hz, Δt is the time duration in seconds, and ΔT is the temperature rise in the material in $^\circ\text{C}$. It is clear from Eq. (3) that the rise in temperature is proportional to the material's dielectric loss factor, in addition to electric field intensity squared, frequency, and treatment time.

In dielectric materials, the electric field strength decreases with distance z from the surface and is written as

$$E = E_0 e^{-\alpha z} \quad (4)$$

The attenuation factor α depends on the dielectric properties of the material [5] and is given by

$$\alpha = \frac{2\pi}{\lambda_0} \left[\frac{1}{2} \epsilon' \left(\sqrt{1 + \left(\frac{\epsilon''}{\epsilon'} \right)^2} - 1 \right) \right]^{1/2} \quad (5)$$

Figure 1. Typical penetration depth inside a large-sized material (larger than the wavelength).

where λ_0 is the free-space wavelength. Substituting Eq. (4) into power equation Eq. (3), one obtains

$$P = P_0 e^{-2\alpha z} \tag{6}$$

Penetration depth of microwave and RF power is defined as the depth where the power is reduced to $1/e$ ($e = 2.718$) of the power entering the surface (Fig. 1). The penetration depth d_p in meters of RF and microwave energy in a lossy material can be calculated by [5]

$$d_p = \frac{c}{2\pi f \sqrt{2\epsilon' \left[\sqrt{1 + \left(\frac{\epsilon''}{\epsilon'}\right)^2} - 1 \right]}} \tag{7}$$

where c is the speed of light in free space (3×10^8 m/s). After obtaining the dielectric properties, the penetration depths of electromagnetic energy into selected materials can be calculated at the required frequency. Given fixed dielectric properties, the penetration depth of a material is inversely proportional to frequency. It is, therefore, expected that in general deeper penetration corresponds to lower frequencies, and that higher frequencies result in greater surface heating. It should be noted that the

dielectric properties of lossy materials vary with frequency but penetration depth does not vary exactly as $1/f$. Nevertheless, EM waves with short wavelength do not penetrate deeply into most moist media [7], where the dielectric constants and loss factors are relatively high.

2.1. Frequency Effect

Dielectric properties of materials are affected by many factors, including frequency, temperature, and moisture content. Dielectric properties can vary significantly with frequency, which will be discussed in detail in this section. The frequency-dependent trend of dielectric properties can provide important information of the material characteristics. In theory, electric conduction and various polarization mechanisms (including dipole, electronic, ionic, and Maxwell–Wagner) contribute to the dielectric loss factor (Fig. 2). For moist dielectric materials ionic conductivity plays a major role at lower frequencies (e.g., < 200 MHz), whereas both ionic conductivity and dipole rotation of free water play a combined role at microwave frequencies. Maxwell–Wagner polarization arises from buildup of charges in the interface between components in heterogeneous systems. The Maxwell–Wagner polarization effect peaks at about 0.1 MHz [7], but in general, its contribution is small compared to that of ionic conductivity. For low-moisture media, bound water plays a major role in dielectric heating in the frequency range between 20 and 30 GHz [10,11] at room temperature (20°C) [12].

For a pure liquid, the Debye model [13] describes the frequency-dependent dielectric properties in the rectangular form

$$\epsilon^* = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + \omega^2 \tau^2} - j \frac{(\epsilon_s - \epsilon_\infty) \omega \tau}{1 + \omega^2 \tau^2} \tag{8}$$

where ϵ_∞ is the infinite or high frequency relative permittivity, ϵ_s is the static or zero-frequency relative permittivity, and τ is the relaxation time in seconds of the material. In general, the larger the molecules, the longer

Figure 2. Contributions of various mechanisms of the loss factor (ϵ'') of moisture materials as a function of frequency (f) [12].

Figure 3. Dielectric constant (ϵ') and loss factor (ϵ'') as a function of frequency for packed lysozyme samples containing nearly two layers of bound water at 25°C [10].

the relaxation time. For a pure liquid, such as water, the dielectric loss factor reaches the maximum at a critical frequency related to the relaxation time ($f_c = 1/2\pi\tau$). Water molecules are polar, and the most important constituent that contributes to the dielectric properties of moist dielectrics. Water molecules bound to the surface of polar materials in monolayers or multilayers have much longer relaxation times than do free water molecules. For example, the relaxation time of bound water in different food materials at 20°C is determined to be between 0.98 and 2.00 ns, corresponding to a peak in ϵ'' at ~ 100 MHz, whereas the relaxation time τ of free water in those foods at 20°C is between 0.0071 and 0.00148 ns, corresponding to a peak in ϵ'' at around 16000 MHz [14]. Harvey and Hoekstra [10] found that ϵ'' of monolayer bound water in lysozyme at 25°C peaked at 300 MHz and ϵ'' for the second layer bound water peaked at about 10000 MHz. The two dispersions observed in Fig. 3 correspond to the first and second layers of bound water, respectively.

Figure 4 shows a good example of Debye dielectric relaxation for butyl alcohol at 20°C with single relaxation time measured with an open-ended coaxial probe connect-

Figure 4. Dielectric constant (ϵ') and loss factor (ϵ'') of butyl alcohol at 20°C [19].

ed to an impedance analyzer [19]. At low frequencies, in a static region, where the dipoles have time to follow the variations of the applied field, the dielectric constant of butyl alcohol has a value of ~ 17 . The loss factor is small for both high and low frequencies and reaches a peak at the relaxation frequency of ~ 250 MHz.

Similar frequency-dependent permittivity can be found in water, methanol, and ethanol and can be expressed in the following relationships, respectively [15]:

$$\begin{aligned}\epsilon^* &= 5.62 + \frac{74.59}{1 + jf/17.0 \times 10^9} \text{ (water)} \\ \epsilon^* &= 5.76 + \frac{27.89}{1 + jf/2.709 \times 10^9} \text{ (methanol)} \\ \epsilon^* &= 4.44 + \frac{20.84}{1 + jf/0.826 \times 10^9} \text{ (ethanol)}\end{aligned}\quad (9)$$

Frequency-dependent characteristics of complex biological materials, including moist foods, cannot be described with simple mathematical expressions.

2.2. Temperature Effect

Temperature of a material has a significant effect on the dielectric properties. Generally, the loss factor increases with increasing temperature at low frequencies due to ionic conductance and decreases with increasing temperature at high frequencies due to free-water dispersion (Fig. 2). In multidispersion materials, for example, the transition is gradual because of the combined effects of relaxation and the ionic conduction and there is a U-shape frequency response in ϵ'' (Fig. 6). Debye related the relaxation time for the spherical molecule to viscosity and temperature as the result of randomizing agitation of the Brownian movement [5]

$$\tau = V \frac{3\nu}{kT} \quad (10)$$

where ν is the viscosity, T is the absolute temperature, V is the volume, and k is a constant. For nonspherical water molecules, we may have the following relation

$$\tau \propto \frac{\nu}{T} \quad (11)$$

while the viscosity of all fluid decreases with increasing temperature [16]

$$\nu = \nu_0 e^{E_a/R_g T} \quad (12)$$

where E_a is activation energy and R_g is the universal gas constant. Therefore, as temperature rises, relaxation time for water decreases. The shifting of the relaxation time toward a lower value (thus the frequency at the maximum ϵ'' shifts toward a higher value as temperature increases) reduces the value of ϵ'' for water at a fixed microwave frequency (Fig. 5). For example, as the relaxation time τ decreases with increasing temperature, the dispersion peak moves to higher frequencies and the loss factor of

Figure 5. Effect of temperature on dielectric constant (ϵ') and loss factor (ϵ'') of free water ($\omega = 2\pi f$, where f is frequency in Hz) [22].

pure water at 2450 MHz decreases with increasing temperature. The dielectric constant ϵ' of free water also decreases with increasing temperature as the result of increased Brownian movement.

The dielectric loss factor ϵ''_{σ} due to conduction decreases with increasing frequency as shown in Eq. (2). The

Figure 6. Effect of temperature on dielectric loss factor (ϵ'') of 0.5N aqueous sodium chloride at three temperatures [18].

contribution of ϵ''_{σ} to the overall loss factors is smaller at 2450 MHz than at 915 Hz (Fig. 6). The electric conductivity σ in ionic solutions increases with temperature due to decreased viscosity and hence increased ion mobility [17]. Therefore, based on Eq. (2), ϵ''_{σ} also increases with temperature (Fig. 6). At 915 MHz the dielectric constant of ionic solutions generally increases with temperature.

The dielectric properties of high-moisture-content substances change with temperature [19]. An example of the dielectric loss factor (ϵ'') of fifth-instar codling moths measured at five temperatures is shown in Fig. 7. The loss factor decreases with increasing frequency, reaching about 12 at 1800 MHz. The loss factor of codling moth larvae increases with temperature, especially at low frequencies. This is due mainly to the increase in ionic conduction at high temperatures [12]. Increasing dielectric loss factor with temperature often results in a well-known phenomenon, commonly referred to as “thermal runaway” [7], in which a preferentially heated subject in an EM field accelerates heating as its temperature rises.

Figure 7. Dielectric loss factor of codling moth larvae (slurry) at five temperatures [19].

Figure 8. Dielectric loss factor of walnut kernels as a function of frequency at five temperatures [19].

Figure 8 shows the loss factor of a typical dry nut (walnut kernels) over the frequency range from 1 to 1800 MHz at five temperatures. The ϵ'' values are less than 1 at frequencies below 50 MHz. The ϵ'' values peak in the range between 500 and 1000 MHz. The peak value of ϵ'' for walnut kernels decreases with increasing temperature, while the frequency corresponding to the peak ϵ'' shifts to a higher value. This temperature-dependent trend is typical of polar molecules [20]. At any selected frequency in the tested range, the loss factor of the walnut kernel generally decreases with increasing temperature; that is, for a given EM field intensity, higher temperature walnuts will absorb less energy than cooler ones, resulting in improved heating uniformity.

Ice is almost transparent to microwaves (Table 1). When a lossy material is frozen, both dielectric constant and loss factor are significantly reduced; the degree of reduction depends, to a large extent, on the amount of water in the unfrozen state and the ionic conductivity of the free water.

2.3. Moisture Effect

Moisture content is one of the major components of most biological materials. In general, the higher the moisture content, the larger the dielectric constant and loss factor of the materials [20, 22, 23]. Water in moist dielectric materials can be divided, in descending mobility, into (1) water held in intercellular space or capillaries, (2) multilayer

water, and (3) monolayer water that is tightly bound to the polar sites. The free-water molecules have dielectric properties similar to those of liquid water, while the bound water exhibits icelike dielectric properties. Dielectric properties of biomaterials, in general, decrease rapidly with decreasing moisture content to a critical moisture level. Below this moisture level, the reduction in loss factor is less significant because of the bound water (Fig. 9). During microwave drying, the wetter parts of biomaterials

Figure 9. Rate of evaporation and dielectric loss factor as affected by food moisture content [7].

Table 1. Dielectric Properties of Water and Ice at 2450 MHz

State of Water	Relative Dielectric Constant (ϵ')	Loss Factor (ϵ'')	Loss Tangent ($\tan \delta$)
Water (25°C)	78	12.5	0.16
Ice	3.2	0.0029	0.0009

Source: Ref. 21.

absorb more microwave energy and tend to level off the uneven moisture distribution.

3. MEASUREMENT PRINCIPLES AND METHODS

3.1. Open-Ended Coaxial Probe Method

Open-ended coaxial probe (OCP) method is currently one of the most popular techniques for measuring of complex dielectric permittivity of many materials. Nondestructive, broadband (RF and microwave ranges), and high-temperature ($\leq 1200^\circ\text{C}$) measurements can be performed with this method using commercially available instrumentation. Its well-developed theory makes it possible to obtain sufficiently accurate results for both medium-loss and high-loss media [24–26].

Figure 10 illustrates an OCP system used at Washington State University. It consists of an automatic network analyzer (ANA) with a calibration kit, custom-built test cell, a programmable circulator, a coaxial cable, and a personal computer connected to the ANA through a special bus. The material under study is placed in a stainless steel pressureproof test cell. The probe is kept in close contact with the sample during the measurements via a stainless steel spring and piston. A thin rigid stainless steel thermocouple probe passes onto the center of the sample to measure sample temperature. The programmable circulator pumps a temperature-controlled liquid (90% ethylene glycol and 10% water by volume) through the water jacket of the test cell, allowing the sample inside to be heated and cooled.

The sensing element of an OCP system is an open-ended cylindrical coaxial line that is excited by transverse electromagnetic (TEM) wave. Parameters (amplitude and phase) of incident and reflected signals are detected by the ANA. The complex dielectric permittivity is determined according to the reflected coefficient ($\Gamma = \Gamma' - j\Gamma''$) as follows [27]

$$\begin{aligned}\varepsilon' &= (A_{ef})^{-1} \left\{ \frac{-2\Gamma''}{(1 + \Gamma')^2 + \Gamma''^2} \right\}; \\ \varepsilon'' &= (A_{ef})^{-1} \left\{ \frac{1 - \Gamma'^2 - \Gamma''^2}{(1 + \Gamma')^2 + \Gamma''^2} \right\}\end{aligned}\quad (13)$$

where A_e is the empirical coefficient dependent on characteristic impedance of the probe and sample size. In order to eliminate the influence of reflections caused by transmission-line discontinuities, a calibration procedure is utilized. The EM characteristics of the measurement system are analyzed using three standard terminations (open, short, and $50\ \Omega$). Then any material with well-known dielectric properties such as deionized water, for example, is tested. The actual reflection coefficient differs from reflection coefficient measured using ANA (Γ_m) [25]

$$\Gamma = \frac{\Gamma_m - a_{11}}{a_{22}(\Gamma_m - a_{11}) + a_{12}} \quad (14)$$

where a_{11} is the directivity error, a_{12} is the frequency response error, a_{22} is the source match error. Taking into account propagation constant (γ) and distance from the connector to the probe head (z) we can calculate a_{ij} in terms of S parameters of the connector:

$$a_{11} = S_{11}; a_{12} = S_{12}S_{21}e^{-2\gamma z}; a_{22} = S_{22}e^{-2\gamma z} \quad (15)$$

In the inverse coaxial probe model, it is assumed that a sample has a semiinfinite size. A few additional conditions must be satisfied to avoid measurement error in the OCP method:

- Minimize thermal expansion of both conductors of coaxial line at high temperatures.
- Intimate contact between the probe and the sample; liquid sample may flush the probe and the surface roughness of solid sample should be less than $0.5\ \mu\text{m}$ [28].
- Minimize disturbance caused by temperature, vibration, or any other external factors after calibration and during measurement.

The OCP method is very well suited for liquids or soft solid samples. It is accurate, fast, and broadband (from 0.2 to up to 20 GHz). The measurement requires little sample preparation. A major disadvantage of this method is that it is not suitable for measuring materials with low dielectric property (plastics, oils, etc.).

Figure 10. Schematic diagram of experimental setup realizing open-ended coaxial probe method [19].

3.2. Transmission-Line Method

The transmission-line method (TLM) belongs to a large group of nonresonant methods of measuring complex dielectric permittivity of different materials in a microwave range [7,51]. Several modifications to this method exist, including the free-space technique [29], the open-circuit network method (see previous section), and the short-circuited network method. Usually three main types of transmission lines are used as the measurement cell in TLM: rectangular waveguide, coaxial line, and microstrip line.

Consider the distribution of the TEM wave in a short-circuited coaxial line partially filled with a lossy material under study (Fig. 11). Analyzed sample is placed near the short-circuited end of the transmission line. The dielectric properties of the sample are determined using the following expressions

$$\begin{aligned} \epsilon' &= \left(\frac{\lambda}{2\pi d}\right)^2 (x^2 - y^2) + \left(\frac{\lambda}{\lambda_{qc}}\right)^2; \\ \epsilon'' &= \left(\frac{\lambda}{2\pi d}\right)^2 2xy \end{aligned} \tag{16}$$

where λ is the free-space wavelength, λ_{qc} is the quasicutoff wavelength, d is the sample thickness (Fig. 11), $x = \text{Re}(Z_{in})$ and $y = \text{Im}(Z_{in})$, and Z_{in} is the input impedance of the short-circuited line

$$Z_{in} = \frac{K_t^2 + tg^2(2\pi/\lambda_a l)}{K_t[1 + tg^2(2\pi/\lambda_a l) + j(1 - K_t^2)tg(2\pi/\lambda_a l)]} \tag{17}$$

where l is the distance between the dielectric surface and the first minimum of the standing wave, λ_a is the wavelength in unloaded part of transmission line, and K_t is the traveling-wave coefficient that is calculated when $K_t \geq 0.4$

as

$$K_t = \sqrt{\frac{E_{min}}{E_{max}}} \tag{18}$$

and when $K_t < 0.4$ as

$$K_t = \frac{\sin(2\pi\Delta x/\lambda_a)}{\sqrt{((E/E_{min}) - 1) \sin(2\pi\Delta x/\lambda_a)}} \tag{19}$$

where E_{min} and E_{max} are the minimum and maximum values of electric field amplitude (see Fig. 11) and $2\Delta x$ is the distance between two points along transmission line on both sides of minimum where measured data are equal and determined from $E = m^2 E_{min}$ ($2 < m < 10$ is the empirical coefficient found from the calibration procedure).

Dielectric permittivity of lossy media may be also successfully measured employing a two ports coaxial cell with a sample placed in the middle of transmission line, so that the TEM wave could propagate from the input port to the output port. Impedance changes and propagation characteristics (S parameters) of the TEM wave measured by means of ANA in empty and partially loaded transmission line lead to determination of the dielectric properties of lossy material. Basic principles of this technique are given in Ref. 30.

In general, a TLM measurement system is more expensive for the same range of frequency than the open-ended coaxial probe system, and the measurements are more difficult and time-consuming. The method described above gives a good accuracy for high-loss materials. But it has rigid requirements on sample shape and sizes. In particular, the sample shape needs to precisely fit the cross section of the transmission line. In some cases, in order to increase accuracy, it is necessary to measure several samples of various thicknesses. Despite these drawbacks, TLM is still widely used in microwave measuring engineering because of its simplicity. Using coaxial line as a

Figure 11. Electric field pattern of TEM wave in empty (solid lines) and partially loaded (lines with circles) short coaxial waveguide. Equations (16)–(19) explain all parameters used in this figure.

basic unit of measurement cell makes this method sufficiently broadband. The accuracy of this method is generally between that of the OCP method and that of the resonance cavity method.

3.3. Resonant Cavity Method

Resonant cavity methods are also widely utilized in measuring complex dielectric permittivity of lossy materials. The most popular resonant cavity method is the perturbation method (PM), which is based on a comparative analysis of certain EM characteristics between empty and a partially loaded rectangular or cylindrical resonance cavity [31]. A schematic diagram of an experimental setup of PM is shown in Fig. 12.

According to PM theory [32,33], dielectric permittivity and losses of a sample under study are determined as follows:

$$\epsilon' = 1 + A^{-1} \frac{V_c \Delta f}{V_s f_0}; \quad \epsilon'' = B^{-1} \frac{V_c}{V_s} \left(\frac{1}{Q_1} - \frac{1}{Q_0} \right) \quad (20)$$

where f_0 and Q_0 are the resonance frequency and Q factor of the empty cavity, f_1 and Q_1 are the resonance frequency and Q factor of the cavity with a sample, V_c is the cavity volume, V_s is the sample volume; and $\Delta f = f_0 - f_1$. A and B are the coefficients that depend on several parameters: shape, sizes, and location of the sample in the cavity, and configuration and excited operating mode of the cavity. In some cases, A and B may be found analytically for a lossy sheet material placed in a rectangular cavity with

operating mode TE_{103} [31], or they may be determined empirically with calibration of the experimental setup. Equation (20) is valid when three main assumptions are satisfied [32]: (1) the dielectric sample does not disturb the general distribution of the EM field in the cavity, (2) metallic wall losses do not influence the resulting losses in the cavity, and (3) Q_0 and Q_1 are measured at the same frequency. Appropriate location of the sample is also a very important factor that affects the accuracy of the measurement. Preliminary numerical modeling of the microwave setup with lossy dielectric material inside the cavity may be a useful approach for determining an optimum sample position in this case [31]. Sometimes, measurement errors are possible when there are airgaps between the specimen and the conducting parts of the metallic resonator.

There are also some restrictions in using conventional resonance PM for measuring the dielectric loss tangent of low-loss media. If conduction losses in cavity walls are higher than (or comparable to) the dielectric losses of the specimen, the resonator Q factor may change and one will not obtain the correct values of ϵ'' . In this case, application of hybrid high-order modes called whispering-gallery modes [34] or a special calibration procedure of Q factor characterization as a function of frequency [32] can help to eliminate the drawbacks of this method.

PM is more accurate than the waveguiding methods. It is particularly suited for medium-loss and low-loss materials and substances. Precisely shaped small-sized samples are usually used with this technique. But PM provides dielectric properties measurements only at a fixed

Figure 12. (a) Microwave system for measuring dielectric properties of lossy materials: microwave generator (1), attenuator (2), wavemeter (3), cavity resonator (4), and sample (5); (b) closeup view of a sample, cavity, and related principles for the measurement.

frequency. Commercial systems from Hewlett-Packard are more expensive than the open-end coaxial probe system.

4. PERMITTIVITY OF ORGANIC AND INORGANIC MATERIALS

4.1. Foodstuff and Agricultural Products

Numerous data are reported in the literature on the dielectric properties of biomaterials, especially food materials. This section only summarizes the dielectric properties for some typical materials commonly used in food processing. Table 2 lists electrical property data for different salt solutions, fruits, and codling moth larvae at 27 MHz RF and 915 MHz microwave. Air and deionized water do not absorb much electromagnetic energy at these two frequencies due to near-zero dielectric loss factors. Dielectric and conductivity properties increase with increasing salt content. However, dielectric constant decreases both with frequency and salt content at 915 MHz.

Dielectric properties of dry food solids, fats, and oils are very low and are relatively independent of frequency and temperature. The dielectric properties of selected oils and low-moisture-content food solids are listed in Table 3.

Figure 13 shows the effect of temperature on the dielectric loss factor of selected foods at 3000 MHz [37]. The high salt content in the ham makes the dielectric properties of this product quite different from those of the remaining materials in the graph. Due to ionic polarization,

the dielectric loss factors increase with temperature above the freezing point, which is contrary to the trend of dielectric properties of other foods in which loss mechanisms are determined mostly by the dipole polarization of free water. One advantage of the decreased loss factor with increasing temperature is the so-called temperature leveling effect. When a certain portion of a food is overheated, the loss factor of that part is reduced, which results in less conversion of microwave energy to heat at that part of the food and helps reduce nonuniform spatial temperature distribution.

When thawing frozen foods at relatively high microwave power levels, one often experiences the thermal runaway phenomenon, in which certain areas of the food are overheated while the other areas are still frozen. This is because faster thawing of a portion of food due to uneven heating dramatically increases the loss factor of that part of the food due to the high loss factor of free water (Fig. 13), which in turn increases microwave absorption, causing more uneven heating. In practice, a low microwave power level is often used in microwave thawing so that heat conduction can reduce nonuniform temperature distribution. In industrial tempering (a process that brings deep-frozen products from -30° or -10°C to a few degrees below freezing point for further processing) of large blocks of meat or fish, convective surface cooling at below freezing temperature is often used to reduce thermal runaway.

Figure 14 shows the dielectric properties of Red Delicious apples as a function of frequency at three selected

moisture contents and two measured temperatures. At a high moisture content (70% wet basis), ϵ' decreases with increasing frequency, while ϵ'' decreases to a minimum value and then increases with frequency (Figs. 14a and 14d). The gradual reduction in ϵ' of high-moisture-content samples with increasing frequency is likely caused by the dispersion of water molecules. In a single dispersion system (e.g., pure water), this transition takes place in a narrow frequency range and follows the Debye equation

Figure 13. Dielectric loss factor (ϵ'') of selected foods at 3000 MHz as affected by temperature [37].

[Eq. (8)]. In multidispersion food systems, the transition is gradual because of the combined effects of relaxation and ionic conduction. A minimum ϵ'' is observed at 1000 MHz (Fig. 14a) at 22°C. The frequency corresponding to the minimum ϵ'' shifts to about 2000 MHz at 60°C (Fig. 14d). This shift can be related to the temperature response of both the free-water dispersion and the ionic conduction.

Figure 15 shows the dielectric constant ϵ' and loss factor ϵ'' of apples at 915 and 2450 MHz as a function of moisture content (MC). In general, ϵ' and ϵ'' decreases with decreasing moisture content. In a drying process, as the drying progresses, water dipole becomes less mobile, resulting in reduced loss factor. Reduced moisture content during drying also reduces ionic conductivity, as a small amount of free water is available as the solvent. In addition, air voids in apple samples as a result of dehydration contribute to the low values of both ϵ' and ϵ'' .

Salty products (e.g., macaroni and cheese) have, on the other hand, much larger loss factors than do fresh fruits (Table 4). In addition, the loss factor of fresh fruits and macaroni and cheese increases sharply with increasing temperature, especially at low frequency (e.g., 27 MHz).

There has been increasing interest in using RF and microwave energy as a new thermal treatment method for postharvest insect control in agricultural commodities [36–40]. Knowledge of dielectric properties of insects and commodities is necessary in guiding development, improvement, and scaleup of RF and microwave treatment protocols. Table 5 summarizes the mean values of the dielectric constant and the loss factor of apples, almond, cherry, grapefruit, orange, and walnut as a function of temperature at 27 and 915 MHz. The dielectric constant and the loss factor of fresh fruits at 27 MHz are significantly higher than those at 915 MHz. The loss factor of fresh fruits increases with increasing temperature at 27 MHz and remains nearly constant at 915 MHz, similar to the pattern shown in Fig. 7. However, the temperature effect on dielectric properties of almond and walnut is different from that on fresh fruits as shown in Fig. 8. The peak value of the loss factor decreases and corresponding frequency shifts to larger values with increasing temperature.

Mean values of the dielectric constant and the loss factor of selected insect larvae as a function of temperatures at 27, 40, 915, and 1800 MHz are listed in Table 6. Both the dielectric constant and the loss factor for insects increased with increasing temperature at 27 MHz, but remained almost constant at 915 MHz. This is due mainly to the increase in ionic conduction at high temperatures [12]. The loss factor of insects at 27 MHz decreased in order at all temperatures: Mexican fruitfly, navel orangeworm, codling moth, and Indian meal moth.

Compared to codling moth larvae, the loss factor values of walnuts are much smaller because of high oil content and less moisture in walnut kernels. It is clear from Figs. 7 and 8 that the difference in the value of the ϵ'' between codling moth larvae and walnut kernels is much larger at lower frequencies than at microwave frequencies, suggesting a better potential for preferential heating of insects

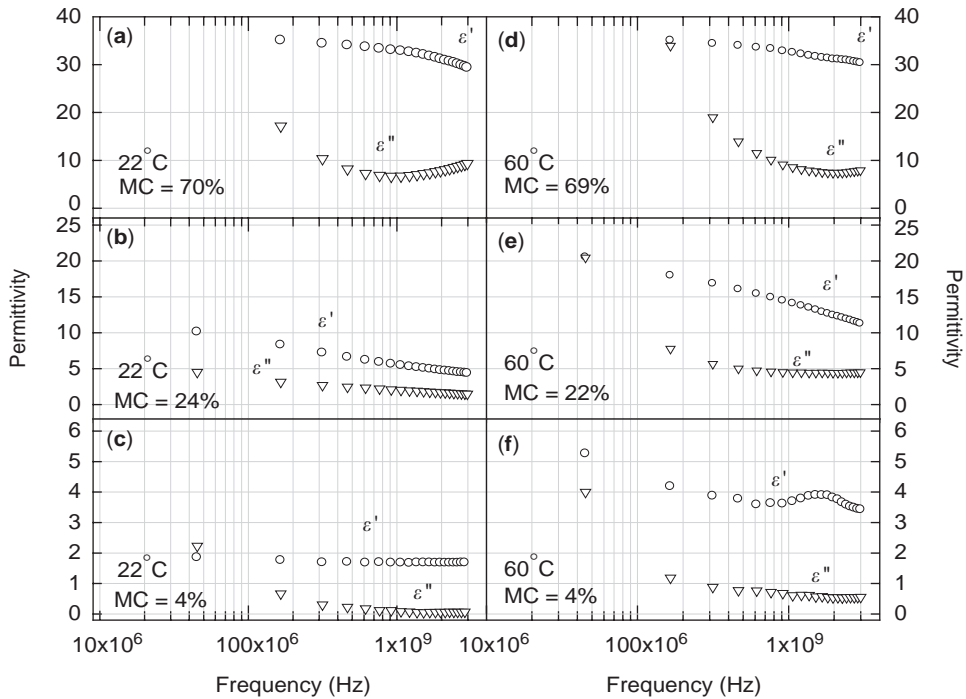

Figure 14. Dielectric properties of Red Delicious apples at three moisture contents and two temperatures [20].

in walnuts when using lower-frequency treatments. A theoretical model and experimental evidence have been provided [18] to support the hypothesis that insect larvae can be preferentially heated in dry nuts by 27 MHz RF

heating for pest control. This differential heating makes possible in the development of practical RF pest control treatments that the walnut industry can use to replace chemical fumigation.

Figure 15. Dielectric properties of Red Delicious apples at 915 and 2450 MHz as influenced by moisture content on a wet basis [20].

4.2. Biological Tissues

High-frequency EM energy is widely used in medical treatments, including physiotherapeutic, diagnostics, rapid rewarming of cryopreserved tissues, pharmacology, reflex therapeutic, blood sterilization, and hyperthermal treatment of cancer [42–45].

The main mechanism for the interaction between EM waves and biological tissues is the same as in foodstuffs: oscillation of polar water molecules (H_2O) and ions. Part of water in biological tissues is linked with albumen (0.3–0.4 g of water on 1 g of albumen), and at relaxation frequencies specific electrical conductivity (σ) of “linked” water sometimes is higher than σ of pure water.

Biological tissues (biotissues) are divided into two main groups: materials with high and low water contents; muscles (73–78%), liver (75–77%), kidneys (76–78%), brain (68–73%), skin (60–76%), lung (80–83%), eye ($\leq 89\%$) compile the first group. Fat (5–10%) and bone (8–16%) tissues may be included in the second group. Moisture content in blood is higher than in other tissues ($\leq 83\%$).

Complex dielectric permittivity of some biological materials at room temperature and 2450 MHz taken from Refs. 46 and 47 is represented in Table 7. Bloodflow seldom influences their dielectric properties, excluding tissues with high blood volume (kidneys) or low moisture content (fat). Experimental results [48] have shown that measured data of ϵ' and ϵ'' of biotissues in vivo (directly in organism) and in vitro (in the test tube) almost coincide at frequencies higher 100 MHz.

A new technology of microwave diagnostics based on measurement of $\epsilon' - j\epsilon''$ of normal and invalid tissues has been proposed [49]. Permittivity of infected gall ($\epsilon' = 63$ – 65 ; $\epsilon'' = 17$ – 19) is higher than that of normal gall ($\epsilon' = 60$; $\epsilon'' = 15$).

4.3. Wood and Fibrous Materials

Most fibrous materials are organic cellulose-based substances; such as wood, paper, cartoon, fabric, and fibers. Wood is highly hygroscopic and anisotropic. The dielectric properties of wood depend on type of wood, density, moisture content, and temperature [50,51]. Normal moisture content of wood is between 8 and 12%.

According to generalized electrophysical model of wood samples proposed [51], one can consider a second-order tensor for evaluation of its complex dielectric permittivity

$$\begin{aligned}
 & \|\epsilon' - j\epsilon''\| \\
 & = \begin{vmatrix} \epsilon'_{LL} - j\epsilon''_{LL} & \epsilon'_{LR} - j\epsilon''_{LR} & \epsilon'_{LU} - j\epsilon''_{LU} \\ \epsilon'_{RL} - j\epsilon''_{RL} & \epsilon'_{RR} - j\epsilon''_{RR} & \epsilon'_{RU} - j\epsilon''_{RU} \\ \epsilon'_{UL} - j\epsilon''_{UL} & \epsilon'_{UR} - j\epsilon''_{UR} & \epsilon'_{UU} - j\epsilon''_{UU} \end{vmatrix} \quad (21)
 \end{aligned}$$

where L , R , and U are the longitudinal, radial and tangential axes of anisotropy, respectively. Rotation of electric field vector (\vec{E}) on a 180° angle does not change the dielectric properties of wood materials; that is L , R , and U are the principal axes of anisotropy, and the tensor in Eq. (21) may be simplified as follows:

$$\|\epsilon' - j\epsilon''\| = \begin{vmatrix} \epsilon'_L - j\epsilon''_L & 0 & 0 \\ 0 & \epsilon'_R - j\epsilon''_R & 0 \\ 0 & 0 & \epsilon'_U - j\epsilon''_U \end{vmatrix} \quad (22)$$

When \vec{E} is arbitrarily oriented in space and forms an angle ϑ_1 with L , angle ϑ_2 with R and angle ϑ_3 with U closed-form

expressions for calculation of ϵ' and $\tan \delta_e$ are derived as follows [51]:

$$\epsilon' = \epsilon'_L \cos^2 \vartheta_1 + \epsilon'_R \cos^2 \vartheta_2 + \epsilon'_U \cos^2 \vartheta_3 \quad (23)$$

$$\tan \delta_e = tg \delta_{eL} \cos^2 \vartheta_1 + tg \delta_{eR} \cos^2 \vartheta_2 + tg \delta_{eU} \cos^2 \vartheta_3 \quad (24)$$

The measured dielectric constant of Douglas fir at 2450 MHz as a function of moisture content [MC (%)] and temperature (°C) is shown in Fig. 16 [50]. Here \vec{E} is oriented parallel to wood fibers. Dependencies ϵ' (MC) and ϵ'' (MC) at 9210 MHz for the same type of wood and softwood hembal when $T=23^\circ\text{C}$ and $0 \leq \text{MC}\% \leq 28$ are presented in Ref. 52.

Density of wood [ρ (g/cm³)] may also influence $\epsilon' - j\epsilon''$. Experimentally obtained functions ϵ' (ρ , MC, T) and ϵ'' (ρ , MC, T) for $0.3 \leq \rho \leq 0.8$, $0 \leq \text{MC} \leq 60$, $20 \leq T \leq 90$ for various

RF and microwave frequencies are given in Ref. 51. These functions are valid for the cases when \vec{E} is perpendicular to wood fibers.

4.4. Resins and Plastics

According to the classification proposed in Ref. 53, resins and plastics are divided into three main groups: (1) no polar high-frequency (HF) dielectrics, including polyethylene, polypropylene, and polyester (2) weak polar and polar HF and low-frequency (LF) dielectrics, including polyformaldehyd, rubbers, and polybutadiene; and (3) polar LF dielectrics such as polyamide, epoxide, and polyvinylchloride.

Rubber-based resins are multimolecular substances described by the formula $(\text{C}_5\text{H}_8)_m$, where m is the number of molecular chains. Vulcanization (heating of rubber after mixing with sulfur containing matters) of crude rubber allows improving its heatproof properties. The dielectric

constant of rubbers in a microwave range has been studied in several works [5,53,54]. For example, temperature dependencies of $\epsilon'(T)$ and $\epsilon''(T)$ of stearine butadiene rubber (SBR) at 2800 MHz are represented in Ref. 7. These dependencies may be approximated with polynomial expressions:

$$\begin{aligned} \epsilon' &= 0.1172 \times 10^{-9}T^5 - 0.6167 \times 10^{-7}T^4 + 0.121 \times 10^{-4} \times T^3 \\ &\quad - 0.001088T^2 + 0.03727T + 8.821 \\ \epsilon'' &= -0.27561 \times 10^{-11}T^6 + 0.163672 \times 10^{-8}T^5 \\ &\quad - 0.38772 \times 10^{-6}T^4 + 0.46581 \times 10^{-4}T^3 - \\ &\quad - 0.0029782 \times T^2 + 0.096531 \times T - 0.971 \end{aligned} \quad (25)$$

Similar functions for cured and vulcanized nitrile butadiene rubber (NBR) at 2450 MHz have been measured [54] (see Fig. 17). Experimental data of the complex dielectric permittivity of some rubbers at various frequencies have also been given [5].

Resins such as polyamide and polyimide have wide practical applications in modern microelectronics electrical, and aerospace engineering. The dielectric properties of

some of these materials at microwave frequencies have been studied closely. In particular, $\epsilon'(T)$ and $\epsilon''(T)$ of Nylon-6 at 2450 MHz have been obtained [55]. These results are represented in Fig. 18.

Plastic dielectrics have weak interaction with EM fields because of their nonpolar molecular structure. Plastics are often used as package material for foods treated by microwaves. Most of plastics have a very weak linear dependence on temperature at RF and microwave frequencies. For example, the dielectric permittivity and loss factor of plastic materials have been analyzed in by Von Hippel [5] at 10,000 MHz: $2.5 \leq \epsilon' \leq 6$; $\tan \delta_e \leq 0.05$. Table 8 lists the dielectric permittivities of selected plastic materials at 2450 MHz.

4.5. Ceramics

Ceramics are widely applied in many areas of science and engineering because of their unique features such as high temperature stability of physical properties, low wearability, thermal conductivity, and weight. Dielectric properties of selected ceramics as a function of temperature and frequency have also been studied [5]. The dielectric constant of ceramic may be sufficiently low (Mullite, $\epsilon' < 10$), average

Table 11. Dielectric Permittivity (ϵ') and Loss Factor (ϵ'') of Selected Minerals [66] at 2450 MHz

Mineral	$T = 25^\circ\text{C}$		$T = 100^\circ\text{C}$		$T = 200^\circ\text{C}$		$T = 300^\circ\text{C}$	
	ϵ'	ϵ''	ϵ'	ϵ''	ϵ'	ϵ''	ϵ'	ϵ''
Chalcoite	16.72	1.64	17.14	1.76	15.46	1.52	11.82	1.12
Chalcopyrite	11.01	8.02	11.41	10.20	11.20	12.5	9.01	1.41

(titanic ceramics N1400-110, N750T, $30 \leq \epsilon' \leq 150$) or high (TiO_2 , CaTiO_3 and LaAlO_3 , $\epsilon' > 200$).

The complex dielectric permittivity of ceramics Hilox-882, which consists of Al_2O_3 , SiO_2 , MgO , CrO_2 , and CaO at two microwave frequencies and three temperatures, is shown in Table 9 [56]. An analytical model that describes the behavior of ϵ' and ϵ'' of composite ceramics in temperature range $0 < T < 2500$ at 2450 MHz has been derived [57]

$$\epsilon = \epsilon_{in} + 10^{-4}(T - 25) - j \cdot 10^{-3}(T - 25) \quad (26)$$

Where $\epsilon_{in} = 3.9 - j0.46$ is the initial value at $T = 25^\circ\text{C}$.

Several types of ceramics—aluminosilicate and zirconia fibre board, alumina, Ni-Zn-ferrite, and PZT ceramics—

were analyzed at 2422 MHz by Hamlin et al. [58], who treated these materials by microwave in a cylindrical applicator with operating mode TM_{010} .

Measured values of $\epsilon'(T) - j\epsilon''(T)$ at 3000 MHz for soda lime glass (Corning 0080), borosilicate glass, Mullite MV20, cupric oxide, aluminum nitride, zeolite Fig. 19, alumina cement AC56, zirconia cement, and felt can be found in Ref. 59. Some of these dependencies (zeolite) may be approximated by expressions:

$$\begin{aligned} \epsilon' &= 0.250933T^{0.499713}, \\ \epsilon'' &= 0.383887e^{0.0047014 \cdot T} \quad R^2 = 0.962 \end{aligned} \quad (27)$$

Where R^2 is the coefficient of determination. Both equations are valid when $300 < ^\circ\text{C} < 500$. The dielectric constant of Mullite MV20 $\epsilon'(T) = 5.3 \sim 7.8$, $\epsilon''(T) = 0.05 \sim 1.3$, $400 \leq ^\circ\text{C} = 1300$ at 915 MHz has been investigated [60].

4.6. Soils and Minerals

Moisture dependent dielectric constants of many soils (sandy, high-clay, loami and etc.) over RF and microwave frequency ranges have been published by several authors [61–64]. Most of these studied have been carried out in the temperature range ($5 \leq ^\circ\text{C} \leq 25$) for fixed values of soils density. As an example in Table 10, complex dielectric permittivity of two types of soils is listed for different moisture content at two microwave frequencies [64].

At 2450 MHz all dry sandy soils may be classified on three groups according to the value of loss factor: sands with low losses ($\epsilon'' = 0.0075$), sands with average losses ($0.011 \leq \epsilon'' \leq 0.031$), and sands with high losses ($0.05 \leq \epsilon'' \leq 0.1$) [65]. Dry clay soils are characterized by $3.91 \leq \epsilon' \leq 4.21$ and $0.14 \leq \epsilon'' \leq 0.32$. Dielectric properties of loami soils with moisture content: $2 \leq \text{MC} \leq 50\%$ and $3.49 \leq \epsilon' \leq 32.53$ and $0.22 \leq \epsilon'' \leq 1.3$.

EM fields are used today in mining industry, geology, road building technologies, and so on. Determination of dielectric properties of minerals allows more accurate mathematical modeling of physical processes of EM waves interaction with lossy media. The open-end-coaxial line method has been utilized [63] for measuring $\epsilon'(f, T) - j\epsilon''(f, T)$ of over 60 minerals in the temperature range $25\text{--}325^\circ\text{C}$ and frequency range $300 \leq f, \text{MHz} \leq 3000$. Some of these experimental data at 2450 GHz are given in Table 11. Most minerals exhibit increasing values of ϵ' and ϵ'' versus temperature, except for minerals presented in Table 11 which have complicated dependencies $\epsilon'(T)$ and $\epsilon''(T)$ [66].

5. CONCLUSION

Wide applications of dielectric materials require the knowledge of their dielectric properties. We have represented data about dielectric permittivity for some of these materials in RF and microwave ranges. Many of the experimental results given in Section 4 have been implemented in mathematical models of RF and microwave technological applicators developed at Washington State University.

Three main factors—frequency, temperature and moisture content—which significantly influence the value of $\epsilon' - j\epsilon''$ are analyzed in details. In many cases, the non-linear characteristic of temperature dependences of dielectric permittivity dictates that the physical processes in RF and microwave systems are highly coupled EM and heat conduction problem. A major challenge in RF and microwave heating research and development is to design RF applicators and microwave cavities that provide uniform E -field patterns in treated materials. With precise measurements of dielectric and thermal

properties for different materials, great success of new designs in industrial implementations will be expected in the future.

1. INTRODUCTION

Since the early 1990s, we have witnessed wide proliferations and acceptance of wireless communication technologies in society. Coupled with this major technological development, the rapid decrease in the prices of wireless technologies is paving the way for new networking paradigms such as wireless local-area networking and wireless personal-area networking. Wireless personal-area networking, the focus of this article, enables a user-centered network concept where an individual user, surrounded by a collection of devices (cellphone, laptops, palm pilot, etc),

communicates wirelessly with them and through them with external networks and devices. The wireless personal-area network (WPAN) communication infrastructure should enable a variety of personal communication-enabled devices to be connected to networks anytime, anywhere, and (through) any media [8]. The idea of networking within the personal space exists in different solutions, including body-area network (BAN) [2,3], Picoradio [4], IrDA [5], and HomeRF [6]. The central concepts that led to the convergence of these solutions are wireless connectivity, cable replacement, and embedded low-power and low-cost radio.

Many wireless systems and devices such as cellular phones, personal digital assistants, pagers, and other portable devices have proliferated in contemporary society. However, they are often used separately and their applications do not interact. One of the goals of PANs [7,8] is to enable such a diverse set of devices to exchange information in a seamless, friendly, and efficient way. One of the emerging short-range wireless networking technologies that shows promise as an enabling technology for realizing PANs is the more recent industry-standard Bluetooth [9]. Bluetooth evolved from the need to replace wires in short-range communications (e.g., serial cable between computers and peripherals) with short-range wireless links among small form factor mobile devices. Bluetooth has a transmission range of approximately 10 m in a free propagation environment and operates in the unlicensed 2.4-GHz ISM (industrial, scientific, medical) band. To increase robustness to interference, Bluetooth uses a frequency-hopping technique where the carrier frequency is changed for every packet transmission. To minimize complexity and reduce the cost of transceivers, the signals are modulated using Gaussian frequency shift keying (GFSK) and transmitted in one of 79 channels by a pseudorandom sequence hopped through the 79 channels at a rate of 1600 hops per second.

2. BLUETOOTH TECHNOLOGY AND WIRELESS PERSONAL-AREA NETWORKING STANDARDS

2.1. Bluetooth Technology

Bluetooth enables the creation of ad hoc networks based on the concept of master/slave devices and provides full-duplex transmissions using a slotted time-division duplex (TDD) scheme. Master-to-slave transmissions always start in an even-numbered slot, whereas slave-to-master transmission starts in an odd-numbered timeslot. The master controls data transmission of up to seven slaves using a polling mechanism. Slaves cannot communicate with each other in Bluetooth. Transmission is only between a slave and a master or vice versa. Slaves are allowed to transmit only after being polled. The device that initiates the connection is defined as the “master”. Three configurations are supported by Bluetooth: point-to-point connection, point-to-multipoint (known as a *piconet*), and multiple interconnected piconets with overlapping areas forming a *scatternet*. A Bluetooth unit can simultaneously be a slave of multiple piconets, but a master in only one, and can transmit and receive data in one piconet at a time,

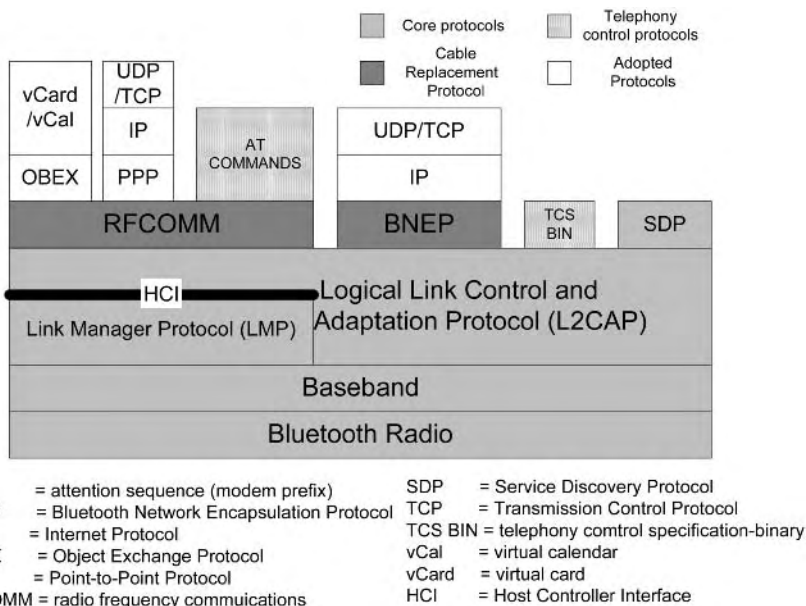

Figure 1. Bluetooth protocol stack.

which implies that time-division multiplexing is needed for participation in multiple piconets. All these characteristics make Bluetooth a strong candidate for establishing PANs. Figure 1 illustrates the Bluetooth protocol stack. Bluetooth is based on a high-performance, low-cost integrated radio transceiver.

Baseband is the physical layer that manages functions such as error correction, packet handling, paging and inquiry to access Bluetooth devices, and Bluetooth security. The baseband transceiver supports a TDD scheme. The Link Manager Protocol (LMP) performs link setup and configuration, authentication, encryption management, and other functions. The Logical Link and Control Adaptation (L2CAP) layer hides the functionalities of Bluetooth lower layers. L2CAP supports protocol multiplexing, provides connection-oriented and connectionless data services to upper layers, and performs segmentation and reassembly operations to and from smaller baseband packets. In addition, L2CAP also supports point-to-multipoint links. The Service Discovery Protocol (SDP) allows Bluetooth applications to discover services available in a Bluetooth environment. Higher-layer protocols such as RFCOMM, OBEX, and TCP/IP can also be used for

Bluetooth to support legacy applications. The Host Controller Interface (HCI) layer provides an interface to access the hardware capabilities of Bluetooth.

Bluetooth supports two types of links between the master and the slave(s): the synchronous connection-oriented (SCO) link and the asynchronous connectionless (ACL) link. The SCO link is a symmetric point-to-point link between a master and a single slave and is typically used for sensitive traffic such as voice. The SCO link (such as between a headset and a cellular handset) reserves two consecutive timeslots: one for transmission and one for reception at fixed intervals. A master can support up to three SCO links to one or different slaves outside its piconet. The slave can support three SCO links from the same master or two links from different masters in their respective piconets. SCO links are symmetric and yield a maximum of 64 kbps (kilobits per second) in both directions. L2CAP supports only ACL links and packet sizes up to 64 kB (kilobytes). The ACL link is point-to-multipoint between a master device and up to seven slaves. ACL links can support both symmetric and asymmetric connections, and ACL packets can be broadcast to all slaves in a piconet. ACL links offer speeds up to 723.2 kbps downlink and

Table 1. ACL Packet Types

Type	Payload Header (bytes)	User Payload (bytes)	FEC	CRC	Symmetric Maximum Rate (kbps)	Asymmetric Maximum Rate (kbps)	
						Forward	Reverse
DM1	1	0-17	2/3	Yes	108.8	108.8	108.8
DH1	1	0-27	No	Yes	172.8	172.8	172.8
DM3	2	0-121	2/3	Yes	258.1	387.2	54.4
DH3	2	0-183	No	Yes	390.4	585.6	86.4
DM5	2	0-224	2/3	Yes	286.7	477.8	36.3
DH5	2	0-339	No	Yes	433.9	723.2	57.6
AUX1	1	0-29	2/3	No	185.6	185.6	185.6

simultaneously 57.6 kbps uplinks for ACL. All ACL packets shown in Table 1 use CRCs (cyclic redundancy checks), and in the presence of errors they are retransmitted. The Bluetooth standard offers a range of data packet types: DH_x and DM_x . The H-type packets have higher payloads whereas the M-type packets support medium payloads but include forward error correction (FEC) for error recovery in noisy operating conditions. The baseband controller can be configured to select the packet type. Actually, the strategy is if a higher-layer (i.e., L2CAP layer and above) packet exceeds the size of the DH or DM packets, the next DH or DM packet of the minimum size is chosen. This method improves link utilization and also reduces overhead.

2.2. WPAN Standards

Future WPANs will require innovative system solutions and appropriate network design architectures to provide mobile users local and global access with high availability, low power, and minimal infrastructure requirement. To achieve these objectives, the IEEE has created the IEEE 802.15 [10] working group, which concentrates on developing consensus standards for WPANs or short-distance wireless networks. The activities within the IEEE 802.15 working group are divided into various task groups, each of which focuses on a different issue; task group 1 deals with Bluetooth, task group 2 deals with coexistence issues between WPANs (802.15) and wireless local-area networks (WLANs) (802.11), task group 3 deals with high-rate (≥ 20 -Mbps) WPANs, task group 3a is chartered to work on higher-speed (≥ 110 -Mbps) WPANs, and task group 4 is investigating a low-data-rate solution (< 0.25 Mbps) with multimonth to multiyear battery life, and very low complexity. We summarize the IEEE 802.15 standards in Table 2.

It is worthwhile pointing out also that IEEE has also approved four projects concerning IEEE 802.15 WPAN standards. These projects deal with a wireless mesh topology standard for WPAN devices and modifications to the high-rate WPAN standard so that it supports wireless multimedia applications more effectively. The task groups include IEEE 802.15.5, which will develop an architectural framework for interoperable, stable, and scalable wireless mesh topologies for WPAN devices. The mesh topologies are expected to extend network coverage without increasing transmission power or receiver sensitivity.

These topologies also aim to improve reliability through route redundancy, simpler network configuration, and longer battery life. The 802.15.3b group deals with modifications of IEEE 802.15.3 to improve ease of implementation and interoperability while maintaining backward compatibility. The 802.15.4a group is expected to design alternate WPAN physical-layer specifications to meet the evolving needs of ultra-low-complexity, ultra-low-cost, ultra-low-power WPAN communications. It will provide for precision to one meter or less, improved communications range, improve link robustness, and the ability to support mobility. The IEEE 802.15.4 standard will be revised by the 802.15.4-REVb group to remove ambiguities and will be extended to support shared time base distribution and new frequency allocations in Europe, China, and Japan.

3. SEAMLESS CONNECTIVITY OF BLUETOOTH TO IP-BASED NETWORKS

The proliferation of IP over all kinds of networks today makes it necessary to support Bluetooth applications over IP-based networks. However, an IP-over-Bluetooth profile was not specified in the Bluetooth specifications. There are currently two ways of running IP-based applications over Bluetooth; one approach is to use the LAN profile [11], and the other approach is to use the PAN profile [12].

3.1. LAN and PAN Profiles

The LAN profile defines how Bluetooth-enabled devices can access services of a LAN using the IETF Point-to-Point Protocol PPP [13] as shown in Fig. 2. A frequent topology used consists of a LAN access point (LAP), which is a Bluetooth device that provides the services of a PPP server, and a data terminal (DT), which is a Bluetooth device that acts as a PPP client. Using appropriate PPP mechanisms, a suitable IP address is negotiated between the LAN access point and the data terminal.

The PAN profile describes how two or more Bluetooth-enabled devices can form an ad hoc network and how the same mechanism can be used to access a remote network through a network access point [12]. It uses the Bluetooth Network Encapsulation Protocol (BNEP) [14] to provide networking capabilities for Bluetooth devices. BNEP encapsulates packets from various networking protocols,

Table 2. IEEE 802.15 Standards

IEEE Standard	Area Covered	Data Rate	Potential Applications
802.15.1	Bluetooth	1 Mbps	Speakers, microphones, headsets, printers, cellphones, PDAs, sensors, etc.
802.15.2	Coexistence between Bluetooth and 802.11	N/A	N/A
802.15.3	High-rate WPAN	> 20 Mbps	Low-power, low-cost solutions for portable consumer digital imaging and multimedia applications
802.15.3a	Higher-rate WPAN	> 110 Mbps	Streaming and other multimedia applications
802.15.4	Low-rate WPAN	2.4 GHz—250 kbps; 868/915 MHz—20/10 kbps	Sensors, smart badges, interactive toys, remote controls, home automation

Source: Ref. 1.

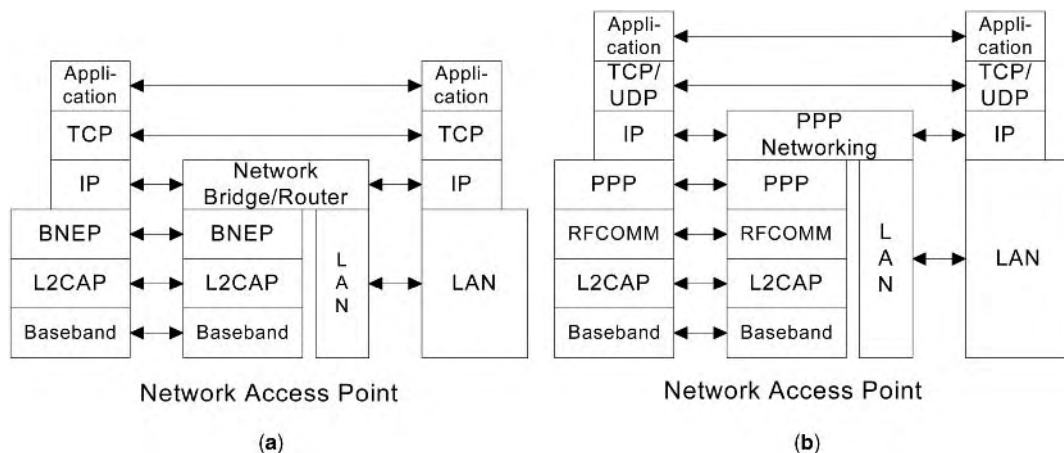

Figure 2. PAN profile using Bluetooth Network Encapsulation Protocol (BNEP) (a) versus LAN access profile (using PPP and RFCOMM) (b).

which are transported directly over L2CAP. BNEP includes support for common networking protocols such as IPv4, IPv6, IPX, and other existing or emerging networking protocols supported by IEEE 802.3/Ethernet encapsulation. BNEP removes and replaces the Ethernet header with the BNEP header, leaving the Ethernet payload unchanged. Both the BNEP header and the Ethernet payload are encapsulated by L2CAP.

3.2. IPv6-Enabled Bluetooth Devices

Depletion of IPv4 addresses is one of the reasons for the development of IPv6. IPv6 also defines *stateful* and *stateless* autoconfiguration [15]. Stateful autoconfiguration is the IPv6 equivalent of DHCP. DHCPv6 is used to pass out addressing and service information in the same way as DHCP is used in IPv4. The stateless configuration works as follows. Appending the interface’s identifier to the well-known link-local prefix forms a link-local address. The node then verifies that this tentative address is unique by sending neighbor solicitation messages. The next phase of autoconfiguration involves obtaining a router advertisement or determining that no routers are present. If routers are present, they will send router advertisements that specify what sort of autoconfiguration a host should do.

We need to exploit the IPv6 feature of autoconfiguration to enable Bluetooth devices to automatically connect to an IPv6-based Internet. This facility enables seamless connectivity as users of Bluetooth-enabled devices such as handheld PDAs and cellphones can roam around a variety of networks—ad hoc networks network hotspots and traditional fixed networks in the home and the office. Most users of these handheld devices will not have the expertise to reconfigure IP parameters. Another incentive for Bluetooth device manufacturers to support IPv6 is the upcoming support for Bluetooth in Windows XP, which will have native Bluetooth support. From a home networking point of view, the IPv6 autoconfiguration feature is also desired [16,17].

3.3. Effect of LAN and PAN Profiles with IPv4, and IPv6 Protocol Stacks on Latency

Our experimental testbed consists of an IPv6 network. The Bluetooth device that acts as a master consists of two interfaces—one is an Ethernet interface that connects it to an IPv6 local-area network and the other is a Bluetooth interface. The Bluetooth master is configured as a router. When a Bluetooth device (slave) establishes a connection to the Bluetooth master, an interface is created on the slave side. The Bluetooth slave is autoconfigured over this interface. The slave can access the IPv6 network without requiring any further configuration from the user. A single Bluetooth piconet consists of one master and up to seven slaves. If such a configuration is performed, all the slaves can access the IPv6 network and can communicate with each other.

We used various performance metrics to explore the impact of PAN and LAN profiles, IPv4, and IPv6 on data and voice transmissions to IP-enabled Bluetooth devices. It is useful for application designers and developers of IP-based Bluetooth applications to know whether the LAN or the PAN profile gives optimal Bluetooth performance. We used latency (measured using Netperf [18]) as the performance metric. Our testbed consisted of two identical laptops (each with an Intel Pentium III, 789-MHz processor, 512 MB of RAM) and one iPAQ pocket PC, all running BlueZ [19] protocol stack, with the laptops running Red Hat 9 Linux operating system, and the pocket PC running Familiar v0.7 Linux operating system. Both laptops and the pocket PC were equipped with BL-500 Bluetooth network adapters (from Brainboxes) and they all had support for both IPv4 and IPv6 protocol stacks as well as PAN and LAN profiles. For the latency tests, we used the two laptops and experimented with packet sizes in the range 64–1600 bytes. The reason for this choice for the packet size range stems from observations that most packet sizes on networks and the Internet are within this range [20].

Figure 3 shows one-way latency results (round-trip latency test measures how long it takes a packet to travel from one host to another and back to the originating host.

Figure 3. Latency using LAN and PAN profiles over IPv4 and IPv6 protocol stacks. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

One-way latency is half of the round-trip latency) obtained with raw data for LAN and PAN over IPv4 and IPv6. For both IPv4 and IPv6, we obtained better (i.e., lower) latencies with PAN compared to LAN. In fact, a close look at the results shown in Fig. 3 reveals that latency of PAN transmission ranges from 14% to 21% and 8% to 32% lower than LAN transmission in the case IPv4 and IPv6, respectively. The serial bit transmission characteristic associated with PPP probably accounts for the higher delays obtained with LAN packetized transmissions.

3.4. Voice Delivery to IPv4 and IPv6-Enabled Bluetooth PDAs

There has been a lot of interest recently (as of 2004) in delivering voice over IP-based networks. For Voice over IP (VoIP) to become reality and widely deployed, we need to support voice transmission and delivery on an *end-to-end* basis. It is no longer sufficient to support VoIP over wired networks only. In fact, the wide proliferation of wireless networks require VoIP support to extend to wireless net-

work segments frequently connected to wired LAN and the Internet. In addition, we should also be capable of delivering voice a range of popular devices such as PDAs and cellular phones. Only when these conditions are satisfied will a true end-to-end VoIP deployment be possible to mobile, handheld devices associated with mobile users. We investigate the deployment of a VoIP implementation that supports these goals—the wireless network under consideration being the Bluetooth network, and the iPAQ pocket PC running, the familiar v0.7 Linux operating system. In addition, we exploit IPv6 in our VoIP implementation to achieve seamless connectivity (i.e., with zero configuration) and delivery of voice to Bluetooth handheld devices connected to IP-based networks.

We experimented with various CODECS, namely G721 (yielding a bit rate of 32 kbps), G723 (yielding a bit rate of 24 kbps) and G723 (yielding a bit rate of 40 kbps). We experimented with two different voice packet sizes (40 and 20 ms) in our voice tests. The 20-ms voice packet size translates to 120, 160, and 200 bytes with G723 (yielding a bit rate of 24 kbps), G721 (yielding a bit rate of 32 kbps), and G723 (yielding a bit rate of 40 kbps), respectively. It is worthwhile explaining how the 20-ms voice packet size used translates to 120 bytes with a G723 CODEC. For a voice recording of 20 ms, a sampling rate of 8000 samples per second, stereo (two channels), a sample size of 16 bits (linear PCM) we get an uncompressed voice packet size of 640 ($20 \times 8000 \times 2 \times 16/8 \times 1000$) bytes. This yields an encoded (compressed) voice packet size output of 120 bytes with the G723 CODEC. In the case of the 40 ms voice packet size translates to 240 bytes, 320 bytes, and 400 bytes with G723, G721, and G723, respectively. To assess the voice quality delivered by the iPAQ running IP and connected to a Bluetooth network, we used end-to-end delay and jitter of the voice delivered.

3.4.1. End-to-End Voice Delay with IPv4 and IPv6. The results shown in Fig. 4 demonstrate that on average we obtained an end-to-end delay of about 60–70 ms in the voice delivery. This is well below the recommended end-to-end delay by ITU Recommendation G.114 [21], which recommends that the maximum one-way end-to-end delay acceptable by most users should be within 150 ms [22,23] to achieve the same speech quality as a normal telephone

Figure 4. End-to-end delay of voice using different CODECs over IPv4, IPv6 stacks on iPAQ. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

conversation. Interestingly, the end-to-end delay results over IPv6 are also very similar to those obtained with IPv4 despite extra overheads (such as larger addresses) with IPv6. Furthermore, from these results, we also note that the execution of the IPv6 stack on the iPAQ does not really introduce any performance degradations in voice performance. These latency results demonstrate the feasibility of delivering high-quality voice over Bluetooth to IPv6-enabled handheld devices such as iPAQs. Another observation worth noting is that the smaller of the voice packet size (i.e., 20 ms) yields the lowest end-to-end delay. As far as the CODECs are concerned, we found that the G723 (yielding a bit rate of 24 kbps) yields the best (i.e., lowest) voice delay performance among the CODECs tested. In the case of jitter, we obtained on average 28–30 ms and 51–54 ms with voice packet sizes of 20 and 40 ms, respectively, with the three CODECs tested. The 20 ms voice packet size yields the lowest jitter, which is well below the recommended jitter for excellent voice quality. Karam and Tobagi [24] found that for best voice quality, the jitter experienced by voice should be at most 50 ms so that the playback at the receiver end remains smooth.

4. COEXISTENCE OF BLUETOOTH AND IEEE 802.11 WLANs

Various radiofrequency technologies such as Bluetooth and IEEE 802.11 WLANs are being adopted at a rapid pace in academic office spaces, buildings, and campuses. One of the major issues arising out of the coexistence of these radiofrequency (RF) systems is the possibility of interference on each other. Various performance studies [25–28] have been conducted by several research groups, including the IEEE 802.15 working group to investigate the impact of IEEE 802.11 on Bluetooth transmissions. Gollmie et al. [28] investigated the effect of several factors, such as transmitted power, offered load, packet size, hop rate, and error correction on performance. They found that power control may have limited benefits in an interference environment. Increasing the Bluetooth transmission power even 10 times is not sufficient to reduce Bluetooth packet loss. They also found that short packets lead to less packet loss for Bluetooth at the cost of causing more interference on wireless LANs. Sriskanthan et al. [29] propose an application of Bluetooth technology in home automation and networking environment. Initially, due to lack of Bluetooth products, most, if not all empirical analyses were based solely on *simulations* that do not really capture the problems often arising in typical *real, physical* networking environments. To address this issue and distinguish our efforts from those previously undertaken, we present *practical* performance results using real Bluetooth and 802.11 networks. We conducted several tests to explore the influence of IEEE 802.11 interference on Bluetooth communication performance using raw data transfers and audio/video streaming. We used performance metrics such as time taken to stream audio/video and throughput in the case of raw-data transfers. We measured the raw application-to-application TCP/IP throughput using Netperf. For the interference measurement

tests, we used TCP/IP data transmission as the interfering traffic and we ensured that the interfering traffic remained present until the end of the test under consideration. This ensures that we do measure the actual performance in the presence of interference.

The testbed we used in our experiments includes four identical laptops (each with an Intel Pentium III, 789-MHz processor, 512 MB of RAM), one 802.11 wireless Ethernet access point, and one AXIS 9010 Bluetooth access point. Two laptops were each equipped with a Xircom Credit Card Bluetooth adapter. The other two laptops were each equipped with a Dell TrueMobile 1150 Series wireless PCI adapter. Thus, on the Bluetooth network, we used two Bluetooth laptops connected to each other via the Bluetooth access point. We used the other two laptops on the 802.11 network connected via the 802.11 access point. It is worthwhile pointing out that in our tests we used a link rate of 1 Mbps for the 802.11 network. We could have used 11 Mbps link speed but we wanted to have comparable link speed with Bluetooth to avoid introducing further parameters that could affect our results and their interpretations. The Bluetooth specification specifies a maximum throughput of about 720 kbps [9].

4.1. Application Throughput without Interference

We first investigated the best performance achievable with Bluetooth and IEEE 802.11 technologies under conditions when each is operating on its own (i.e., without any interference from the other technology). We varied the distance between the two laptops and measured the effect of distance on the application throughput. The Bluetooth technology is expected to deliver uniform performance within 10 m range. Our experiment indeed reveals negligible changes in the throughput with increasing distance between the Bluetooth nodes (as shown in Fig. 5). We obtained similar results with increasing distance between the 802.11 wireless nodes. However, we obtained around 680 kbps (68% link utilization) with 802.11 transmissions compared to Bluetooth transmissions where we obtained around 200 kbps (only ~28% link utilization).

Figure 5. Variation of throughput of Bluetooth and 802.11 nodes with distance. The throughput of each was measured on its own (without interference).

Figure 6. Throughput of Bluetooth in the presence of interference caused by 802.11 LAN transmissions. The 802.11 nodes are set at distances of 1, 1.5, and 2 m apart. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

4.2. Application Throughput with Interference

Figures 6 and 7 show variations in throughput using Bluetooth and 802.11 nodes. It is interesting to note from Fig. 7 that in the presence of interfering Bluetooth traffic, there is almost *no* impact on the 802.11 wireless transmission rate, which yields almost the same application throughput for different distances between the Bluetooth nodes. However, the converse is not true for the performance observed with Bluetooth in the presence of competing 802.11 LAN traffic. In this case, as Fig. 6 illustrates, we obtained much lower performance (~50 kbps) with Bluetooth compared to the case with no interference. This translates to almost a *fourfold* degradation in Bluetooth throughput in the presence of 802.11 LAN interference traffic.

Figure 7. Throughput of 802.11 node in the presence of Bluetooth interference. The distances between the two Bluetooth nodes are set at 1, 1.5, and 2 m. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 8. Time taken to stream different audio file sizes. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

4.3. Audio/Video Streaming

We investigated the impact of interference on Bluetooth devices performing audio/video streaming. The streaming test used different file sizes between two Bluetooth nodes. One node (at the client side) had Windows Media Player for audio/video streaming and playback. The other Bluetooth node (the server side) was configured as a Web server using Microsoft Information Services). Audio and video were streamed from one Bluetooth node to the other via the Bluetooth access point (connected to the local LAN).

Figures 8 and 9 show the audio/video streaming results. For both audio and video, we report the *time taken* to stream and play the audio (using Windows Media Audio format) or video (using Windows Media Video format).

Figures 8 and 9 show that the time taken to stream continuous media increases by almost 3 times for video and almost 2 times for audio in the presence of 802.11 traffic interference. The closer the 802.11 wireless nodes are to the Bluetooth devices, the higher the interference

Figure 9. Time taken to stream different video file sizes. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

leading to slightly higher times for a distance of one meter compared to a distance of two meters.

It is clear from the experimental results that the interference caused by 802.11 traffic on Bluetooth transmissions is significant and seriously impedes performance of the latter. We speculate some possible explanations for the Bluetooth performance degradation. A Bluetooth channel is divided into timeslots, each 625 μs in length. Bluetooth packets may extend up to five timeslots depending on the packet type in use, and the frequency remains fixed for the duration of the packet. In the presence of 802.11 traffic, Bluetooth shares the same frequency band, and a static packet format may lead to low efficiency since multislot packets are more likely to face interference for longer durations, thereby decreasing Bluetooth throughput. This is a direct result of the fact that Bluetooth lacks the ability to automatically adapt to meet changing channel conditions. Another possible explanation could be due to increased retransmissions by the sender because of frequent timeouts for not receiving acknowledgments since these acknowledgments also compete with 802.11 traffic for channel access.

We explored the performance of individual DH_x and DM_x (where x can have values 1,3,5) packet types in the presence and absence of IEEE 802.11 interference. We used the results (shown in Fig. 10) obtained as the basis to change the packet type in the design of a novel dynamic implementation that will improve Bluetooth performance in the presence of 802.11 traffic. We observe from the results of Fig. 10, in the absence of IEEE 802.11 interference, DH₅ and DM₅ yield maximum throughput and in the presence of IEEE 802.11 interference, DM₅ gives a maximum throughput of 269 kbps (L2CAP MTU is 2016 bytes).

The L2CAP MTU field represents the largest L2CAP payload, in bytes, that the originator of a request can accept for that channel. The default MTU value is 672 bytes. This default MTU is selected based on the payload carried by two DH₅ packets (2 × 341 = 682 bytes), excluding the baseband ACL headers (2 × 2 = 4 bytes) and L2CAP header (6 bytes). Each Bluetooth profile specifies a particular L2CAP MTU. For example, the PAN profile requires a minimum L2CAP MTU of 1691 bytes [12]. We performed another preliminary experiment between two Bluetooth

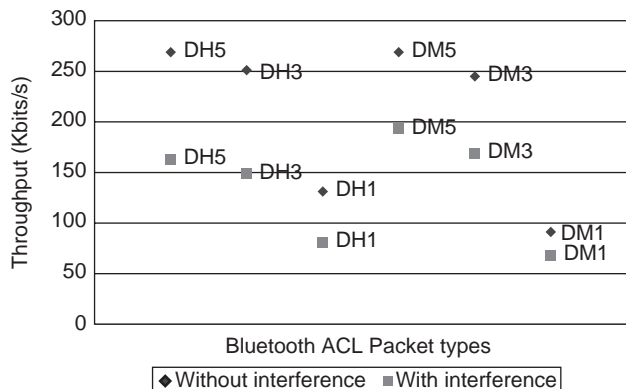

Figure 10. Performance of ACL packet type. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 11. Variation of throughput with L2CAP MTU. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

devices to study the optimal L2CAP maximum transmission unit (MTU) value. The L2CAP MTU value was varied and we calculated the corresponding throughput by measuring using the time taken to transfer a fixed number of packets for an L2CAP client-server socket program. The results are shown in Fig. 11. In the absence of interference, the throughput increases with increase in MTU. In the presence of interference, an L2CAP MTU of 2016 bytes (3 times the default value of 672 bytes) yields the best throughput (120 kbps) and shows a 140% increase in throughput over the default L2CAP MTU value of 672 bytes (50 kbps).

4.4. Novel Dynamic Approach to Improve Bluetooth Performance in the Presence of Interfering 802.11 LAN Traffic

We designed and implemented a scheme that enables robust Bluetooth transmissions that is minimally affected by 802.11 interference traffic. Our proposed design works at the L2CAP layer of Bluetooth and dynamically adapts the ACL packet type to improve Bluetooth performance. It is worthwhile pointing out that we also investigated several other parameters such as the L2CAP flush timeout, ACL MTU, and transmission window size, but none of them really showed significant performance improvements that mitigate the interference effects of 802.11 traffic. Two parameters, namely, the L2CAP MTU and the ACL packet type, yield considerable improvement in the performance of Bluetooth even in the presence of interference. We therefore exploited these parameters in our implementation.

4.4.1. Implementation. To implement a design that dynamically adapts the Bluetooth transmission parameters according to dynamic conditions requires access to the Bluetooth stack or the underlying Bluetooth hardware. Since we are using commercially available Bluetooth hardware adapters, we do not have access to the link manager, baseband layer, or the radio layer. Other researchers and designers also face similar constraints. Consequently, if we were to modify Bluetooth, we could do so only at the application layer or at the kernel layer. We chose a kernel implementation (at the L2CAP layer) for

our proposed scheme since it allows us to modify the Bluetooth stack and secondly, the modified stack can be used by others without modifying their Bluetooth applications. Furthermore, the implementation could have also been implemented using higher-layer sockets such as RFCOMM, but such a layer would not be used by all the other Bluetooth profiles, and any improvements obtained would be limited to that profile only.

We used the BlueZ Bluetooth protocol stack running on Red Hat Linux version 9. The Host Controller Interface (HCI) provides a uniform command method for accessing the underlying Bluetooth hardware capabilities. HCI link commands provide the host with the ability to control link layer connections to other Bluetooth devices. These commands enable the link manager (LM) to exchange LMP commands with remote Bluetooth devices. The HCI firmware implements the HCI commands for the Bluetooth hardware by accessing the baseband/link manager commands, hardware status registers, control registers, and event registers. Several layers may exist between the HCI driver on host system and the HCI firmware on the Bluetooth hardware. These intermediate layers (such as the Host Controller Transport Layer) provide the ability to transfer data. Bluetooth ACL packet types and sizes are selected by the baseband layer which, as mentioned previously, is not accessible to the user or host device driver software. However, it is possible to force the baseband layer to use a particular packet type by using the link command `Change_Connection_Packet_Type`.

Our implementation relies on the dynamic adaptation of packet sizes during a Bluetooth transmission subjected to interference caused by IEEE 802.11 LAN traffic. We established a connection between a Bluetooth slave and a Bluetooth master on L2CAP connection-oriented sockets. Using the previous results illustrated in Figs. 10 and 11, our implementation of the proposed dynamic approach works as follows. In the initial phase, our implementation chooses the ACL packet size to avoid overheads due to padding. For instance, if the user payload is less than 10 bytes, our implementation chooses a DM_1 packet. If the user payload is greater than 177 bytes, our implementation chooses DM_5 rather than DM_3 since better performance is obtained with DM_5 in the presence of interference.

At various stages during transmission, our implementation periodically calculates the throughput delivered and simultaneously obtains the link quality (an indicator of how much interference is taking place). To obtain the link quality, we exploit the HCI command `Get_Link_Quality`, which returns a value for the current link quality (in the range 0–255) of the ACL link between the two Bluetooth devices. The higher the value returned, the better is the link quality. From the preliminary experiments, we found that the value of the link quality is above 230 in the absence of IEEE 802.11 interference traffic but below 215 in the presence of 802.11 traffic.

Our implementation periodically checks the link quality and the actual throughput value obtained for that signal quality. Depending on the value of the throughput obtained, the packet size chosen by the baseband layer is varied accordingly using the HCI command `Change_Connection_Packet_Type` (as explained earlier) to yield the

highest throughput. Basically, the dynamic implementation changes the ACL packet type to DM_5 if the user payload is greater than 120 bytes or if the user payload is between 20 and 120 bytes, DM_3 is chosen. If the user payload is less than 20 bytes, DH_1 is selected (rather than DM_1 since in the presence of interference DH_1 yields higher performance). One issue that we faced during the implementation is the rate at which we check the link quality and measure the actual throughput experienced. We have implemented a timer function to perform the periodic sampling at small enough intervals to ensure a smooth adaptation based on actual channel conditions.

4.4.2. Evaluation of Dynamic Approach. To evaluate our implementation, we conducted file transfer performance tests that measured the time taken to perform file transfers with and without interference, with and without using the dynamic implementation. For the interference measurement tests, we used TCP/IP data transmission as the interfering traffic. We ensured that the interfering traffic remained present for the duration of the test under consideration thereby making sure that we measure the actual performance in the presence of interference.

The testbed used in our experiments included four identical laptops (each with an Intel Pentium III, 789-MHz processor, with 512 MB of RAM) running Linux Red Hat 9 operating system, and one 802.11 wireless Ethernet access point. Two of the laptops were each equipped with a Brainboxes BL-500 Bluetooth adapter using the BlueZ (the official Bluetooth protocol stack for Linux). The other two laptops were each equipped with a Dell TrueMobile 1150 Series wireless PCI adapter. Thus, on the Bluetooth network, we used two Bluetooth laptops connected to each other via ACL link. The Bluetooth specification specifies a maximum throughput of ~ 720 kbps. We used the other two laptops on the 802.11 network connected via the 802.11 access point. We performed experiments with link speed of 1 Mbit/s for the 802.11 network to have comparable link speed to Bluetooth transmissions.

4.4.3. File Transfer Performance. We executed a file transfer application and measured the time taken to transfer different file sizes. The results we obtained are shown in Fig. 12. In the absence of interference, we found that the time taken when the dynamic implementation is used is close to the case when it is not used. This demonstrates that the dynamic implementation does not really introduce significant overheads to the overall performance delivered to users. When Bluetooth is subjected to 802.11 traffic interference, for the different file sizes tested, we obtained a performance improvement (in terms of time taken to transfer files) of 51–85% over the case when our dynamic implementation is not used.

As mentioned previously, the experimental tests were conducted by transferring a fixed number of packets. The time measured is the time taken to transfer all the packets. For the L2CAP program (without our dynamic packet size adaptation implementation), more time is taken in the presence of interference. However, our implementation improves the performance of Bluetooth in the presence of interference, and therefore the time taken to

Figure 12. Time taken for file transfers using and without using the dynamic implementation in the presence and absence of 802.11 traffic interference. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

transfer the same number of packets is smaller. It is worthwhile noting that our proposed dynamic packet size adaptation needs to be implemented at the L2CAP layer. Our approach is designed using L2CAP sockets as we had no access to Baseband. However, Bluetooth ACL packets are defined at the Baseband layer. We dynamically configure the Baseband layer to use a particular packet type by using HCI Commands. Given direct access to the Baseband layer, the dynamic packet size adaptation can be implemented at the Baseband layer.

5. MULTIMEDIA SUPPORT OVER BLUETOOTH

Audio/video streaming applications have become increasingly popular. Advances in hardware and software technologies are making it possible to support these applications types on a wide range of devices. We expect future deployment of devices such as Bluetooth-enabled personal digital assistants (PDAs) and pocket PCs will support a wide variety of streaming applications involving audio and video [30].

5.1. Audio/Video Distribution Transport Protocol (AVDTP)

The Audio/Video (A/V) Distribution Protocol [31] defines the transport protocol and procedures that enable the distribution of advanced audio and video content of high quality on ACL channels. The basic audio functionality in Bluetooth only supports uncompressed voice connection with pulse-code modulation (PCM), and a bandwidth of 64 kbps is assigned to each voice connection. The term “advanced audio” should be distinguished from “Bluetooth audio,” which indicates distribution of narrowband voice on SCO channels as defined by the Bluetooth Baseband specification [9]. A typical usage case for AVDTP is the streaming of music content from a stereo music player to headphones or speakers. The audio data are compressed in an appropriate format for efficient use of the limited

bandwidth. The SCO link allocates a fixed bandwidth between the master and the slave. The master maintains the SCO link by using reserved slots at regular intervals. The basic unit of reservation is two consecutive slots (one in each transmission direction). The reservation of slots by SCO links leaves very limited piconet bandwidth for the other ACL links in the piconet. Furthermore, it is worthwhile noting that the transmission of audio/video over the Internet requires the support of an audio encoding/decoding scheme and a packet-switched network connection—which is not offered by the SCO connection. Therefore, in order to support the transfer of high-quality A/V data using limited bandwidth and a packet transfer mode, ACL channel is a better alternative.

The Audio Video Working group has defined a Bluetooth profile that allows streaming of high-quality mono or stereo audio directly over L2CAP from another device. This profile, the Advanced Audio Distribution Profile (A2DP) [32], is based on the Generic Audio/Video Profile Distribution Profile (GAVDP) [33], which in turn uses Audio/Video Distribution Transport Protocol (AVDTP). AVDTP specifies the transport protocol for audio and video distribution and streaming over the Bluetooth air interface using ACL links. AVDTP provides rules and procedures to provide high-quality isochronous communication (required for the transmission of clock-dependent processes) for the transfer of A/V data. Figure 13 shows the protocol stack model for AVDTP. The transport mechanism and message formats of the AVDTP are based on the Real-time Transport Protocol (RTP).

AVDTP defines the signaling mechanism between Bluetooth devices for stream setup and media streaming of audio or video using ACL links. A/V streaming and signaling setup messages are transported via L2CAP packets. A dedicated Protocol/Service Multiplexer (PSM) value (the PSM value for AVDTP is 25) is used to identify L2CAP packets that are intended for AVDTP. AVDTP applies point-to-point signaling over connection-oriented L2CAP channel set up in advance between two devices participating in A/V streaming.

Before A/V applications transport A/V streams over a Bluetooth link, AVDTP performs A/V parameter negotiation. Based on the result of this negotiation, applications transfer A/V content. Figure 14 shows the AVDTP architecture (as defined by the AVDTP specification). We summarize the major functions of the AVDTP components below:

- *Stream manager*—provides the following functions: streaming, media framing, timestamp management,

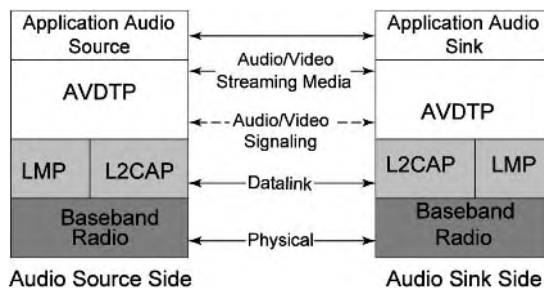

Figure 13. AVDTP protocol model and the Bluetooth protocol stack.

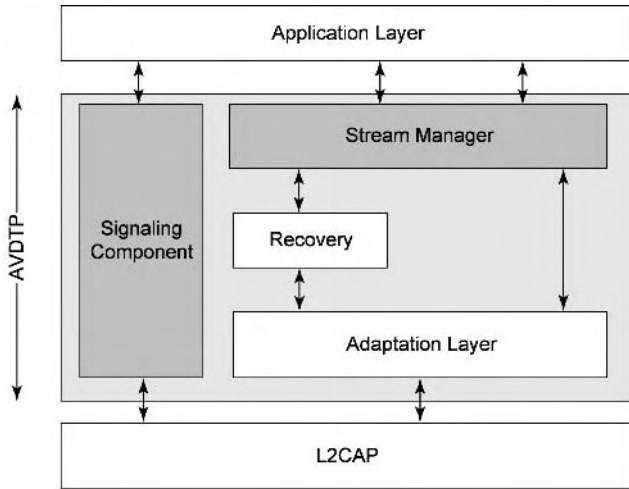

Figure 14. AVDTP architectural components in the Bluetooth protocol stack.

media packet sequence numbering, reporting of packet loss to higher layers, and calculation of jitter

- *Recovery component*—provides no FEC and equal FEC
- *Adaptation layer*—performs header compression and multiplexing to allow several transport sessions to be multiplexed onto one transport channel
- *Signaling*—provides the discovery of application and transport service capability, stream negotiation, stream connection establishment, stream connection teardown, stream suspension and resumption

AVDTP represents a scalable architecture with different support levels of services provided to the upper layer. The services provided to the application layer are defined as the *application service capabilities*. This comprises of negotiation and configuration of source CODECs, content protection systems, and support of media synchronization. The *transport service capabilities* correspond to more specifically transport related “services” inside the A/V transport layer. These comprise framing and segmentation, encapsulation, reporting of delivery performance, packet loss detection, packet recovery, robust header compression, and multiplexing transport sessions to transport

channels. Transport services are broadly classified into following services: basic, recovery, reporting, and adaptation (multiplexing and robust header compression).

We have designed and implemented the AVDTP protocol for multimedia support in Bluetooth. However, in this article, we focus on the delivery of audio only. Our design supports the specification of the AVDTP protocol as defined by Bluetooth SIG and implements the following:

- A means to discover the capabilities of the devices, as well as the means to negotiate for A/V stream setup as well as the establishment and tearing down of a stream
- Mechanisms that associate data with timing information required for playback of media streams at the receiver side
- Capability to report “quality of service” and status of transport of media packets to the application layer (i.e., reporting the status of transport of media packets to the application)
- Mechanisms to optimize the use of available bandwidth
- Mechanisms to minimize the transmission delay for real-time streams
- Independent functions for use on devices of limited complexity (although this feature is not yet fully supported; only MP3 CODEC is supported in our current implementation)

Our current AVDTP implementation does not yet provide recovery mechanisms and functions to reduce the overhead of the headers in the transport protocol.

5.2. Implementation of AVDTP for Bluetooth

We have implemented only the *signaling* and the *stream manager* (shown in Fig. 15) components, which together constitute the *basic service* transport functionality of AVDTP for Bluetooth devices. When AVDTP is configured for basic services, two main functions are performed: stream discovery and negotiation and media streaming using signaling and the stream manager. The signaling procedure requires ACL link between a pair of interconnected

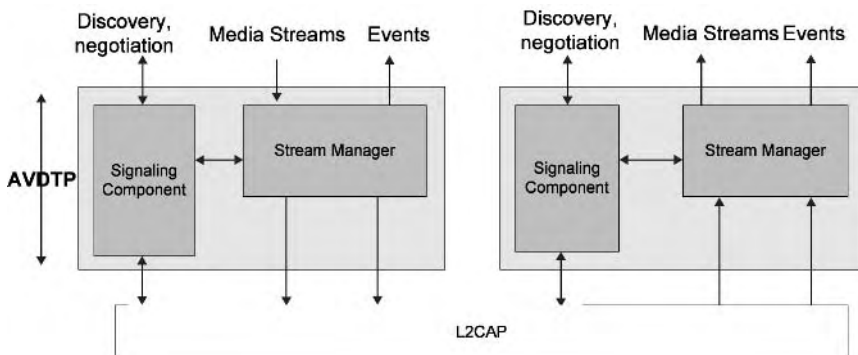

Figure 15. Implementation of the AVDTP basic service components.

devices. Transactions are performed on a connection-oriented channel established between communicating devices, and consist of bidirectional asynchronous message exchanges. To establish a stream, the upper layer requests the *signaling component* to discover, configure, and establish streams. After establishing the *stream* (a Bluetooth A/V stream represents the logical end-to-end connection of media data (audio or video) between two A/V devices), the upper layer can send or receive streaming media.

In our design, the *stream manager* is the core component of AVDTP, and it performs the following functionalities: setting up application service capability of the service endpoint based on the upper layer description of audio data, initiating the signal interface, setting up transport service parameters, framing of the audio data, media packet sequence numbering, buffering of the data at receiver end, reporting of packet loss to upper layer, jitter calculation, and timestamp management. In addition to the components we have implemented for the basic service, we have also included an L2CAP interface component, which can be used to set L2CAP and Host Controller Interface (HCI) layer parameters based on the transport service capability. The L2CAP interface component initiates the L2CAP layer commands to connect, listen, send, and receive audio data. Establishment of the connection-oriented L2CAP channels, used for media streaming, is initiated by the application layer. These channels are set up and released by AVDTP. Once the stream has been established, the application layer starts A/V streaming.

The application layer initiates the streaming procedure by registering itself with AVDTP as a stream endpoint (SEP). A SEP is a concept used to expose the available application capabilities. The application registers its SEP in AVDTP to allow other devices to discover and connect to it and is assigned a unique SEID (the SEID represents the cross device reference to a specific stream). This reference is used in the signaling transactions between peer AVDTP entities. The application also specifies the role of acceptor/initiator (ACP/INT) and the mode Source/Sink (SRC/SNK) of communication while registering with AVDTP. AVDTP returns a stream handle (represents a top-level reference to a stream), which is exposed to the application layer and represents the *stream context* associated with that stream. The application then provides the application service capability information to the A/V transport layer (AVDTP). This information typically comprises of the audio CODEC type supported by the application and its properties. The application on one Bluetooth device initiates streaming by setting up a connection-oriented link, established by a signaling procedure, to another Bluetooth device over the L2CAP layer. As illustrated in Fig. 16, the stream endpoint discovery command (optional) retrieves the type and the identifier (SEID) for one stream endpoint, or jointly multiple stream endpoints present in the particular Bluetooth device. Since SEID is needed as a reference in subsequent procedures, the stream endpoint discovery must be first invoked. However, the discovery procedure is not needed for repeated configuration attempts. The “stream get capabilities” (optional) procedure is also optional, as an initiator can guess the capabilities of the acceptor and directly invokes the *stream configuration* procedure. The

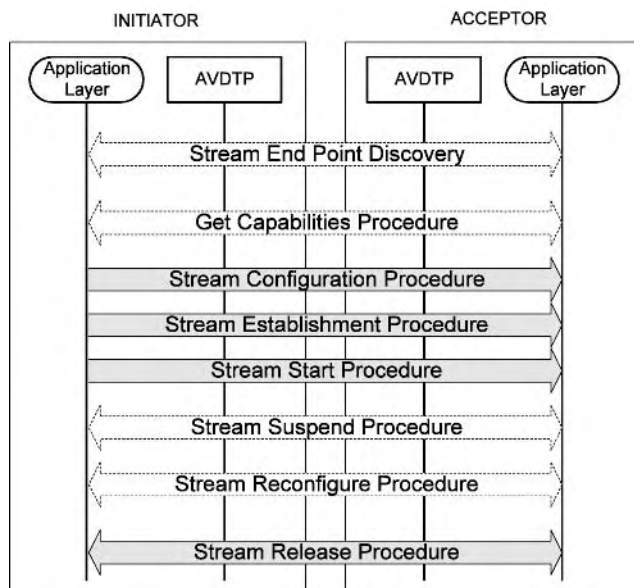

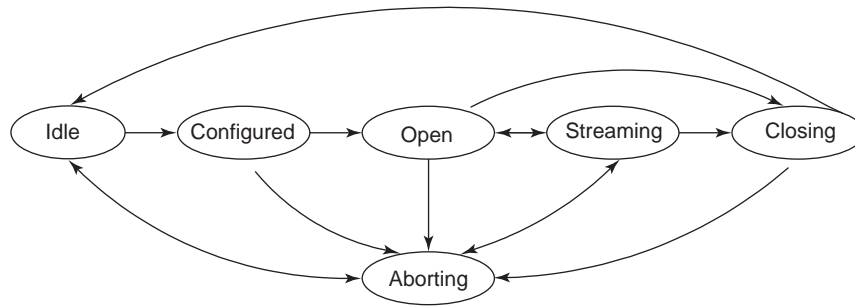

Figure 16. Signaling procedure implemented in our AVDTP design. Stream configuration, establishment, start, and release functions are mandatory, but the others optional.

“stream get capabilities” procedure can be triggered by any of the devices with no effect on the stream endpoint states. Either or both devices may initiate a stream by calling the *stream configuration procedure*, *stream establishment procedure*, and the *stream start procedure*. The *stream configuration* procedure constitutes a dedicated connection between peer stream endpoints in both devices. The stream configuration procedure also establishes the set of application and transport service parameters to be used during the transfer of audio/video content. These parameters include the audio CODEC capability—the media CODEC supported by source and sink. The most suitable audio CODEC parameter is selected and based on the audio CODEC capability; the media packet header requirements and the media payload format are defined by the AVDTP entity. Only the initiator of a stream configuration procedure may be the initiator of the *stream establishment* and *stream start* procedures and performs streaming over the configured SEP. After the start procedure has completed, both the devices may trigger any of the “stream suspend,” “stream reconfigure,” or “*stream release*” procedures. The use of “stream suspend” and “stream reconfigure” procedures depends on the application. The AVDTP state diagram is illustrated in Fig. 17.

Once the signaling procedure is executed, a streaming session will be established via AVDTP between the source and sink devices, ready to send and receive data respectively. The source device starts sending the audio data to the A/V transport layer where data are encapsulated in a frame with a media header (based on the RTP format), and sent to the L2CAP layer for the transmission over the air interface using an ACL link. The L2CAP layer adds an L2CAP header, one of the fields of which has a *PSM* to identify the connection at the receiving end. At the receiver side, the A/V transport layer retrieves media

packets from the L2CAP layer and checks the validity of the data received. If the packet received is a media packet, then the receiver-specific information (such as packet loss, jitter calculation, payload received, etc.) is updated. The media header part is stripped off and audio data are sent to the application layer for playback. After audio streaming is performed, a signaling command is sent from source to the sink to indicate the stream end and close the streaming connection.

6. BLUETOOTH SECURITY

The ad hoc nature and wireless characteristic of Bluetooth make authentication, authorization, and privacy important issues that need to be dealt when deployed in WPANs. Proper resource access and usage, reliable user identification, and accounting functionalities all need to be efficiently supported in WPANs.

Four different entities (shown in Table 3) are used to implement security at the link layer [34] in Bluetooth: a public address that is unique for each user, two secret keys, and a random number different for each new transaction are used. The secret keys are derived during initialization and are never disclosed. Normally, the

encryption key is derived from the authentication key during the authentication process. Each time encryption is activated, a new encryption key is generated.

However, the Bluetooth security architecture, although relatively simple, suffers from several weaknesses. Several authors [35–37] have identified and demonstrated several security flaws, including:

Spoofing through Keys. A simple attack, although not so simple to implement in practice, is a “man-in-the-middle attack” to steal identification and encryption keys before the start of a session [37]. The identification and keys can then be used to impersonate and/or eavesdrop on communications. This problem is, of course, not specific to Bluetooth as most key exchange systems are prone to this type of attack. One way to mitigate such an attack in all systems is to include support for a digital certificate-based authentication system. Another approach, applicable to Bluetooth, is to make it difficult for an attacker to lock onto the frequency used for communication. Making the frequency hopping intervals and patterns reasonably unpredictable can help to prevent an attacker from locking onto the device’s signal.

Spoofing through a Bluetooth Address. Each Bluetooth device has a unique address, allowing users to have some trust in the identity of the device at the other end of the transmission. Once a device identifier is associated with a user of the device, an intruding device can change its address to match the device address of the user. The intruder can then impersonate the user with the spoofed address.

PIN Length. Another vulnerability relates to the PIN (personal identification number) itself [37]. Most devices have extremely short (usually four decimal digits) PINs. This is itself is a security weakness,

Table 3. Entities Used in Authentication and Encryption Procedure in Bluetooth

Entity	Number of bits (bits)
Bluetooth address	48
Private user key, authentication	128
Private user key, encryption configurable length (byte-wise)	8–128
Random number for each transaction	128

although it is a property of the implementation and not the specification. Attackers can exhaustively search through the set of short PINs to determine a key.

Location Attacks. If a device is in discoverable mode, then it will respond to inquiries unless other baseband activity prohibits it. When responding to an inquiry, a slave transmits its identity on the baseband. Therefore, an attacker can determine the location and movements of victim devices by maintaining geographically distributed devices that continuously inquire all devices entering within their reach, and recording the identities given in the responses. Since devices use the same identities all the time, this allows the attacker to determine their movements [37].

Clearly, if Bluetooth technology is to be widely deployed as a strong enabler for WPANs, we need to improve the current security features to make it more robust to various kinds of intruder attacks.

7. CONCLUSIONS

The WPAN networking paradigm, coupled with IP as an integration mechanism, will play a fundamental role in supporting a user-centered network concept that provides seamless access to local and global networking capabilities. In this article, we focused on Bluetooth as an enabler for WPANs. We described and discussed mechanisms and novel approaches that enable Bluetooth to provide efficient WPAN support. Our focus areas dealt with crucial issues such as seamless IP connectivity to other IP-based networks, coexistence with IEEE 802.11b WLANs, and support for high-quality audio transmission over new protocols such as AVDTP. However, major drawbacks of the Bluetooth technology such as poor scalability, adaptability, and weak security, along with the dynamic nature of WPANs, present further research design challenges that need to be addressed before the WPAN networking paradigm can be fully integrated into widely deployed network solutions. Novel technical solutions are required for low-cost, low-power system architectures, physical-layer access techniques, middleware and adaptive protocols, and security, as well as human aspects (dealing with friendly communication with devices using face recognition or voice recognition technologies and health issues with the various wireless technologies) [8].

Acknowledgments

This work was supported by an equipment grant from Wayne State University, and grants from Microsoft Corporation (Seattle), Ixia Corporation, and OPNET. We would like to express our gratitude to Monica Brockmeyer and Farshad Fotouhi for making the wireless equipment available to us to conduct our tests. We thank Aruna Banda for her help, support, and contribution to the implementation of the dynamic approach for Bluetooth. We also thank the anonymous reviewers for their comments and suggestions. We are grateful to Kai Chang and Cassie

Craig for their kind help, support, patience, and understanding during the preparation of this manuscript.

applied effectively to many cases. Electromagnetic problems expressed in integral form are particularly useful for obtaining approximate solution and developing general theory. Two techniques usually used for integral equations are (1) the variational method and (2) the perturbation method. The variational procedure gives an approximate value to the desired quantity rather than the changes in the quantity. The formula is relatively insensitive to the variations in an assumed field for which there is an exact or correct field.

2. PERTURBATION METHODS

The meaning of the term *perturbation* is the disturbance or a slight change. Perturbation methods are simple and accurate for calculating changes in some quantity due to small changes in the problem. Many of the electromagnetic field problems can be very effectively solved by this simple method. The method involves two situations, namely, the “unperturbed” and “perturbed” states. In the unperturbed problem the solution is known. The perturbed problem is slightly different from the unperturbed one. There are two cases of perturbation: perturbation of cavity walls and cavity material perturbation. Although many researchers [1–4] handled the perturbation problems in many different ways, it was R. F. Harrington [5] who made a systematic and almost exhaustive theoretical study on the perturbation problem.

2.1. Perturbation of Cavity Walls

A *cavity resonator* can be formed by a conductor carrying a surface S and enclosing a lossless region τ , as shown in Fig. 1a. A deformation of the original cavity changes the cavity surface to S' and volume to τ' (Fig. 1b) such that $\Delta S = S - S'$ and $\Delta\tau = \tau - \tau'$. The change in the resonant frequency due to the change in the cavity wall can be determined by analyzing Maxwell's integral equations [6]. Let E_0, H_0 , and ω_0 , represent the electric and magnetic fields and the resonant frequency of the original cavity, respectively, and E, H , and ω represent the corresponding quantities of the perturbed cavity. The *field equations* are satisfied in both cases:

$$-\nabla \times E_0 = j\omega_0\mu H_0 \quad -\nabla \times E = j\omega\mu H \quad (1)$$

$$\nabla \times H_0 = j\omega_0\varepsilon E_0 \quad \nabla \times H = j\omega\varepsilon E \quad (2)$$

Figure 1. Perturbation of cavity walls in an original cavity (a) and a perturbed cavity (b).

PERTURBATION THEORY

1. INTRODUCTION

Electromagnetic field problems can be expressed and solved mathematically in differential or integral equation forms. The differential form leads to an exact solution of the mathematical problems. But this approach cannot be

The permittivity and permeability of the medium are assumed to be lossless.

Multiplying Eq. (2) scalarly by E_0^* and the conjugate of E_0 and the conjugate of Eq. (1) by H as

$$E_0^* \cdot \nabla \times H = j\omega \epsilon E_0^* \cdot E \tag{3}$$

$$-H \cdot \nabla \times E_0^* = -j\omega_0 \mu H_0^* \cdot H \tag{4}$$

applying the identity

$$\nabla \cdot (M \times N) = N \cdot \nabla \times M - M \cdot \nabla \times N$$

and adding Eqs. (3) and (4), we get

$$\nabla \cdot (H \times E_0^*) = j\omega \epsilon E \cdot E_0^* - j\omega_0 \mu H_0^* \cdot H \tag{5}$$

Similarly, we obtain

$$\nabla \cdot (H_0^* \times E) = j\omega \mu H \cdot H_0^* - j\omega_0 \epsilon E_0^* \cdot E \tag{6}$$

Adding Eqs. (5) and (6) and integrating the sum throughout the volume of the perturbed cavity, we obtain

$$\begin{aligned} & \iiint_{\tau} [\nabla \cdot (H \times E_0^*) + \nabla \cdot (H_0^* \times E)] d\tau \\ &= j(\omega - \omega_0) \iiint_{\tau} (\epsilon E \cdot E_0^* + \mu H \cdot H_0^*) d\tau \end{aligned} \tag{7}$$

Applying the divergence theorem on left-hand-side (LHS) terms, the resulting equation is

$$\begin{aligned} & \oiint_{S'} (H \times E_0^*) ds + \oiint_{S'} (H_0^* \times E) ds \\ &= j(\omega - \omega_0) \iiint_{\tau} (\epsilon E \cdot E_0^* + \mu H \cdot H_0^*) d\tau \end{aligned} \tag{8}$$

Since $n \times E = 0$ on S' , second term on the LHS is reduced to zero.

Therefore

$$\begin{aligned} & \oiint_{S'} (H \times E_0^*) ds \\ &= j(\omega - \omega_0) \iiint_{\tau} (\epsilon E \cdot E_0^* + \mu H \cdot H_0^*) d\tau \end{aligned} \tag{9}$$

Since $n \times E_0 = 0$ on S , we have

$$\oiint_S (H \times E_0^*) ds = 0$$

and hence the LHS of the equation can be written as

$$\begin{aligned} & \oiint_{S'} (H \times E_0^*) ds - \oiint_S (H \times E_0^*) ds \\ &= \oiint_{S' - S} H \times E_0^* \cdot ds = - \oiint_{\Delta S} H \times E_0^* \cdot ds \end{aligned} \tag{10}$$

Negative sign is taken to indicate that ds is extended outward. Thus the Eq. (9) can be rearranged as follows:

$$\begin{aligned} & - \oiint_{\Delta S} H \times E_0^* \cdot ds = j(\omega - \omega_0) \\ & \iiint_{\tau} (\epsilon E \cdot E_0^* + \mu H \cdot H_0^*) d\tau \\ \omega - \omega_0 &= \frac{j \oiint_{\Delta S} (H \times E_0^*) \cdot ds}{\iiint_{\tau} (\epsilon E \cdot E_0^* + \mu H \cdot H_0^*) d\tau} \end{aligned} \tag{11}$$

This expression gives the change in resonant frequency due to an inward perturbation of the cavity walls.

An approximation to the perturbation equation is to be made by replacing E and H by the unperturbed fields E_0 and H_0 . If the perturbation of the field due to the deformation of the cavity is shallow and smooth, the approximation is very reasonable and won't affect the accuracy of the result substantially. Thus

$$\oiint_{\Delta S} (H \times E_0^*) \cdot ds \approx \oiint_{\Delta S} (H_0 \times E_0^*) \cdot ds$$

Applying the Poynting theorem for the conservation of complex power, this expression leads to

$$\oiint_{\Delta S} (H_0 \times E_0^*) \cdot ds = j\omega_0 \iiint_{\Delta \tau} (\epsilon |E_0|^2 - \mu |H_0|^2) d\tau \tag{12}$$

Substituting E_0, H_0 for E, H in the denominator in Eq. (11), the perturbation equation becomes

$$\frac{\omega - \omega_0}{\omega_0} \approx \frac{\iiint_{\Delta \tau} (\mu |H_0|^2 - \epsilon |E_0|^2) d\tau}{\iiint_{\tau} (\mu |H_0|^2 + \epsilon |E_0|^2) d\tau} \tag{13}$$

The numerator represents the electric and magnetic energies removed by perturbation, while the denominator is proportional to the total energy stored in the cavity. In terms of energy, the perturbation equation is changed to

$$\frac{\omega - \omega_0}{\omega_0} \approx \frac{\Delta \bar{W}_m - \Delta \bar{W}_e}{W} \tag{14}$$

where $\Delta \bar{W}_m$ and $\Delta \bar{W}_e$ are time-average magnetic and electric energies originally contained in $\Delta \tau$ and W is the total energy stored in the original cavity. If $\Delta \tau$ is small, the $\Delta \bar{W}$ values can be approximated to $\Delta \tau$ times the energy densities. Similarly the W can be written as τ times the space average energy density \dot{w}

$$\frac{\omega - \omega_0}{\omega_0} = \frac{(\bar{w}_m - \bar{w}_e)\Delta \tau}{\dot{w}\tau} = C \frac{\Delta \tau}{\tau} \tag{15}$$

where C is a constant depending on the geometry of the cavity and the position of perturbation. Thus an inward

perturbation will increase the resonant frequency if it is made at a point of large H (high value of \bar{w}_m) and lower the resonant frequency if it is made at a point of large E (high \bar{w}_e). The opposite behavior will occur from an outward perturbation. The greatest resonant frequency will result when the perturbation is at a position of maximum E and zero H . Vice versa for minimum resonant frequency shift.

2.2. Cavity Material Perturbation

This case is more significant than the previous one as far as the practical applications are concerned. The resonant frequency of the cavity is changed due to the perturbation of the material within the cavity. Figures 2a and 2b represent the situation before and after the perturbation of the cavity. μ and ε respectively are the permeability and permittivity of the medium of the original cavity. In the perturbed cavity the parameters of the medium are changed to $\mu + \Delta\mu$ and $\varepsilon + \Delta\varepsilon$. The field equations in the two cases are

$$\begin{aligned} -\nabla \times \mathbf{E}_0 &= j\omega_0 \mu \mathbf{H}_0 & -\nabla \times \mathbf{E} &= j\omega(\mu + \Delta\mu) \mathbf{H} \\ \nabla \times \mathbf{H}_0 &= j\omega_0 \varepsilon \mathbf{E}_0 & \nabla \times \mathbf{H} &= j\omega(\varepsilon + \Delta\varepsilon) \mathbf{E} \end{aligned} \quad (16)$$

Take the conjugate of the first equation and multiply it scalarly by \mathbf{H} and the last equation scalarly by \mathbf{E}_0^* . Add these resulting equations to give rise to

$$\nabla \cdot (\mathbf{H} \times \mathbf{E}_0^*) = j\omega(\varepsilon + \Delta\varepsilon) \mathbf{E} \cdot \mathbf{E}_0^* - j\omega_0 \mu \mathbf{H}_0^* \cdot \mathbf{H}$$

Similarly we get

$$\nabla \cdot (\mathbf{H}_0^* \times \mathbf{E}) = j\omega(\mu + \Delta\mu) \mathbf{H} \cdot \mathbf{H}_0^* - j\omega_0 \varepsilon \mathbf{E}_0^* \cdot \mathbf{E}$$

Add the two equations above and integrate throughout the cavity to get

$$\begin{aligned} \iiint_{\tau} [\nabla \cdot (\mathbf{H} \times \mathbf{E}_0^*) + \nabla \cdot (\mathbf{H}_0^* \times \mathbf{E})] d\tau &= \\ \iiint_{\tau} j\{[\omega(\varepsilon + \Delta\varepsilon) - \omega_0 \varepsilon] \mathbf{E} \cdot \mathbf{E}_0^* &+ \\ + [\omega(\mu + \Delta\mu) - \omega_0 \mu] \mathbf{H} \cdot \mathbf{H}_0^*\} d\tau & \end{aligned} \quad (17)$$

with $n \times \mathbf{E}$ and $n \times \mathbf{E}_0$ on S , both equal to zero. Then apply the divergence theorem to the LHS, and it vanishes to zero

Figure 2. Perturbation of matter in an original cavity (a) and a perturbed cavity (b).

as

$$\begin{aligned} 0 &= \iiint_{\tau} \{[\omega(\varepsilon + \Delta\varepsilon) - \omega_0 \varepsilon] \mathbf{E} \cdot \mathbf{E}_0^* \\ &+ [\omega(\mu + \Delta\mu) - \omega_0 \mu] \mathbf{H} \cdot \mathbf{H}_0^*\} d\tau \\ 0 &= (\omega - \omega_0) \iiint_{\tau} [\varepsilon \mathbf{E} \cdot \mathbf{E}_0^* + \mu \mathbf{H} \cdot \mathbf{H}_0^*] d\tau \\ &+ \omega \iiint_{\tau} [\Delta\varepsilon \mathbf{E} \cdot \mathbf{E}_0^* + \Delta\mu \mathbf{H} \cdot \mathbf{H}_0^*] d\tau \\ \frac{\omega - \omega_0}{\omega} &= - \frac{\iiint_{\tau} (\Delta\varepsilon \mathbf{E} \cdot \mathbf{E}_0^* + \Delta\mu \mathbf{H} \cdot \mathbf{H}_0^*) d\tau}{\iiint_{\tau} (\varepsilon \mathbf{E} \cdot \mathbf{E}_0^* + \mu \mathbf{H} \cdot \mathbf{H}_0^*) d\tau} \end{aligned} \quad (18)$$

In the limit, as $\Delta\varepsilon \rightarrow 0$ and $\Delta\mu \rightarrow 0$, we can approximate \mathbf{E} , \mathbf{H} , ω by $\mathbf{E}_0, \mathbf{H}_0, \omega_0$ to obtain

$$\frac{\omega - \omega_0}{\omega_0} \approx - \frac{\iiint_{\tau} (\Delta\varepsilon |\mathbf{E}_0|^2 + \Delta\mu |\mathbf{H}_0|^2) d\tau}{\iiint_{\tau} (\varepsilon |\mathbf{E}_0|^2 + \mu |\mathbf{H}_0|^2) d\tau} \quad (19)$$

This equation states that a small increase in ε and/or μ decreases the resonant frequency. In terms of energy stored in the fields, the above perturbation equation becomes

$$\frac{\omega - \omega_0}{\omega_0} \approx - \frac{1}{W} \iiint_{\tau} \left(\frac{\Delta\varepsilon}{\varepsilon} \bar{w}_e + \frac{\Delta\mu}{\mu} \bar{w}_m \right) d\tau$$

where \bar{w} is the energy density and W is the total energy stored in the original cavity.

Let us take $\Delta\varepsilon = \varepsilon - \varepsilon_0$ and $\Delta\mu = \mu - \mu_0$:

$$\begin{aligned} \frac{\omega - \omega_0}{\omega} &= - \frac{\iiint_{\tau} [(\varepsilon - \varepsilon_0) \mathbf{E} \cdot \mathbf{E}_0^* + (\mu - \mu_0) \mathbf{H} \cdot \mathbf{H}_0^*] d\tau}{\iiint_{\tau} (\varepsilon_0 \mathbf{E} \cdot \mathbf{E}_0^* + \mu_0 \mathbf{H} \cdot \mathbf{H}_0^*) d\tau} \\ &= - \frac{\iiint_{\tau} [(\varepsilon - \varepsilon_0) \mathbf{E} \cdot \mathbf{E}_0^* + (\mu - \mu_0) \mathbf{H} \cdot \mathbf{H}_0^*] d\tau}{2 \iiint_{\tau} \varepsilon_0 \mathbf{E} \cdot \mathbf{E}_0^* d\tau} \end{aligned} \quad (20)$$

If the element is introduced into an of E -field region, then

$$\frac{\omega - \omega_0}{\omega} = - \frac{\iiint_{\tau} [(\varepsilon - \varepsilon_0) \mathbf{E} \cdot \mathbf{E}_0^*] d\tau}{2 \iiint_{\tau} \varepsilon_0 \mathbf{E} \cdot \mathbf{E}_0^* d\tau} \quad (21)$$

The approximation applied for the fields under original and perturbed conditions are that $\Delta\varepsilon$, $\Delta\mu$, and $\Delta\tau$ all be small. But the restrictions on $\Delta\varepsilon$ and $\Delta\mu$ can be removed by applying certain procedures at the expense of further complication. We have to apply constraint to the shape of the

sample and location. We assume that the internal field of $\Delta\tau$ is related to the field external to $\Delta\tau$ in the same manner as for static fields. This assumption is justifiable as the Helmholtz equation can be approximated by Laplace' equation in a small region compared to wavelength [7]. Four special cases of dielectric samples are considered for relating the internal and external fields. Thus E_{int} for a slab with E normal to it is given by

$$E_{\text{int}} = \frac{1}{\epsilon_r} E_{\text{ext}}$$

and for a long thin cylinder with E along the axis, the relation is $E_{\text{int}} = E_{\text{ext}}$; for E normal to the axis of the circular cylinder, we obtain

$$E_{\text{int}} = \frac{2}{1 + \epsilon_r} E_{\text{ext}}$$

Finally for E normal to a small sphere, we have

$$E_{\text{int}} = \frac{3}{2 + \epsilon_r} E_{\text{ext}}$$

where ϵ_r is the relative permittivity given by $\epsilon_r \epsilon_0 = \epsilon$.

The modified field in the quasistatic approximations can be substituted for E in the numerator of the general equation. The denominator remains unaltered as the contribution from $\Delta\tau$ is small compared to that from the rest of τ . For $\Delta\mu = 0$ (pure dielectric), the quasistatic correction to the perturbation formula is

$$\frac{\omega - \omega_0}{\omega_0} \approx - \frac{\iint \Delta\epsilon E_{\text{int}} \cdot E_0^* d\tau}{2 \iint \epsilon |E_0|^2 d\tau} \quad (22)$$

This equation is most valuable for solving problems for which the exact solution is not known. The validity of the above equation can be checked by applying to problem for which an exact solution is known. Perturbation method in conjunction with the quasistatic approach gives excellent accuracy to the solution of the problem. By simply measuring the shift in resonant frequency caused by the introduction of a dielectric sample in the cavity resonator, the constituent parameters of matter can be determined.

2.3. Waveguide Perturbations

Cavity perturbation equations are efficient tools to determine the dielectric and magnetic parameters of materials. The techniques developed for the evaluation of these parameters based on the perturbation theory are called *cavity perturbation techniques*. From the analysis of the perturbation equation it is clear that the knowledge about the frequency shift and resonant frequency as well as the information of the field are necessary for the determination of the parameters. This necessitates the use of standard resonant cavities such as waveguide (rectangular or circular cross section) or coaxial cables. Let us consider cylindrical waveguides first and then rectangular wave-

guide which are widely used as *cavity resonators*. The cross section along the Z axis is constant. At the cutoff frequency a waveguide is a two-dimensional resonator. We can apply perturbation formula to waveguides at cutoff. The waveguide cavity resonator is constructed with a section of a waveguide bounded by two $z = \text{const}$ (constant) planes with conducting sheets. Since the fields are independent of z axis, the surface integrals over these two cross sections cancel each other. For the integral equation $\iint (H \times E_0^* + H_0^* \times E) \cdot ds$, the surface integral only over the wall is needed. Hence the cutoff frequency ω_c and the change in cutoff frequency $\Delta\omega_c$ due to an inward perturbation of the waveguide cavity wall are related as

$$\frac{\Delta\omega_c}{\omega_c} \approx \frac{\iint_{\Delta S} (\mu |H_0|^2 - \epsilon |E_0|^2) ds}{\iint_S (\mu |H_0|^2 + \epsilon |E_0|^2) ds} \quad (23)$$

The approximation is due to the fact that the perturbed fields E and H are replaced by unperturbed fields E_0 and H_0 for small perturbations. An inward perturbation of the waveguide walls at a position of high E will lower the cutoff frequency, while that at a position of high H will raise the cutoff frequency. An example of waveguide cavity wall perturbation is the ridge waveguide [8], formed from the rectangular waveguide by adding ridges along the center of the top and bottom walls. Such ridges will lower the cutoff frequency of the dominant mode and will raise the cutoff frequency of the next-higher mode. The ridges also decrease the characteristic impedance of the guide, and hence they are used for impedance matching.

Likewise, the material perturbation in a waveguide cavity at cutoff can be treated in a similar way to develop the formula. We can obtain the exact formula for the change in cutoff frequency due to a change of parameters of matter enclosed by the waveguide cavity resonator. It is

$$\frac{\Delta\omega_c}{\omega_c} = - \frac{\iint (\Delta\epsilon E \cdot E_0^* + \Delta\mu H \cdot H_0^*) ds}{\iint (\epsilon E \cdot E_0^* + \mu H \cdot H_0^*) ds} \quad (24)$$

It is clear that an increase in ϵ or μ decreases the cutoff frequency of a waveguide. If $\Delta\epsilon$ and $\Delta\mu$ are small, we can replace the perturbed field by the original field:

$$\frac{\Delta\omega_c}{\omega_c} \approx - \frac{\iint (\Delta\epsilon |E_0|^2 + \Delta\mu |H_0|^2) ds}{\iint (\epsilon |E_0|^2 + \mu |H_0|^2) ds}$$

But for large values of $\Delta\epsilon$ and $\Delta\mu$ but of small spatial extent, the quasistatic approximation can be made. For a nonmagnetic case

$$\frac{\Delta\omega_c}{\omega_c} \approx - \frac{\iint \Delta\epsilon |E_0|^2 ds}{\iint (\epsilon |E_0|^2 + \mu |H_0|^2) ds}$$

So far the perturbed waveguide cavity is assumed to be homogeneous. When the cavity is filled with a nonhomogeneous medium, the perturbation formula for a wall perturbation and material perturbation is given by

$$\beta - \beta_0 = -j \frac{\oint_{\Delta c} (\hat{\mathbf{E}}_0^* \times \hat{\mathbf{H}}) \cdot \mathbf{n} \cdot d\mathbf{l}}{\iint_{S^1} (\hat{\mathbf{E}}_0^* \times \hat{\mathbf{H}} + \hat{\mathbf{E}} \times \hat{\mathbf{H}}_0^*) \cdot \mathbf{u}_Z ds} \quad (25a)$$

$$\beta - \beta_0 = \omega \frac{\iint_S (\Delta\epsilon \hat{\mathbf{E}} \cdot \hat{\mathbf{E}}_0^* + \Delta\mu \hat{\mathbf{H}} \cdot \hat{\mathbf{H}}_0^*) ds}{\iint_S (\hat{\mathbf{E}}_0^* \times \hat{\mathbf{H}} + \hat{\mathbf{E}} \times \hat{\mathbf{H}}_0^*) \cdot \mathbf{u}_Z ds} \quad (25b)$$

where β_0 and β are phase shift constants in the two cases. The field configuration within the waveguide depends on the cross section of the waveguide, which can easily be found from the dimension of the waveguide. The derivation for the material perturbation equation in a waveguide is given in the Appendix.

Many experimental techniques have been developed based on the theory of perturbation for the determination of the dielectric and magnetic properties of materials. Of the two types of cavity perturbation the latter has more practical applications. The work of R. A. Waldron [9] is worth mentioning in the development of perturbation theory in this direction. According to his concept, it is assumed that the fields in the perturbed case due to a sample is the sum of the unperturbed fields E_0, H_0 and additional fields E_1, H_1 with a frequency change $\delta\omega$. Starting from the fundamental equations of Maxwell and applying the vector identity, we have

$$\text{Curl } E_0 = - \frac{\delta B_0}{\delta t} = -j\omega B_0$$

$$\text{Curl } (E_0 + E_1) = -j(\omega + \delta\omega)(B_0 + B_1)$$

Subtracting, we obtain

$$\text{Curl } E_1 = -j[\omega B_1 + \delta\omega(B_0 + B_1)]$$

Similarly

$$\text{Curl } H_1 = j[\omega D_1 + \delta\omega(D_0 + D_1)]$$

Following the same procedure of Harrington, we get

$$\begin{aligned} (E_0 \cdot \nabla \times H) + (H_0 \cdot \nabla \times E) &= j\omega[E_0 \cdot D_1 - H_0 \cdot B_1] \\ &+ j\delta\omega[(E_0 \cdot D_0 - H_0 \cdot B_0) \\ &+ (E_0 \cdot D_1 - H_0 \cdot B_1)] \end{aligned} \quad (26)$$

For the sample outside

$$B_0 = \mu_0 H_0, \quad B_1 = \mu_0 H_1$$

$$D_0 = \epsilon_0 E_0, \quad D_1 = \epsilon_0 E_1$$

and for the sample inside

$$B_1 = \mu_0[\mu_r(H_0 + H_1) - H_0]$$

$$D_1 = \epsilon_0[\epsilon_r(E_0 + E_1) - E_0]$$

For gyromagnetic material, inside the sample B_1 becomes

$$B_1 = \mu_0\{[\mu_r](H_0 + H_1) - H_0\}$$

Use the vector identity

$$\begin{aligned} \nabla \cdot [(H_0 \times E_1) + (E_0 \times H_1)] \\ &= E_1 \cdot \nabla \times H_0 - H_0 \cdot \nabla \times E_1 \\ &+ H_1 \cdot \nabla \times E_0 - E_0 \cdot \nabla \times H_1 \end{aligned}$$

Substituting for curl E and curl H in this expression and rearranging, we get

$$\begin{aligned} H_0 \cdot \nabla \times E_1 + E_0 \cdot \nabla \times H_1 \\ &= j\omega(E_1 \cdot D_0 - H_1 \cdot B_0) \\ &- \nabla \cdot [(H_0 \times E_1) + (E_0 \times H_1)] \end{aligned} \quad (27)$$

Equating (27) to the LHS of Eq. (26), we obtain

$$\begin{aligned} j\omega(E_1 \cdot D_0 - H_1 \cdot B_0) - \nabla \cdot [(H_0 \times E_1) \\ &+ (E_0 \times H_1)] = j\omega(E_0 \cdot D_1 - H_0 \cdot B_1) \\ &+ j\delta\omega[(E_0 \cdot D_0 - H_0 \cdot B_0) \\ &+ (E_0 \cdot D_1 - H_0 \cdot B_1)] \end{aligned}$$

Let V_0 be the volume of cavity and V_1 the volume of the sample. Thus $(V_0 - V_1)$ is the part of the cavity not occupied by the sample. Integrate equation over the volume V_0

$$\begin{aligned} j\omega \iiint_{V_0} (E_1 \cdot D_0 - H_1 \cdot B_0) dV \\ &- \iiint_{V_0} \nabla \cdot [(H_0 \times E_1) + (E_0 \times H_1)] dV \\ &= j\omega \iiint_{V_0} (E_0 \cdot D_1 - H_0 \cdot B_1) dV \\ &+ j\delta\omega \iiint_{V_0} [(E_0 \cdot D_0 - H_0 \cdot B_0) \\ &+ (E_0 \cdot D_1 - H_0 \cdot B_1)] dV \end{aligned} \quad (28)$$

If the inner surface of the cavity is perfectly conducting, the divergence integral on the LHS is zero. The contribution from the region $(V_0 - V_1)$, the region of the cavity outside the sample, to the first term of LHS and the right-hand side (RHS) is the same.

Thus we only require the contribution to these integrals from the region V_1 . When $\delta\omega \ll \omega$, E_1 and H_1 are small compared with E_0 and D_0 and in the neighborhood of

the sample, the contribution to the integral will be small. So there is no harm to neglect the second integral of the RHS of the equation above. Thus Eq. (28) becomes

$$\frac{\delta\omega}{\omega} = \frac{\iiint_{V_1} [(E_1 \cdot D_0 - E_0 \cdot D_1) - (H_1 \cdot B_0 - H_0 \cdot B_1)] dV}{\iiint_{V_0} (E_0 \cdot D_0 - H_0 \cdot B_0) dV} \tag{29}$$

Knowing the field and measuring the frequency shift, dielectric parameters are determined assuming that the influence of the sample at the magnetic field is negligible. Thus the general expression for the frequency shift is given by

$$\frac{\delta\omega}{\omega} = \frac{\iiint_{V_1} (E_1 \cdot D_0 - E_0 \cdot D_1) dV}{2 \iiint_{V_0} E_0 \cdot D_0 dV} \tag{30}$$

The sample size should be uniform over a volume large compared to that of the sample.

Sample size will be selected to have small $\delta\omega/\omega$ value. This is particularly important for high-loss materials. In order to use the perturbation theory for the evaluation of dielectric and magnetic parameters, the concept of complex frequency shift was introduced. A waveguide cavity resonator is equivalent to a resonant circuit, and the complex resonant frequency shift $d\Omega$ and resonant frequency ω_0 are related to the quality factor Q of the resonator by the expression [10,11]

$$\frac{\delta\Omega}{\omega_0} = \frac{\delta\omega}{\omega_0} + \frac{j}{2} \left(\frac{1}{Q_1} - \frac{1}{Q_0} \right) \tag{31}$$

Q_0 and Q_1 are quality factors of empty cavity and cavity with perturbing sample. Thus in the perturbation theory $\delta\omega/\omega_0$ is replaced by $\delta\Omega/\omega_0$.

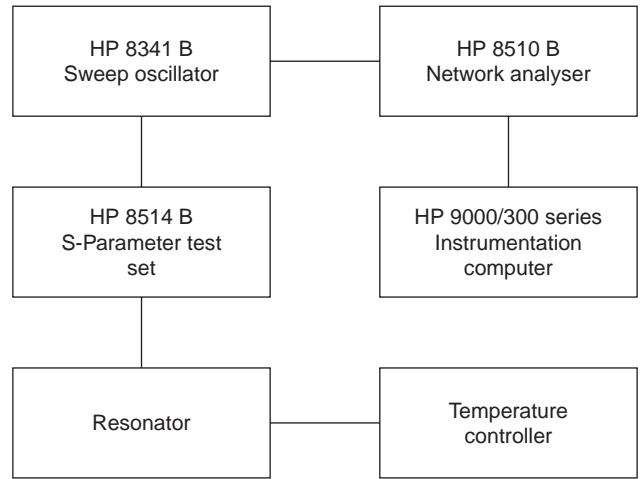

Figure 3. Block diagram of experimental setup.

3. MEASUREMENT TECHNIQUES

A block diagram of the experimental set up for the measurement of dielectric and magnetic parameters of materials is shown in Fig. 3. The experimental setup consists of a cavity resonator, HP8510C/8714ET network analyzer assembly and an interfacing computer.

3.1. Rectangular Waveguide Cavity Resonator

The closed section of a rectangular waveguide constitutes a cavity resonator. The cavity resonator can be of transmission or reflection type. A transmission-type cavity resonator [12] is shown in Fig. 4. Electromagnetic energy is coupled to the cavity through coupling irises at the ends of the cavity. A nonradiating slot is provided at the broadwall of the cavity for the introduction of the sample. On exciting the cavity resonator in the TE_{10p} mode, a typical resonant frequency spectrum is obtained. The cavity resonates at different frequencies depending on its dimensions. The basic principle involved in the technique is that the field within the cavity resonator is perturbed by in-

Figure 4. Schematic diagram of rectangular cavity resonator.

roduction of the dielectric sample through the nonradiating slot. The resonant frequency and the quality factor of the cavity get shifted because of perturbation. The determination of the complex permittivity and conductivity is based on the theory of perturbation. When the sample is introduced into the cavity, the relative complex frequency shift of the resonator is given as [5]

$$\frac{d\Omega}{\omega_0} \approx \frac{(\bar{\epsilon}_r - 1)\epsilon_0 \int_{V_s} E \cdot E_0^* dV + (\bar{\mu}_r - 1)\mu_0 \int_{V_s} H \cdot H_0^* dV}{\int_{V_c} (D_0 \cdot E_0^* + B_0 \cdot H_0^*) dV} \quad (32)$$

where E_0 is the electric field in the unperturbed cavity, E is the electric field in the perturbed cavity, D is the displacement current density, and H_0 , H , and B the respective magnetic quantities. $\bar{\epsilon}_r$ is the relative complex permittivity of the sample. But $\bar{\epsilon}_r = \bar{\epsilon}'_r - j\bar{\epsilon}''_r$ where $\bar{\epsilon}'_r$ the real is part of the complex permittivity and $\bar{\epsilon}''_r$ is the imaginary part of the complex permittivity. μ is the permeability. The numerator of Eq. (32) represents the total energy stored in the sample and the denominator represents the total energy stored in the cavity.

3.1.1. Dielectric Parameters. When a dielectric material is introduced in a cavity resonator at the position of maximum electric field, the contribution of magnetic field for the perturbation is minimum. The field perturbation due to the introduction of dielectric sample at the position of maximum electric field is related as

$$\frac{d\Omega}{\omega_0} \approx \frac{(\bar{\epsilon}_r - 1) \int_{V_s} E \cdot E_{0 \max}^* dV}{2 \int_{V_c} |E_0|^2 dV} \quad (33)$$

where $d\Omega$ is the complex frequency shift, V_s and V_c are the volumes of the sample and the cavity resonator, respectively. The complex frequency shift is related to the quality factor as

$$\frac{d\Omega}{\omega_0} = \frac{d\omega}{\omega_0} + \frac{j}{2} \left(\frac{1}{Q_s} - \frac{1}{Q_c} \right) \quad (34)$$

where Q_s and Q_c are the quality factors of cavity resonator with and without the sample.

Quality factor Q is given by $Q = f/\Delta f$, where f is the resonant frequency and Δf is the corresponding 3 dB bandwidth. For a small sample, we assume that $E = E_0$, which is one of the assumptions taken in the theory of perturbation. For dominant TE_{10p} mode in rectangular waveguide [6], we have

$$E_0 = E_{0 \max} \sin \frac{\pi x}{a} \sin \frac{p\pi z}{d}, \quad p = 1, 2, 3, \dots \quad (35)$$

$E_{0 \max}$, a , and d are the peak values of E_0 , the broader dimension and the length of the waveguide cavity resonator, respectively.

From Eqs. (33)–(35), we get

$$\epsilon'_r - 1 = \frac{f_c - f_s}{2f_s} \left(\frac{V_c}{V_s} \right) \quad (36)$$

$$\epsilon''_r = \frac{V_c}{4V_s} \left(\frac{Q_c - Q_s}{Q_c Q_s} \right) \quad (37)$$

The real part, ϵ'_r of the complex permittivity is usually known as the *dielectric constant*. The imaginary part, ϵ''_r of the complex permittivity is associated with dielectric loss of the material. The effective conductivity, σ_e is given as

$$\sigma_e = \omega \epsilon''_r = 2\pi f \epsilon_0 \epsilon''_r \quad (38)$$

The dielectric loss of a material will be usually expressed by a term loss tangent or $\tan \delta$ as

$$\tan \delta = \epsilon''_r / \epsilon'_r \quad (39)$$

3.1.2. Magnetic Parameters. When a magnetic material is introduced at the position of maximum magnetic field [12], the perturbation equation becomes

$$\frac{d\Omega}{\omega_0} = - \frac{\int_{V_s} \Delta\mu (H \cdot H_0^*) dv}{2\mu_0 \int_{V_c} |H_0|^2 dv} \quad (40)$$

where V_s and V_c are the volumes of the sample and cavity respectively, $\Delta\mu = \bar{\mu} - \mu_0$ and $\bar{\mu} = \bar{\mu}_r \mu_0$. But $\bar{\mu}_r = \mu'_r - j\mu''_r$. Thus Eq. (40) becomes

$$\frac{d\Omega}{\omega_0} = - \frac{\int_{V_s} (\bar{\mu}_r - 1) H \cdot H_0^* dv}{2 \int_{V_c} |H_0|^2 dv} \quad (41)$$

The components of the magnetic field for the TE_{10n} modes are

$$H_x = -C \frac{\beta a}{\pi} \sin \left(\frac{\pi x}{a} \right) \sin(\beta z)$$

$$H_z = C \cos \left(\frac{\pi x}{a} \right) \sin(\beta z)$$

The denominator of Eq. (41) becomes

$$\begin{aligned} \int_{V_c} |H_0|^2 dV &= \int_{V_c} H_x^2 dV + \int_{V_c} H_z^2 dV \\ &= \frac{C^2 V_0}{4} \frac{\lambda_g^2 + 4a^2}{\lambda_g^2} \end{aligned}$$

The numerator of Eq. (41) is reduced to

$$(\bar{\mu}_r - 1) \int_{V_s} \mathbf{H} \cdot \mathbf{H}_0^* dV = (\bar{\mu}_r - 1) \frac{4C^2 a^2 V_s}{\lambda_g^2}$$

Thus

$$\frac{d\Omega}{\omega_0} = -(\bar{\mu}_r - 1) \frac{8a^2}{(\lambda_g^2 + 4a^2)} \frac{V_s}{V_c} \quad (42)$$

Equating the real and the imaginary parts of (42), we obtain

$$(\mu'_r - 1) = \frac{(\lambda_g^2 + 4a^2) f_c - f_s V_0}{(8a^2) f_s V_s} \quad (43)$$

$$\mu''_r = \frac{(\lambda_g^2 + 4a^2) V_c}{16a^2} \left(\frac{1}{Q_s} - \frac{1}{Q_c} \right) \quad (44)$$

Q_s and Q_c are the quality factors of the cavity with and without the sample in the cavity, and f_s and f_c are the resonant frequencies of the cavity with and without the sample on the sample holder. λ_g is the guided wavelength. For the TE_{10n} mode, $\lambda_g = 2d/n$, where d is the length of the cavity and $n = 1, 2, 3, \dots$

3.2. Coaxial Transmission-Line Resonator

The experimental procedure is the same as that explained in Section 3.1. The coaxial transmission-line resonator consists of a circular waveguide that operates below cutoff for the TM_{01} mode. A typical coaxial transmission-line resonator is shown in Fig. 5. Along the waveguide axis there is a removable center conductor. Thus the TEM mode can propagate up to the end of the center conductor. The standing-wave field components of the resonant TEM mode are obtained by combining the forward and backward propagating waves (in cylindrical coordinate

system $\{\rho, \phi, z\}$)

$$E_{\rho s}^0 = \frac{Ae^{j\beta z}}{\rho} + \frac{Be^{-j\beta z}}{\rho} \quad (45)$$

$$H_{\phi s}^0 = -\frac{Ae^{j\beta z}}{\eta\rho} + \frac{Be^{-j\beta z}}{\eta\rho}$$

where η is the free-space impedance and A and B are constants. The boundary conditions require that $E_{\rho s}^0$ vanish at $z = 0$, which is the fixed end of the center conductor. At $z = L$ (where L is the length of the center conductor), the maximum field corresponding to resonance occurs. The first condition gives $A = -B$, while the second gives the resonance condition. Now the preceding equations become

$$E_{\rho s}^0 = 2j \frac{A}{\rho} \sin \beta z = jE_{av} \sin \beta z$$

$$H_{\phi s}^0 = -2 \frac{A}{\eta\rho} \cos \beta z = -\frac{E_{av}}{\eta} \cos \beta z \quad (46)$$

Since ρ varies from a to b (from the surface of the center conductor to the inner radius of the resonator), the average field acting on the sample may be considered. Thus E_{av} is the average electric field. The electrical energy stored in the cavity is

$$W_e = \frac{\epsilon_0}{2} \int_{V_c} E_{\rho s}^0{}^2 dV$$

On substituting the value of $E_{\rho s}^0$ from (46), we get

$$W_e = \frac{\epsilon_0}{2} \int_0^{2\pi} \int_a^b \int_0^L E_{av}^2 \sin^2 \beta z \rho d\rho d\phi dz \quad (47)$$

Here b is the inner radius of the outer conductor and a is the radius of the center conductor.

Figure 5. Schematic diagram of coaxial cavity resonator.

When the dielectric sample is introduced at the position of maximum electric field, the relative frequency shift is given by [13,14]

$$\frac{d\Omega}{\omega_0} \approx \frac{(\bar{\epsilon}_r - 1) \int_{V_s} \epsilon_0 E_{\rho s \max} \cdot E_{\rho s \max}^{0*} dV}{4W_e} \quad (48)$$

Substituting for W_e , we obtain

$$\begin{aligned} \frac{d\Omega}{\omega_0} &\approx \frac{(\bar{\epsilon}_r - 1) \int_{V_s} E_{\rho s \max} \cdot E_{\rho s \max}^{0*} dV}{2 \int_0^{2\pi} \int_a^b \int_0^L E_{av}^2 \sin^2 \beta z \rho d\rho d\phi dz} \quad (49) \\ &\approx \frac{(\bar{\epsilon}_r - 1) V_s}{\pi L (b^2 - a^2)} \end{aligned}$$

For a small volume of the sample, $E_{\rho s \max} = E_{\rho s \max}^0 = E_{av} \cdot V_s = \pi r r^2 (b - a)$, where r is the inner radius of the capillary tube. However, $\bar{\epsilon}_r = \epsilon'_r - j\epsilon''_r$:

$$\frac{d\Omega}{\omega_0} \approx -\frac{(\epsilon'_r - 1)r^2}{L(b+a)} + \frac{j\epsilon''_r r^2}{L(b+a)} \quad (50)$$

Equating the real and imaginary part of (50), we obtain

$$(\epsilon'_r - 1) = \frac{L(b+a)}{r^2} \frac{(f_c - f_s)}{f_s} \quad (51)$$

$$\epsilon''_r = \frac{L(b+a)}{2r^2} \left[\frac{1}{Q_s} - \frac{1}{Q_c} \right] \quad (52)$$

4. SOURCES OF ERROR AND ACCURACY CONSIDERATION

In general cavity resonator techniques based on perturbation theory offer an accurate method of measurement for the study of dielectric and magnetic properties of materials. The main sources of experimental error are high relative resonant frequency shift, decrease in Q factor of the cavity, and irregular shape of the materials. Study shows that the perturbation condition is satisfied mostly when the relative frequency shift is of the order of 1 in 1000 and, the decrease in the quality factor due to the introduction of the sample by a factor of 10–15%. This shows that the sample size will vary for different materials (low, medium, and high loss). The assumption that the fields in the cavity under perturbed and unperturbed conditions are the same [14–17] will be valid only when the sample size satisfies the conditions mentioned above. A comparative study of the dielectric parameters of water using perturbation technique and other rigorous technique is given in Table 1 [12].

Table 1. Comparison of Dielectric Parameters of Water Obtained with Cavity Perturbation Technique and the Rigorous Method

Frequency (GHz)	Rectangular Cavity Perturbation Technique		Rigorous Method (Wei and Sridhar) [21]	
	ϵ'_r	ϵ''_r	ϵ'_r	ϵ''_r
2.44	78.58	7.01	78.14	7.12
2.68	76.56	7.90	75.46	8.24
3.29	74.47	11.98	74.12	11.27
3.63	74.06	14.89	73.88	15.12
3.98	72.88	16.20	73.22	16.56
5.10	72.13	16.45	72.27	16.89
5.63	70.61	17.69	71.94	17.45
6.93	67.53	21.57	69.56	22.17
8.57	64.10	24.35	65.09	25.44
10.14	60.29	27.97	61.50	29.18
10.97	58.47	29.23	59.72	30.25

5. PRACTICAL APPLICATIONS OF PERTURBATION THEORY

Perturbation theory finds application in industrial, scientific, and medical (ISM) research. For the development of new materials for various applications, especially in microelectronics and MMICs, thorough knowledge about the dielectric and magnetic properties of the test materials is essential. Low- and medium-frequency measurements are rather simple and well established. Measurements in UHF and microwave frequency ranges need special attention. Cavity perturbation techniques are assumed to be most accurate. This technique is very important in the case of samples (solid, liquid, or gaseous), which are available in extremely small quantities. Biological samples such as bile and pancreatic juice are examples [18,19]. More recent study reveals that imaging of materials using perturbation technique [20] has been effectively applied in *medical imaging*.

6. APPENDIX: DERIVATION FOR MATERIAL PERTURBATION EQUATION IN A WAVEGUIDE

The unperturbed fields in a waveguide can be written as follows:

$$E_0 = E_{0 \max} e^{j\omega t - \gamma_0 z}$$

$$H_0 = H_{0 \max} e^{j\omega t - \gamma_0 z}$$

$$E = E_{\max} e^{j\omega t - \gamma z}$$

$$\nabla \times E_0 = -j\omega\mu_0 H_0$$

$$\nabla \times H_0 = j\omega\epsilon_0 E_0$$

$$\nabla \times E = -j\omega\mu_0 H \quad (\text{exterior to the sample})$$

$$= -j\omega\mu H \quad (\text{interior to the sample})$$

$$\nabla \times H = j\omega\epsilon_0 E \quad (\text{exterior to the sample})$$

$$= j\omega\epsilon E \quad (\text{interior to the sample})$$

The same procedure for derivation of the frequency shift in the preceding cases is employed here also. It can be easily shown that

$$\gamma_p - \gamma_u = \frac{\omega \int_{\Delta_s} [(\mu - \mu_0)H \cdot H_0^* + (\varepsilon - \varepsilon_0)E \cdot E_0^*] ds}{\int_S \mu_0 H \cdot H_0^* + \varepsilon_0 E \cdot E_0^* ds}$$

If the sample is a lossy medium

$$\gamma_p = \beta_p - j\alpha_p$$

$$\gamma_u = \beta_u \quad \text{for free space}$$

$$\gamma_p - \gamma_u = (\beta_p - \beta_u) - j\alpha_p$$

For a nonmagnetic material $\mu = \mu_0$ and

$$\varepsilon - \varepsilon_0 = \bar{\varepsilon}_r \varepsilon_0 - \varepsilon_0 = \varepsilon_0(\bar{\varepsilon}_r - 1), \quad \bar{\varepsilon}_r = \varepsilon'_r - j\varepsilon''_r$$

$$\beta_p - \beta_u = \frac{\omega \int_{\Delta_s} (\varepsilon'_r - 1)E \cdot E_0^* ds}{2 \int_S E \cdot E_0^* ds}$$

$$\alpha_p = \frac{\omega \varepsilon'' \int_{\Delta_s} E \cdot E_0^* ds}{2 \int_S E \cdot E_0^* ds}$$

Putting $E = E_0$, we obtain

$$\beta_p - \beta_u = \frac{\omega(\varepsilon'_r - 1) \int_{\Delta_s} |E_0|^2 ds}{2 \int_S |E_0|^2 ds}$$

$$\alpha_p = \frac{\omega \varepsilon'' \int_{\Delta_s} |E_0|^2 ds}{2 \int_S |E_0|^2 ds}$$

Thus the insertion of a nonmagnetic dielectric material in to a uniform waveguide will produce a phase shift and attenuation between the incoming and outgoing waves. This property is utilized in the design of phase shifters and strip attenuators.

Cavity perturbation theory can be modified to obtain an expression for the frequency shift for a ferrite material. It is assumed that a ferrite is sufficiently small to cause only a small perturbation in the resonant cavity. Thus the frequency shift

$$\frac{\delta\omega}{\omega} = \frac{\int_{\text{sample}} (E_1 \cdot D_0 - E_0 \cdot D_1 + H_0 \cdot B_1 - H_1 \cdot B_0) dv}{\int_{\text{cavity}} (E_0 \cdot D_0 - H_0 \cdot B_0) dv}$$

will be modified as

$$\frac{\delta\omega}{\omega} = \frac{\int_{\text{sample}} [(\chi^e \cdot H) \cdot H - \chi_e^e E \cdot E] dv}{\int_{\text{cavity}} (\varepsilon_0 E_0 \cdot E - \mu_0 H_0 \cdot H) dv}$$

where χ^e and χ_e^e are the external forms of the tensor susceptibility and dielectric susceptibility, respectively.

PHASE LOCKED LOOPS

GÉZA KOLUMBÁN
 Budapest University of
 Technology and Economics
 Hungary

1. INTRODUCTION

Although the first description of the phase-locked loop (PLL) was published by Appleton [1] in 1923, the PLL did not attract widespread attention until much later. Today PLLs of various types are used extensively in electrical engineering, from telecommunication systems to measurement equipment.

Depending on the loop components, especially on the operation of the phase detector, analog, digital, and hybrid PLLs are distinguished. The behavior of these circuits is described by differential, difference, and mixed integro-difference equations.

Even though applications of PLLs require a variety of circuit configurations, and the mathematical models mentioned above require different kinds of mathematical treatment, their behavior can be approximated and studied by means of a simple feedback structure. Unfortunately, the behavior of this structure is complicated to analyze because it is nonlinear, may contain edge-triggered digital circuits, and is driven by random noise. In many cases, analytical results are not available in closed form; they are often buried in complicated mathematics that cannot be assimilated easily by the circuit designer. On the other hand, the design of PLLs for many applications can be performed successfully on the basis of a simple linearized model and by means of a few rules of thumb. In this article the essential elements and secondary effects of loop behavior are clearly differentiated, the key assumptions and approximations involved in the analysis are highlighted, and the conditions under which the approximations are valid are collected. The main goals are to provide a survey of PLL theory and applications and to summarize the most important design rules and equations.

If the PLL must operate in a noisy environment, then an analog multiplier has to be used as phase detector (PD) to get the best noise performance. The PLL built with an analog multiplier is called an *analog phase-locked loop* (APLL). The other phase detectors such as digital or

edge-triggered circuits have much worse performance in a noisy environment. This is why APLLs are used to build amplifiers, demodulators and carrier recovery circuits.

The other important PLL application is frequency synthesis, where the reference signal has very high spectral purity. In frequency synthesis the edge-triggered phase detectors such as sample-and-hold and phase-frequency detectors offer the best system parameters.

The article is organized according to these applications. Section 1 is devoted to APLL theory. First the baseband model is developed, then the linear theory of APLL (tracking, modulation, and noise) is discussed. Finally, the most important nonlinear effects (acquisition, cycle slips, hang-up) are surveyed. Section 2 discusses the most common PLL applications. Section 3 is devoted to frequency synthesis, where both the sampling (sample-and-hold-type PD) and charge-pump (phase-frequency detector with charge pump) PLLs are considered. These phase detectors are edge-triggered circuits; the discrete-time operation makes the analysis of these PLLs very complex. The problem of discrete-time operation arising from the application of edge-triggered circuits is discussed and design methods are given.

2. ANALOG PHASE-LOCKED LOOP

In an APLL, all loop components are analog circuits and the phase detector is an analog multiplier. The APLL operation is modeled by an ordinary differential equation.

The APLL was the first, and is the most widely studied, version of the PLLS. Many excellent books [2–11], two IEEE special issues [12,13], and a tutorial [14] have been devoted to the theory and applications of the APLL.

In many applications, the block diagram of an APLL has to be completed with extra loop components such as frequency divider and mixer. That is why the results developed for the APLL cannot be used directly in many cases. However

- APLL theory is very well developed and is relatively easy to understand.
- Equations describing the loop behavior in different applications can be developed in closed form.
- Having understood the operation of the APLL, it is easy to study more complex PLL configurations.
- If the closed-loop bandwidth [defined later by Eq. (37)] is at least 10 times less than the frequency of the input signal, then the theory of any kind of PLLs even including edge-triggered circuits may be approximated by the APLL theory.

This section presents a *concise* treatment of the APLL. First, the baseband model for the APLL is developed. Then the linear APLL theory is discussed. In the majority of applications, the APLL operates in its linear region. The linear theory can be applied only if the *phase-locked* condition has been achieved and is maintained. Under phase-locked condition the average input and voltage-

controlled oscillator (VCO) frequencies are exactly equal and the VCO phase tracks the input phase.

The phase-locked condition is achieved as a result of a highly nonlinear, acquisition process. In the last part of this section, the most important aspects of nonlinear APLL theory are surveyed.

2.1. Basic Loop Configuration

A PLL is a feedback system that continuously tries to track the phase of an input signal. It contains a *phase detector*, a time-invariant linear *loop filter*, and a *voltage-controlled oscillator* the oscillator to be synchronized. As shown in Fig. 1, the phase detector compares the phase of input signal against the phase of VCO output and produces an error signal. This error signal is then filtered, in order to remove noise and other unwanted components of the input spectrum, and the filter output controls the instantaneous VCO frequency.

A nonzero output voltage must be provided by the PD in order to change the VCO frequency if the input frequency differs from the VCO center frequency. Consequently, the PLL tracks the phase of input signal with some phase error. However, this phase error can be kept very small in a well-designed PLL.

Figure 1 shows a few important telecommunication applications of a phase-locked loop; it may be used to demodulate both phase- (PM) and frequency- (FM) modulated signal, to implement an FM modulator, or for recovery of carrier signal.

2.1.1. Acquisition and Tracking. In every application, the PLL tracks the phase of an input signal. However, before a PLL can track, it must first reach the phase-locked condition.

In general, the VCO center frequency ω_0 differs from the frequency ω_i of input signal. Therefore, first the VCO frequency has to be tuned to ω_i by the loop. This process is called *frequency pull-in*. Then the VCO phase has to be adjusted according to the input phase. This process is known as *phase lock-in*.

In connection with acquisition and tracking, three important loop characteristics are defined.

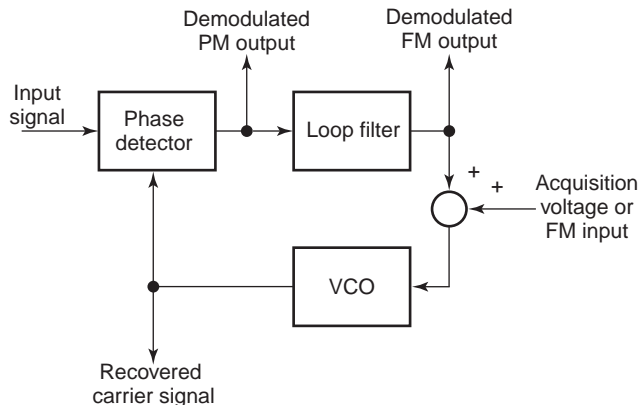

Figure 1. APLL block diagram showing inputs and outputs for various telecommunication applications.

2.1.1.1. Pull-in Range. $\Delta\omega_P = |\omega_i - \omega_0|$ is the maximum initial frequency difference between the input and VCO center frequencies in both positive and negative directions, for which the PLL eventually achieves the phase-locked condition. The pull-in range is related to the dynamics of the APLL.

2.1.1.2. Lockin Range. $\Delta\omega_L = |\omega_i - \omega_0|$ is the frequency range over which the PLL achieves the phase-locked condition without cycle slips. Cycle slips will be defined later.

2.1.1.3. Holdin Range. Suppose that the phase-locked condition has been achieved in the PLL. Now vary the input frequency ω_i slowly, and the VCO frequency will follow it. The holdin range $\Delta\omega_H = |\omega_i - \omega_0|$ is determined by the lower and upper values of ω_i for which the phase-locked condition is lost. The holdin range represents the maximum static tracking range and is determined by the saturation characteristics of the nonlinear loop elements in the PLL.

2.2. Loop Equation and Nonlinear Baseband Model

The block diagram of the APLL to be studied is shown in Fig. 2, where $F(p)$ denotes the transfer function of the loop filter. In the equations developed in this article, the time variable t is suppressed for conciseness where it does not cause misunderstanding. In order to write the differential equations in compact form, the differentiation d/dt in the time domain is denoted by the multiplication of *Heaviside operator* p . If the transfer function $F(s)$ of a linear network is given in the complex frequency domain s , then $F(p) = F(s)|_{s=p}$. For more details on the Heaviside operator, see p. 73 in Ref. 6.

It is assumed in the APLL analysis that the loop components are linear; the only source of nonlinearity is the phase detector. The instantaneous VCO frequency may be varied about its center value ω_0 by the VCO control voltage $v_c(t)$.

Almost all signals and random processes appearing in electrical engineering may be considered narrowband [15]. Let the input signal

$$s(t, \Phi) = \sqrt{2}A \sin \Phi \tag{1}$$

be a narrowband signal, where $A(t)$ describes the *amplitude modulation* produced at the transmitter on purpose

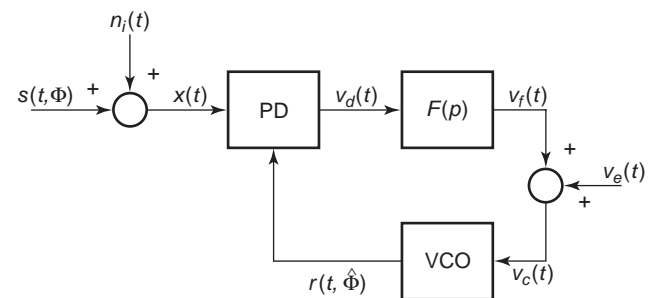

Figure 2. APLL block diagram indicating the additive input noise that corrupts the input signal.

and/or caused by the time-varying channel through which the signal is transmitted. Let the phase of the incoming signal be expressed with respect to the VCO center frequency as

$$\Phi = \omega_0 t + \theta_i \quad (2)$$

where $\theta_i(t)$ is the *input phase modulation* produced at the transmitter and/or caused by the channel. Note that $\theta_i(t)$ also incorporates the input frequency error $\Delta\omega_i = \omega_i - \omega_0$.

As shown in Fig. 2, the incoming signal $s(t, \Phi)$ is corrupted by additive input noise $n_i(t)$. In almost all applications, the additive input noise is a narrowband random process centered about ω_0 . By means of the analytic signal approach [15], narrowband random processes or signals can be expressed as a product of a slowly varying complex envelope and a sinusoidal carrier. For example, an arbitrary narrowband signal $w(t)$ centered about ω_0 can be expressed in terms of a complex envelope $\tilde{w}(t)$ as

$$w(t) = \text{Re}\{\tilde{w}(t) \exp(j\omega_0 t)\} \quad (3)$$

Since the carrier frequency component has been removed, the complex envelope is a slowly varying function

$$\tilde{w}(t) = w_I(t) + jw_Q(t) \quad (4)$$

where $w_I(t)$ and $w_Q(t)$ are the low-frequency *in-phase* and *quadrature components* of the narrowband signal $w(t)$.

Let $n_i(t)$ be modeled by a narrowband Gaussian random process of zero mean and symmetric power spectral density. Then the sample function of the narrowband noise can be expressed from Eqs. (3) and (4) in *canonical form* [6,15] as

$$n_i = \sqrt{2}[n_I \cos(\omega_0 t) - n_Q \sin(\omega_0 t)] \quad (5)$$

The in-phase and quadrature components are

$$n_I = \frac{1}{\sqrt{2}}[n_i \cos(\omega_0 t) + \hat{n}_i \sin(\omega_0 t)] \quad (6)$$

and

$$n_Q = \frac{1}{\sqrt{2}}[\hat{n}_i \cos(\omega_0 t) - n_i \sin(\omega_0 t)] \quad (7)$$

where $\hat{n}_i(t)$ is the Hilbert transform of $n_i(t)$ [15].

The VCO output is also a narrowband signal

$$r(t, \hat{\Phi}) = \sqrt{2}V_o \cos \hat{\Phi} \quad (8)$$

where $\hat{\Phi}(t)$ is the loop estimate of $\Phi(t)$ that can be expressed, with respect to the VCO center frequency, as

$$\hat{\Phi} = \omega_0 t + \theta_o \quad (9)$$

In Eqs. (8) and (9) V_o and $\theta_o(t)$ denote the RMS amplitude and phase of the VCO output, respectively.

The PD multiplies the input signal $x(t) = s(t, \Phi) + n_i(t)$ and VCO output $r(t, \hat{\Phi})$ and produces both difference- and sum-frequency terms. The PD always contains a lowpass filter that eliminates the sum-frequency component. By means of simple trigonometric identities the PD output is obtained

$$\begin{aligned} v_d &= AV_o \sin \theta_e + V_o(n_I \cos \theta_o + n_Q \sin \theta_o) \\ &= K_d[A \sin \theta_e + N(t, \theta_o)] \end{aligned} \quad (10)$$

where the *phase error* is defined by

$$\theta_e(t) = \Phi(t) - \hat{\Phi}(t) = \theta_i(t) - \theta_o(t) \quad (11)$$

and $K_d = V_o$, a dimensionless quantity, is the gain of PD. The *equivalent phase noise process* is defined by

$$N(t, \theta_o) = n_I \cos \theta_o + n_Q \sin \theta_o \quad (12)$$

For the statistical properties of $N(t, \theta_o)$, refer to the following subsection.

From Eqs. (10) and (12), two conclusions may be drawn:

- Even in the noise-free case, the PD output depends not only on the phase error $\theta_e(t)$ but also on the amplitude $A(t)$ of incoming signal.
- The equivalent noise process $N(t, \theta_o)$ is independent of $\theta_e(t)$; it appears as an additive term in the PD output.

The instantaneous VCO frequency $\dot{\theta}_o(t) = d\theta_o(t)/dt$ referenced to ω_0 is related to its input through

$$\dot{\theta}_o = K_v v_c + \dot{\Psi}_2 = K_v(v_f + v_e) + \dot{\Psi}_2 \quad (13)$$

where $v_c(t) = v_f(t) + v_e(t)$ denotes the VCO control voltage, $v_f(t) = F(p)v_d(t)$ is the output voltage of the loop filter, $v_e(t)$ denotes the external control voltage, K_v is the VCO gain in $\text{rad/V} \cdot \text{s}$, and $\Psi_2(t)$ denotes the VCO jitter, that is, the VCO phase noise.

Taking into account the transfer function of the loop filter, the output phase is obtained from Eqs. (10) and (13) as

$$\theta_o = \frac{KF(p)}{p}[A \sin \theta_e + N(t, \theta_o)] + \frac{K_v}{p}v_e + \Psi_2 \quad (14)$$

where $K = K_d K_v$ defines the *loop gain* in $\text{rad/V} \cdot \text{s}$. Substituting Eq. (14) into Eq. (11), the following nonlinear stochastic integro-differential equation is obtained

$$\dot{\theta}_e = \theta_i - \frac{KF(p)}{p}[A \sin \theta_e + N(t, \theta_o)] - \frac{K_v}{p}v_e - \dot{\Psi}_2 \quad (15)$$

which describes the operation of APLL. In general, the input phase modulation $\theta_i(t)$ consists of three terms

$$\theta_i = d + M + \Psi_1 \quad (16)$$

where $d(t)$ describes the Doppler effect appearing in the channel, $M(t)$ is the digital or analog phase/frequency modulation, and $\Psi_1(t)$ denotes the jitter, that is, phase noise of the transmitter oscillator.

The loop equation given by Eq. (15) has two important features. Due to the introduction of a phase error, the high-frequency terms have been dropped and all signals involved in the loop equations have become low-frequency signals, that is, slowly varying functions. This means that instead of angle-modulated signals, only their modulation has to be considered and in computer simulation the lowest sampling frequency may be used. A further advantage, the phase error approach simplifies the problem to be studied in many cases. For example, Eq. (15) becomes an autonomous differential equation during acquisition that is relatively easy to study.

Note that, in an implemented APLL, the phase error does not exist as an explicit variable; it has been introduced only to derive a simple mathematical model for the APLL. However, if $\theta_e(t)$ is known, then all signals appearing in a built APLL can be expressed easily by the equations developed above.

The baseband model of the APLL can be developed from Eq. (15) as shown in Fig. 3. The sinusoidal nonlinearity in Eq. (15) is due to the particular type of PD and the sinusoidal VCO and input waveforms. However, other kinds of PD and signals may be also applied. Fortunately, the unified baseband model shown in Fig. 3 remains valid for each loop configuration if the loop nonlinearity $g(\cdot)$ is selected according to the actual PD characteristics and $n_g(t)$ describes the equivalent noise process for the case to be studied. If an analog multiplier is used as the PD and the signals are sinusoidal, then $g(\cdot) = \sin(\cdot)$ and $n_g(t) = N(t, \theta_o)$. Lindsey and Chie have collected $g(\cdot)$ and $n_g(t)$ for many other loop configurations [11].

Note that the input and output of baseband model are not measurable signals but are the input and output phase modulations, respectively. If the real input and output signals have to be determined, then $s(t, \Phi)$ and $r(t, \hat{\Phi})$ are obtained from Eqs. (1) and (8).

2.3. Statistical Properties of Equivalent Noise

In order to use the baseband model in PLL analysis and design, the statistical properties of equivalent noise

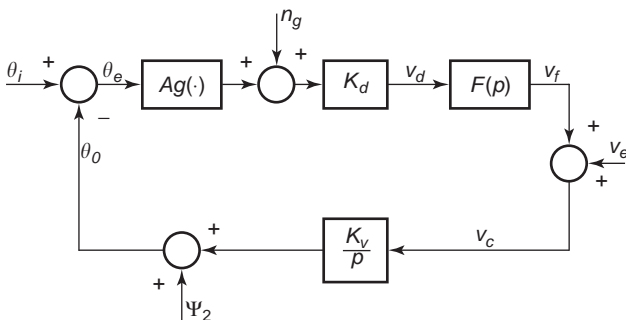

Figure 3. Unified baseband model of APLL.

process $N(t, \theta_o)$ must be known. This subsection summarizes the properties of the in-phase and quadrature components of $n_i(t)$ and gives the statistical properties of $N(t, \theta_o)$

The additive input noise is modeled by a narrow-band Gaussian random process with zero mean. It may be expressed either in canonical form or as a sinusoidal signal

$$n_i = \sqrt{2} [n_I \cos(\omega_0 t) - n_Q \sin(\omega_0 t)] = \sqrt{2} N_n(t) \cos(\omega_0 t + \theta_n) \tag{17}$$

where the envelope $N_n(t)$ and phase $\theta_n(t)$ processes are defined by

$$N_n(t) = \sqrt{n_I^2(t) + n_Q^2(t)} \text{ and} \tag{18}$$

$$\theta_n(t) = \tan^{-1} \left[\frac{n_Q(t)}{n_I(t)} \right]$$

Note that the envelope $N_n(t)$ differs from the complex envelope defined by Eq. (3). If the power spectral density of $n_i(t)$ is symmetric about ω_0 , then a very simple relationship exists between the autocorrelation functions of $n_i(t)$ and $N_n(t)$

$$R_n(\tau) = 2r(\tau) \cos(\omega_0 \tau) \tag{19}$$

where $R_n(\tau)$ and $r(\tau)$ denote the autocorrelation functions of $n_i(t)$ and $N_n(t)$, respectively.

If $n_i(t)$ has a symmetric power spectral density about ω_0 , then the most important properties of the in-phase $n_I(t)$ and quadrature $n_Q(t)$ components of $n_i(t)$ are as follows [10,15]:

1. If $n_i(t)$ is a Gaussian process, then both $n_I(t)$ and $n_Q(t)$ are also Gaussian.
2. If $n_i(t)$ has zero mean, then both $n_I(t)$ and $n_Q(t)$ have zero-mean values. Note that $n_i(t)$ is a bandpass signal, consequently, it always has zero mean.
3. The in-phase and quadrature components have the same variance as the narrowband noise $n_i(t)$.
4. The correlation functions of $n_I(t)$ and $n_Q(t)$ may be expressed [6] as

$$\overline{n_I(t)n_I(t+\tau)} = \overline{n_Q(t)n_Q(t+\tau)} = r(\tau) \tag{20}$$

$$\overline{n_I(t)n_Q(t+\tau)} = \overline{-n_Q(t)n_I(t+\tau)} = 0$$

5. where overbar symbolizes the time-averaging operation. The first equation shows that the autocorrelation functions of $N_n(t)$, $n_I(t)$, and $n_Q(t)$ are equal to each other, while the second one means that $n_I(t)$ and $n_Q(t)$ are independent.

6. Both the in-phase and quadrature noise components have the same power spectral density that is related to the power spectral density $S_N(f)$ of $n_i(t)$ as

$$S_I(f) = S_Q(f) = \begin{cases} \frac{1}{2}[S_N(f - f_0) + S_N(f + f_0)], & -B \leq f \leq B \\ 0, & \text{elsewhere} \end{cases} \quad (21)$$

where $S_N(f)$ occupies the frequency band $f_0 - B \leq |f| \leq f_0 + B$ and $f_0 > B$.

To complete the APLL baseband model, the statistical properties of $N(t, \theta_o)$ have to be determined. The problem is that the equivalent noise depends not only on $n_i(t)$ but also on $\theta_o(t)$. Due to the closed loop, the noise modulates the VCO and $\theta_o(t)$ also becomes a random process. Because the PD is nonlinear, the fluctuations in $\theta_o(t)$ intermodulate with the incoming signal and additive input noise $n_i(t)$.

The nonlinear operation of the PD makes exact analysis impossible, so some kind of approximation must be used. Viterbi [3] introduced two assumptions in order to get a simple but useful result:

1. The additive bandpass noise $n_i(t)$ has a symmetric power spectral density.
2. The bandwidth of $n_i(t)$ is much wider than that of $\theta_o(t)$.

The bandwidth of $\theta_o(t)$ is determined by the noise bandwidth of the loop, which will be defined later. Since the APLL noise bandwidth is always much less than the bandwidth of $n_i(t)$, the correlation time [6] of the additive input noise is much less than that of the output phase. Consequently, $\theta_o(t)$ can be thought of as a slowly varying function compared to $n_i(t)$ and the two processes are approximately independent [3].

Under these assumptions the equivalent noise process can be approximated by white noise. The process $N(t, \theta_o)$ shall be treated as though it were white so that $\theta_o(t)$ embedded in $N(t, \theta_o)$ does not enter into the APLL analysis, either linear or nonlinear. Thus, if the additive input noise $n_i(t)$ is white with spectral density $N_0/2$, then the power spectral density of the equivalent noise $n_g(t)$ indicated in Fig. 3 is uniform with value $N_0/2$.

Fortunately, the assumptions listed above are valid for almost all practical APLL applications and the design of different circuit configurations operating in either the linear or nonlinear region can be performed on the basis of a simple baseband model.

2.4. Linear Operation of the APLL

Linear APLL theory is used extensively in designing APLLs for different applications from telecommunication to measurement engineering. Many system parameters used in circuit development and characterization are introduced and defined in the linear theory.

The linear operation of APLL assumes that

- The phase-locked condition has been achieved and is maintained.
- The phase error remains in the neighborhood of its quiescent value, that is, one may write

$$g(\theta_e) \approx g(\theta_{ss}) + \left. \frac{dg(\theta_e)}{d(\theta_e)} \right|_{\theta_{ss}} \Delta\theta_e,$$

where θ_{ss} is the quiescent value of $\theta_e(t)$ and $\Delta\theta_e(t)$ denotes its perturbation.

In this section the linear baseband model for the APLL is developed and then the APLL transfer functions are defined. After evaluating the stability properties, the tracking (transient and modulation) behavior and noise performance of the APLL are studied using the linear baseband model.

2.4.1. Linear Baseband Model. As shown above, the behavior of the APLL is described by a nonlinear stochastic differential equation

$$\dot{\theta}_e = \theta_i - \frac{KF(p)}{p} [Ag(\theta_e) + n_g] - \frac{K_v}{p} v_e - \Psi_2 \quad (22)$$

where $g(\cdot)$ describes all nonlinearities of the loop and $n_g(t)$ denotes the equivalent noise process. Recall that the linear approximation may be used only if the APLL operates under phase-locked condition.

First the quiescent value of the phase error must be determined. Let $n_g(t) = \Psi_2(t) = 0$, and let the input phase modulation be

$$\theta_i = (\omega_i - \omega_0)t + \theta_{i0} = \Delta\omega_i t + \theta_{i0}$$

where $\Delta\omega_i$ is the initial frequency detuning and θ_{i0} denotes the phase of the incoming signal. Taking into account that under steady-state conditions all signals are constant and that the Heaviside operator p means d/dt in the time domain, the quiescent value θ_{ss} of $\theta_e(t)$ may be obtained from Eq. (22) as

$$\theta_{ss} = g^{-1} \left(\frac{\Delta\omega_i - K_v v_{e0}}{KF(0)A} \right) \quad (23)$$

where v_{e0} denotes the external DC VCO control voltage and $F(0)$ is the DC gain of the loop filter.

If the phase error remains in the neighborhood of θ_{ss} , then $g(\Delta\theta_e) \approx dg(\theta_e)/d\theta_e|_{\theta_{ss}} \Delta\theta_e$, where $\Delta\theta_e = \theta_e - \theta_{ss}$. Let $K_g = dg(\theta_e)/d\theta_e|_{\theta_{ss}}$ be lumped with K_d . To show explicitly the dependence of APLL transfer functions on the amplitude of input signal, A is not lumped with K_d .

From Eq. (22) the linear loop equation for phase error is obtained as

$$\dot{\theta}_e = \theta_i - \frac{KF(p)}{p} \left(A\theta_e + \frac{n_g}{K_g} \right) - \frac{K_v}{p} v_e - \Psi_2 \quad (24)$$

where, in order to have a compact notation, $\theta_e(t)$ is not distinguished from its perturbation $\Delta\theta_e(t)$, and the new

value of loop gain is $K=K_gK_dK_v$. Note that K_g is measured in rad^{-1} and the new value of loop gain K is given in $(V \cdot s)^{-1}$. The output phase is obtained as

$$\theta_0 = \frac{KF(p)}{p} \left(A\theta_e + \frac{n_g}{K_g} \right) - \frac{K_v}{p} v_e - \Psi_2 \tag{25}$$

The linear baseband model is constructed from Eqs. (24) and (25). Although every built APLL is nonlinear, the linear model shown in Fig. 4 is valid in many applications, where after acquisition the APLL must operate in the linear region in order to avoid distortion.

2.4.2. Transfer Functions. The transfer function concept gives a simple tool to express the output signal(s) of a linear system in the complex frequency domain. Let the Laplace transform variable be denoted by s and let the Laplace transform of a signal be denoted by a capital letter.

In order to describe the behavior of APLL by means of transfer functions, Eq. (24) has to be rearranged as

$$\Theta_e(s) = [1 - H(s)] \left[\Theta_i(s) - \frac{K_v}{s} V_e(s) - \Psi_2(s) \right] - H(s) \frac{N_g(s)}{AK_g} \tag{26}$$

and substituting Eq. (11) into Eq. (25) the output phase has to be expressed as

$$\Theta_o(s) = H(s) \left[\Theta_i(s) + \frac{N_g(s)}{AK_g} \right] - [1 - H(s)] \left[\frac{K_v}{sV_e(s)} - \Psi_2(s) \right] \tag{27}$$

where $\Psi_2(s)$ denotes the Laplace transform of $\Psi_2(t)$.

Note that only two transfer functions are required to characterize the APLL completely, namely, the *closed-loop transfer function*

$$H(s) = \frac{AKF(s)}{s + AKF(s)} \tag{28}$$

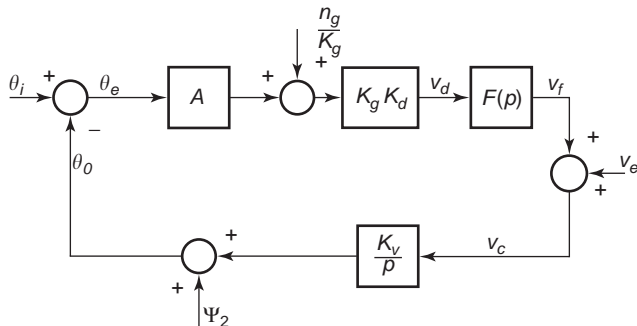

Figure 4. Linear baseband model of APLL.

and *error function*

$$1 - H(s) = \frac{s}{s + AKF(s)} \tag{29}$$

The closed-loop transfer and error functions have lowpass and highpass characteristics, respectively. The parameters of $H(s)$ and $[1 - H(s)]$ are determined by the loop filter $F(s)$, the loop gain K , and the RMS amplitude of the input signal. If $A(t)$ varies as a result of either amplitude modulation or a time-varying channel, then both $H(s)$ and $[1 - H(s)]$ also vary with time. In the majority of applications, this time dependence is not allowed; consequently, an AGC circuit preceding the APLL must be used in order to fix the amplitude of the input signal.

APLLs are classified according to the type and order of the loop. Let

$$G(s) = \frac{AKF(s)}{s} \tag{30}$$

denote the open-loop transfer function. The loop type is determined by the number of poles at the origin, that is, by the number of perfect integrators in $G(s)$, while the loop order is equal to the number of poles in $G(s)$.

The derivation of closed-loop APLL parameters is shown here to the two most important loop filter configurations. The closed-loop parameters for other loop filter configuration are given in Table 1.

First-Order, Type 1 Loop. In the simplest case $F(s) = 1$, that is, no loop filter is used. The first-order APLL is very rarely used in real applications but plays an important role in understanding the APLL operation. Substituting $F(s) = 1$ into Eqs. (28) and (29), the closed-loop transfer function

$$H(s) = \frac{1}{1 + \frac{s}{AK}} \tag{31}$$

and error function

$$1 - H(s) = \frac{\frac{s}{AK}}{1 + \frac{s}{AK}} \tag{32}$$

are obtained. The transfer function $H(s)$ has a lowpass characteristic with a well-defined 3 dB bandwidth, called the *closed-loop bandwidth*. Note that the closed-loop bandwidth $\omega_{3dB} = AK$ varies with the amplitude A of the input signal. The disadvantage of a first-order APLL is that only one free design parameter is available. The loop gain K determines all parameters of the APLL. For example, the quiescent phase error θ_{ss} given by Eq. (23) and the closed-loop bandwidth appearing in Eq. (31) may not be selected independently of each other; a small θ_{ss} results in a large closed-loop bandwidth. It is not possible to

Table 1. Parameters of Linearized APPLs (B_L Denotes APPL Noise Bandwidth)

Loop Order	Type	Loop Filter $F(s)$	Key Parameters	$H(s)$
First	1	1	$\omega_{3\text{ dB}} = AK$ $B_L = AK/4$	$\frac{4B_L}{s + 4B_L}$
Second	1	Passive lag filter $\frac{1}{1 + s\tau_1}$	$\omega_n^2 = AK/\tau_1$ $2\zeta\omega_n = 1/\tau_1$	$\frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$
		Passive lag-lead filter $\frac{1 + s\tau_2}{1 + s\tau_1}$	$B_L = AK/4$ $\omega_n^2 = AK/\tau_1$ $2\zeta\omega_n = \frac{1 + AK\tau_2}{\tau_1}$	$\frac{\left(2\frac{\zeta\omega_n - \omega_n^2}{AK}\right)s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$
Third	2	Active filter $\frac{1 + s\tau_2}{s\tau_1}$	$\omega_n^2 = AK/\tau_1$ $2\zeta\omega_n = \frac{AK\tau_2}{\tau_1}$	$\frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$
			$B_L = \frac{\omega_n}{2} \left[\zeta \left(1 - \frac{\omega_n}{2AK\zeta} \right)^2 + \frac{1}{4\zeta} \right]$ $B_L = \frac{\omega_n}{2} \left(\zeta + \frac{1}{4\zeta} \right)$	$B_L = \frac{5}{6} B_0$

implement simultaneously a small tracking error and a small closed-loop bandwidth.

Second-Order, Type 2 Loop. The circuit diagram of the most frequently used active loop filter is shown in Fig. 5. Because of the finite DC gain, the transfer function of the loop filter

$$F(s) = \frac{1 + s\tau_2}{s\tau_1} \quad (33)$$

may not be implemented, but is approximated closely by an operational amplifier. The time constants in Eq. (33) are $\tau_1 = R_1 C$ and $\tau_2 = (R_1 + R_2)C$. A loop implemented with an active loop filter is often referred to as an *ideal second-order APPL*. After substituting Eq. (33) into Eqs. (28) and (29), the closed-loop trans-

fer function

$$H(s) = \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (34)$$

and the error function

$$1 - H(s) = \frac{s^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (35)$$

are obtained, where the *natural frequency* ω_n and the *damping factor* ζ of loop are given by

$$\omega_n = \sqrt{\frac{AK}{\tau_1}} \quad \text{and} \quad \zeta = \frac{\tau_2\omega_n}{2} \quad (36)$$

The closed-loop bandwidth can be expressed as

$$\omega_{3\text{ dB}} = \omega_n \sqrt{2\zeta^2 + 1 + \sqrt{(2\zeta^2 + 1)^2 + 1}} \quad (37)$$

The magnitudes of the APPL frequency response and error response are plotted in Figs. 6 and 7, respectively, for several values of damping factor. Note that $H(s)$ and $[1 - H(s)]$ really have lowpass and highpass characteristics, respectively, as claimed.

The quiescent value of the phase error, the APPL transient behavior, and the closed-loop bandwidth are in the three basic APPL parameters that have to be selected in

Figure 5. Circuit diagram of the most widely used active loop filter.

Figure 6. Frequency response of APLL implemented with an active loop filter for several values of damping factor: (a) $\zeta = 0.3$; (b) $\zeta = 0.707$; (c) $\zeta = 1$; (d) $\zeta = 2$.

design of every APLL. The main advantage of the ideal second-order APLL is that these parameters may be chosen independently of each other:

- The high DC gain of the operational amplifier ensures that $\theta_{ss} \approx 0$; furthermore, θ_{ss} does not depend on A .
- Equation (37) shows that ω_n may be calculated from the required closed-loop bandwidth and damping factor. Then AK/τ_1 is calculated from ω_n using Eq. (36).
- The transient behavior of the loop is controlled by the damping factor. From Eq. (36), τ_2 may be calculated.

A further advantage of second-order loop is that it is unconditionally stable for all values of loop gain. However, note that all closed-loop parameters depend on the RMS amplitude of the input signal.

Other loop filters are also used in built APLL circuits. A short summary of loop parameters and closed-loop trans-

Figure 7. Error response of an ideal second-order APLL for various values of damping factor: (a) $\zeta = 0.3$; (b) $\zeta = 0.707$; (c) $\zeta = 1$; (d) $\zeta = 2$.

fer functions is given in Table 1 for different loop filter configurations.

2.4.3. Stability Considerations. So far, stability of the APLL has been assumed. A necessary and sufficient condition for stability is that all the poles of the closed-loop transfer function given by Eq. (28) lie in the left half-plane. As shown by Eq. (28), the positions of the poles vary as the loop gain is changed.

The poles of the first- and second-order APLLs always lie in the left half-plane; that is, these circuits are unconditionally stable. However, the third-order APLL may become unstable for low values of AK [10]. Because $A(t)$ is the RMS amplitude of the input signal, a third-order APLL may become unstable for weak signals, even if it is stable under normal operating conditions. The unconditional stability of the second-order APLL makes it popular in situations where the amplitude of the input signal is not constant.

A complete APLL analysis may be performed graphically by means of Bode plots [10]. Its features are as follows:

- All the important closed-loop parameters appear as distinctive points on the Bode plot.
- Loop stability and stability margin may be checked.
- Effect of variation in loop parameters such as loop gain, and pole and zero frequencies of loop filter on closed-loop APLL parameters may be tracked easily.

The Bode plot consists of a pair of graphs, where both the magnitude and phase of the open-loop transfer function are plotted. The frequency ω_B , where the open-loop gain becomes 0 dB, is a good approximation of the closed-loop bandwidth. The Bode criterion for stability is that the absolute value of the phase of $G(j\omega)$ at ω_B must be less than 180° , in case of the APLLs the typical phase shift is 135° that gives a phase margin of 45° .

The open-loop transfer function for the most commonly used second-order APLL implemented with the active loop filter is

$$G(s) = AK \frac{F(s)}{s} = AK \frac{1 + s\tau_2}{s^2\tau_1} \tag{38}$$

Figure 8 shows the Bode plot, where pole and zero frequencies and the most important closed-loop parameters are also indicated. Note that the absolute value of the phase shift never exceeds 180° ; that is, this loop is unconditionally stable. The Bode plot shows that the damping factor is controlled by the zero frequency of the loop filter. Placing the zero at the unity-gain point ω_B yields a damping factor $\zeta = 0.5$. The natural frequency ω_n is assigned by the frequency at which the extension of the -40 dB/decade line segment crosses the unity-gain ordinate.

Since

$$H(s) = \frac{G(s)}{1 + G(s)} \tag{39}$$

Figure 8. Bode plot of ideal second-order APLL.

the closed-loop transfer function may be also determined graphically from the Bode plot. For $\omega \ll \omega_n |G(s)| \gg 1$ and $H(s) = 1$, while for $\omega \gg \omega_n |G(s)| \ll 1$ and $H(s) = G(s)$.

The open-loop transfer function depends on the amplitude of incoming signal, as shown by Eq. (38). If A varies, then the Bode plot has to be shifted up or down along the vertical axis. In these cases both ω_n and ζ vary, but the second-order APLL remains stable for any amplitude of input signal.

2.4.4. Linear Tracking. The phase of input signal must be tracked with a small phase error. To evaluate the track-

ing properties of APLL, the phase error response to different input phases $\theta_i(t)$ has to be determined. Three cases are considered here:

1. Transient response to phase step, frequency step, and frequency ramp
2. Sinusoidal modulation
3. Modulation with an arbitrary stationary process

From Eq. (26) we obtain the phase error response to the input phase

$$\Theta_e(s) = [1 - H(s)]\Theta_i(s) = \frac{s}{s + AKF(s)}\Theta_i(s) \quad (40)$$

Recall that this linear approximation is valid for perturbations of variables about their quiescent values and requires $\theta_e(t)$ to remain small enough both during the transient and under steady-state conditions. For the sinusoidal PD and if $\theta_{ss} = 0$, the magnitude of phase error has to be less than 1 radian. Then the approximation $\sin \theta_e \approx \theta_e$ may be used.

The excitations described by *phase step*, *frequency step*, and *frequency ramp* are of the form

$$\theta_i(t) = \left(\Delta\theta_i + \Delta\omega_i t + \Delta\dot{\omega}_i \frac{t^2}{2} \right) u(t) \quad (41)$$

where $u(t)$ is the unit step function. The steady-state value of phase error may be expressed by means of the final value theorem of Laplace transform

$$\lim_{t \rightarrow \infty} \theta_e(t) = \lim_{s \rightarrow 0} s[1 - H(s)]\Theta_i(s) \quad (42)$$

The steady-state value of phase error for different loop filter configurations are summarized in Table 2. Note that the overall phase error is the sum of θ_{ss} and the phase error is given in Table 2.

A heuristic derivation of the steady-state phase response to a frequency step input helps to understand better the APLL operation. In steady-state, the input and VCO frequencies are equal. The control voltage needed to retune the VCO by $\Delta\omega_i$ is $\Delta\omega_i/K_v$. Since the DC gain of the loop filter is $F(0)$, the steady-state value of the PD output is $\Delta\omega_i/K_v F(0)$. The phase error required to produce this

Table 2. Steady-State Values of Phase Error Response to a Few Commonly Encountered Excitations

Loop			Steady-State Phase Error Response in radians to		
Order	Type	Loop Filter $F(s)$	Phase Step	Frequency Step	Frequency ramp
First	1	1	0	$\frac{\Delta\omega}{AK}$	∞
Second	1	$\frac{1+s\tau_2}{1+s\tau_1}$	0	$\frac{\Delta\omega}{AK}$	∞
		$\frac{1+s\tau_2}{s\tau_1}$	0	0	$\frac{\Delta\dot{\omega}}{\omega_n^2}$

output voltage is

$$\theta_e = \frac{\Delta\omega_i}{AK_d K_v F(0)} = \frac{\Delta\omega_i}{AKF(0)} \quad (43)$$

Table 2 shows the most important advantage of the ideal second-order APLL. In real applications, the frequency of the input signal always differs from the VCO center frequency. Even if an ideal integrator cannot be implemented, the high DC gain of the operational amplifier used in the active loop filter keeps the steady-state phase error extremely small, regardless of the magnitude of frequency error. Because of the *constant* and *almost zero* phase error,

- PD gain becomes constant and the closed-loop APLL parameters do not depend on the frequency error.
- $\sin \theta_e \approx \theta_e$, and the widest linear region of the analog multiplier can be exploited.

The error responses of APLL to different inputs may be calculated by taking the inverse Laplace transform of Eq. (40) or may be found in the literature. For a good survey, see Ref. 11, Table III, p. 19.

Next the error response to *angle-modulated inputs* is determined. For sinusoidal input phase modulation

$$\theta_i(t) = \Delta\theta \sin(\omega_m t) \quad (44)$$

where $\Delta\theta$ is the peak phase deviation and ω_m denotes the modulation frequency.

The steady-state phase error response may be calculated from Eq. (40) as

$$\theta_e(t) = |1 - H(\omega_m)| \Delta\theta \sin(\omega_m t + \Theta) \quad (45)$$

where the gain $|1 - H(\omega_m)|$ and phase shift Θ are given by

$$|1 - H(\omega_m)| e^{j\Theta} \equiv [1 - H(s)]_{s=j\omega_m} \quad (46)$$

For input frequency modulation

$$\theta_i(t) = \int_0^t \Delta\omega \sin(\omega_m \tau) d\tau = \frac{\Delta\omega}{\omega_m} \cos(\omega_m t) \quad (47)$$

where $\Delta\omega$ denotes the peak frequency deviation. The phase error is

$$\theta_e(t) = |1 - H(\omega_m)| \frac{\Delta\omega}{\omega_m} \cos(\omega_m t + \Theta) \quad (48)$$

where $|1 - H(\omega_m)|$ and Θ are given by Eq. (46).

The normalized error response to the input frequency modulation is shown in Fig. 9 for the first-order [where $F(s) = 1$] and ideal second-order loops. The high-frequency asymptote is the same for both loops, but the responses are completely different below ω_n , namely, the second-order APLL ensures a much smaller tracking error than the first-order loop. Recall that if the APLL is used to process

Figure 9. Phase error generated by sinusoidal FM in a (a) first-order and ideal second-order APLL for (b) $\zeta = 1$ and (c) $\zeta = 0.3$. The modulation frequency ω_m and the peak frequency deviation $\Delta\omega$ are normalized to AK in the first-order loop and to ω_n in the second-order loop. To make the figures comparable, $AK = \omega_n$.

angle-modulated signals, then a smaller phase error results in less distortion.

Inspection of Figs. 7 and 9 shows that the tracking error becomes very large at ω_n in the second-order loop for small damping factors. Recall that the linear approximation can be used only if the phase error remains small enough, even at ω_n .

It has been assumed above that the input angle modulation is produced by a single sinusoidal signal. In general, the modulating signal is a random process and all that may be known are its mean and covariance function. In this case the aim is to determine the power spectral density and variance of the phase error process caused by the input PM and FM.

Let the *input phase modulation process* $\theta_{i,PM}(t)$ be a wide-sense stationary process with zero mean and power spectral density $S_{i,PM}(\omega)$. As shown in Ref. 3, the power spectral density of the phase error process in steady-state may be expressed as

$$S_{e,PM}(\omega) = |1 - H(\omega)|^2 S_{i,PM}(\omega) \quad (49)$$

and its variance is

$$\sigma_{e,PM}^2 = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_{e,PM}(\omega) d\omega \quad (50)$$

The variance of $\theta_e(t)$ represents the mean-square value of the phase error process, which must be kept small for almost all t in order to make the linear model valid. If the input of the phase modulator generating $\theta_i(t)$ is a stationary random process of zero mean and power spectrum $S_m(\omega)$, then

$$S_{i,PM}(\omega) = K_{PM}^2 S_m(\omega) \quad (51)$$

where K_{PM} is the modulator gain. Substituting Eq. (51) into Eq. (49), the parameters of the phase error process may be expressed.

In the case of FM, the input phase modulation is

$$\theta_i(t) = K_{\text{FM}} \int_0^t m(\tau) d\tau \quad (52)$$

where K_{FM} denotes the modulator gain. Even if the modulating process $m(t)$ is stationary, its integral will not necessarily be, so that the relationship between the power spectral densities of the input frequency modulation process and the phase error process may not be expressed. However, Viterbi [3] has shown that the power spectrum of the phase error process may be obtained as

$$S_{e,\text{FM}}(\omega) = K_{\text{FM}}^2 \frac{|1 - H(\omega)|^2}{\omega^2} S_m(\omega) \quad (53)$$

where $S_m(\omega)$ is the power spectrum of $m(t)$. The variance of the phase error process is

$$\sigma_{e,\text{FM}}^2 = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_{e,\text{FM}}(\omega) d\omega \quad (54)$$

2.4.5. Noise Performance for High SNR. A narrowband additive input noise $n_i(t)$ can be modeled by an equivalent noise process $n_g(t)$ entering the baseband model after the PD nonlinearity $g(\cdot)$ as shown in Fig. 3. If an analog multiplier is used as the PD, then $n_g(t) = N(t, \theta_o)$. The statistical properties of $N(t, \theta_o)$ have been summarized earlier: if $n_i(t)$ has a symmetric power spectral density of $N_0/2$ and the bandwidth of $\theta_o(t)$ is much less than that of $n_i(t)$, then the equivalent noise $n_g(t)$ is a Gaussian process with uniform spectral density $N_0/2$. Furthermore, if the variance of phase error caused by noise and input angle modulation, if any, is sufficiently small, then the linear baseband model shown in Fig. 4 may be used to evaluate the noise performance of the APLL. Provided that the linear model is valid, the superposition theorem holds and the effect of noise and input angle modulation may be determined independently of each other.

The equivalent-noise process having a power spectral density $S_N(\omega) = N_0/2$ is stationary in the wide sense with zero mean. Let the point where $n_g(t)$ is applied to the loop be considered as input, and let $\theta_e(t)$ and $\theta_o(t)$ be considered as outputs. The magnitude of the two frequency responses is obtained as

$$\left| \frac{K_d K_v F(\omega)}{j\omega + AK_d K_v F(\omega)} \right| = \frac{|H(\omega)|}{A} \quad (55)$$

Consequently, the power spectral densities of the phase error $S_{e,N}(\omega)$ and the output phase $S_{o,N}(\omega)$ processes become

$$S_{e,N}(\omega) = S_{o,N}(\omega) = |H(\omega)|^2 \frac{N_0}{2A^2} \quad (56)$$

from which is obtained the variances of the phase error and the output phase

$$\sigma_{e,N}^2 = \sigma_{o,N}^2 = \frac{N_0}{2A^2} \frac{1}{2\pi} \int_{-\infty}^{\infty} |H(\omega)|^2 d\omega \quad (57)$$

Let the noise bandwidth B_L of the loop be defined as the bandwidth of an ideal lowpass filter, whose output variance is $\sigma_{e,N}^2$ when it is driven with Gaussian white noise of power spectral density $N_0/2A^2$:

$$B_L = \frac{1}{2\pi} \int_0^{\infty} |H(\omega)|^2 d\omega \quad (58)$$

Then Eq. (57) becomes

$$\sigma_{e,N}^2 = \sigma_{o,N}^2 = \frac{N_0 B_L}{A^2} \quad (59)$$

To suppress noise, B_L has to be chosen as small as possible. The noise bandwidths for the most important loop filter configurations are given in Table 1.

Noise bandwidth for the ideal second-order loop is plotted against damping in Ref. 9,10 (see Fig. 3.3 on p. 32). The minimum B_L is achieved for $\zeta = 0.5$, but the noise bandwidth does not exceed the minimum by more than 25% for any damping between 0.25 and 1.0.

Since the input additive noise and angle modulation are independent processes, the total variance of phase error is the sum of Eqs. (50) and (57) for PM and the sum of Eqs. (54) and (57) for FM. For PM

$$\sigma_e^2 = \sigma_{e,\text{PM}}^2 + \sigma_{e,N}^2 = \frac{1}{2\pi} \int_{-\infty}^{\infty} |1 - H(\omega)|^2 S_{i,\text{PM}}(\omega) d\omega + \frac{N_0 B_L}{A^2} \quad (60)$$

The linear approximation can be used only if the total variance of $\theta_e(t)$ is small enough. For the ideal second-order loop, σ_e^2 has to be less than 0.2 [10]. If, in addition to the input noise and angle-modulation, other random processes such as VCO noise or frequency modulation of the VCO output signal are present then the effects of these processes must also be accommodated in σ_e^2 by applying the technique described above.

Since there is no real signal in the baseband model of the APLL, an unambiguous definition of the signal-to-noise ratio (SNR) in the loop may not be given. The variance of the phase error is used by Viterbi [3] and Lindsey [6] to define the SNR in APLL:

$$\text{SNR}_L = \frac{A^2}{2B_L N_0} \quad (61)$$

2.5. Nonlinear Operation of the APLL

The linear theory of the APLL has been very well developed and is easy to use. In the majority of circuit design

and development, the linear APLL model is applied and the nonlinearity is considered only as an unwanted effect.

However, there are situations where the nonlinear APLL model has to be considered, for example, if the lock limits or acquisition properties have to be determined, if the APLL operates at low SNR, and so forth.

In contrast to the linear APLL theory, a unified theory describing the nonlinear operation of APLL in closed form does not exist. Many times heuristic arguments are used to solve a nonlinear problem. The details of nonlinear mathematical analysis are beyond the scope of this article. In this section only the most important aspects of nonlinear APLL theory will be discussed; the interested reader should refer to the literature for further details. The latest results on nonlinear analysis may be found in three IEEE publications [11–13], while the nonlinear APLL theory is given in many excellent books [3–10].

2.5.1. Nonlinear Tracking in the Absence of Noise. It is assumed in this subsection that the phase-locked condition has been achieved, but the frequency or phase of input signal is changed. First the hold-in range is determined; then the nonlinear transient response to a phase or/and frequency step is determined by means of the phase-plane portrait. Only the noise-free case is considered here.

The input frequency error was defined by Eq. (2) as $\Delta\omega_i = \omega_i - \omega_0$. The *hold-in range* is equal to the input frequency error, which can be tracked by the APLL, that is, for which the phase-locked condition is maintained. Mathematically the hold-in range is equal to the maximum frequency error for which Eq. (15) has a steady-state solution

$$\sin \theta_e = \frac{\Delta\omega_i - K_v v_{e0}}{AKF(0)} = \frac{\Lambda_0}{AKF(0)} \tag{62}$$

where v_{e0} is a DC voltage, $\Lambda_0 = \Delta\omega_i - K_v v_{e0}$ denotes the initial equivalent frequency detuning, and $F(0)$ is the DC gain of loop filter. Because the sine function cannot exceed unit magnitude, the hold-in range is

$$|\Delta\omega_H - K_v v_{e0}| = AKF(0) \tag{63}$$

The physical meaning of “hold-in range” is that the PD output voltage is bounded and so the maximum VCO frequency detuning is also bounded.

Equation (63) states that the holdin range can be made arbitrarily large by using very high loop gain K . Of course, this is not entirely correct because some other loop component will then saturate before the phase detector. In the ideal second-order loops, generally saturation of the loop amplifier limits the hold-in range. Note that the hold-in range is a *static parameter*; that is, its value does not depend on the order of APLL.

Consider next the nonlinear tracking properties, that is, the *dynamics* of a first-order APLL in the absence of noise. Substituting $F(p) = 1$, $N(t, \theta_o) = \Psi_2 = 0$ and $d\theta_i/dt = \Delta\omega_i$ into Eq. (15), a nonlinear differential equation is

obtained:

$$\frac{d\theta_e}{dt} = \Delta\omega_i - K_v v_{e0} - AK \sin \theta_e = \Lambda_0 - AK \sin \theta_e \tag{64}$$

Solution of this autonomous nonlinear differential equation gives the transient response of APLL.

Assume that the APLL is operating in steady-state when the input phase is suddenly changed. To get the nonlinear transient response to the input phase step $\theta_{i01}(t)$, Eq. (64) must be solved. The initial value θ_{e0} of phase error depends on the phase error measured under the previous steady-state conditions and θ_{i0} .

The APLL dynamics may be determined graphically in the phase plane shown in Fig. 10 for the first-order APLL, where the *frequency error* $\hat{\theta}_e = d\theta_e/dt$ is plotted as a function of θ_e . A plot of a single solution in the phase plane is called a *trajectory*. The trajectory starts from the initial value θ_{e0} of the phase error and goes to its steady-state value for which $d\theta_e/dt = 0$. An ensemble of trajectories emerging from different initial conditions is known as *phase-plane portrait* or *flow*. A trajectory shows the dynamics of a loop against time as it settles (or fails to settle) toward an equilibrium.

As shown in Fig. 10, all trajectories of a first-order APLL coincide with each other. Let the trajectory start from an initial phase error θ_{e0} . If $d\theta_e/dt$ is positive for that value of θ_{e0} , then the phase error increases as a function of time. In fact, the APLL follows the trajectory plotted in Fig. 10 and moves toward the right until it reaches the steady-state for which $d\theta_e/dt = 0$. Similarly, if $d\theta_e/dt$ is negative for θ_{e0} , then the phase error decreases until it reaches the steady-state conditions. A point belonging to steady-state is stable, if after a small perturbation of θ_e in either direction, the system tends to return to the steady-state. The stability of steady-state phase errors is also shown in Fig. 10.

Since almost all phase detectors have a periodic characteristic, they cannot distinguish a phase step of $\Delta\theta_i + 2\pi n$, $n = 1, 2, 3 \dots$ from one of $\Delta\theta_i$. Therefore, the APLL never loses lock when it is driven by a pure phase step, irrespective of the magnitude of the loop order.

Figure 10. Phase-plane portrait for first order APLL, where the stability of steady-state phase errors θ_{ss} is also shown.

In the first-order APLL, a frequency step breaks the lock if, and only if, the frequency error exceeds the holdin limit. In this case, the phase-locked condition cannot be recovered and the APLL remains unlocked.

To obtain the phase-plane trajectories for the ideal second-order APLL, first the time variable has to be eliminated in Eq. (15). Substitution of $F(p) = (p\tau_2 + 1)/p\tau_1$ and

$$\theta_i(t) = \Delta\omega_i t + \theta_i$$

into Eq. (15) gives

$$\frac{d^2\theta_e}{dt^2} + \left(AK \frac{\tau_2}{\tau_1} \cos \theta_e \right) \frac{d\theta_e}{dt} + \frac{AK}{\tau_1} \sin \theta_e = 0 \quad (65)$$

Letting $t = \tau/[AK(\tau_2/\tau_1)]$ so that $(d\theta_e/dt) = AK(\tau_2/\tau_1)(d\theta_e/d\tau)$, and taking into account that $AK(\tau_2/\tau_1) \neq 0$, Eq. (65) may be rewritten as

$$\frac{d^2\theta_e}{d\tau^2} + \cos \theta_e \frac{d\theta_e}{d\tau} + \frac{\tau_1}{AK\tau_2^2} \sin \theta_e = 0 \quad (66)$$

Dividing Eq. (66) by $\dot{\theta}_e = d\theta_e/d\tau$ and recognizing that $(d^2\theta_e/d\tau^2) = (d^2\dot{\theta}_e/d\tau)$, the first term in Eq. (66) becomes $\dot{\theta}_e/d\theta_e = (d\dot{\theta}_e/d\tau)/(\dot{\theta}_e/d\tau) = d\dot{\theta}_e/d\theta_e$. Eliminating τ in Eq. (66), the phase error θ_e and the normalized frequency error $\dot{\theta}_e$ may be treated as independent variables:

$$\frac{d\dot{\theta}_e}{d\theta_e} = -\cos \theta_e - \frac{\tau_1}{AK\tau_2^2} \frac{\sin \theta_e}{\dot{\theta}_e} \quad (67)$$

To get the phase-plane portrait, the solution of Eq. (67) must be determined for different initial conditions. The phase-plane trajectories for an ideal second-order APLL are shown in Fig. 11.

The phase-plane portrait of an APLL with periodic phase detector characteristic is also periodic with the same period in variable θ_e , but is aperiodic in $\dot{\theta}_e$. Trajec-

Figure 11. Phase-plane trajectories of the ideal second-order APLL for $\zeta = 0.707$.

tories proceed as a function of time clockwise only as marked by arrows in Fig. 11. Intersection of trajectories may occur only at *singular points*, which assign the possible steady-state solutions of loop equation. Both stable and unstable singular points appear; equilibrium occurs at stable singularities. In a second-order APLL, an equilibrium is called a *stable node* or *stable focus* if the loop is overdamped ($\zeta > 1$) or underdamped ($\zeta < 1$), respectively. The steady-state phase-locked conditions which are reached asymptotically are called *equilibria*.

The unstable singularity is called a *saddle point*. Even if the loop state gets just into a saddle point, where it is in equilibrium, it cannot remain there, because any disturbance, such as noise, will displace it slightly and then the saddle point repels the loop state.

A trajectory that terminates on a saddle point is called *separatrix*.

Consider a stable singular point and the two separatrices that terminate on the two adjacent saddle points. If the initial conditions lie between these separatrices and the initial phase error is in the 2π interval centered about the stable equilibria to be achieved, then the trajectories emerging from these initial conditions will terminate at that equilibrium point without cycle slip. If the initial conditions lie outside these separatrices, then the loop slips one or more complete cycles before achieving the phase-locked condition.

We are now ready to evaluate the nonlinear transient graphically for a second-order APLL. First, the initial conditions have to be determined from the input phase and frequency steps, and the previous steady-state conditions. Then the initial conditions have to be plotted on the phase-plane portrait, and the trajectory emerging from them gives the actual transient response of APLL.

The phase-plane portrait is a very useful tool for the determination of APLL dynamics. Phase-plane portraits for other loop configurations can be found in Refs. 3 and 6.

2.5.2. Acquisition Behavior in the Absence of Noise.

Before a PLL can track, it must first acquire the phase-locked condition. In general, the PLL quiescent frequency differs from the frequency of the incoming signal. Therefore, first the VCO frequency has to be tuned to the incoming frequency by the loop. This process is called *frequency pull-in*. Then the VCO phase has to be adjusted according to the input phase. This process is known as *phase lock-in*.

The two parts of acquisition process may be identified by checking the cycle slips between the input and VCO phases. During phase lock-in, cycle slips do not occur.

Acquisition is inherently a highly nonlinear phenomenon. It starts from given initial conditions (initial phase and frequency errors), and no external excitation is applied. This means that acquisition may be described by an autonomous nonlinear differential equation and it may be studied by the phase-plane portrait introduced in the previous subsection.

If the loop acquires lock by itself, the process is called *self-acquisition*. If it is assisted by extra circuits, it is called *aided acquisition*. Since self-acquisition is relatively

slow and unreliable, acquisition-aids are often used. For a good survey of different aided acquisition techniques, see Ref. 10.

The acquisition behavior of a first-order APLL is modeled by Eq. (64). Under steady-state conditions $d\theta_e/dt = 0$ and the phase error becomes

$$\theta_{ss} = \sin^{-1}\left(\frac{\Lambda_0}{AK}\right) \pm 2n\pi, \quad n = 0, 1, 2, \dots$$

$$\hat{\theta}_{ss} = -\sin^{-1}\left(\frac{\Lambda_0}{AK}\right) + (1 \pm 2n)\pi, \quad n = 0, 1, 2, \dots$$
(68)

provided $|\Lambda_0| \leq AK$. Figure 10 shows that the equilibrium points denoted by θ_{ss} and $\hat{\theta}_{ss}$ are stable and unstable, respectively. If the phase error is equal to $\hat{\theta}_{ss}$, then any perturbation in either direction, caused by noise, for example, will cause θ_e to move until it reaches the next stable equilibrium. If $|\Lambda_0| > AK$, no stable equilibrium exists and the loop never reaches the phase-locked condition, but $\theta_e(t)$ moves along a sinusoidal trajectory.

Figure 10 and Eq. (68) show that an infinitely large number of equilibrium points exist. Since every cycle of the trajectory has a stable equilibrium, $\theta_e(t)$ cannot change by more than one cycle before phase-locking. Thus the pull-in and lock-in ranges are equal; consequently, cycle slipping never occurs during acquisition in the first-order loop.

The phase transients of the first-order APLL during acquisition are shown in Fig. 12 for different values of the initial phase error θ_{i0} . Note that for small θ_{i0} , the loop operation remains near the equilibrium and the phase transient is almost exponential, as expected from the linear theory of the APLL. However, if $\theta_{i0} > 135^\circ$, the waveforms diverge considerably from exponential and the acquisition time becomes very long. The acquisition parameters of the first-order loop are given in Table 3.

The first-order loop always achieves the phase-locked condition without cycle slips. The same is not valid for the second- and higher-order loops; for these, the lock-in range is smaller than the pull-in range.

Figure 12. Acquisition behavior of first-order APLL. The frequency detuning $\Lambda_0 = 0$ and the initial values of phase error θ_{i0} are (a) 45° , (b) 135° , (c) 170° , (d) 178.86° , and (e) 179.886° .

Table 3. Acquisition parameters of First- and Second-Order APPLs

Loop Order	Loop Filter $F(s)$	Pull-in Range (rad/s)	Pull-in Time (s)
First	1	AK	$\frac{8}{AK}$
Second	$\frac{1+s\tau_2}{1+s\tau_1}$	$2\sqrt{AK\zeta\omega_n}$	$\frac{\Lambda_0^2}{2\zeta\omega_n^3}$
	$\frac{1+s\tau_2}{s\tau_1}$	∞	$\frac{\Lambda_0^2}{2\zeta\omega_n^3}$

The acquisition behavior of ideal second-order APLL is described by Eq. (67). The trajectories and steady-state phase error ($\theta_{ss} = \pm 2\pi n, n = 0, 1, 2, \dots$) may be determined from the phase-plane portrait shown in Fig. 11.

Gardner has proposed a simple method to estimate the lock-in range of higher order PLLs [10]. Let $F(\infty)$ denote the high-frequency asymptotic gain of loop filter, for a second-order loop $F(\infty) = \tau_2/\tau_1$. If the deviation of the input frequency from the VCO center frequency is greater than $1/\tau_2$, then the second-order loop behaves like a first-order one, with loop gain $K = K_d K_v F(\infty)$. As a useful engineering approximation, the lock-in range of higher-order loops is approximated by the lock-in range of the first-order one with equivalent gain $F(\infty)$. If $v_{e0} = 0$, then

$$\omega_L \approx \pm AKF(\infty)$$
(69)

The frequency pull-in, or simply pull-in, is much slower than the lock-in process. The acquisition problem cannot be solved in closed form; some approximation must be used. Richman has developed a model [16] for the analysis of the pull-in process.

Consider an ideal second-order APLL. The loop filter can be divided into two parallel paths

$$F(s) = \frac{1+s\tau_2}{s\tau_1} = \frac{1}{s\tau_1} + \frac{\tau_2}{\tau_1}$$
(70)

as shown in Fig. 13. Note that there is a high-frequency AC path from the PD output to the VCO input with flat gain of τ_2/τ_1 and a DC path that contains a perfect integrator.

The pull-in process may be understood easily by plotting the relevant spectra in the loop. Initially, the input

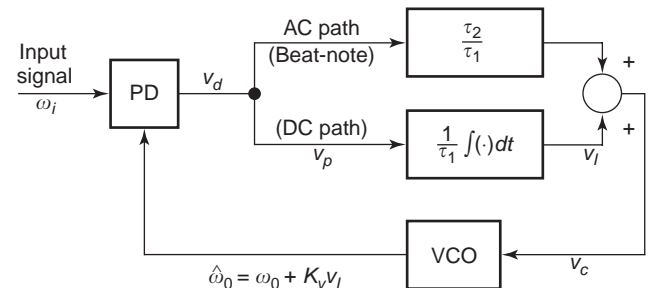

Figure 13. Pullin model for the ideal second-order APLL.

Figure 14. Pullin spectra. The instantaneous center VCO frequency is denoted by $\hat{\omega}_0$.

and VCO frequencies are ω_i and $\hat{\omega}_0$, respectively, as shown by the upper two traces of Fig. 14. Let $\hat{\omega}_0(t)$ denote the instantaneous VCO frequency, which is a slowly varying function, and which is determined by the integrator output v_1 . The frequency difference $\Delta\omega = \hat{\omega}_0 - \omega_i$ is called the *beatnote*.

The analog multiplier used as phase detector generates the beatnote, which gets through the AC path and modulates the VCO, generating FM sidebands as shown in the lower trace of Fig. 14. Observe that the FM sideband ($\hat{\omega}_0 - \Delta\omega$) coincides with ω_i and produces a negative DC voltage at the PD output denoted by v_p in Fig. 13. This DC voltage is integrated by the DC path and the slowly varying output $v_1(t)$ of integrator pushes $\hat{\omega}_0$ toward ω_i . The pull-in process is terminated when $\hat{\omega}_0 = \omega_i$.

Many approximate formulas for pull-in limits and pull-in time have been developed by different authors for various loop configuration. For a good survey, see Sect. 5.3 of Ref. 10. Formulas giving the acquisition parameters of first- and second-order loops are given in Table 3.

2.5.3. Hangup Phenomenon. APLLs occasionally have extremely long acquisition time that cannot be tolerated in many applications. In these cases, the loop seems to stick for a long time at a certain value of phase error before moving toward the phase-locked condition. This phenomena is known as the *hangup effect* [17].

Due to the periodicity of PD characteristic, the loop equation has two steady-state solutions in every period. The locations of steady-state solutions have been called the *normal equilibrium null* (stable steady-state) and *reverse null* (unstable steady-state) by Gardner [10].

Consider an APLL implemented with an analog multiplier and assume that $\Lambda_0 = 0$, that is, that the steady-state

phase error is zero. The phase trajectories originating near 180° remain in that vicinity for a long time before decaying toward equilibrium at 0° .

Figure 12 shows the hangup phenomenon for a first-order APLL. It must be emphasized that the hangup effect appears in every APLL, independently of the loop order.

It is obvious from Fig. 13 that the rate of VCO control voltage is proportional to the DC output v_p of the phase detector. The slowly varying v_p may be considered as a restoring force. If v_p is very small, as occurs near the reverse null, the restoring force is also small and the loop converges extremely slowly toward the phase-locked condition.

2.5.4. False Lock to Data Sidebands. The recovery of suppressed carriers is also performed by PLLs. The most commonly used circuit configurations will be discussed later. Since the carrier is completely suppressed in these systems, the carrier recovery circuit must regenerate a harmonic of the carrier (squaring loop) or, equivalently, must generate a phantom carrier (Costas loop). In both solutions, the loop operation may be modeled by a nonlinear operation followed by a CW tracking loop.

In addition to the regenerated signal, discrete frequency components spaced by integer multiples of half the symbol rate also appear about the desired frequency because of the nonlinear operation [18,19]. If the quiescent frequency of the VCO is close enough to one of these sidebands, then the loop will lock onto that spectral component instead of the desired frequency. This phenomenon is called *false lock to data sidebands*. The probability of false lock is especially high when the SNR_L is high.

2.5.5. APLL Behavior in the Presence of Noise. When a built APLL is tested in the presence of noise and the SNR_L is reduced below ~ 7 dB, the fluctuation in phase error, called “phase jitter”, becomes greater than predicted from Eq. (60). In this section, the behavior of the APLL for low SNR_L when the linear approximation is no longer applicable is briefly discussed and the most important conclusions for circuit designers are drawn¹.

We have seen that PLLs have an infinitely large number of stable equilibrium points. At low SNR_L , the phase error migrates among the different stable equilibrium points; that is, the *probability density function* (pdf) of θ_e appears as a multimodal function with each mode centered about a stable equilibrium point. Consequently, the phase error process is nonstationary and the pdf of phase error has an unbounded variance. Unfortunately, the phase error process cannot be treated mathematically.

The migration among different equilibrium points causes cycle slipping in the built APLL, which is not allowed in many applications such as coherent communication.

Tikhonov [20,21] and Viterbi [22] have shown that the phase error process reduced by modulo- 2π is stationary

¹The loop operation can be described in the presence of noise by a nonlinear stochastic differential equation [see Eq. (15)]. An exact nonlinear theory for APLL may be developed by means of Fokker-Planck theory [6]. The solution of the Fokker-Planck equation gives the pdf for the *reduced phase error process* in closed form.

Figure 15. Probability density functions of reduced phase error for a first-order APLL with zero detuning. The curves are given for SNR_L values of (a) 0 dB, (b) 5 dB, and (c) 10 dB.

and possesses a bounded variance. The APLL behavior for low SNR_L may be analyzed by considering the cycle slipping as an independent problem and by calculating the pdf of reduced phase error process.

The reduced phase error process has a Tikhonov pdf as shown in Fig. 15 for the first-order APLL [3]. Lindsey has shown in [6] that pdf of reduced phase error process of higher-order loops may also be approximated by the Tikhonov distribution. For a comparison of measured and calculated distributions, refer to Ref. 7.

Cycle slips in the carrier recovery circuit are very important since they destroy the performance of digital telecommunication systems. Cycle slips may occur either in isolated form or in bursts [23].

Consider a first-order APLL with zero detuning. Using the Fokker–Plank technique, Lindsey [6] has shown that the mean time between cycle slips is

$$\tau = \frac{\pi^2 \alpha I_0(\alpha)}{2B_L} \quad (71)$$

where $\alpha = 4A/(N_0K)$ and $I_0(x)$ denotes the zeroth-order modified Bessel function. Observe that τ is inversely proportional to the noise bandwidth of the APLL; that is, for efficient carrier recovery a narrowband loop must be used.

Equation (71) can approximate the mean time between cycle slips in higher-order APLLs if the parameter α is modified appropriately [6]. A better theory, giving more accurate results, has been published in Ref. 24; for measured data, refer to Ref. 23.

3. PLL APPLICATIONS

The PLL is one of the most commonly used circuits in electrical engineering. This section discusses the most important PLL applications and gives guidelines for the de-

sign of these circuits. A detailed discussion of different applications is beyond the scope of this article; for a comprehensive survey, see Refs. 11 and 14.

The baseband model of the analog phase-locked loop and its linear theory were discussed in the previous sections. In all PLL applications, the phase-locked condition must be achieved and maintained. In order to avoid distortion, many applications require operation in the linear region; that is, the total variance of the phase error process resulting from noise and modulation must be kept small enough. If the PLL operates in the linear region then the linearized baseband model may be used in circuit design and development.

Recall that only the PD output, VCO control voltage, input phase $\theta_i(t)$, and output phase $\theta_o(t)$ appear in the PLL baseband model. All these signals are low-frequency signals. The RF input and output signals may be expressed from $\theta_i(t)$ [see Eqs. (1) and (2)] and $\theta_o(t)$ [see Eqs. (8) and (9)], respectively.

Amplitude-modulated (AM) signals may not be generated or processed by PLLs; even more, the PLL may be used to reject input AM.

In order to achieve the best circuit performance, different phase detectors are used in the different applications, and many of them are edge-triggered. A PLL may contain other edge-triggered circuits, such as a frequency divider, for example. The operation of PLLs including edge-triggered circuits may not be described exactly by the simple APLL model. However, Gardner has shown that the APLL theory may be used as a good approximation of the real operation if the closed-loop bandwidth is less than one-tenth of the input frequency [25].

Sampling involved in edge-triggered operation and non-linearity always increase the noise level. Consequently, if the input SNR is low, then an analog multiplier has to be used as PD to get the best noise performance.

In addition to the conventional applications, new applications for the various PLLs have been published. It has been shown that both the analog [26] and sampling [27] PLLs may exhibit chaotic behavior. Bernstein and Lieberman have proposed the application of an ideal sampling PLL for random number generation [28]. The quality of generated random numbers has been evaluated by the run test in Ref. 29.

3.1. Tracking Bandpass Filter for Angle-Modulated Signals

Because of their temperature dependence, narrowband bandpass filters cannot be implemented by conventional analog filters. In other applications, the carrier frequency of angle-modulated signals to be selected varies. These problems may be overcome if a PLL tracking the carrier is used as a bandpass filter. The PLL separates the spectrum of the angle-modulated signal from other interfering signals, or limits the transmitted spectrum to within specified bounds. The relationship between the input and output phase modulation is determined by the closed-loop transfer function

$$\Theta_o(s) = H(s)\Theta_i(s) \quad (72)$$

Figure 16. PLL configuration for bandpass tracking filter and CW carrier recovery. The AGC circuit is used to keep the input amplitude, that is, the loop parameters, constant.

The filter characteristic is determined by the closed-loop transfer function. A further advantage of the PLL bandpass tracking filter is that it rejects the amplitude modulation; that is, it may also be used as a limiter.

The block diagram of a bandpass tracking filter is shown in Fig. 16. If the loop parameters depend on the amplitude of the input signal, an AGC (automatic gain control) circuit must precede the PD in order to keep the filter parameters constant. Note that the problems of and the difficulties associated with the design and implementation of a high-frequency bandpass filter are reduced to the design and implementation of a baseband loop filter. The design of PLL bandpass filters is discussed in detail in Ref. 30.

3.2. CW Carrier Recovery

In every coherent receiver, the carrier has to be recovered from the noisy input signal [15]. Here, it is assumed that the carrier is present all the time in the received spectrum; the recovery of a suppressed carrier will be considered later. The aim of CW carrier recovery is to retrieve the carrier and to suppress as much noise, modulation, and interference as possible. The CW carrier recovery circuit is a narrowband bandpass tracking filter implemented by a PLL as shown in Fig. 16.

The noise-free recovery of a carrier in a noisy environment requires a very narrowband PLL [see Eq. (59)]. As shown in Table 3, the acquisition properties of narrowband PLLs are very poor. This problem may be eliminated by using two different loop bandwidths: a wide one during acquisition and a narrow one in steady-state, after the phase-locked condition has been achieved [10].

The Doppler effect must also be considered in many carrier recovery circuits. The ideal second-order PLL may track a frequency ramp, but the reduction of tracking error requires a wide loop bandwidth (see Table 2). Unfortunately, the noise-rejection performance of a PLL is inversely proportional to the loop bandwidth. For low SNR, this contradiction may be solved by using third- or higher-order loop configurations [31].

3.3. PLL Frequency Divider and Multiplier

The PLL may be used as a frequency divider if a frequency multiplier is placed into the feedback path as shown in Fig. 17, where M denotes the frequency multiplier ratio.

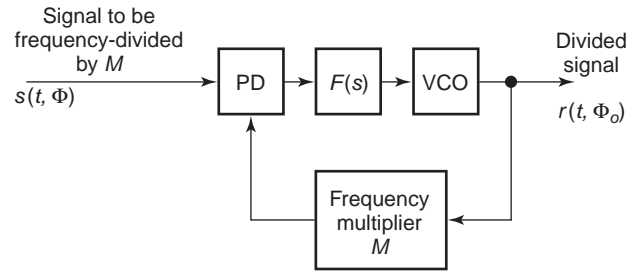

Figure 17. Block diagram of a PLL frequency divider.

Let ω_i denote the frequency of input signal $s(t, \Phi)$. Under phase-locked conditions the PLL divides the input frequency by M :

$$r(t, \Phi_o) = \sqrt{2} V_o \cos \Phi_o = \sqrt{2} V_o \cos\left(\frac{\omega_i}{M} t + \theta_o\right)$$

When the carrier frequency of an angle modulated signal is divided, its modulation frequency f_m does not change, but its phase/frequency deviation is divided by M :

$$\Theta_o(s) = \frac{1}{M} H(s) \Theta_i(s)$$

The closed-loop transfer function $H(s)$ is given by Eq. (28), but the frequency multiplier in the feedback path increases the loop gain:

$$K = MK_g K_d K_v$$

The PLL may be used as a frequency multiplier if, instead of the multiplier, a frequency divider with division ratio of N is placed into the feedback path in Fig. 17. Again, the modulation frequency of an angle modulated signal does not change, but the carrier frequency and the phase/frequency deviation is multiplied by N :

$$\Theta_o(s) = NH(s) \Theta_i(s)$$

where the loop gain is

$$K = \frac{K_g K_d K_v}{N}$$

3.4. PLL Amplifier for Angle-Modulated Signals

The high-gain amplifiers operating in the extremely high-frequency bands are very expensive. The PLL may be used for amplification of angle-modulated signals, the signal to be amplified is applied to the PLL input and the VCO output is the amplified signal. The gain is determined by the ratio of VCO output and PLL input powers. Note that the amplification is performed in the baseband. In addition to amplification, the PLL also operates as a limiter and filter for the incoming angle-modulated signals.

Figure 18. Amplification of angle-modulated high-frequency signals by PLL.

Sometimes it is cheaper to implement the VCO and power amplifier below the input frequency band, as shown in Fig. 18. Due to the frequency multiplier placed in the feedback path, the VCO output frequency is f_i/M , where f_i is the input frequency. The input phase/frequency deviation is also divided by M ; however, the modulating frequency remains unchanged. The frequency multiplier following the power amplifier restores the original carrier frequency and its phase/frequency deviation.

3.5. Frequency Synthesis and Angle Modulation by PLL

Signals with high-frequency stability and high spectral purity are often required in electrical engineering. In many applications, the frequency of generated signal must be varied by a digital code.

The PLL is widely used in frequency synthesis to generate spectrally pure signals and, if necessary, to operate as an analog or digital frequency or phase modulator. Frequency multiplication or division and frequency addition or subtraction may be performed using a PLL in conjunction with programmable frequency dividers and mixers as shown in Fig. 19. As a result, the output frequency f_o depends on the reference f_R and offset f_S frequencies, and moreover, on the division ratios of frequency dividers. In frequency synthesis, the PLL input is called *reference signal* and its frequency is denoted by f_R . To optimize the system performance, a multiloop circuit configuration [32] is frequently used.

In frequency synthesis, the dominant noise sources are the VCO, frequency dividers, mixers, and phase detectors. The main design goals are to minimize the output phase noise, to avoid the generation of spurious output signals, and to minimize the unwanted output FM caused by the periodic output of the phase detector. These requirements

can be satisfied with special PD configurations, such as a sample-and-hold phase detector or a phase-frequency detector with a charge-pump circuit. The operation of these edge-triggered PDs will be discussed later.

Many system-level aspects must be considered during the development of frequency synthesizers, a detailed discussion of these questions may be found in Refs. 32–35.

In addition to frequency synthesis, PLLs may be also used as an FM or PM modulator. The corresponding transfer functions for FM and PM are

$$s\Theta_o(s) = [1 - H(s)]K_v V_{FM}(s) \tag{73}$$

$$\Theta_o(s) = H(s) \frac{N}{AK} V_{PM}(s)$$

where K_v and $N/(AK)$ are the gains of the FM and PM modulators, respectively. The closed-loop error $[1 - H(s)]$ and transfer $H(s)$ functions are given by Eqs. (29) and (28), respectively. The only difference is that the frequency synthesizer has a frequency divider in the feedback path; consequently, the loop gain becomes

$$K = \frac{K_g K_d K_v}{N} \tag{74}$$

3.6. Coherent Demodulation by APLL

The noise performance of coherent demodulators is better than that of their noncoherent counterparts [15]. A circuit configuration that is suitable for coherent PM, FM, and AM demodulation is shown in Fig. 20.

3.6.1. PM Demodulator. Assume first that the input signal $s(t, \Phi)$ is phase-modulated and $a(t) = A = \text{constant}$. The demodulated PM signal appears at the output of the phase detector

$$V_d(s) = [1 - H(s)]AK_d \Theta_i(s) \tag{75}$$

where $\Theta_i(s)$ denotes the input PM and AK_d is the gain of the PM demodulator. The demodulated PM signal is multiplied by the closed-loop error function, which has a high-pass characteristic. Distortion is avoided if the closed-loop

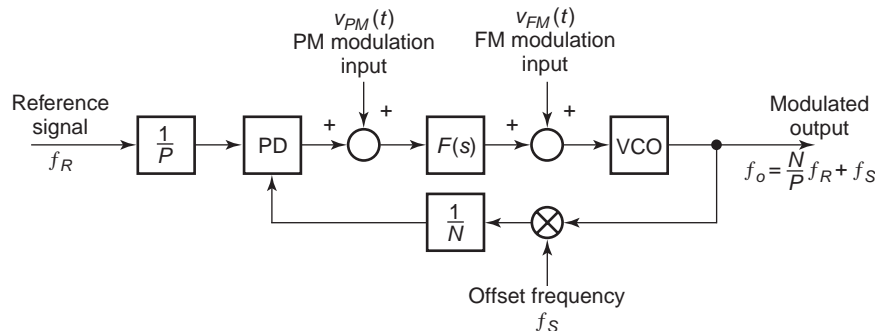

Figure 19. Frequency synthesis by phase lock.

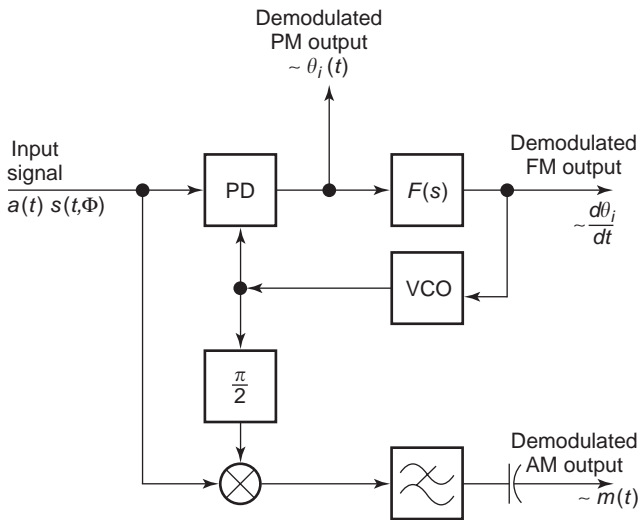

Figure 20. Coherent PM, FM, and AM demodulation by APLL.

bandwidth is less than the lowest modulation frequency. The other source of distortion is the PD nonlinearity. This type of distortion does not appear if the total variance of the phase error given by Eq. (60) remains small enough.

3.6.2. FM Demodulator. Assume that a frequency-modulated input signal is applied to the PLL input. Due to the phase-locked condition, the VCO frequency follows the incoming frequency. Since the instantaneous VCO frequency is proportional to the VCO control voltage, the FM modulation may be recovered from the VCO control voltage. By means of the transfer function concept, the demodulated signal is obtained

$$V_c(s) = H(s) \frac{1}{K_v} s \Theta_i(s) \quad (76)$$

where $1/K_v$ is the gain of the FM demodulator. This equation shows that the FM demodulator output, that is, the VCO control voltage, is proportional to the input FM if the closed-loop bandwidth exceeds the highest modulation frequency.

The distortion caused by the PD nonlinearity is reduced by feedback; consequently, the PD distortion is not critical. However, the VCO transfer function must be linear in order to get an FM demodulator with low distortion.

3.6.3. AM Demodulator. Let the input signal be amplitude-modulated

$$x(t) = [1 + m(t)] \sqrt{2} A \sin(\omega_c t + \theta_{i0}) \quad (77)$$

where $m(t)$ carries the information, and A , ω_c , and θ_{i0} are constants. The PLL demodulator contains a carrier recovery circuit (see the PLL in Fig. 20) and an AM demodulator (see the analog multiplier and lowpass filter in Fig. 20). Since the PLL needs an input signal to be tracked

continuously, the spectrum of the AM signal must contain a carrier component.

The carrier is recovered by the PLL, its VCO output is

$$r(t, \hat{\Phi}) = \sqrt{2} V_o \cos(\omega_c t + \theta_{i0}) \quad (78)$$

This signal is multiplied by the AM input signal. The lowpass filter selects the difference-frequency output of multiplier and the DC blocking capacitor removes its DC component. The demodulated signal is obtained as

$$AV_o m(t) \quad (79)$$

where AV_o is the gain of the AM demodulator.

3.7. Suppressed Carrier Recovery Circuits

In digital telecommunications, the optimum detection of transmitted data requires that both carrier and clock signals be available at the receiver [15]. The carrier and clock recovery circuits are used to retrieve these signals from the noisy digitally modulated received waveform.

In order to maximize the power efficiency, modern digital modulation techniques suppress the carrier completely; consequently, all transmitted energy resides in the data sidebands. Narrowband PLLs cannot be used for carrier recovery, because the carrier frequency is missing from the input spectrum.

The missing carrier can be regenerated by nonlinear circuits called *regenerators*. The regenerator may be placed before the narrowband PLL as an entirely separate circuit, or it may be included in the loop. Examples for the first and second solutions are the squaring and Costas loops, respectively.

Many factors have to be considered during the selection and development of a suppressed carrier recovery circuit [36]. Here, only the basic operating principles of these circuits are surveyed. Interested readers should refer to the literature [7,10,36–39].

For the sake of simplicity, only *binary phase shift keying* (BPSK) modulation is considered here. In BPSK, the binary information to be transmitted is mapped to the phase of a sinusoidal carrier. If the data bit is a “1,” the phase of the carrier is zero; while if the data bit is a “0,” the carrier phase becomes -180° . If the probabilities of “1”s and “0”s are equal, then the carrier is completely suppressed. In the noise-free case, the received signal may be expressed in the form

$$v_i(t) = m(t) \sin(\omega_c t + \theta_i) \quad (80)$$

where ω_c is the carrier frequency and the carrier phase θ_i is arbitrary but constant. The binary datastream is given by $m(t) = \pm 1$. Three basic types of carrier recovery circuits are discussed in the next subsection: the *squaring loop*, the *Costas loop* and the *inverse modulator*.

3.7.1. Squaring Loop. In this case, the nonlinear operation is performed by a square-law device, that is, a frequency doubler circuit. As shown in Fig. 21, the nonlinear operation precedes the narrowband APLL. From Eq. (80)

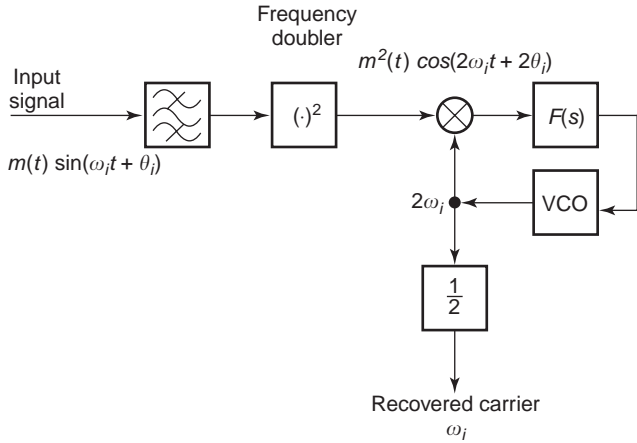

Figure 21. Suppressed carrier recovery by squaring loop.

the output of frequency doubler circuit is obtained:

$$v_x(t) = v_i^2(t) = \frac{1}{2} m^2(t) [1 - \cos(2\omega_i t + 2\theta_i)] \tag{81}$$

Since $m(t) = \pm 1$, then $m^2(t) = 1$ and

$$v_x(t) \sim \cos(2\omega_i t + 2\theta_i) \tag{82}$$

Equation (82) shows that, after the frequency doubler, a conventional narrowband PLL can be used to recover the second harmonic of the carrier. Finally, the double-frequency output of the PLL is frequency divided by 2, in order to recover the original carrier.

3.7.2. Costas Loop. In the squaring loop the nonlinear operation is performed in the RF band. The Costas loop offers an alternative solution, where the BPSK modulation is removed in the baseband.

The block diagram of Costas loop is shown in Fig. 22. The circuit contains *in-phase* (I-arm) and *quadrature* (Q-arm) channels and an analog multiplier, that is, a phase detector that precedes the loop filter. The I and Q arms consist of an analog multiplier and a lowpass filter.

To understand the operation of the Costas loop, assume that the phase-locked condition has been achieved and

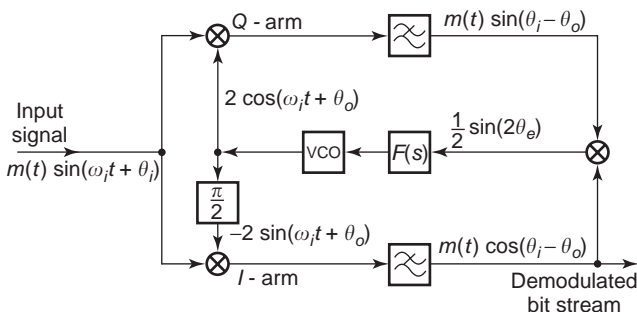

Figure 22. Demodulation of BPSK signal by a Costas loop.

that the VCO output is

$$2 \cos(\omega_i t + \theta_o) \tag{83}$$

The outputs of lowpass filters in the Q and I arms are $m(t) \sin(\theta_i - \theta_o)$ and $m(t) \cos(\theta_i - \theta_o)$, respectively. Taking into account that $m^2(t) = 1$, the output of the baseband multiplier is obtained as

$$\frac{1}{2} m^2(t) \sin[2(\theta_i - \theta_o)] = \frac{1}{2} \sin(2\theta_e) \tag{84}$$

By comparing Eqs. (10) and (84) we conclude that, except for a constant multiplier, the output of the baseband multiplier in a Costas loop is equal to the PD output of a conventional APLL in the noise-free case. Consequently, the Costas loop behaves like an APLL.

In addition to carrier recovery, the Costas loop demodulates the incoming BPSK signal. If the phase error is small, then the output of the lowpass filter in the I arm becomes

$$m(t) \cos(\theta_i - \theta_o) \approx m(t) \tag{85}$$

3.7.3. Inverse Modulator. Two slightly different versions of the inverse modulator or remodulator may be found in the literature [10]. The terms inverse modulator and remodulator are used interchangeably and indiscriminantly. As an example, the operation of an inverse modulator is discussed here.

The block diagram of an inverse modulator contains demodulator and modulator circuits, as shown in Fig. 23. Assume that the PLL involved has achieved the phase-locked condition and that the VCO output is

$$2 \cos(\omega_i t + \theta_o) \tag{86}$$

Then the output of the demodulator is obtained as

$$m(t - t_d) \cos(\theta_i - \theta_o) \tag{87}$$

where $(\theta_i - \theta_o)$ is the phase error of the PLL and t_d denotes the time delay of the lowpass filter involved in the demodulator. This demodulated signal modulates the recovered carrier in the modulator and produces an output

$$2m(t - t_d) \cos(\theta_i - \theta_o) \cos(\omega_i t + \theta_o) \tag{88}$$

which is multiplied in the phase detector by the delayed input signal $m(t - t_d) \sin(\omega_i t + \theta_i)$. The input signal has to be delayed in order to cancel the effect of delay in the demodulator.

Neglecting the sum frequency component, the PD output is obtained:

$$m^2(t - t_d) \cos(\theta_i - \theta_o) \sin(\theta_i - \theta_o) \approx \sin(2\theta_e) \tag{89}$$

As in Eq. (84), this signal can be considered as the PD output of an equivalent PLL. Observe that if the phase

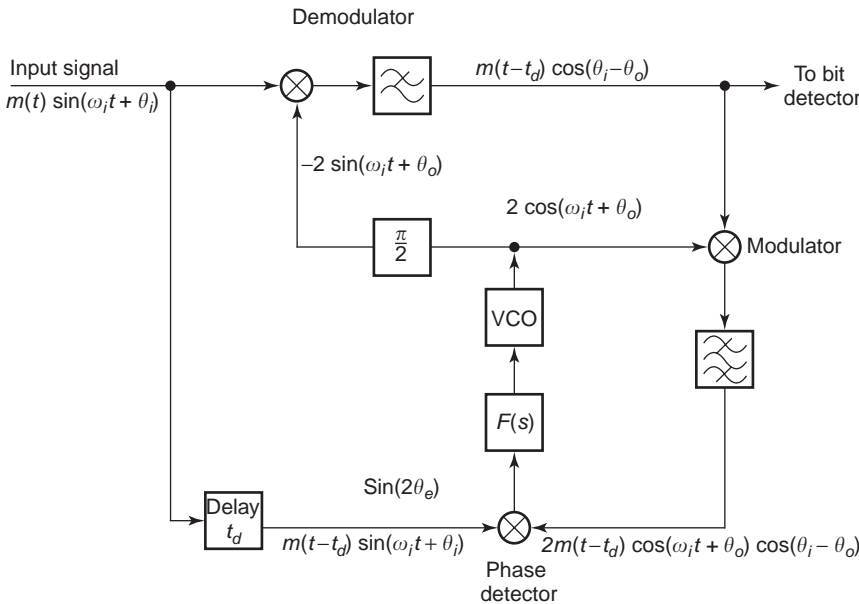

Figure 23. Block diagram of an inverse modulator.

error is small enough, then the demodulator output is equal to $m(t - t_d)$.

3.8. Clock Recovery Circuit

The timing information, that is, the clock signal, also has to be recovered in a digital telecommunication system [7,36]. There are two basic classes of clock recovery circuits, but a PLL can be recognized behind both solutions.

The clock frequency component is regenerated from the incoming signal via some nonlinear operation in the first class of clock recovery circuits. These approaches offer the simplest solution, but their performance is only suboptimal. These solutions are analogous to the squaring loop used in suppressed carrier recovery. Examples for these circuits are the cross-symbol synchronizer [40] and the squaring loop symbol synchronizer [41].

The other class of clock recovery circuits is based on *maximum a posteriori estimation* (MAP) techniques [7,42]. Many variants of this technique are currently

used; they differ mainly in the phase detector (also called *clock error detector*) characteristics. The operation of the early-late gate clock recovery circuit [43], as an example, is discussed here.

The block diagram of the early-late gate clock recovery circuit is shown in Fig. 24. The circuit contains a pair of gated integrators called *early* and *late* gates, each performing its integration over a time interval of $T/2$. The input bitstream is

$$\sum_n a_n p(t - nT) \tag{90}$$

where T is the symbol duration and $p(t)$ denotes a rectangular pulsewidth duration T . Integration by the early and late gates are performed during the $T/2$, just before and after, respectively, the estimated location of data transition. Gate intervals adjoin each other, but do not overlap.

Waveforms are shown in Fig. 25 to clarify the operation of the clock recovery circuit. If the timing error is zero,

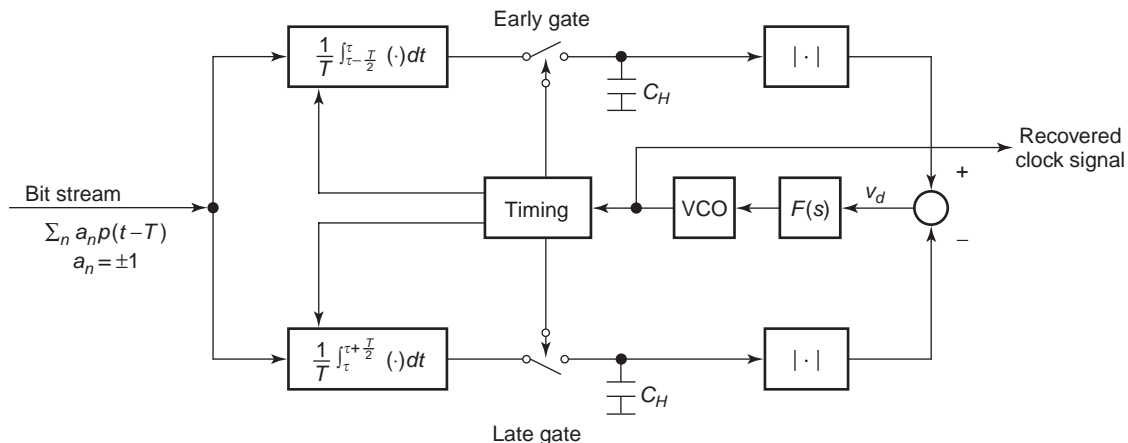

Figure 24. Block diagram of the early-late gate clock recovery circuit.

Figure 25. Typical waveforms in the early-late gate clock recovery circuit.

then the data transition falls just on the boundary between the operation of the early and late gates. In this case, the estimated and incoming data transitions coincide with each other, and the output of the two integrators, stored in the hold capacitors C_H , are equal. As a result, the error voltage $v_d(t)$ becomes zero.

Because the error voltage is produced from the absolute values of the integrator outputs, it is also zero if the data transition is missing.

If a transition of input data does not coincide with the estimated time instant of a transition, then a timing error denoted by τ in Fig. 25 appears. In this case, the data transition does not fall on the boundary of operation of the early and late gates, but occurs within the operation interval of one of gates as shown in Fig. 25. Since the input signal changes its polarity during the gate operation, the associated integration reaches a magnitude smaller than that for the other gate, where a transition does not occur. Comparing the magnitudes of the two integrators gives the error voltage $v_d(t)$, which is used after lowpass filtering to control the VCO frequency.

4. FREQUENCY SYNTHESIS BY PHASE LOCK

In addition to the desired DC voltage, a periodic signal appears at the output of phase detectors in steady-state. This periodic signal is attenuated, but cannot be completely suppressed by the lowpass filter included in the phase detector, and the loop filter. The periodic signal getting through the loop filter to the VCO input causes unwanted frequency modulation of the output signal; that is, sidebands appear around the generated signal.

A frequency synthesizer has to generate a signal with very high spectral purity; consequently, both phase noise and unwanted sidebands must be extremely low. The unwanted output FM, or sidebands, caused by the periodic PD output may not be reduced by the feedback since the digital frequency divider used in the feedback path eliminates this FM under steady-state conditions [35]. More exactly, due to the edge-triggered operation of frequency dividers, feedback does not exist for the output FM if the modulation frequency is equal to lf_R , where $l = 1, 2, 3, \dots$ and f_R denotes the reference frequency.

The sampling and charge-pump PLLs offer the best system performance in frequency synthesis. A sample-

and-hold-type phase detector is used in the sampling, as well as a phase-frequency detector with charge-pump circuit in the charge-pump PLLs. These are edge-triggered circuits, where the information is transmitted only at discrete-time instants.

Another source of discrete-time operation is the edge-triggered digital frequency dividers.

If a PLL contains edge-triggered circuit(s), then its mathematical model becomes an integrodifferential equation. These loops are called “hybrid PLLs” in the literature. Unfortunately, the integrodifferential equations may be solved only very rarely in closed form. This is why the analysis of these mixed-signal circuits is a very difficult problem.

In the development of sampling and charge-pump PLLs, intuitive extension of APLL theory, which may be used if the closed-loop bandwidth of PLL is less than one-tenth of reference frequency, and heuristic considerations are frequently used. However, these approximations obscure the special benefits and problems arising from the mixed-signal operation.

4.1. Sampling Phase-Locked Loop

The sampling phase-locked loop (SPLL) is used mainly in frequency synthesis [33–35]. The unique feature of the SPLL is that the sample-and-hold phase detector produces a pure DC output in steady-state [35]. The only source of a periodic signal at the PD output is the feedthrough of the digital signal, which controls the sampling switch. SPLL frequency synthesizer offers the following features:

- The loop filter may be omitted; consequently, a very short frequency switching time can be achieved.
- The unwanted output FM, that is, the sidebands, are extremely low.

4.1.1. Sample-and-Hold Phase Detector. The sample-and-hold PD shown in Fig. 26 is an edge-triggered circuit, that is, a sequential phase detector. Let f_R denote the frequency of the reference signal. The first stock generates block generates the sampled signal $v_R(t)$, which is synchronized with the reference signal. The sampled signal may have any shape; assume that it is a sawtooth waveform in our case. Since the PD is edge-triggered, this sawtooth waveform converts the time interval elapsed between the transitions of the reference and sampling signals into a voltage. The sampling switch is driven by the feedback signal, that is, by the divided VCO output. The switch is closed at the sampling time instants $t_k, k = 0, 1, 2, \dots$ and

Figure 26. Simplified circuit diagram of sample-and-hold phase detector.

Figure 27. Waveforms in the sample-and-hold phase detector, $T_R = 1/f_R$.

the voltage of the hold capacitor C_H becomes equal to the instantaneous value of the sampled signal. Note that the voltage $v_d(t)$ of the hold capacitor, which is the PD output, is linearly proportional to the time elapsed between transitions of the reference and sampling signals, that is, to the phase error. The capacitor C_H holds this voltage until the next sampling time instant.

The sampling switch may be implemented by an integrated CMOS or discrete FET switch. In both cases, the switch has a series resistance modeled by R_S in Fig. 26. Due to R_S , a finite sampling time is required to charge up or discharge the hold capacitor. The sampling switch is closed at the sampling time instant t_k and remains closed during the sampling time t_S .

The sampled signal $v_R(t)$ and PD output $v_d(t)$ are plotted by solid and dashed lines, respectively, in Fig. 27. When the sampling switch is closed, the PD output voltage $v_d(t)$ varies exponentially from its previous value to the new one. The time constant $R_S C_H$ of the sampling switch has to be much less than the sampling time t_S . Note that the sampled signal is kept constant during the finite sampling time t_S . This must be done in order to avoid the appearance of a periodic signal at the PD output in steady-state.

Figure 28 shows the waveforms of sample-and-hold phase detector in steady-state. Since the sampled signal (solid line) is kept constant during the finite sampling time, the PD output (dashed line) becomes a pure DC voltage under phase-locked conditions.

Figure 28. Steady-state waveforms in the sample-and-hold phase detector. [Note: If the sampled signal $v_R(t)$ (solid line) is kept constant during t_S , then the PD output $v_d(t)$ (dashed line) becomes a pure DC voltage.]

More details on the sample-and-hold phase detector and its design are given in Refs. 34 and 35.

4.1.2. SPLL Loop Equation. A block diagram of the SPLL is shown in Fig. 29. The sinusoidal reference signal $s(t)$ corrupted by noise $n_i(t)$ synchronizes a sawtooth waveform in the phase detector. The sampled signal $v_R(t)$ is kept constant during the finite sampling time t_S , as shown in Fig. 27. The PD output $v_d(t)$ is an *analog signal* that is processed by an analog loop filter $F(s)$. The instantaneous VCO frequency is controlled by $v_c(t)$ and is divided by a frequency divider; the division ratio is N . The sampling time instants t_k are determined by the frequency divider output.

The waveforms of sample-and-hold PD are shown in Fig. 27. Let x_k denote the value of the sampled signal at t_k and assume that $R_S C_H \ll t_S$. When the sampling switch is closed, the PD output voltage $v_d(t)$ changes from x_{k-1} to x_k . In the time interval $[t_k + t_S, t_{k+1})$ the sampling switch is open, that is, $v_d(t) = x_k$.

Due to sampling, subharmonic locking is also possible in the SPLL. In subharmonic locking, one sample is taken every M th reference period; that is, in steady-state the output frequency becomes

$$f_o = \frac{N}{M} f_R$$

To derive the governing equation, first the sampling time instants have to be expressed as a function of VCO

Figure 29. Block diagram of SPLL. A frequency divider with a division ratio of N is placed in the feedback path to control the output frequency.

output phase. Let $T_{k+1} = t_{k+1} - t_k$ denote the time elapsed between two adjacent sampling time instants. Due to the edge-triggered operation of frequency divider, the phase of VCO signal increases by $2\pi N$ radians between two adjacent sampling time instants. If $t_0 = 0$, then the time instant of the k th sampling may be expressed by means of the steady-state output frequency as

$$\frac{N}{M} \omega_R t_k + \theta_{ok} = 2\pi N k \tag{91}$$

where $\theta_{ok} = \theta_o(t)|_{t=t_k} = \theta_o(t_k)$ is the phase modulation of the VCO output at t_k . The sampling time instants are obtained from Eq. (91)

$$t_k = \left(k - \frac{\theta_{ok}}{2\pi N} \right) M T_R, \quad k = 1, 2, 3, \dots \tag{92}$$

Next the synchronization of the sampled signal with the reference signal has to be modeled. Let ω_R , φ_{R0} , and $\hat{\theta}_R(t)$ denote the frequency, phase, and phase modulation, respectively, of the reference signal:

$$s(t) = \sqrt{2} V_R \sin[\omega_R t + \varphi_{R0} + \hat{\theta}_R(t)] \tag{93}$$

The synchronization of the sampled signal is edge-triggered; that is, a new voltage ramp is started at each positive zero crossing of the noisy reference signal. Because the signal-to-noise ratio is extremely high at the PD input, false triggering does not occur and the synchronization process may be described by

$$s(t_n) + n_i(t_n) = 0 \quad \text{and} \quad \left. \frac{ds(t)}{dt} \right|_{t=t_n} > 0 \tag{94}$$

where $t_n, n = 0, 1, 2, \dots$ denotes the starting time instants of voltage ramps. To get t_n , Eq. (94) has to be solved. In the general case, this synchronization and the sampling at t_k are independent of each other. This means that the value of the sampled signal at t_k depends on two variables, n and k , where n describes the synchronization, while k appears as a result of sampling. A governing equation in closed form can be developed only if a relationship between k and n is found.

It has been shown [44] that if cycle slipping does not occur, then $n = Mk$, and the independent variable n may be eliminated from the equations. Henceforth, we assume that cycle slipping does not occur in the SPLL.

Knowing t_n , we may express the sampled signal as

$$v_R(t) = \sum_{n=0}^{\infty} \hat{g}(t - t_n) \tag{95}$$

where the nonlinear periodic function $\hat{g}(\cdot)$ describes the shape of the sampled signal.

The time instants t_n are influenced by both the additive noise $n_i(t)$ and the phase modulation $\hat{\theta}_R(t)$ of the reference signal. Both effects may be incorporated in the equivalent input phase modulation [44] if the signal-to-noise ratio is high at the PD input and if the phase deviation of $\hat{\theta}_R(t)$ is

small:

$$\begin{aligned} \theta_{Rk} &= \varphi_{R0} + \hat{\theta}_R \left(k M T_R - \frac{\varphi_{R0}}{\omega_R} \right) \\ &+ \frac{1}{\sqrt{2} V_R} n_i \left(k M T_R - \frac{\varphi_{R0}}{\omega_R} \right) \end{aligned} \tag{96}$$

Then, by linearizing Eq. (94), the starting time instants of the voltage ramps may be expressed as

$$t_n = M k T_R - \frac{\varphi_{Rk}}{\omega_R} \tag{97}$$

Let the phase error θ_{ek} be defined according to conventional PLL terminology

$$\theta_{ek} = \theta_{Rk} - \frac{M}{N} \theta_{ok} \tag{98}$$

By substituting Eqs. (92) and (97) into Eq. (95), the sampled signal is obtained at the k th sampling time instant:

$$x_k = v_R(t_k) = \hat{g}(t_k - t_n) = g(\theta_{ek}) \tag{99}$$

Finally, using Eqs. (91) and (98) and the definition of T_{k+1} , the phase error is obtained as

$$\theta_{ek} = \theta_{Rk} - \omega_R \frac{z^{-1}}{1 - z^{-1}} (M T_R - T_{k+1}) \tag{100}$$

Equation (100) is the governing equation of the SPLL. Its main advantage is that it contains only those variables that are well known from the PLL baseband models [14]. However, the baseband model can be determined only if T_{k+1} is found in closed form.

According to Fig. 27, the time interval T_{k+1} may be divided into two distinct periods; from t_k to $(t_k + t_S)$ the sampling switch is closed, while from $(t_k + t_S)$ to t_{k+1} the switch is open. This means that the topology of the SPLL is changed at t_k and at $(t_k + t_S)$; consequently, the SPLL is a time-varying circuit. A time-varying circuit may be analyzed by the event-driven approach, where the next sampling time instant t_{k+1} is predicted from the state of the SPLL measured at t_k .

Since the VCO output is a sinusoidal signal and the frequency divider is edge-triggered, the variation in the VCO phase is $2\pi N$ between t_k and t_{k+1} . Let ω_0 denote the VCO center frequency. The variation in the VCO phase between t_k and t_{k+1} is

$$\begin{aligned} \int_{t_k}^{t_{k+1}} [\omega_0 + K_v v_c(t)] dt &= \omega_0 T_{k+1} \\ &+ K_v \left[\int_{t_k}^{t_k + t_S} v_c(t) dt + \int_{t_k + t_S}^{t_{k+1}} v_c(t) dt \right] \equiv 2\pi N \end{aligned} \tag{101}$$

Calculation of the $(k + 1)$ th sampling time instant requires the solution of this integro-difference equation.

In general, Eq. (101) cannot be solved in closed form. The solution is available only if Eq. (101) is separated into

a pure difference and a pure differential equation. This separation may be done in the following cases [44]

- If the dominant time constant of the open-loop transfer function is much less than t_S .
- If the dominant time constant of the open-loop transfer function is much greater than T_k .
- If the SPLL remains in the neighborhood of its quiescent point during the operation.

Fortunately, at least one of these conditions is almost always valid in practical situations.

For the sake of simplicity, only the SPLL implemented without loop filter is considered in this article. For more complex SPLL configurations (passive lag-lead filter, double sampling SPLL), refer to Ref. 44.

When the loop filter is omitted, $F(s) = A_0$ and the dominant time constant is $R_S C_H$, which is much less than t_S . The time elapsed between two adjacent sampling time instants is obtained as follows:

$$T_{k+1} = \frac{2\pi N + A_0 K_v (x_k - x_{k-1}) R_S C_H}{\omega_0 + A_0 K_v x_k} \quad (102)$$

4.1.3. Nonlinear Baseband Model. The SPLL outputs are analog signals. Equations (100) and (99) give the signals at the sampling time instants only, the analog signals have to be expressed in terms of x_k . Inspection of Fig. 27 shows that the PD output voltage $v_d(t)$ may be generated from x_k by means of a zero-order hold circuit followed by an RC lowpass filter. Note that the sampling is not uniform in the SPLL; consequently, the hold time of zero-order hold circuit varies during the operation.

The discrete part of the nonlinear baseband model is constructed from Eqs. (100) and (99) as shown in Fig. 30.

To get the signals in the continuous-time domain, the discrete-time signal x_k has to be converted to an analog signal by a zero-order hold circuit. The time constant of sample-and-hold circuit is accounted by a lowpass filter (see R_S and C_H in Fig. 30) and the analog PD output $v_d(t)$ appears at the output of this lowpass filter. The time interval T_{k+1} may be calculated from Eq. (102) if the loop filter is omitted. Recall that expressions for T_{k+1} are given in Ref. 44 for other loop configurations.

Recall that θ_{Rk} is the equivalent input phase modulation in Fig. 30, which, according to Eq. (96), incorporates both the phase modulation $\hat{\theta}_R(t)$ of reference signal and additive input noise $n_i(t)$. The phase modulated reference signal was given by Eq. (93).

Because of the systematic application of conventional PLL terminology, the nonlinear baseband model of SPLL shown in Fig. 30 is very similar to the baseband models that have been developed for analog and digital PLLs in the literature. The most important properties of the SPLL baseband model are

- Due to the edge-triggered operation of sample-and-hold PD and frequency divider, the feedback operates in the discrete-time domain.
- The signals measured in a built SPLL are analog signals; consequently, each signal is expressed in the continuous-time domain.

4.1.4. Linear SPLL Theory. To get the linear SPLL baseband model, first the quiescent value of phase error has to be determined. In phase-locked condition $T_{k+1} = MT_R$, and the phase error is obtained from Eqs. (102) and (99) as

$$\theta_{ss} = g^{-1} \left[\frac{1}{A_0 K_v} \left(\frac{N}{M} \omega_R - \omega_0 \right) \right]$$

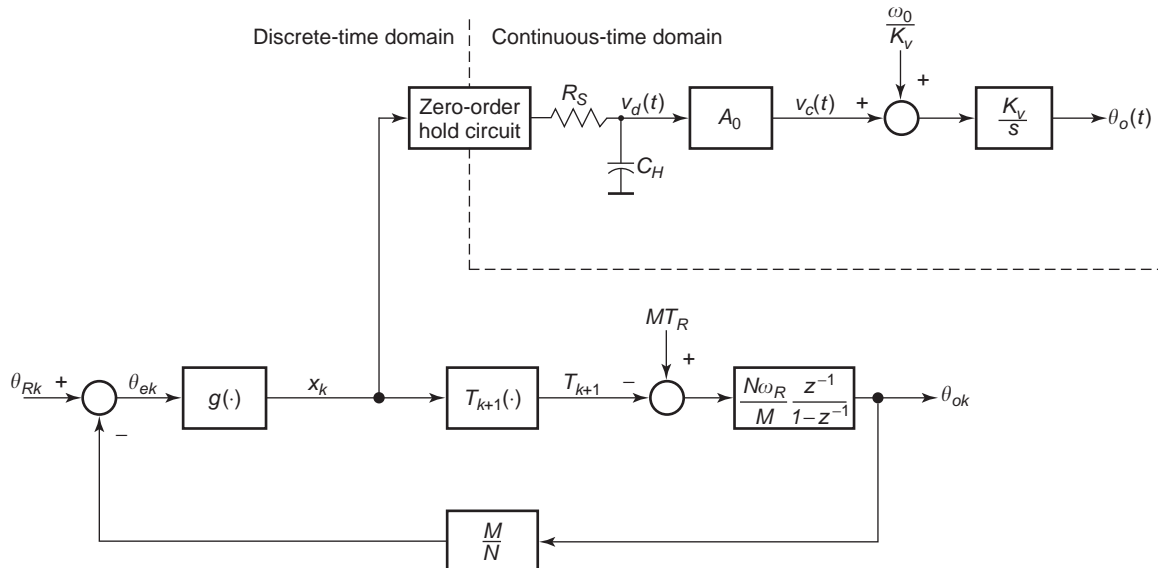

Figure 30. Nonlinear baseband model of SPLL for $F(s) = A_0$. The dashed line separates the discrete- and continuous-time domains.

One of the most important design parameters of an SPLLL is the loop gain that appears in many design equations. In the case of the SPLLL, it is defined by the following equation:

$$G_0 = \left. \frac{dg(\theta_e)}{d\theta_e} \right|_{\theta_e = \theta_{ss}} \frac{A_0 K_v}{N f_R} \tag{103}$$

The SPLLL implemented without a loop filter is stable [44] if

$$M^2 G_0 < \frac{2}{1 - 2B_1} \tag{104}$$

where

$$B_1 = \frac{R_S C_H}{M T_R}$$

If the phase error remains in the neighborhood of θ_{ss} , then the nonlinear baseband model may be linearized. For the sake of simplicity, assume that $\varphi_{R0} = 0$ in Eq. (96). Then

$$\begin{aligned} \theta_{Rk} &= \hat{\theta}_R(kMT_R) + \frac{1}{\sqrt{2}V_R} n_{ik}(kMT_R) \\ &= \hat{\theta}_{Rk} + \frac{1}{\sqrt{2}V_R} n_{ik} \end{aligned} \tag{105}$$

From Eq. (105) and Fig. 30, the linear SPLLL baseband model may be constructed as shown in Fig. 31. In the figure

$$G(z) = \frac{(1 - B_1)z + B_1}{z}$$

is the transfer function of sample-and-hold phase detector and

$$K_v M T_R \frac{z^{-1}}{1 - z^{-1}}$$

gives the VCO transfer function in the discrete-time domain. To have compact notations in Fig. 31 and in the linear SPLLL analysis, the variables are not distinguished from their perturbations. Note that besides the equivalent input phase modulation θ_{Rk} , both the phase modulation $\hat{\theta}_{Rk} = \hat{\theta}_R(kMT_R)$ of the reference signal and noise $n_{ik} = n_i(kMT_R)$ corrupting the reference signal are shown explicitly in the linear SPLLL baseband model.

The SPLLL transfer functions are derived from the linear baseband model. The equations shown here are valid for the SPLLL built without a loop filter; for more complex SPLLL configurations, refer to Ref. 44.

Similar to the APLL theory, the output phase modulation of SPLLL at the sampling time instants may be expressed as

$$\Theta_o(z) = H(z)\hat{\Theta}_R(z)$$

where $H(z)$ is the closed-loop transfer function, $\hat{\Theta}_R(z)$ and $\Theta_o(z)$ denote the z-transform of input $\hat{\theta}_{Rk}$ and output θ_{ok} , respectively, phase modulation. Since the SPLLL is a feedback system, its closed-loop transfer function is obtained by applying the rules of block diagram algebra to Fig. 31:

$$H(z) = \frac{N}{M} M^2 G_0 \frac{(1 - B_1)z + B_1}{z^2 - [1 - M^2 G_0(1 - B_1)]z + M^2 G_0 B_1} \tag{106}$$

In many applications, the output phase modulation must also be expressed in the continuous-time domain. Transforming x_k from the discrete- to the continuous-time

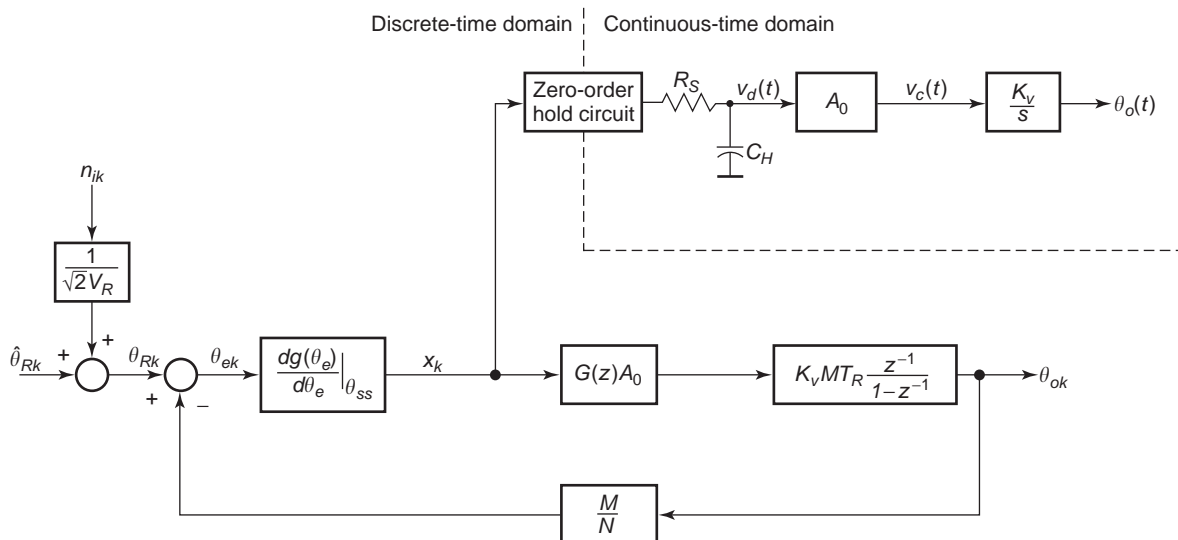

Figure 31. Linear baseband model of SPLLL for $F(s) = A_0$.

domain by a zero-order hold circuit as shown in Fig. 31, and taking into account the effect of the phase detector, loop-amplifier, and VCO, the Fourier transform of the output phase modulation is obtained [45] as

$$\Theta_o(\omega) = \left[1 - \frac{M}{N} H(z) \Big|_{z=e^{j\omega MT_R}} \right] A(\omega) \sum_{n=-\infty}^{\infty} \hat{\Theta}_R \left(\omega - n \frac{\omega_R}{M} \right) \quad (107)$$

where $A(\omega)$ gives the relationship between x_k and the Fourier transform of the output phase modulation

$$A(\omega) = \frac{N}{M} \frac{M^2 G_0}{j\omega MT_R} \frac{\sin\left(\frac{\omega MT_R}{2}\right)}{\frac{\omega MT_R}{2}} \frac{1}{1 + j\omega R_S C_H} e^{-j(\omega MT_R/2)} \quad (108)$$

Assume that the SPLL reference signal is an angle-modulated signal where the modulation frequency is low. Since in Eq. (107)

$$\lim_{\omega \rightarrow 0} \left[1 - \frac{M}{N} H(z) \Big|_{z=e^{j\omega MT_R}} \right] A(\omega) = \frac{N}{M} \quad (109)$$

the SPLL multiplies the input phase/frequency deviation by N/M , but leaves the modulation frequency ω unchanged. Recall that this effect was also observed in the APLL frequency multiplier.

A harmful consequence of edge-triggered PD operation is that the output phase noise is increased by overlapping. To examine this effect, assume that the noisy reference signal is bandlimited by an ideal lowpass filter with cutoff frequency of

$$\omega_L = \left(L + \frac{1}{2} \right) \frac{f_R}{M}$$

where L is an arbitrary integer. This filter passes the reference signal without any distortion but limits the bandwidth of additive Gaussian white noise $n_i(t)$ characterized by its power spectral density $N_0/2$. The power spectral density of output phase process is obtained from Eq. (107):

$$S_{\Theta_o, N}(\omega) = (2L + 1) \left| 1 - \frac{M}{N} H(z) \Big|_{z=e^{j\omega MT_R}} \right|^2 |A(\omega)|^2 \frac{N_0}{4V_R^2} \quad (110)$$

Inspecting Eqs. (110) and (109), two important conclusions are drawn that are valid to every frequency synthesizer using edge-triggered phase detector:

1. Sampling causes overlapping, and this effect multiplies the power spectral density of input noise by a factor of $(2L + 1)$. Consequently, a filter must be used

before each edge-triggered PD to limit the bandwidth of $n_i(t)$.

2. If a frequency divider is used in the feedback path, then it multiplies the power spectral density of input noise by a factor of N/M in the vicinity of output frequency.

To illustrate that the APLL theory may not be used for the design of an SPLL if the closed-loop bandwidth is not much less than f_R , the frequency response of a built SPLL to input phase modulation was predicted from Eq. (107) and measured. The parameters of SPLL under test were $R_S = 100 \Omega$, $C_H = 1 \text{ nF}$, $t_S = 1.4 \mu\text{s}$, $N = 3000$, and $f_R = 33.33 \text{ kHz}$.

Since the deviation of output phase modulation was kept low to make the linear approximation valid, the sideband-to-carrier ratio J_1/J_0 at the VCO output was calculated and measured. Recall that the levels of sidebands are given by the Bessel functions in PM and that for small values of phase deviation $\Delta\theta$

$$J_0(\Delta\theta) \approx 1, \quad J_1(\Delta\theta) \approx \frac{\Delta\theta}{2} \quad \text{and}$$

$$J_n(\Delta\theta) \approx 0 \quad \text{for } n \geq 2$$

The calculated (solid, dashed, and dotted lines) and measured (marked by crosses) frequency responses of the SPLL implemented without a loop filter to the phase modulation $\hat{\theta}_R(t)$ of the reference signal are shown in Fig. 32. The results are compared for three values of loop gain: $G_0 = 0.67$ (solid line), $G_0 = 1.0$ (dashed line), $G_0 = 1.5$ (dotted line). J_1/J_0 denotes the sideband-to-carrier ratio at the VCO output. The frequency axis $f_0 = f_o/f_R - N$ shows the frequency detuning from the carrier normalized to the reference frequency.

Figure 33 shows the calculated (solid line) and measured (marked by crosses) frequency response of an SPLL

Figure 32. Frequency response of the SPLL implemented without loopfilter to the input phase modulation. The phase deviation of input PM was 6.67×10^{-5} rads.

Figure 33. Frequency response of the SPLL implemented with a passive lead-lag filter to the input phase modulation. The phase deviation of input PM was 6.67×10^{-5} rads.

implemented with a passive lag-lead filter

$$F(s) = \frac{1 + sR_2C}{1 + s(R_1 + R_2)C}$$

to $\hat{\theta}_R(t)$. The parameters of the loop filter were $R_1 = 6.8 \text{ k}\Omega$, $R_2 = 680 \Omega$ and $C = 220 \text{ nF}$. The loop gain defined by Eq. (103) was $G_0 = 16.5$.

Figures 32 and 33 show clearly that a simple extension of APLL theory cannot be used for the design of a sampling phase-locked loop. For example, first- and second-order APLLs have a lowpass frequency response to the input phase modulation. If the APLL is implemented without a loop filter, then the loop gain G_0 controls the closed-loop bandwidth. These effects cannot be observed in Figs. 32 and 33. Even more, high-attenuation poles appearing in the SPLL frequency response at the entire multiples of the reference frequency (see Figs. 32 and 33), do not occur in analog PLLs. The real SPLL frequency responses are even qualitatively different from that one predicted from the APLL theory.

It was also shown that the stability properties of the SPLL may not be predicted from classical APLL theory [44]. For example, it is obvious from Eq. (104) that even an SPLL implemented without a loop filter may become unstable.

4.2. Charge-Pump Phase-Locked Loop

The PLL acquisition incorporates the frequency pullin and phase lockin processes. In higher-order PLLs, the pullin time may be extremely long; worse still, for many loop configurations there is no guarantee that the phase-locked condition will be ever reached. This problem may be overcome by means of a *phase-frequency detector* (PFD) [46] that operates as a phase detector under phase-locked condition, but provides a frequency-sensitive signal to aid frequency pullin when the loop is out of lock.

As shown in Table 2, a type 2 PLL is required to elicit a zero steady-state phase error response to a frequency step input. Unfortunately, an integrator cannot be implemented if the input of loop filter is a voltage.

In the charge-pump phase-locked loop (CP-PLL) [10,35,47], a charge-pump (CP) circuit converts the PFD output into current that charges up or discharges the loop filter capacitor. The current sources of charge pump and the capacitor of loop filter together constitute an integrator, the CP-PLL is the only phase-locked loop that implements a type 2 feedback loop.

The CP-PLL is the most frequently used PLL configuration in frequency synthesis because:

- The pull-in and hold-in ranges of CP-PLL are identical.
- Theoretically, the output of charge pump circuit is zero in steady-state (an explanation will be given in sec. 4.2.2), consequently, it does not generate unwanted output FM.
- The PFD characteristic has the widest linear region (4π rad) among the phase detectors.

4.2.1. Phase-Frequency Detector With Charge Pump

The simplified block diagram of a phase-frequency detector with charge pump is shown in Fig. 34. It contains an edge-triggered logic circuit (the phase-frequency detector) and a charge pump, which includes two controlled current sources I_U and I_D . The PFD and charge-pump circuit together constitute the PFD-CP phase detector. Note, that the output of PFD-CP phase detector is not a voltage but a current $i_d(t)$.

Assume that the state of the sequential-logic PFD circuit is controlled by the rising edges of reference $s(t)$ and frequency-divided VCO output $r(t)$ signals connected to the R and F inputs, respectively. The PFD has two outputs U and D; if one of them is high, then the other is low.

If the edge of the R input leads that of the F input, then the edge of R input sets the U output high unless the

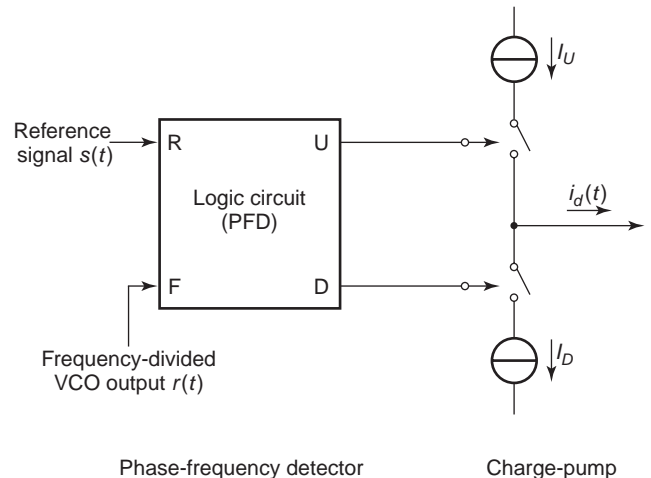

Figure 34. Simplified circuit diagram of the PFD-CP phase detector. Recall that the phase-frequency detector and charge-pump circuit together constitute the PFD-CP phase detector.

Figure 35. Input and output signals of the PFD-CP phase detector.

U-output is already high, in which case the R input has no effect. The next edge of the F input resets the U output low. As long as the R input leads the F input, the D output is low. If the F input leads the R input, then the edge of the F input sets the D output high and the next edge of the R input resets the D output low. As long as the F input leads the R input, the U output remains low.

The current sources I_U and I_D are controlled by the U and D outputs of PFD. Note that both current sources may never be switched on simultaneously. The input and output waveforms of the PFD-CP phase detector are shown in Fig. 35, where t_{ON} denotes the width of current pulses generated by the charge-pump circuit.

Based on Fig. 35, the operation of PFD with charge pump may be summarized as follows. This phase detector is an edge-driven circuit, and its output $i_d(t)$ is a series of current pulses. The sign of pulses is determined by the sign of frequency error, while their duration is proportional to the phase error. If the edges of R and F inputs coincide with each other, that is, if the phase error is zero, then the PFD-CP phase detector has no output $i_d(t)$.

4.2.2. CP-PLL Operation. The block diagram of CP-PLL is shown in Fig. 36. Note that an impedance $Z_F(s)$ is used as loop filter; this impedance converts the discrete-time current output $i_d(t)$ of PFD-CP phase detector into the analog VCO control voltage $v_c(t)$. The loop filter may be either passive or active; for the sake of simplicity, the CP-PLL configuration incorporating a PFD with charge-pump and a passive loop filter is considered here. For other loop configurations, refer to Ref. 25. To get a first-order loop filter and to have a zero² in the open-loop transfer function, the impedance $Z_F(s)$ is implemented by a series connection of a resistor R and a capacitor C .

Consider the noise-free case and assume that the reference signal $s(t)$ in Fig. 36 is an unmodulated signal. Consider the CP-PLL acquisition process and assume that the reference frequency f_R is greater than the frequency-

divided VCO frequency f_o/N initially. Figure 35 shows that the sign of output current pulses $i_d(t)$ of PDF-CP phase detector is determined by the sign of frequency error $f_R - f_o/N$. If $f_R > f_o/N$, then positive current pulses appear at the PDF-CP phase detector output that charge up the loop filter capacitor C , that is, increase the VCO frequency. In a locked CP-PLL under steady-state, the VCO output frequency f_o and VCO control voltage $v_c(t)$ are constant; consequently, $i_d(t) = 0$. It means that the steady-state phase error is zero as claimed in sec. 4.2.

The zero steady-state phase error is extremely important in the frequency synthesizer applications. If the phase error is zero, then $i_d(t) = 0$ and the VCO input is free from the periodic signal of period T_R that would produce an unwanted output FM, that is, sidebands in the output signal. Recall that the unwanted output FM caused by the periodic PD output may not be attenuated by the PLL feedback since the digital frequency divider eliminates this FM.

Unfortunately, in an implemented CP-PLL the phase error must exceed a certain limit to avoid crossover distortion [35]. The unwanted FM appearing due to the finite phase error may be attenuated but not fully eliminated by an additional capacitor connected in parallel with $Z_F(s)$ [25].

Similarly to the SP-PLL, the CP-PLL is a time-varying circuit. The PFD-CP phase detector is an edge-triggered circuit, its discrete-time output is converted into the continuous-time domain by the impedance $Z_F(s)$. An exact analysis and baseband model must take into account the variations in the loop topology.

Unfortunately, an exact CP-PLL baseband model has not yet been published. A time-averaged and linearized model has been developed by Gardner [25]; that baseband model, discussed in Section 4.2.3, is an intuitive extension of APLL theory that may be used successfully in circuit design if the closed-loop bandwidth calculated from the model is less than one-tenth of reference frequency f_R .

4.2.3. Time-Averaged Linear Baseband Model of the CP-PLL. To get an approximate but simple CP-PLL baseband model, Gardner linearized each nonlinear CP-PLL block independently from one another and removed the discrete-time operation by time averaging.

Assume that the CP-PLL is locked, and let

$$\Phi(t) = \omega_R t + \theta_R(t) \quad \text{and}$$

$$\hat{\Phi}(t) = \frac{\Phi_o(t)}{N} = \omega_R t + \frac{\theta_o(t)}{N}$$

denote the phases of reference $s(t)$ and frequency-divided VCO $r(t)$ respectively, signals. According to the PLL terminology, let

$$\theta_e = \theta_R - \frac{\theta_o}{N} \quad (111)$$

define the phase error. Recall that in the CP-PLL shown in Fig. 36, the quiescent value of phase error is zero.

²This zero is used to set the stability margin, that is, to control the loop dynamics.

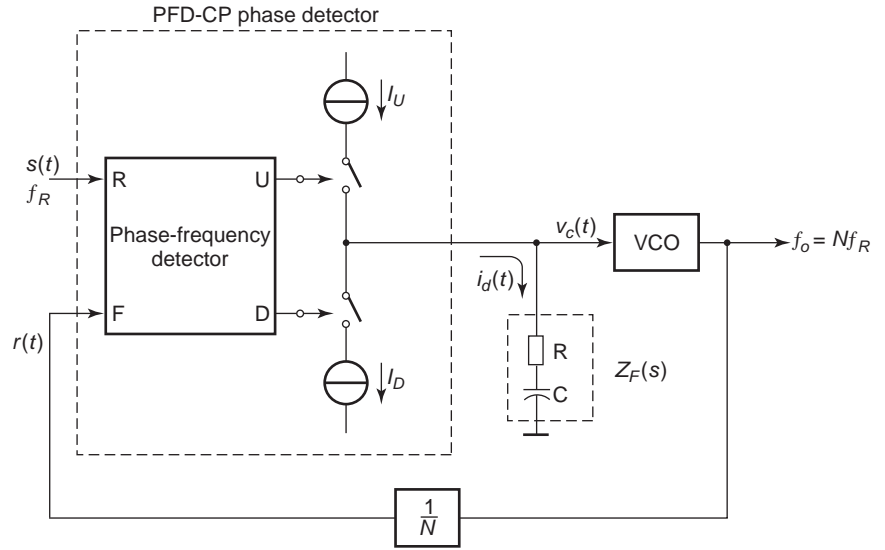

Figure 36. Block diagram of CP-PLL implemented with an impedance $Z_F(s)$. The steady-state output frequency f_o is controlled by the division ratio N of frequency divider.

The width of PD output current pulses may be approximated by

$$t_{ON} \approx \frac{\theta_e}{2\pi} T_R = \frac{1}{\omega_R} \left(\theta_R - \frac{\theta_o}{N} \right) \quad (112)$$

Note that the sign of t_{ON} depends on the sign of phase error; if the VCO signal leads the reference one, then $t_{ON} > 0$; if the edges of two signals coincide with one another, then $t_{ON} = 0$; otherwise $t_{ON} < 0$. Equation (112) is exact if the VCO signal leads the reference one, but otherwise it is an approximation. The approximation arises out of the fact that the phase of VCO signal varies during the time interval t_{ON} . The error caused by this approximation is negligible if the closed-loop bandwidth of CP-PLL calculated from the linear baseband model is much less than the reference frequency f_R .

In the majority of applications, narrowband CP-PLLs are used. If the closed-loop CP-PLL bandwidth is less than one-tenth of reference frequency f_R , then the state of the CP-PLL changes by only a very small amount on each reference cycle. If one is not interested in the CP-PLL behavior within a single reference cycle, then the time-averaging technique may be used. As a result, the effect of time-varying operation is removed and the CP-PLL loop equation becomes a pure differential equation.

Assume that the absolute values I_P of the currents provided by the two current sources of charge pump are identical and apply the time-averaging technique to the output current $i_d(t)$ of PFD-CP phase detector. The average error current over a reference cycle is

$$i_d^{AV}(t) = \frac{1}{T_R} \int_{T_R} i_d(t) dt = I_P \frac{t_{ON}}{T_R} \quad (113)$$

Substituting Eq. (112) into Eq. (113), the following relationship between average error current and phase error is

found:

$$i_d^{AV}(t) = \frac{I_P}{2\pi} \theta_e$$

Let $I_d^{AV}(s)$ denote the Laplace transform of $i_d^{AV}(t)$. Then, taking into account the transfer functions of loop filter and VCO, the output phase is obtained as

$$\Theta_o(s) = \frac{K_v}{s} V_c(s) = \frac{I_P}{2\pi} Z_F(s) \frac{K_v}{s} \Theta_e(s) \quad (114)$$

From Eqs. (111) and (114) the phase error

$$\Theta_e(s) = [1 - H(s)] \Theta_R(s) \quad (115)$$

and the output phase

$$\Theta_o(s) = NH(s) \Theta_R(s) \quad (116)$$

are obtained, where the closed-loop transfer function takes the form

$$H(s) = \frac{\frac{I_P K_v}{2\pi N} Z_F(s)}{s + \frac{I_P K_v}{2\pi N} Z_F(s)} \quad (117)$$

The time-averaged linear CP-PLL baseband model constructed from Eqs. (115) and (114) is depicted in Fig. 37.

Figure 37. Time-averaged linear baseband model of CP-PLL.

A comparison of Eqs. (115), (116) and (117), respectively, to Eqs. (26), (27) and (28) shows that time-averaged linear baseband model of CP-PLL is an extension of linear APLL theory. This relationship may be also recognized by comparing Fig. 37 to Fig. 4.

A second-order type-two feedback loop is implemented with the most frequently used passive loop filter shown in Fig. 36. In this case the closed-loop transfer function becomes

$$H(s) = \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \quad (118)$$

where the natural frequency ω_n and the damping factor ζ are given by

$$\omega_n = \sqrt{\frac{I_P K_v}{2\pi N C}} \quad \text{and} \quad \zeta = \frac{\tau\omega_n}{2}$$

and where $\tau = RC$.

The linear baseband model shown in Fig. 37 may be successfully used in the development of CP-PLL circuits until the closed-loop bandwidth calculated from Eq. (118) is less than one-tenth of f_R . However, never forget that the time-averaged model is based on an approximation that has the most serious consequence on the loop stability.

Equation (118) suggests that the CP-PLL shown in Fig. 36 is unconditionally stable. Unfortunately, this is not true. Gardner [25] showed that this CP-PLL would go unstable for large loop gain.

Let the loop gain be defined by

$$K = \frac{I_P K_v}{2\pi N} R$$

The exact characteristic equation, which includes the effect of edge-triggered operation, takes the form [25]

$$D(z) = (z-1)^2 + (z-1) \frac{2\pi K}{\omega_R} \left(1 + \frac{2\pi}{\omega_R \tau}\right) + \frac{4\pi^2 K}{\omega_R^2 \tau}$$

The CP-PLL implemented with a passive loop filter is stable if the roots of characteristic equation lie inside the unit circle in the z plane.

4.2.4. Crossover Distortion. Timing uncertainties in the edge-triggered PFD together with the finite risetimes and fall times cause an error in the amount of charge delivered by the charge pump to the loop filter capacitor. This error may be neglected for large phase error, but it changes severely the gain of PFD-CP phase detector about the zero-phase error. Egan observed more than ± 20 dB variations in the PD gain in this crucial small phase error region [48]. This variation in PD gain has a serious influence on closed-loop CP-PLL parameters and, even worse, may cause a stability problem. This effect is called *crossover distortion* [35]. To avoid crossover distortion, the phase error must exceed a minimum value in steady-state. The phase error region that may not be used is called the dead zone [47].

The phase error may be increased by connecting a resistor in parallel with $Z_F(s)$ in Fig. 36. But recall that,

because of the nonzero phase error, a periodic signal appears at the VCO input that causes an unwanted output FM, that is, sidebands at the CP-PLL output.

4.2.5. Exact Analysis of the CP-PLL. The time-averaging approach was used in the previous subsection to develop a baseband model and transfer functions for the CP-PLL. The transfer functions facilitate the design of a CP-PLL, but the time averaging neglects the discrete nature of the loop. Consequently, the validity of that model is limited, and application of the model may result in a disagreement between the predicted and measured CP-PLL behavior.

Event-driven models have been published for the CP-PLL more recently. These models are exact and take into account the discrete-time operation of CP-PLL. Their disadvantage is that a baseband model and transfer functions cannot be developed from these equations; consequently, these models may be used only in computer simulations. The detailed discussion of the event-driven models goes beyond the scope of this article, the interested readers should refer to the papers mentioned below.

Paemel published an event-driven model for the CP-PLL implemented with a first-order passive loop filter in 1994 [49]. Based on the order of edges of reference and frequency-divided VCO signal, Paemel distinguished four different situations. Two state variables and, according to the four possible orders of edges, four nonlinear difference equations were used to describe the behavior of CP-PLL. The equations developed are also valid for the transient analysis and, even more, if the loop is out of lock.

Another event-driven model was developed for the CP-PLL implemented with a first-order passive loop filter by Hedayat et al. in 1997 [50]. Later the validity of that model was extended to the second-order passive loop filter [51]. According to the three possible output of the PFD-CP phase detector (up, down, no output current), a set of three nonlinear difference equations was used to model the operation of CP-PLL. These equations may be used to write a computer program to simulate the behavior of CP-PLL under various conditions.

5. CLOSING REMARKS

The goal of this article was to survey the theory and the most important applications of phase-locked loops. The main emphasis was put on the APLL theory and frequency synthesis. The former is relatively easy to understand and is the basis of every other PLL analysis. The latter is crucial in RF engineering since frequency synthesizers are used everywhere from telecommunication systems to measurement equipment.

While the APLL theory has been very well established, the theory of the hybrid PLLs including both analog and edge-triggered circuits is subject to continuous development. For example, it has been shown [52] that false lock limits the pull-in range of SPLL implemented with a first-order loop filter. For the latest results in the field of PLLs, refer to Ref. 53.

The majority of PLLs developed recently (as of 2004) are used in integrated circuits. The discussion of special

requirements arising from the IC implementation goes beyond the scope of this article, for a good survey, refer to Ref. 54.

wireless communication systems such as cellphones, require these building blocks [1]. Based on a frequency standard, the synthesizer provides a stable reference frequency for the system.

Synthesizers are used to generate frequencies with arbitrary resolution covering the frequency range from audio to millimeter-wave. Today, simple frequency synthesizers consist of a variety of synthesizer chips, an external voltage-controlled oscillator (VCO), and a frequency standard. For high-volume applications, such as cellphones, cordless telephones, walkie-talkies, or systems where frequency synthesizers are required, a high integration is desired. The requirements for synthesizers in cordless telephones are not as stringent as in test equipment. Synthesizers in test equipment use customized building blocks and can be modulated to be part of arbitrary waveform generators [2].

The VCO typically consists of an oscillator with a tuning diode attached. The voltage applied to the tuning diode tunes the frequency of the oscillator. Such a simple system is a phase-locked loop (PLL). The stability of the VCO is the same as the reference. There are single-loop and multiloop PLL systems. Their selection depends on the characteristic requirements. Figure 1 shows the block diagram of a single-loop PLL [3].

The PLL consists of a VCO, a frequency divider, a phase detector, a frequency standard, and a loop filter [4–7].

There are limits to how high the frequency division ratio can be. Typically, the loop where the RF frequency is divided below 1 kHz, becomes unstable. This is because microphonic effects of the resonator will unlock the system at each occurrence of mechanical vibration. At 1 GHz, this would be a division ratio of one million. To avoid such high division ratios, either multiloop synthesizers are created or a new breed of PLL synthesizers called fractional- N division synthesizers will be considered. At the same time, direct digital synthesis is being improved. Using direct digital synthesis in loops can also overcome some of the difficulties associated with high division ratios. There are

1. INTRODUCTION

Frequency synthesizers are found in all modern communication equipment, and signal generators, particularly

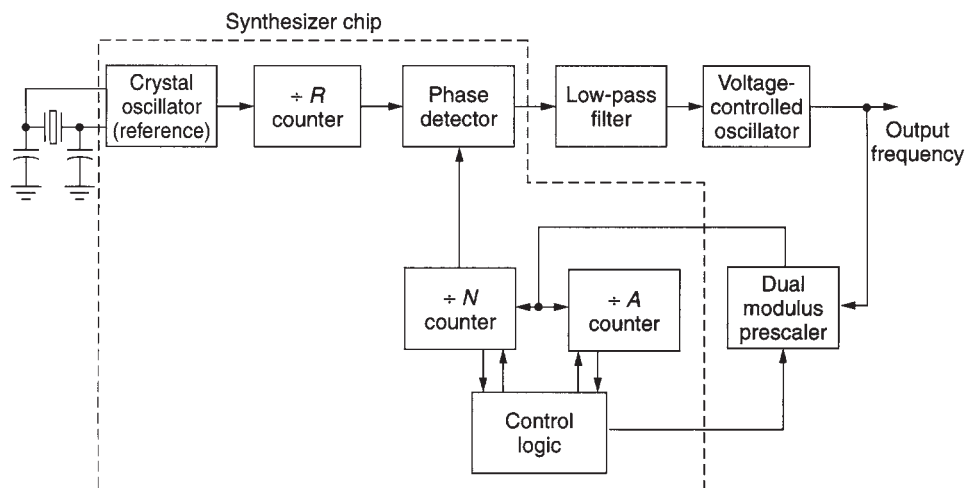

Figure 1. Block diagram of an integrated frequency synthesizer. In this case, the designer has control over the VCO and the loop filter; the reference oscillator is part of the chip. In most cases (up to 2.5 GHz), the dual-modulus prescaler is also inside the chip.

also combinations of techniques that I would like to refer to as “hybrid synthesizers.” They will be covered here.

The quality of the system, or signal generator, is determined by the properties of the synthesizer and, of course, its building blocks. There are a variety of parameters in characterizing the synthesizer. To name a few important ones, we need to worry about the frequency stability, spurious suppression, and phase noise characteristics. The frequency resolution of the synthesizer tends to be covered by the switching speed and its spurious response. A lot of research is put into developing the ideal synthesizer, whatever ideal means. For portable applications such as cellphones, size and power consumption are real issues, as well as the cost of the system. As mentioned, there are several competing approaches. In particular, there is a race between the fractional-*N* division synthesizer and the direct digital synthesis. The fractional synthesizer allows for generation of the output frequencies, which are not exact integers of the reference frequency. This results in an average frequency and problems with spurious sidebands. The direct digital synthesis uses a look-up table to construct a sine wave, and the size of the lookup table and the sample rate determine the quality of the signal and its output frequency.

2. FREQUENCY SYNTHESIZER FUNDAMENTALS

There are several approaches to “synthesize” a frequency, as we already mentioned. Probably the first and the oldest approach is the direct frequency synthesis, where a bank of crystals, as frequency standards, will be used to generate output frequencies. Such a system is called “frequency-incoherent.” There is no phase coherency among the various oscillators [8].

A simple example of direct synthesis is shown in Fig. 2. The new frequency $\frac{2}{3} f_0$ is realized from f_0 by using a divide-by-3 circuit, a mixer, and a bandpass filter. In this example, $\frac{2}{3} f_0$ has been synthesized by operating directly on f_0 .

Figure 3 illustrates the form of direct synthesis module most frequently used in commercial frequency synthesizers of the direct form. The method is referred to as the “double-mix-divide” approach.

An input frequency f_{in} is combined with a frequency f_1 , and the upper frequency $f_1 + f_{in}$ is selected by the bandpass filter. This frequency is then mixed with a switch-selectable frequency $f_2 + f^*$ (in the following, f^* refers to any one of 10 switch-selectable frequencies). The output of the second mixer consists of the two frequencies $f_{in} + f_1 + f_2 + f^*$ and $f_{in} + f_1 - f_2 - f^*$; only the higher frequency term appears at the output of the bandpass filter. If the

frequencies f_{in} , f_1 , and f_2 are selected so that

$$f_{in} + f_1 + f_2 = 10f_{in} \tag{1}$$

then the frequency at the output of the divide by 10 will be

$$f_{out} = f_{in} + \frac{f^*}{10} \tag{2}$$

The double-mix-divide module has increased the input frequency by the switch-selectable frequency increment $f^*/10$. These double-mix-divide modules can be cascaded to form a frequency synthesizer with any degree of resolution. The double-mix-divide modular approach has the additional advantage that the frequencies f_1 , f_2 , and f_{in} can be the same in each module, so that all modules can contain identical components.

A direct frequency synthesizer with three digits of resolution is shown in Fig. 4. Each decade switch selects one of 10 frequencies $f_2 + f^*$. In this example, the output of the third module is taken before the decade divider.

For example, it is possible to generate the frequencies between 10 and 19.99 MHz (in 10-kHz increments), using the three module synthesizer, by selecting

$$f_{in} = 1 \text{ MHz}$$

$$f_1 = 4 \text{ MHz}$$

$$f_2 = 5 \text{ MHz}$$

As

$$f_{in} + f_1 + f_2 = 10 f_{in} \tag{3}$$

the output frequency will be

$$f_0 = 10 f_{in} = f_3^* + \frac{f_2^*}{10} + \frac{f_1^*}{100} \tag{4}$$

As f^* occurs in 1-MHz increments, $f_1^*/100$ will provide the desired 10-kHz frequency increments.

Theoretically, either f_1 or f_2 could be eliminated provided that

$$f_{in} + f_1 \text{ (or } f_2) = 10f_{in} \tag{5}$$

but the additional frequency is used in practice to provide additional frequency separation at the mixer output. This frequency separation eases the bandpass filter requirements. For example, if f_2 is eliminated, $f_1 + f_{in}$ must equal $10f_{in}$ or 10 MHz. If an f_1^* of 1 MHz is selected, the output of the first mixer will consist of the two frequencies 9 and

Figure 2. Direct frequency generation using the mix-and-divide principle. It requires excessive filtering.

Figure 3. Direct frequency synthesizer using a mix-and-divide technique to obtain identical modules for high resolution.

11 MHz. The lower of these closely spaced frequencies must be removed by the filter. The filter required would be extremely complex. If, instead, a 5-MHz signal f_2 is also used so that $f_{in} + f_1 + f_2 = 10$ MHz, the two frequencies at the first mixer output will (for an f_1^* of 1 MHz) be 1 and 11 MHz. In this case, the two frequencies will be much easier to separate with a bandpass filter. The auxiliary frequencies f_1 and f_2 can be selected in each design only after considering all possible frequency products at the mixer output.

Direct synthesis can produce fast frequency switching, almost arbitrarily fine frequency resolution, low phase noise, and the highest-frequency operation of any of the methods. Direct frequency synthesis requires considerably more hardware (oscillators, mixers, and bandpass filters) than do the two other synthesis techniques to be described. The hardware requirements result in direct synthesizers being larger and more expensive. Another disadvantage of the direct synthesis technique is that unwanted (spurious) frequencies can appear at the output. The wider the frequency range, the more likely that the spurious components will appear in the output. These disadvantages are offset by the versatility, speed, and flexibility of direct synthesis.

2.1. PLL Synthesizer

The most popular synthesizer is based on PLL [9]. An example of such a PLL-based synthesizer is shown in Fig. 5. In preparing ourselves for hybrid synthesizers, it needs to be noted that the frequency standard can also be replaced

by a direct digital synthesizer (DDS). The number of references for synthesizers seems endless, but the most complete and relevant ones are given at the end. It's also very important to monitor the patents. If any incremental improvements are achieved there, the inventors immediately try to protect them with a patent. The following will give some insight into the major building blocks used for PLL and hybrid synthesizers. It should be noted that most designers use a combination of available integrated circuits, and most of the high-performance solutions are due to the careful design of the oscillator, the integrated/low-pass filter, and the systems architecture. All of these items will be addressed, particularly the fractional- N synthesizer, which requires a lot of handholding in the removal of spurious products. How does the PLL work? According to Fig. 5, we have a free-running oscillator, which can operate anywhere from audio to millimeter wave. The output is typically sinusoidal. The VCO also is occasionally called a VTO (voltage-tuned oscillator), which drives an output stage and a pulseshaping stage to prepare the signal to drive a frequency divider chain. The frequency divider chain consists of silicon germanium or GaAs dividers to reduce the signal below 1000 MHz. At these frequencies, either silicon-based dividers or CMOS dividers can take over. The frequency divider, typically part of an integrated circuit, is a synchronous divider, which is programmable over a large range. Division ratios as low as four and as high as one million are possible [10].

The output of the frequency divider is fed to a phase comparator, which in most cases is actually a phase-frequency detector. The phase-frequency detector compares

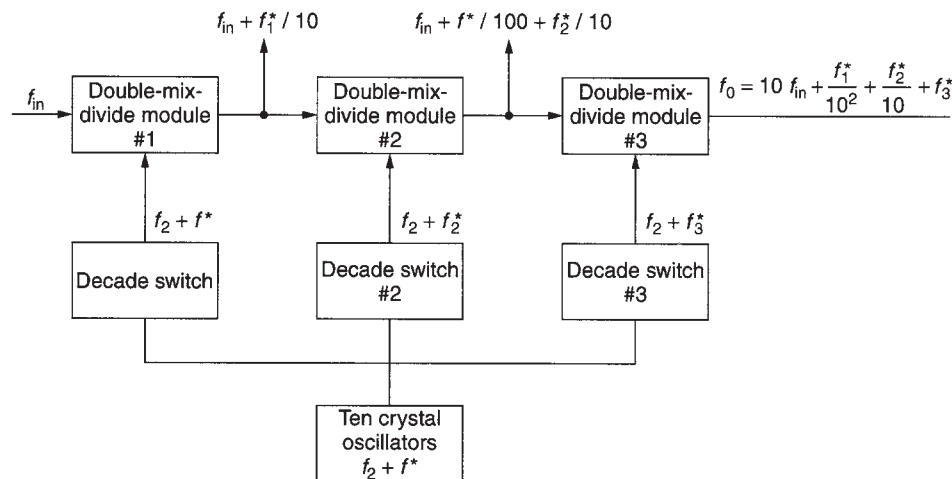

Figure 4. Phase-incoherent frequency synthesizer with three-digit resolution.

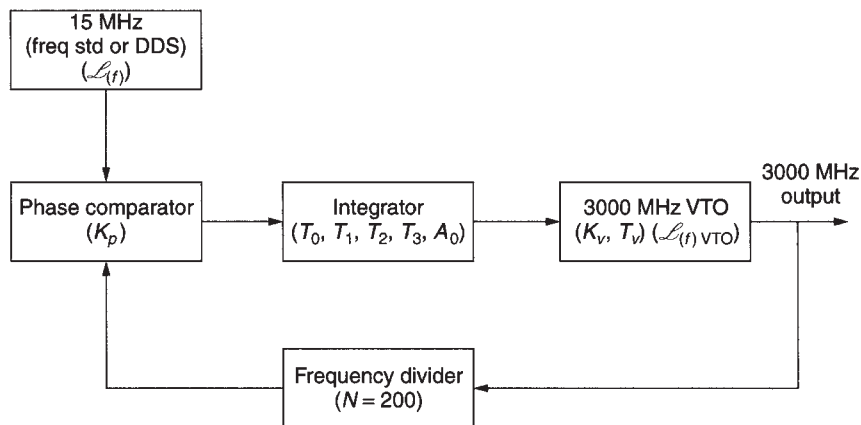

Figure 5. Block diagram of a PLL synthesizer driven by a frequency standard, DDS, or fractional-*N* synthesizer for high resolution at the output. The last two standards allow a relatively low division ratio and provide quasiarbitrary resolution.

the output of the frequency divider, which typically is the same magnitude as the reference frequency, with a reference frequency, which is derived from a frequency standard. Frequency standards come as precision standards such as atomic frequency standards, followed by oven-controlled crystal oscillators, to temperature-compensated crystal oscillators. Sometimes even simple crystal oscillators will do the trick. The output from the phase comparator is a dc voltage typically between 1 and 25 V, which is applied to the tuning diode of the VTO or VCO. This tuning voltage is modulated by the differences of the two prior to lock. The frequency detector portion of the phase-frequency comparator jams the voltage to one extreme, charging the capacitors and integrator and acquiring frequency lock. After frequency lock is obtained, the control voltage will change the frequency at the output to have a fixed phase relationship compared to the reference frequency. The advantage of having a frequency detector in parallel to a phase detector is that the system always requires frequency lock [11,12].

2.2. Fractional-*N* Phase-Locked Loops

The principle of the fractional-*N* PLL synthesizer has been around for a while. In the past, implementation of this has been done in an analog system [13,14]. It would be ideal to be able to build a single-loop synthesizer with a 1.25-MHz or 50-MHz reference and yet obtain the desired stepsize resolution, such as 25 kHz. This would lead to the much smaller division ratio and much better phase noise performance. Figure 6 shows the block of an analog fractional-*N* synthesizer.

An alternative would be for *N* to take on fractional values. The output frequency could then be changed in fractional increments of the reference frequency. Although a digital divider cannot provide a fractional division ratio, ways can be found to accomplish the same task effectively.

The most frequently used method is to divide the output frequency by *N* + 1 every *M* cycles and to divide by *N* the rest of the time. The effective division ratio is then

N + 1/*M*, and the average output frequency is given by

$$f_0 = \left(N + \frac{1}{M} \right) f_r \tag{6}$$

This expression shows that *f*₀ can be varied in fractional increments of the reference frequency by varying *M*. The technique is equivalent to constructing a fractional divider, but the fractional part of the division is actually implemented using a phase accumulator. The phase accumulator approach is illustrated in Section 6. This method can be expanded to frequencies much higher than 6 GHz using the appropriate synchronous dividers. For more details, see Section 6 [15–53].

2.3. Digital Direct Frequency Synthesizer

The digital direct frequency uses sampled data methods to produce waveforms [54–69].

The digital hardware block provides a datastream of *K* bits per clock cycle for DAC. Ideally, the DAC is a linear device with glitch-free performance. The practical limits of the DAC will be discussed later in this article. The DAC output is the desired signal plus replications of it around the clock frequency and all of the clock’s harmonics. Also

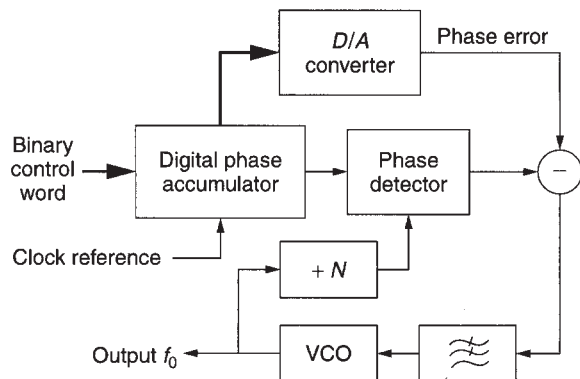

Figure 6. Simplified block diagram of an analog fractional-*N* synthesizer.

Figure 7. Ideal DAC output with F_0 , a sampled-and-held sine wave, at its output. Notice the $(\sin x)/x$ envelope rolloff. As F_0 moves up in frequency, an aliased component $F_c - F_0$ moves down into the passband.

present in the DAC output signal is a small amount of quantization noise from the effects of finite math in the hardware block. Figure 7 shows the frequency spectrum of an ideal DAC output with a digitally sampled sine-wave datastream at its input. Note that the desired signal, F_0 (a single line in the frequency domain), is replicated around all clock terms. Figure 8 shows the same signal in the time domain.

The DAC performs a sample-and-hold operation as well as converting digital values to analog voltages. The sample occurs on each rising edge of the clock; the hold occurs during the clock period. The transfer function of a sample-and-hold operator is a $(\sin x)/x$ envelope response with linear phase. In this case, $x = (\pi F/F_{\text{clock}})$.

It should be noted that the sinc function rolloff affects the passband flatness. A 2.4 dB should be expected at 40% of F_{clock} .

Referring to Fig. 9, the output of the DAC is passed through a lowpass filter (LPF). With proper attention to design, an LPF may be realized that has linear phase in a flat passband with width of $0.4F_{\text{clock}}$. With this design, the maximum available bandwidth is achieved. For example,

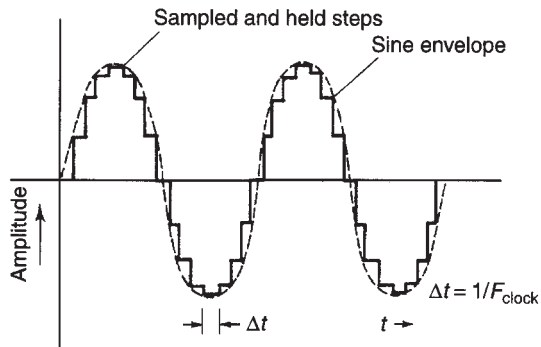

Figure 8. Samples/cycle sine wave. This is typical of a single-tone DAC output. $F_0 = F_{\text{clock}}/16$ after lowpass filtering; only the sine envelope is present. The LPF removes the sampling energy. Each amplitude step is held for a clock period.

Figure 9. Direct digital frequency synthesizer.

with $F_{\text{clock}} = 125 \text{ MHz}$, the useful synthesized bandwidth of about 50 MHz is attained. The LPF output is the desired signal without any sampling artifacts. Viewing the LPF strictly as a device to remove sampling energy, it is obvious why the output contains only the desired signal. It is also instructive to view the LPF from the time domain. From this point, the LPF may be seen as the perfect interpolator. It fills the space between time samples with a smooth curve to reconstruct perfectly the desired signal.

In the design of a DDS, the following guidelines apply:

- The desired frequency resolution determines the lowest output frequency f_L .
- The number of D/A conversions used to generate f_L is $N = 4k = 4f_U/f_L$ provided that four conversions are used to generate f_U ($P = 4$).
- The maximum output frequency f_U is limited by the maximum sampling rate of the DDS, $f_U \leq \frac{1}{4}T$. Conversely, $T \leq \frac{1}{4}f_U$.

To generate nf_L , the integer n addresses the register, and each clock cycle kn is added to the content of the accumulator so that the content of the memory address register is increased by kn . Each kn th point of the memory is addressed, and the content of this memory location is transferred to the D/A converter to produce the output sampled waveform.

To complete the DDS, the memory size and length (number of bits) of the memory word must be determined. The wordlength is determined by system noise requirements. The amplitude of the D/A output is that of an exact sinusoid corrupted with the deterministic noise due to truncation caused by the finite length of the digital words (quantization noise). If an $(n + 1)$ -bit wordlength (including one sign bit) is used and the output of the A/D converter varies between ± 1 , the mean noise from the quantization will be

$$\rho^2 = \frac{1}{12} \left(\frac{1}{2}\right)^{2n} = \frac{1}{3} \left(\frac{1}{2}\right)^{2(n+1)} \tag{7}$$

The mean noise is averaged over all possible waveforms. For a worst-case waveform, the noise is a square wave with amplitude $\frac{1}{2}(\frac{1}{2})^n$ and $\rho^2 = \frac{1}{4}(\frac{1}{2})^{2n}$. For each bit added to the wordlength, the spectral purity improves by 6 dB.

The main drawback of a low-power DDS is that it is limited to relatively low frequencies. The upper frequency is directly related to the maximum usable clock frequency; today, the limit is about 1 GHz. DDS tends to be noisier than other methods, but adequate spectral purity can be obtained if sufficient lowpass filtering is used at the output. DDS systems are easily constructed using readily available microprocessors. The combination of DDS for fine frequency resolution plus other synthesis techniques to obtain higher-frequency output can provide high resolution with very rapid setting time after a frequency change. This is especially valuable for frequency-hopping spread-spectrum systems.

In analyzing both the resolution and signal-to-noise ratio (or rather signal-to-spurious performance) of the DDS, one has to know the resolution and input frequencies. As an example, if the input frequency is approximately 35 MHz and the implementation is for a 32-bit device, the frequency resolution compared to the input frequency is $35\text{E}6 \div 2^{32} = 35\text{E}6 \div 4.294967296\text{E}9$ or $0.00815\text{Hz} \approx 0.01\text{Hz}$. Given the fact that modern shortwave radios with a first IF of about 75 MHz will have an oscillator between 75 and 105 MHz, the resolution at the output range is more than adequate. In practice, one would use the microprocessor to round it to the next increment of 1 Hz relative to the output frequency.

As to the spurious response, the worst-case spurious response is approximately $20 \log 2^R$, where R is the resolution of the digital/analog converter. For an 8-bit A/D converter, this would mean approximately 48 dB down (worst case), as the output loop would have an analog filter to suppress close-in spurious noise. Modern devices

have a 14-bit resolution. Fourteen bits of resolution can translate into $20 \log 2^{14}$ or 80 dB, worse case, of suppression. The actual spurious response would be much better. The current production designs for communication applications, such as shortwave transceivers, despite the fact that they are resorting to a combination of PLLs and DDSs, still end up somewhat complicated. By using 10 MHz from the DDS and using a single-loop PLL system, one can easily extend the operation to above 1 GHz but with higher complexity and power consumption. This was shown in Fig. 5. Figure 10 shows a multiple loop synthesizer using a DDS for fine resolution.

3. IMPORTANT CHARACTERISTICS OF SYNTHESIZERS

The following sections list the parameters used to describe the performance of the synthesizer. These are referred to as *figures of merit*.

3.1. Frequency Range

The output frequency of a synthesizer can vary over a wide range. A synthesizer signal generator typically offers output frequencies from as low as 100 kHz to as high as several gigahertz. The frequency range is determined by the architecture of the signal generator as the system frequently uses complex schemes of combining frequencies in various loops. A standard loop-based synthesizer has a frequency range typically less than 1–2, as an example, 925–1650 MHz.

3.2. Phase Noise

Oscillators unfortunately are not clean, but the various noise sources in and outside of the transistor modulate the VCO, resulting in energy or spectral distribution on both

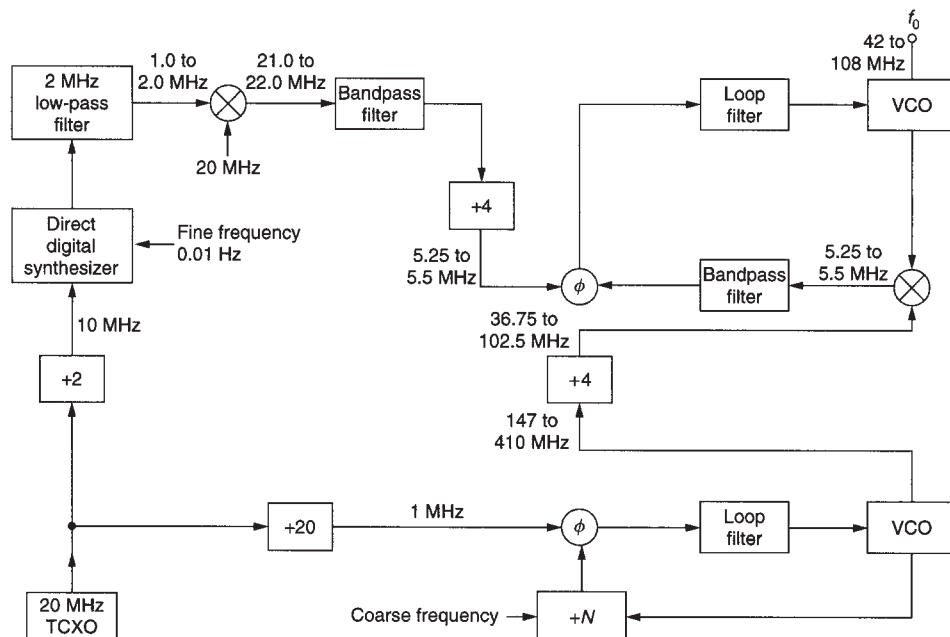

Figure 10. A multiple-loop synthesizer using a DDS for fine resolution.

sides of the carrier. This occurs via modulation and conversion. The noise, or better, FM noise is expressed as the ratio of output power divided by the noise power relative to 1 Hz bandwidth measured at an offset of the carrier. Figure 11 shows a typical phase noise plot of a synthesizer. Inside the loop bandwidth, the carrier signal is cleaned up, and outside the loop bandwidth, the measurement predicts the performance of the VCO itself.

3.3. Output Power

The output power is measured at the designated output port of the frequency synthesizer. Practical designs require an isolation stage. Typical designs require one or more isolation stages between the oscillator and the output. The output power needs to be flat. Although the synthesized generator typically is flat with only 0.1-dB \pm deviation, the VCO can vary as much as ± 2 dB over the frequency range.

3.4. Harmonic Suppression

The VCO inside a synthesizer has a typical harmonic suppression of better than 15 dB. For high-performance applications, a set of lowpass filters at the output will reduce the harmonic contents to a desired level. Figure 12 shows a typical output power plot of a VCO.

3.5. Output Power as a Function of Temperature

All active circuits vary in performance as a function of temperature. The output power of an oscillator over a temperature range should vary less than a specified value, such as 1 dB.

3.6. Spurious Response

Spurious outputs are signals found around the carrier of a synthesizer that are not harmonically related. Good, clean synthesizers need to have a spurious-free range of 90 dB, but these requirements make them expensive. Although

oscillators typically have no spurious frequencies besides possibly 60 and 120 Hz pickup, the digital electronics in a synthesizer generate a lot of signals, and when modulated on the VCO, are responsible for these unwanted output products. (See also Fig. 11).

3.7. Stepsize

The resolution, or stepsize, is determined by the architecture.

3.8. Frequency Pushing

Frequency pushing characterizes the degree to which an oscillator’s frequency is affected by its supply voltage. For example, a sudden current surge caused by activating a transceiver’s RF power amplifier may produce a spike on the VCO’s DC power supply and a consequent frequency jump. Frequency pushing is specified in frequency/voltage form and is tested by varying the VCO’s DC supply voltage (typically ± 1 V) with its tuning voltage held constant.

3.9. Sensitivity to Load Changes

To keep manufacturing costs down, many wireless applications use a VCO alone, without the buffering action of a high reverse-isolation amplifier stage. In such applications, frequency pulling, the change of frequency resulting from partially reactive loads, is an important oscillator characteristic. Pulling is commonly specified in terms of the frequency shift that occurs when the oscillator is connected to a load that exhibits a nonunity VSWR (such as 1.75, usually referenced to 50 Ω), compared to the frequency that results with unity-VSWR load (usually 50 Ω). Frequency pulling must be minimized, especially in cases where power stages are close to the VCO unit and short pulses may affect the output frequency. Such poor isolation can make phase locking impossible.

Figure 11. Measured phase noise of an 880-MHz synthesizer using a conventional synthesizer chip.

Figure 12. Predicted harmonics at the output of a VCO.

3.10. Tuning Sensitivity

This is a VCO parameter also expressed in frequency/volt- age and is not part of a synthesizer specification.

3.11. Posttuning Drift

After a voltage step is applied to the tuning diode input, the oscillator frequency may continue to change until it settles to a final value. Posttuning drift is one of the pa- rameters that limits the bandwidth of the VCO input.

3.12. Tuning Characteristic

This specification shows the relationship, depicted as a graph, between the VCO operating frequency and the tun- ing voltage applied. Ideally, the correspondence between operating frequency and tuning voltage is linear.

3.13. Tuning Linearity

For stable synthesizers, a constant deviation of frequency versus tuning voltage is desirable. It is also important to make sure that there are no breaks in tuning range, for example, that the oscillator does not stop operating with a tuning voltage of 0 V.

3.14. Tuning Sensitivity and Tuning Performance

These data, typically expressed in megahertz per volt (MHz/V), characterize how much the frequency of a VCO changes per unit of tuning voltage change.

3.15. Tuning Speed

This characteristic is defined as the time necessary for the VCO to reach 90% of its final frequency on the application of a tuning voltage step. Tuning speed depends on the in-

ternal components between the input pin and the tuning diode, including, among other things, the capacitance present at the input port. The input port’s parasitic ele- ments determine the VCO’s maximum possible modula- tion bandwidth.

3.16. Power Consumption

This characteristic conveys the DC power, usually speci- fied in milliwatts and sometimes qualified by operating voltage, required by the oscillator to function properly [70].

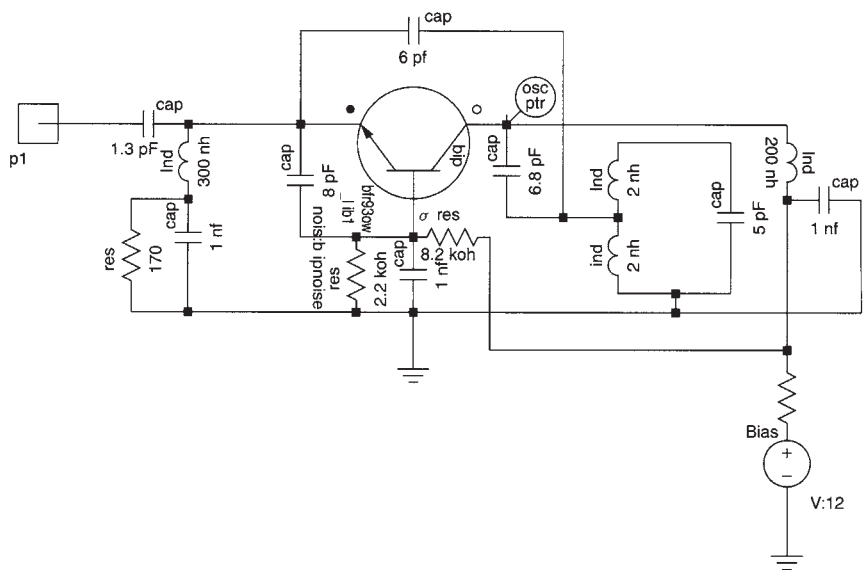

4. BUILDING BLOCKS OF SYNTHESIZERS

4.1. Oscillator

An oscillator is essentially an amplifier with sufficient feedback so that the amplifier becomes unstable and be- gins oscillation. The oscillator can be divided into an am- plifier, a resonator, and a feedback system [71]. One of the most simple equations describes this. It describes the in- put admittance of an amplifier with a tuned circuit at the output described by the term Y_L :

$$Y_{11}^* = Y_{11} - \frac{Y_{12} \times Y_{21}}{Y_{22} + Y_L} \tag{8}$$

The feedback is determined by the term Y_{12} , or in practical terms, by the feedback capacitor. The transistor oscillator (Fig. 13a) contains a grounded base circuit. For this type of oscillator, using microwave transistors, the emitter and collector currents are in phase. That means that the input circuit of the transistor needs to adjust the phase of the oscillation. The transistor stage forms the amplifier, the tuned resonator at the output determines the frequency of oscillation, and the feedback capacitor provides enough energy back into the transistor so that oscillation can

(a)

(b)

(c)

Figure 13. (a) A grounded base VHF/UHF oscillator with a tuned resonator tapped in the middle to improve operational Q ; (b) the predicted phase noise of the oscillator in Fig. 13a; (c) the equivalent circuit of the oscillator configuration of Fig. 13a. For the grounded base configuration, emitter and collector currents have to be in phase. The phase shift introduced by C_f is compensated by the input tuned circuit.

occur. To start oscillation, the condition, relative to the output, can be derived in a similar fashion from the input:

$$Y_{22}^* = (Y_{22} + Y_L) - \frac{Y_{12} \times Y_{21}}{Y_{11} + Y_T} \quad (9)$$

If the second term of the equation on the right side is larger than the first term on the right of the = sign, then $\text{Re}(Y_{22}^*)$ is negative and oscillation at the resonant frequency occurs.

This oscillator circuit is good for low-frequency applications, but the Colpitts oscillator is preferred for

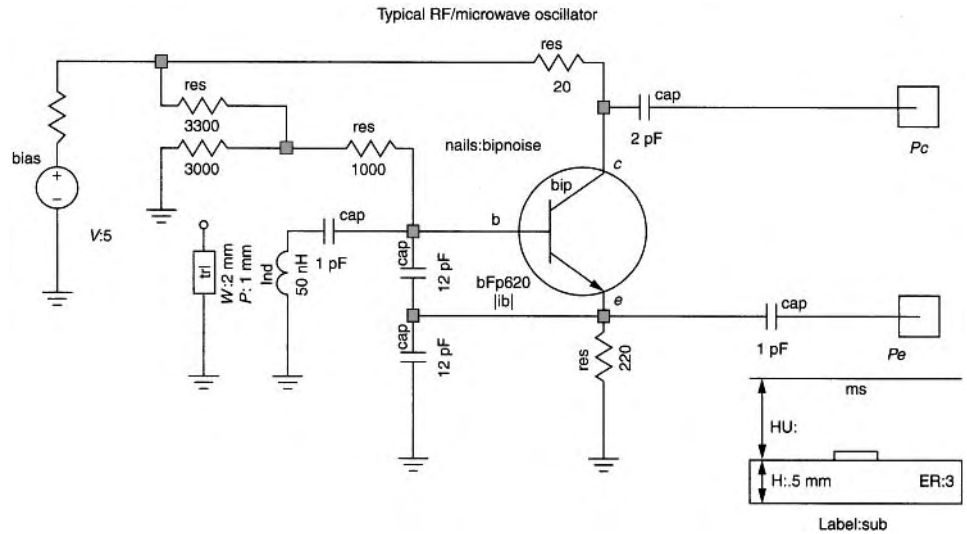

Figure 14. Colpitts oscillator using a coil inductor or a transmission line as a resonator. In this case, all the physical parameters of the transmission line have to be provided.

higher frequencies. The Colpitts oscillator works by rotating this circuit and grounds the collector instead of the base. The advantage of the Colpitts oscillator is the fact that it is an emitter follower amplifier with feedback and shows a more uniform gain of a wider frequency range (see Fig. 14). Oscillators with a grounded emitter or source have more stability difficulties over wider frequency ranges.

Depending on the frequency range, there are several resonators available. For low frequencies up to about 500 MHz, lumped elements such as inductors are useful. Above these frequencies, transmission-line-based resonators are microwave resonators, which are better. Very small oscillators use printed transmission lines. High-performance oscillators use ceramic resonators (CROs), dielectric resonators (DROs), and surface acoustical wave resonators (SAWs), to name only a few. The frequency standard, if not derived from an atomic frequency standard, is typically a crystal oscillator. Even the atomic frequency standards synchronize a crystal against an atomic resonance to compensate for the aging of the crystal. Figure 15a shows a circuit of a crystal oscillator with typical component values that are based on a 10-MHz third overtone AT cut crystal. Q is the ratio of stored energy divided by dissipated energy. The Q of the crystal can be as high as one million. The figure of merit Q is defined by $\omega L/R$. In our case, $\omega L/R$ is

$$\frac{2\pi \times 1Hy \times 10E6}{50} = 1.25 \text{ million}$$

Therefore, the resulting Q is 1.25 million. Typical resonator Q values for LC oscillators are 200; for structure-based resonators like ceramic resonators or dielectric resonators, Q values of 400 are not uncommon.

An oscillator operating at 700 MHz is shown in Fig. 15a, including its schematic. CAD simulation was used to determine the resonance frequency phase noise and the harmonic contents, shown in Fig. 15b. The output power

can be taken off either the emitter, the emitter that provides better harmonic filtering, or from the collector that provides smaller interaction between the oscillator frequency and the load. This effect is defined as frequency pulling. The tuned capacitor can now be replaced by a voltage-dependent capacitor. A tuning diode is a diode operated in reverse. Its PN-junction capacitance changes as a function of applied voltage.

A two-port oscillator analysis will now be presented. It is based on the fact that an ideal tuned circuit (infinite Q), once excited, will oscillate infinitely because there is no resistance element present to dissipate the energy. In the actual case where the inductor Q is finite, the oscillations die out because energy is dissipated in the resistance. It is the function of the amplifier to maintain oscillations by supplying an amount of energy equal to that dissipated. This source of energy can be interpreted as a negative resistor in series with the tuned circuit. If the total resistance is positive, the oscillations will die out, while the oscillation amplitude will increase if the total resistance is negative. To maintain oscillations, the two resistors must be of equal magnitude. To see how a negative resistance is realized, the input impedance of the circuit in Fig. 16 will be derived.

If Y_{22} is sufficiently small ($Y_{22} \ll 1/R_L$), the equivalent circuit is as shown in Fig. 16. The steady-state loop equations are

$$V_{in} = I_{in}(X_{C1} + X_{C2}) - I_b(X_{C1} - \beta X_{C2}) \tag{10}$$

$$0 = -I_{in}(X_{C1}) + I_b(X_{C1} + h_{ie}) \tag{11}$$

After I_b is eliminated from these two equations, Z_{in} is obtained as

$$Z_{in} = \frac{V_{in}}{I_{in}} = \frac{(1 + \beta)X_{C1}X_{C2} + h_{ie}(X_{C1} + X_{C2})}{X_{C1} + h_{ie}} \tag{12}$$

(a)

Typical-noise curve for R 10 MHz frequency standard

(b)

Figure 15. (a) Abbreviated circuit of a 10-MHz crystal oscillator; (b) measured phase noise for this frequency standard by HP of Fig. 15a.

If $X_{C_1} \ll h_{ie}$, the input impedance is approximately equal to

$$Z_{in} \approx \frac{1 + \beta}{h_{ie}} X_{C_1} X_{C_2} + (X_{C_1} + X_{C_2}) \quad (13)$$

$$Z_{in} \approx \frac{-g_m}{\omega^2 C_1 C_2} + \frac{1}{j\omega [C_1 C_2 / (C_1 + C_2)]} \quad (14)$$

That is, the input impedance of the circuit shown in Fig. 17 is a negative resistor,

$$R = \frac{-g_m}{\omega^2 C_1 C_2} \quad (15)$$

in series with a capacitor,

$$C_{in} = \frac{C_1 C_2}{C_1 + C_2} \quad (16)$$

which is the series combination of the two capacitors.

With an inductor L (with the series resistance R_S) connected across the input, it is clear that the condition for sustained oscillation is

$$R_S = \frac{g_m}{\omega^2 C_1 C_2} \quad (17)$$

Figure 16. Calculation of input impedance of the negative-resistance oscillator.

and the frequency of oscillation is

$$f_o = \frac{1}{2\pi\sqrt{L[C_1C_2/(C_1 + C_2)]}} \tag{18}$$

This interpretation of the oscillator readily provides several guidelines that can be used in the design. First, C_1 should be as large as possible so that

$$X_{C_1} \ll h_{ie} \tag{19}$$

and C_2 is to be large so that

$$X_{C_2} \ll \frac{1}{Y_{22}} \tag{20}$$

When these two capacitors are large, the transistor base-to-emitter and collector-to-emitter capacitances will have a negligible effect on the circuit's performance. However, there is a maximum value of the capacitances because

$$r \leq \frac{g_m}{\omega^2 C_1 C_2} \leq \frac{G}{\omega^2 C_1 C_2} \tag{21}$$

where G is the maximum value of g_m . For a given product of C_1 and C_2 , the series capacitance is at maximum when

Figure 17. Equivalent small-signal circuit of Fig. 16.

$C_1 = C_2 = C_m$. Thus

$$\frac{1}{\omega C_m} > \sqrt{\frac{r}{G}} \tag{22}$$

Design rule:

$$C_2 = C_1 \times \left| \frac{Y_{21}}{Y_{11}} \right| \tag{23}$$

This equation is important in that it shows that for oscillations to be maintained, the minimum permissible reactance $1/\omega C_m$ is a function of the resistance of the inductor and the transistor's mutual conductance, g_m . Figure 18 shows the resonant and oscillation condition for optimum performance. The negative real value should occur at $X = 0$!

An oscillator circuit known as the *Clapp circuit* or *Clapp-Gouriet circuit* is shown in Fig. 19. This oscillator is equivalent to the one just discussed, but it has the practical advantage of being able to provide another degree of design freedom by making C_o much smaller than C_1 and C_2 .

It is possible to use C_1 and C_2 to satisfy the condition of Eq. (20) and then adjust C_o for the desired frequency of oscillation ω_o , which is determined from

$$\omega_o L - \frac{1}{\omega_o C_o} - \frac{1}{\omega_o C_1} - \frac{1}{\omega_o C_2} = 0 \tag{24}$$

Figure 20 shows the Clapp-Gouriet oscillator. Like the Colpitts, the Clapp-Gouriet obtains its feedback via a capacitive voltage divider; unlike the Colpitts, an additional capacitor series tunes the resonator. The Pierce oscillator, a configuration used only with crystals, is a rotation of the Clapp-Gouriet oscillator in which the emitter is at RF ground [72-75].

4.1.1. Phase Noise. An estimate of the noise performance of an oscillator is

$$\mathcal{L}(\omega_m) = \frac{1}{8} \frac{FkT}{P_{sav}} \frac{\omega_0^2}{\omega_m^2} \left(\frac{P_{in}}{\omega_0 W_e} + \frac{1}{Q_{unl}} + \frac{P_{sig}}{\omega_0 W_e} \right)^2 \left(1 + \frac{\omega_c}{\omega_m} \right)$$

Phase perturbation

Resonator Q

Flicker effect

Input power/reactive power ratio

Signal power/reactive power ratio

(25)

This equation is based on work done by Dieter Scherer of Hewlett-Packard about 1978. He was the first to introduce the flicker effect to the Leeson equation by adding the AM-to-PM conversion effect, which is caused by the nonlinear capacitance of the active devices [76]. Figure 21 shows details of the noise contribution. This equation must be

Figure 18. The CAD-based linearized currents. Conditions for oscillation are $X=0$ and $R<0$.

further expanded:

$$\mathcal{L}(f_m) = 10 \log$$

$$\times \left\{ \left[1 + \frac{f_0^2}{(2f_m Q_{load})^2} \right] \left(1 + \frac{f_c}{f_m} \right) \frac{FkT}{2P_{sav}} + \frac{2kTRK_0^2}{f_m^2} \right\} \quad (26)$$

where

$\mathcal{L}(f_m)$ = ratio of sideband power in 1 Hz bandwidth at f_m to total power in decibels

f_m = frequency offset

f_0 = center frequency

f_c = flicker frequency

Q_{load} = loaded Q of the tuned circuit

F = noise factor

kT = 4.1×10^{-21} at 300 K₀ (room temperature)

P_{sav} = average power at oscillator output

R = equivalent noise resistance of tuning diode (typically 200 Ω–10 kΩ)

K = oscillator voltage gain

Table 1 shows the flicker corner frequency f_c as a function of I_C for a typical small-signal microwave BJT. $I_{C(max)}$ of this transistor is about 10 mA.

Note that f_c , which is defined by AF and KF in the SPICE model, increases with I_C . This gives us a clue about how f_c changes when a transistor oscillates. As a result of the bias point shift that occurs during oscillation, an oscillating BJT's average I_C is higher than its small-signal I_C . KF is therefore higher for a given BJT operating as an oscillator than for the same transistor operating as a small-signal amplifier. This must be kept in mind when considering published f_c data, which are usually determined under small-signal conditions without being qualified as such. Determining a transistor's oscillating f_c is best done through measurement—operate the device as a high- Q UHF oscillator (we suggest using a ceramic-resonator-based tank in the vicinity of 1 GHz), and measure its close-in (10 Hz–10 kHz) phase noise versus offset from the carrier. f_c will correspond to a slight decrease in the slope of the phase noise versus offset curve. Generally, f_c varies with device type as follows: silicon JFETs, 50 Hz and higher;

microwave RF BJTs, 1–10 kHz (as above); MOSFETs, 10–100 kHz; GaAs FETs, 10–100 MHz. Figure 22 shows the phase noise of oscillators using different semiconductors and resonators.

The additional term introduces a distinction between a conventional oscillator and a VCO. Whether the voltage- or current-dependent capacitance is internal or external makes no difference; it simply affects the frequency.

For a more complete expression for a resonator oscillator’s phase noise spectrum, we can write

$$\begin{aligned}
 S_\phi(f_m) = & \frac{\alpha_R F_0^4 + \alpha_E \left(\frac{F_0}{2Q_L}\right)^2}{f_m^3} \\
 & + \frac{\left(\frac{2GFkT}{P_0}\right) \left(\frac{F_0}{2Q_L}\right)^2}{f_m^2} \\
 & + \frac{2\alpha_R Q_L F_0^3}{f_m^2} \\
 & + \frac{\alpha_E}{f_m} + \frac{2GFkT}{P_0}
 \end{aligned} \tag{27}$$

where

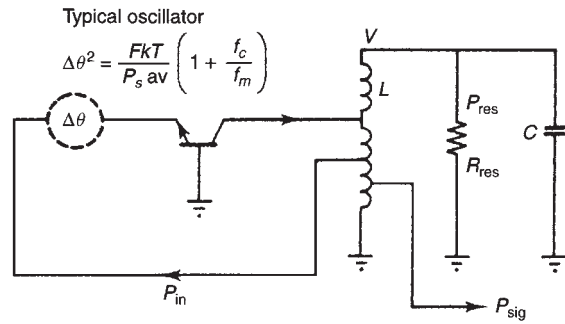

- G = compressed power gain of the loop amplifier
- F = noise factor of the loop amplifier
- k = Boltzmann’s constant
- T = temperature in Kelvin
- P_0 = carrier power level (in watts) at the output of the loop amplifier
- F_0 = carrier frequency in hertz
- f_m = carrier offset frequency in hertz

$Q_L (= \pi F_0 \tau_g)$ = loaded Q of the resonator in the feedback loop

α_R and α_E = flicker noise constants for the resonator and loop amplifier, respectively [77–86]

4.2. Frequency Divider

The output from the VCO has to be divided down to the reference frequency. The reference frequency can vary from a few kilohertz to more than 100 MHz [87–89]. A smaller division ratio provides better phase noise. Most of the frequency dividers are either off-the-shelf devices or custom devices. A typical frequency divider consists of a CMOS synchronous divider that can handle division ratios as low as 5 and as high as 1 million. The division ratio

For $f_m < \frac{f_o}{2Q_{load}}$

$$\mathcal{L}(f_m) = \frac{1}{2} \frac{1}{\omega_m^2} \left(\frac{\omega_o}{2Q_{load}} \right)^2 \frac{FkT}{P_{sav}} \left(1 + \frac{f_c}{f_m} \right)$$

$$\begin{aligned}
 Q_{load} &= \frac{\omega_o W_e}{P_{diss, total}} = \frac{\omega_o W_e}{P_{in} + P_{res} + P_{sig}} \\
 &= \frac{\text{Reactive power}}{\text{Total dissipated power}}
 \end{aligned}$$

Maximum energy in C or L: $W_e = \frac{1}{2} C V^2$

$$\mathcal{L}(\omega_m) = \frac{1}{8} \frac{FkT}{P_{sav}} \frac{\omega_o^2}{\omega_m^2} \left(\frac{P_{in}}{\omega_o W_e} + \frac{1}{Q_{uni}} + \frac{P_{sig}}{\omega_o W_e} \right) \left(1 + \frac{\omega_c}{\omega_m} \right)$$

Figure 21. Diagram for a feedback oscillator showing the key components considered in the phase noise calculation and its contribution.

is determined by the number of dividers. Typical CMOS dividers end at 250 MHz. To extend the frequency range by using an asynchronous divider means to extend the frequency range up to several gigahertz, but then the frequency resolution is compromised. This prescaler has to be

Figure 22. Phase noise of oscillators using different semiconductors and resonators.

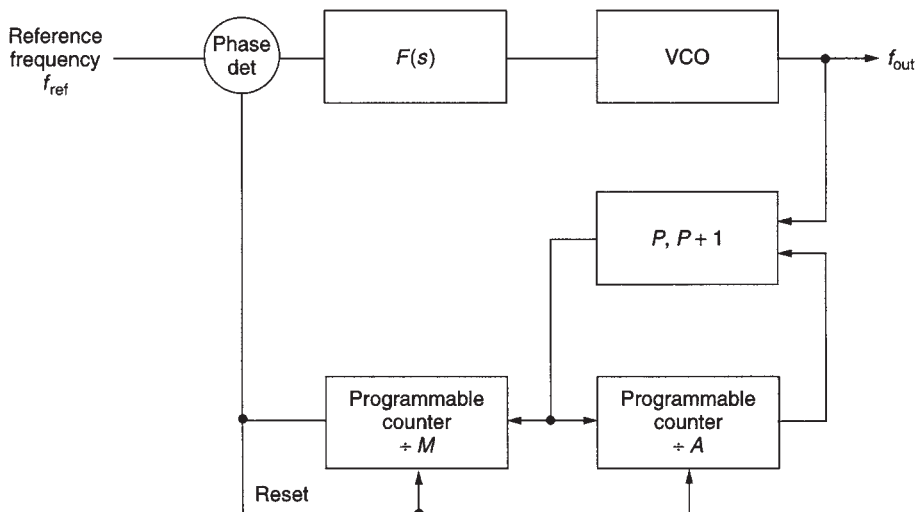

Figure 23. System using dual-modulus counter arrangement.

a synchronized counter that has to be clocked by the main divider, but because of propagation delays, this can become difficult to achieve and can introduce phase jitter. A way around this is to use a dual modulus prescaler that toggles between two stages, dividing by N and dividing by $N + 1$. Dual modulus counters are available in numbers like 5/6, 10/11, and 20/21.

Consider the system shown in Fig. 23. If the $P/(P + 1)$ is a 10/11 divider, the A counter counts the units and the M counter counts the tens. The mode of operation depends on the type of programmable counter used, but the system might operate as follows. If the number loaded into A is greater than zero, then the $P/(P + 1)$ divider is set to divide by $P + 1$ at the start of the cycle. The output from the $P/(P + 1)$ divider clocks both A and M . When A is full, it ceases count and sets the $P/(P + 1)$ divider into the P mode. Only M is then clocked, and when it is full, it resets both A and M , and the cycle repeats.

$$(M - A)P + A(P + 1) = MP + A \tag{28}$$

Therefore

$$f_{out} = (MP + A)f_{ref} \tag{29}$$

If A is incremented by one, the output frequency changes by f_{ref} . In other words, the channel spacing is equal to f_{ref} . This is the channel spacing that would be obtained with a fully programmable divider operating at the same frequency as the $P/(P + 1)$ divider.

For this system to work, the A counter must underflow before the M counter does; otherwise, $P/(P + 1)$ will remain permanently in the $P + 1$ mode. Thus, there is a minimum system division ratio, M_{min} , below which the $P/(P + 1)$ system will not function. To find that minimum ratio, consider the following.

The A counter must be capable of counting all numbers up to and including $P - 1$ if every division ratio is to be

possible, or

$$A_{max} = P - 1 \tag{30}$$

$$M_{min} = P \text{ because } M > A \tag{31}$$

The divider chain divides by $MP + A$; therefore, the minimum systems division ratio is

$$\begin{aligned} M_{min} &= M_{min}(P + A_{min}) \\ &= P(P + 0) = P^2 \end{aligned} \tag{32}$$

Using a 10/11 ratio, the minimum practical division ratio of the system is 100.

In the system shown in Fig. 23, the fully programmable counter, A , must be quite fast. With a 350-MHz clock to the 10/11 divider, only about 23 ns is available for counter A to control the 10/11 divider. For cost reasons, it would be desirable to use a TTL fully programmable counter, but when the delays through the ECL-to-TTL translators have been taken into account, very little time remains for the fully programmable counter. The 10/11 function can be extended easily, however, to give a $+N(N + 1)$ counter with a longer control time for a given input frequency, as shown in Figs. 24 and 25. Using the 20/21 system shown in Fig. 24, the time available to control 20/21 is typically 87 ns at 200 MHz and 44 ns at 350 MHz. The time available to control the 40/41 (Fig. 25) is approximately 180 ns at 200 MHz and 95 ns at 350 MHz.

Figure 26 shows the block diagram of an advanced digital synthesizer block, which is produced by analog devices. There are numerous manufacturers of such chips on the market. Figure 25 gives some insight into the frequency divider system. The top accepts input from a frequency standard, also referred to as a *reference signal*, which is reduced to a number between 5 kHz and 20 MHz. The use of a high-frequency reference requires a higher division ratio, but typically these reference frequencies are also used for some other mixing processes. The 24-bit input

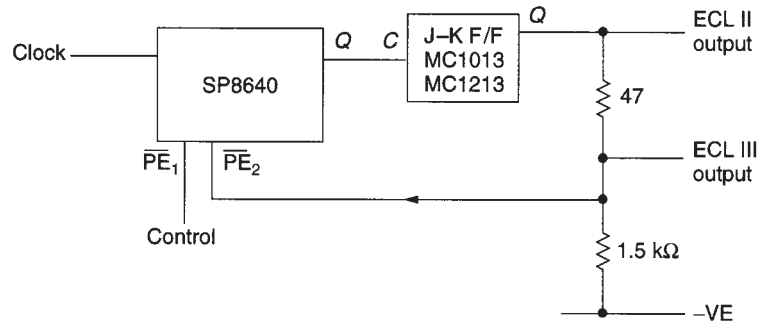

Figure 24. Level shifting information for connecting the various ECL₂ and ECL₃ stages.

register controls both the reference divider and the frequency divider. The frequency divider uses a prescaler like 5/6 or 10/11, and its output is applied to the phase frequency detector. The multiplex unit on the right is doing all the housekeeping and providing information like block, detect, and others. The divider typically has very little control over this portion of the synthesizer, and it's a constant battle to find better parts. Very few high-end synthesizers use custom IC's. To have those built is typically very costly and is cost-effective only if the frequency resolution required is not provided by any other chip on the market. Most of the high-end fractional-*N* synthesizer chips fall in this category.

4.3. Phase Detector

The phase detector at minimum consists of a phase sensitive circuit such as a double-balanced mixer [90–93]. Such a simple circuit has two disadvantages: (1) it's not sensitive to frequency changes and (2) the DC output level is only 0.7V per diode in the ring, and therefore, a poor signal-to-noise ratio can be expected. Today, modern circuits use a phase discriminator with a charge-pump output. The phase frequency is edge triggered and sensitive to both phase and frequency changes. Figure 27 shows a digital phase frequency discriminator with a programmable delay. Under locked condition, the charge pump does not supply current. Under unlocked condition, the current at the point CP charges or discharges a capacitor, which is

part of the integrated system and smoothes the output voltage to become ripple-free. The output from the reference divider is a pulsetrain with a small duty cycle, and the input from the frequency divider(/*N*) is a pulse train with a very small duty cycle. The duty cycle typically is as short as a division ratio is high. So, for a division ratio of 1000, the duty cycle is 0.1%, but the repetition frequency is equal to the output. The charge output, therefore, is also a very narrow train of pulses that are fed to the loop filter. The phase detector has to deal with complicated issues like zero crossings causing instability. The best phase frequency detectors are either TTL or CMOS because they have a larger voltage output swing. In some cases, the charge pump is built from discrete components if a very high performance is required.

4.4. Loop Filter

Loop filters range from a simple lowpass filter to a complex arrangement of active filters. Figure 28 shows the configuration and frequency response of passive and active loop filters. Figure 29 shows an arrangement of more complex filters, including their calculations. The charge pumps can frequently lift with a purely passive filter, as seen in Fig. 30; however, the DC gain of the active filters provides better close-in phase noise and tracking. There may be a penalty if the active circuit is noisy; however, the latest available operation amplifiers have sufficient performance [94].

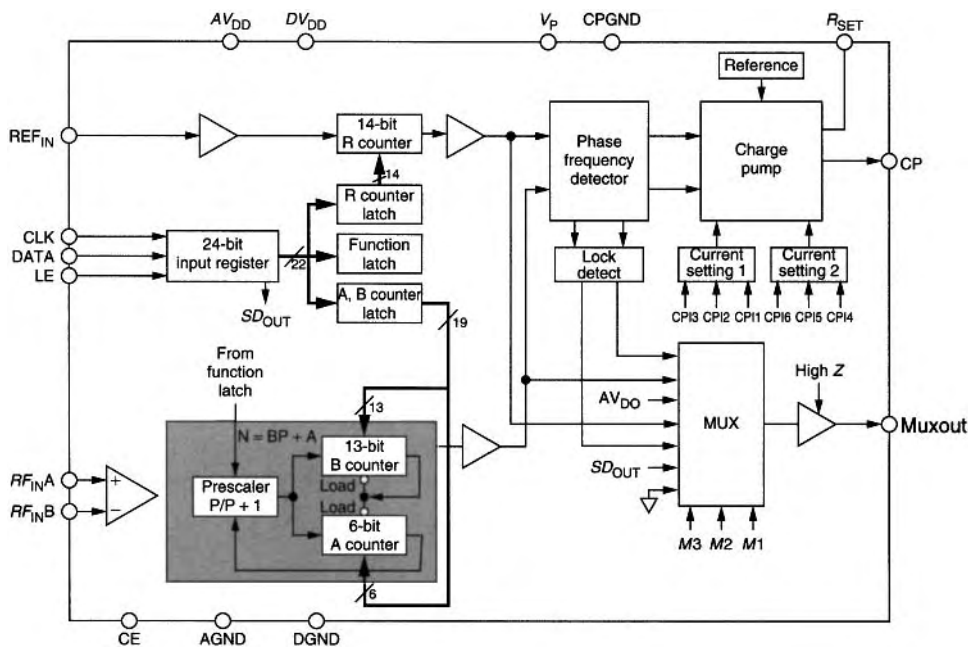

Figure 26. Shows the block diagram of an advanced digital fractional-*N* synthesizer.

5. PHASE LOCKED LOOP DESIGNS

5.1. The Type 2, Second-Order Loop

The following is a derivation of the properties of the type 2, second-order loop. This means that the loop has two integrators—the diode and the operational amplifier—and it

is built with the order of 2, as can be seen from Fig. 29. The basic principle to derive the performance for higher-order loops follows the same principle, although the derivation is more complicated. Following the math section, we will show some typical responses [95].

The type 2, the second-order loop uses a loop filter in the form

$$F(s) = \frac{1}{s} \frac{\tau_2 s + 1}{\tau_1} \tag{33}$$

The multiplier $1/s$ indicates a second integrator, which is generated by the active amplifier. In Table 1, this is the type 3 filter. The type 4 filter is mentioned there as a possible configuration but is not recommended because, as stated previously, the addition of the pole of the origin creates difficulties with loop stability and, in most cases, requires a change from the type 4 to the type 3 filter. One can consider the type 4 filter as a special case of the type 3 filter, and therefore, it does not have to be treated separately. Another possible transfer function is

$$F(s) = \frac{1}{R_1 C} \frac{1 + \tau_2 s}{s} \tag{34}$$

with

$$\tau_2 = R_2 C \tag{35}$$

Under these conditions, the magnitude of the transfer function is

$$|F(j\omega)| = \frac{1}{R_1 C \omega} \sqrt{1 + (\omega R_2 C)^2} \tag{36}$$

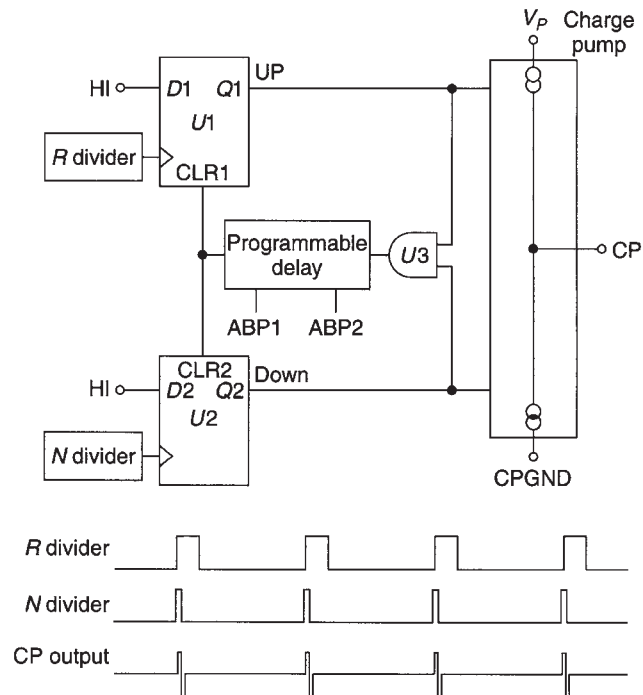

Figure 27. A digital phase frequency discriminator with a programmable delay.

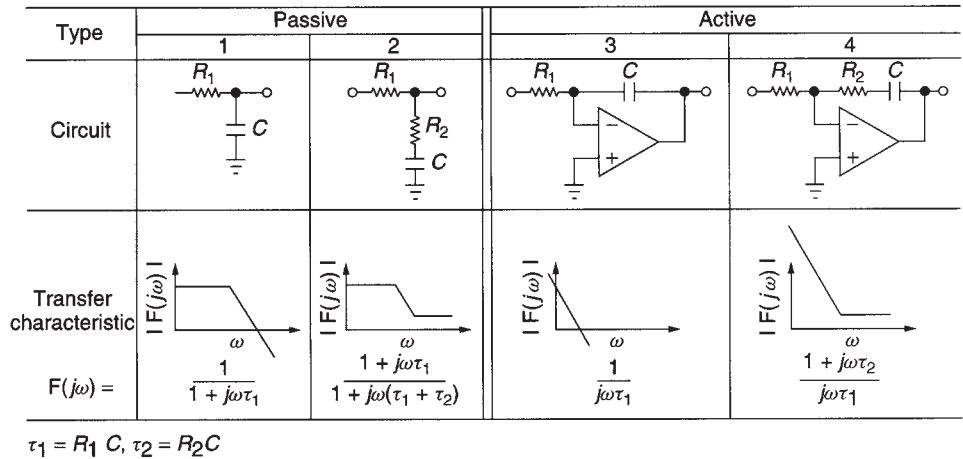

Figure 28. Circuit and transfer characteristics of several PLL filters.

and the phase is

$$\theta = \arctan(\omega\tau_2) - 90^\circ \tag{37}$$

and

$$R_2 = \frac{\tau_2}{C} \tag{41}$$

Again, as if for a practical case, we start off with the design values ω_n and ζ , and we have to determine τ_1 and τ_2 . Taking an approach similar to that for the type 1, second-order loop, the results are

$$\tau_1 = \frac{K}{\omega_n} \tag{38}$$

The closed-loop transfer function of a type 2, second-order PLL with a perfect integrator is

$$B(s) = \frac{K(R_2/R_1)[s + (1/\tau_2)]}{s^2 + K(R_2/R_1)s + (K/\tau_2)(R_2/R_1)} \tag{42}$$

By introducing the terms ζ and ω_n , the transfer function now becomes

$$\tau_2 = \frac{2\zeta}{\omega_n} \tag{39}$$

$$B(s) = \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{43}$$

and

with the abbreviations

$$R_1 = \frac{\tau_1}{C} \tag{40}$$

$$\omega_n = \left(\frac{K R_2}{\tau_2 R_1}\right)^{1/2} \text{ rad/s} \tag{44}$$

Type 2, 2 nd order	Type 2, 3 rd order	Type 2, 4 th order

Figure 30. Recommended passive filters for charge pumps.

and

$$\zeta = \frac{1}{2} \left(K\tau_2 \frac{R_2}{R_1} \right)^{1/2} \quad (45)$$

and $K = K_0 K_o / N$.

The 3 dB bandwidth of the type 2, second-order loop is

$$B_{3dB} = \frac{\omega_n}{2\pi} \left[2\zeta^2 + 1 + \sqrt{(2\zeta^2 + 1)^2 + 1} \right]^{1/2} \text{ Hz} \quad (46)$$

and the noise bandwidth is

$$B_n = \frac{K(R_2/R_1) + 1/\tau_2}{4} \text{ Hz} \quad (47)$$

Again, we ask the question of the final error and use the previous error function,

$$E(s) = \frac{s\theta(s)}{s + K(R_2/R_1)\{[s + (1/\tau_2)]/s\}} \quad (48)$$

or

$$E(s) = \frac{s^2\theta(s)}{s^2 + K(R_2/R_1)s + (K/\tau_2)(R_2/R_1)} \quad (49)$$

As a result of the perfect integrator, the steady-state error resulting from a step change in input phase or change of magnitude of frequency is zero.

If the input frequency is swept with a constant range change of input frequency ($\Delta\omega/dt$), for $\theta(s) = (2\Delta\omega/dt)/s^3$, the steady-state phase error is

$$E(s) = \frac{R_1}{R_2} \frac{\tau_2(2\Delta\omega/dt)}{K} \text{ rad} \quad (50)$$

The maximum rate at which the VCO frequency can be swept for maintaining lock is

$$\frac{2\Delta\omega}{dt} = \frac{N}{2\tau_2} \left(4B_n - \frac{1}{\tau_2} \right) \text{ rad/s} \quad (51)$$

The introduction of N indicates that this is referred to the VCO rather than to the phase/frequency comparator. In the previous example of the type 1, first-order loop, we referred it only to the phase/frequency comparator rather than to the VCO.

Figure 31 shows the closed-loop response of a type 2, third-order loop having a phase margin of 10° and with the optimal 45° .

Figure 31. Measured spectrum of a synthesizer where the loop filter is underdamped, resulting in ≈ 10 dB increase of the phase noise at the loop filter bandwidth. In this case, we either do not meet the 45° phase margin criterion or the filter is too wide, so it shows the effect of the upconverted reference frequency.

Figure 32. Integrated response for various loops as a function of the phase margin.

A phase margin of 10° results in overshoot, which in the frequency domain would be seen as peaks in the oscillator noise-sideband spectrum. Needless to say, this is a totally undesirable effect, and as the operational amplifiers and other active and passive elements add to this, the loop filter has to be adjusted after the design is finalized to accommodate the proper resulting phase margin ($35\text{--}45^\circ$). The open-loop gain for different loops can be seen in Figs. 32 and 33.

5.2. Transient Behavior of Digital Loops Using Tristate Phase Detectors

5.2.1. Pullin Characteristic. The type 2, second-order loop is used with either a sample/hold comparator or a tristate phase/frequency comparator.

We will now determine the transient behavior of this loop. Figure 34 shows the block diagram.

Very rarely in the literature is a clear distinction between pullin and lockin characteristics or frequency and phase acquisition made as a function of the digital phase/frequency detector. Somehow, all the approximations or linearizations refer to a sinusoidal phase/frequency comparator or its digital equivalent, the exclusive-OR gate.

Figure 33. Closed-loop response of a type 2, third-order PLL having a phase margin of 10° .

The tristate phase/frequency comparator follows slightly different mathematical principles. The phase detector gain is

$$K'_d = \frac{V_d}{\omega_0} = \frac{\text{phase detector supply voltage}}{\text{loop idling frequency}}$$

and is valid only in the out-of-lock state and is a somewhat coarse approximation to the real gain, which, due to non-linear differential equations, is very difficult to calculate.

However, practical tests show that this approximation is still fairly accurate. Definitions are

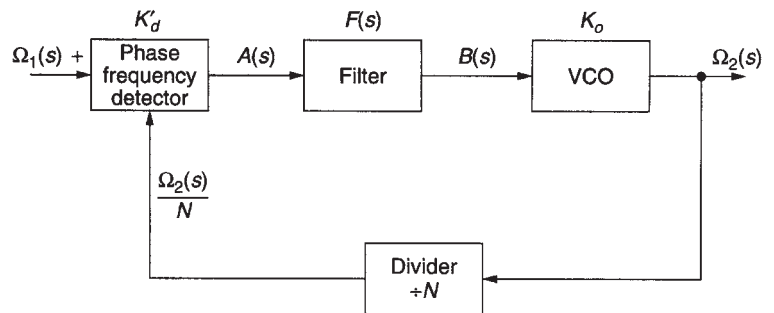

$$\Omega_1(s) = \mathcal{L}[\Delta\omega_1(t)] \text{ (reference input to } \delta/\omega \text{ detector)}$$

$$\Omega_2(s) = \mathcal{L}[\Delta\omega_2(t)] \text{ (signal VCO output frequency)}$$

$$\Omega_e(s) = \mathcal{L}[\omega_e(t)] \text{ (error frequency at } \delta/\omega \text{ detector)}$$

$$\Omega_e(s) = \Omega_1(s) - \frac{\Omega_2(s)}{N}$$

$$\Omega_2(s) = [\Omega_1(s) - \Omega_e(s)]N$$

Note: The frequency transfer const. of the VCO = K_o (not $\frac{K_o}{s}$, which is valid for phase transfer only.)

Figure 34. Block diagram of a digital PLL before lock is acquired.

From the circuit above, we obtain

$$\begin{aligned} A(s) &= \Omega_e(s)K'_d \\ B(s) &= A(s)F(s) \\ \Omega_2(s) &= B(s)K_o \end{aligned}$$

The error frequency at the detector is

$$\Omega_e(s) = \Omega_1(s)N \frac{1}{N + K_oK'_dF(s)} \quad (52)$$

The signal is stepped in frequency:

$$\Omega_1(s) = \frac{\Delta\omega_1}{s} \quad (\Delta\omega_1 = \text{magnitude of frequency step}) \quad (53)$$

Active Filter of First Order. If we use an active filter

$$F(s) = \frac{1 + s\tau_2}{s\tau_1} \quad (54)$$

and insert this in Equation (51), the error frequency is

$$\Omega_e(s) = \Delta\omega_1N \frac{1}{s \left(N + K_oK'_d \frac{\tau_2}{\tau_1} \right) + \frac{K_oK'_d}{\tau_1}} \quad (55)$$

Utilizing the Laplace transformation, we obtain

$$\omega_e(t) = \Delta\omega_1 \frac{1}{1 + K_oK'_d(\tau_2/\tau_1)(1/N)} \exp \left[-\frac{t}{(\tau_1N/K_oK'_d) + \tau_2} \right] \quad (56)$$

and

$$\lim_{t \rightarrow 0} \omega_e(t) = \frac{\Delta\omega_1N}{N + K_oK'_d(\tau_2/\tau_1)} \quad (57)$$

$$\lim_{t \rightarrow \infty} \omega_e(t) = 0 \quad (58)$$

Passive Filter of First Order. If we use a passive filter

$$\lim_{t \rightarrow \infty} \omega_e(t) = 0 \quad (59)$$

for the frequency step

$$\Omega_1(s) = \frac{\Delta\omega_1}{s} \quad (60)$$

the error frequency at the input becomes

$$\begin{aligned} \Omega_e(s) &= \Delta\omega_1N \left\{ \frac{1}{s [N(\tau_1 + \tau_2) + K_oK'_d\tau_2] + (N + K_oK'_d)} \right. \\ &\quad \left. + \frac{\tau_1 + \tau_2}{s [N(\tau_1 + \tau_2) + K_oK'_d\tau_2] + (N + K_oK'_d)} \right\} \quad (61) \end{aligned}$$

For the first term, we will use the abbreviation A , and for the second term, we will use the abbreviation B :

$$A = \frac{1/[N(\tau_1 + \tau_2) + K_oK'_d\tau_2]}{s \left[s + \frac{N + K_oK'_d}{N(\tau_1 + \tau_2) + K_oK'_d\tau_2} \right]} \quad (62)$$

$$B = \frac{\frac{(\tau_1 + \tau_2)}{N(\tau_1 + \tau_2) + K_oK'_d\tau_2}}{s + \frac{N + K_oK'_d}{N(\tau_1 + \tau_2) + K_oK'_d\tau_2}} \quad (63)$$

After the inverse Laplace transformation, our final result becomes

$$\mathcal{L}^{-1}(A) = \frac{1}{N + K_oK'_d} \left\{ 1 - \exp \left[-t \frac{N + K_oK'_d}{N(\tau_1 + \tau_2) + K_oK'_d\tau_2} \right] \right\} \quad (64)$$

$$\mathcal{L}^{-1}(B) = \frac{\tau_1 + \tau_2}{N(\tau_1 + \tau_2) + K_oK'_d\tau_2} \exp \left[-t \frac{N + K_oK'_d}{N(\tau_1 + \tau_2) + K_oK'_d\tau_2} \right] \quad (65)$$

and finally

$$\omega_e(t) = \Delta\omega_1N [\mathcal{L}^{-1}(A) + (\tau_1 + \tau_2)\mathcal{L}^{-1}(B)] \quad (66)$$

What does the equation mean? We really want to know how long it takes to pull the VCO frequency to the reference. Therefore, we want to know the value of t , the time it takes to be within 2π or less of lock-in range.

The PLL can, at the beginning, have a phase error from -2π to $+2\pi$, and the loop, by accomplishing lock, then takes care of this phase error.

We can make the reverse assumption for a moment and ask ourselves, as we have done earlier, how long the loop stays in phase lock. This is called the *pullout range*. Again, we apply signals to the input of the PLL as long as the loop can follow and the phase error does not become larger than 2π . Once the error is larger than 2π , the loop jumps out of lock.

When the loop is out of lock, a beat note occurs at the output of the loop filter following the phase/frequency detector.

The tristate phase/frequency comparator, however, works on a different principle, and the pulses generated and supplied to the charge pump do not allow the generation of an ac voltage. The output of such a phase/frequency detector is always unipolar, but relative to

the value of $V_{batt}/2$, the integrator voltage can be either positive or negative. If we assume for a moment that this voltage should be the final voltage under a locked condition, we will observe that the resulting DC voltage is either more negative or more positive relative to this value, and because of this, the VCO will be “pulled in” to this final frequency rather than swept in. The swept-in technique applies only in cases of phase/frequency comparators, where this beat note is being generated. A typical case would be the exclusive-OR gate or even a sample/hold comparator. This phenomenon is rarely covered in the literature and is probably discussed in detail for the first time in the book by Roland Best [9].

Let us assume now that the VCO has been pulled in to final frequency to be within 2π of the final frequency, and the time t is known. The next step is to determine the lockin characteristic.

5.2.2. Lockin Characteristic. We will now determine the lockin characteristic, and this requires the use of a different block diagram. Figure 5, of the section on frequency synthesizer fundamentals shows the familiar block diagram of the PLL, and we will use the following definitions:

$$\theta_1(s) = \mathcal{L}[\Delta\delta_1(t)] \text{ (reference input to } \delta/\omega \text{ detector)}$$

$$\theta_2(s) = \mathcal{L}[\Delta\delta_2(t)] \text{ (signal VCO output phase)}$$

$$\theta_e(s) = \mathcal{L}[\delta_e(t)] \text{ (phase error at } \delta/\omega \text{ detector)}$$

$$\theta(s) = \theta_1(s) - \frac{\theta_2(s)}{N}$$

From the block diagram, the following is apparent:

$$A(s) = \theta_e(s)K_d$$

$$B(s) = A(s)F(s)$$

$$\theta_2(s) = B(s) \frac{K_o}{s}$$

The phase error at the detector is

$$\theta_e(s) = \theta_1(s) \frac{sN}{K_oK_dF(s) + sN} \tag{67}$$

A step in phase at the input, where the worst-case error is 2π , results in

$$\theta_1(s) = 2\pi \frac{1}{s} \tag{68}$$

We will now treat the two cases using an active or passive filter:

Active Filter. The transfer characteristic of the active filter is

$$F(s) = \frac{1 + s\tau_2}{s\tau_1} \tag{69}$$

This results in the following formula for the phase error at the detector:

$$\theta_e(s) = 2\pi \frac{s}{s^2 + (sK_oK_d\tau_2/\tau_1)/N + (K_oK_d/\tau_1)/N} \tag{70}$$

The polynomial coefficients for the denominator are

$$a_2 = 1$$

$$a_1 = (K_oK_d\tau_2/\tau_1)/N$$

$$a_0 = (K_oK_d/\tau_1)/N$$

and we have to find the roots W_1 and W_2 . Expressed in the form of a polynomial coefficient, the phase error is

$$\theta_e(s) = 2\pi \frac{s}{(s + W_1)(s + W_2)} \tag{71}$$

After the inverse Laplace transformation has been performed, the result can be written in the form

$$\delta_e(t) = 2\pi \frac{W_1e^{-W_1t} - W_2e^{-W_2t}}{W_1 - W_2} \tag{72}$$

with

$$\lim_{t \rightarrow 0} \delta_e(t) = 2\pi$$

and

$$\lim_{t \rightarrow \infty} \delta_e(t) = 0$$

The same can be done using a passive filter.

Passive Filter. The transfer function of the passive filter is

$$F(s) = \frac{1 + s\tau_2}{1 + s(\tau_1 + \tau_2)} \tag{73}$$

If we apply the same phase step of 2π as before, the resulting phase error is

$$\theta_e(s) = 2\pi \frac{[1/(\tau_1 + \tau_2)] + s}{s^2 + s \frac{N + K_oK_d\tau_2}{N(\tau_1 + \tau_2)} + \frac{K_oK_d}{N(\tau_1 + \tau_2)}} \tag{74}$$

Again, we have to find the polynomial coefficients, which are

$$a_2 = 1$$

$$a_1 = \frac{N + K_oK_d\tau_2}{N(\tau_1 + \tau_2)}$$

$$a_0 = \frac{K_oK_d}{N(\tau_1 + \tau_2)}$$

and finally find the roots for W_1 and W_2 . This can be written in the form

$$\theta_e(s) = 2\pi \left[\frac{1}{\tau_1 + \tau_2} \frac{1}{(s + W_1)(s + W_2)} + \frac{s}{(s + W_1)(s + W_2)} \right] \tag{75}$$

Now we perform the inverse Laplace transformation and obtain our result

$$\delta_e(t) = 2\pi \left(\frac{1}{\tau_1 + \tau_2} \frac{e^{-W_1 t} - e^{-W_2 t}}{W_2 - W_1} + \frac{W_1 e^{-W_1 t} - W_2 e^{-W_2 t}}{W_1 - W_2} \right) \tag{76}$$

with

$$\lim_{t \rightarrow 0} \delta_e(t) = 2\pi$$

with

$$\lim_{t \rightarrow \infty} \delta_e(t) = 0$$

When analyzing the frequency response for the various types and orders of PLLs, the phase margin played an important role. For the transient time, the type 2, second-order loop can be represented with a damping factor or, for higher orders, with the phase margin. Figure 35 shows the normalized output response for a damping factor of 0.1 and 0.47. The ideal Butterworth response would be a damping factor of 0.7, which correlates with a phase margin of 45° .

5.3. Loop Gain/Transient Response Examples

Given the simple filter shown in Fig. 36 and the parameters as listed, the Bode plot is shown in Fig. 37. This approach can also be translated from a type 1 into a type 2

Figure 35. Normalized output response of a type 2, second-order loop with a damping factor of 0.1 and 0.05 for $\Omega_n = 0.631$.

filter as shown in Fig. 38 and its frequency response as shown in Fig. 39. The lockin function for this type 2, second-order loop with an ideal damping factor of 0.707 (Butterworth response) is shown in Fig. 40. Figure 41 shows an actual settling-time measurement. Any deviation from ideal damping, as we'll soon see, results in ringing (in an underdamped system), or, in an overdamped system, the voltage will crawl to its final value. This system can be increased in its order by selecting a type 2, third-order loop using the filter shown in Fig. 42. For an ideal synthesis of the values, the Bode diagram looks as shown in Fig. 43 and its resulting response is given in Fig. 44.

The order can be increased by adding an additional low-pass filter after the standard loop filter. The resulting system is a type 2, fifth-order loop. Figure 45 shows the Bode diagram or open-loop diagram, and Fig. 46 shows the locking function. By using a very wide loop bandwidth, this can be used to clean up microwave oscillators with

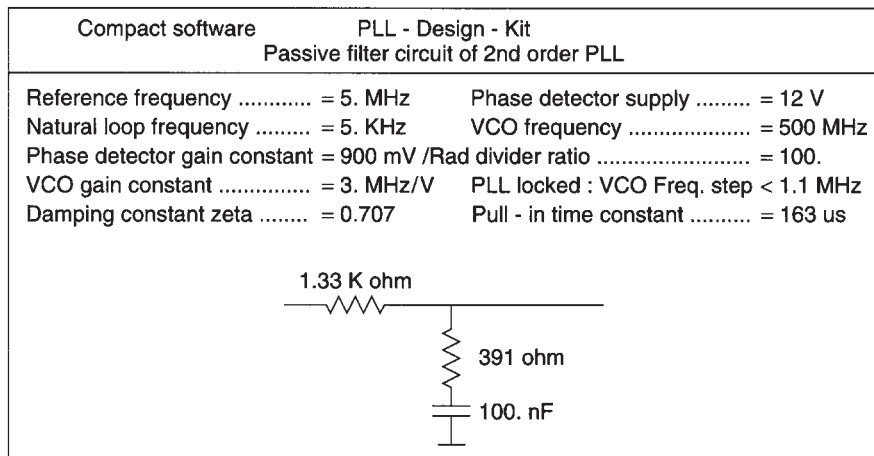

Figure 36. Loop filter for a type 1, second-order synthesizer.

Figure 37. Type 1, second-order loop response.

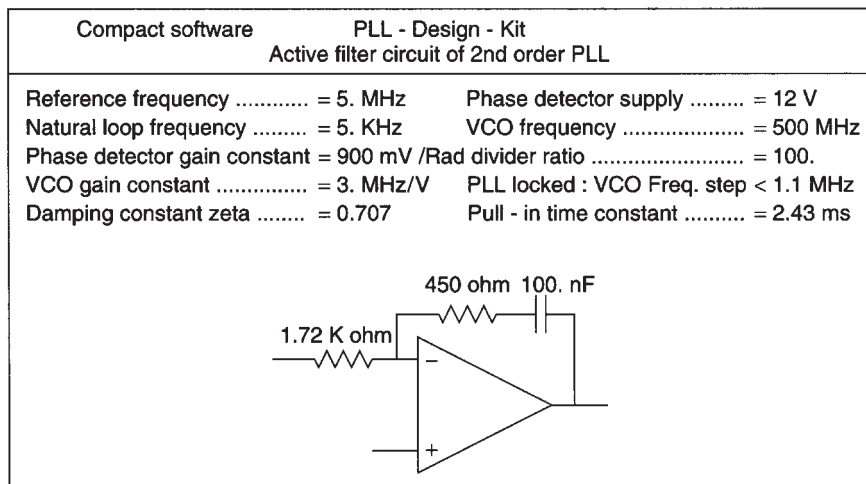

Figure 38. Loop filter for a type 2, second-order synthesizer.

Figure 39. Response of the type 2, second-order loop.

Figure 40. Lockin function of the type 2, second-order PLL. It indicates a lock time of 271 μ s and an ideal response.

Figure 41. Example of settling-time measurement.

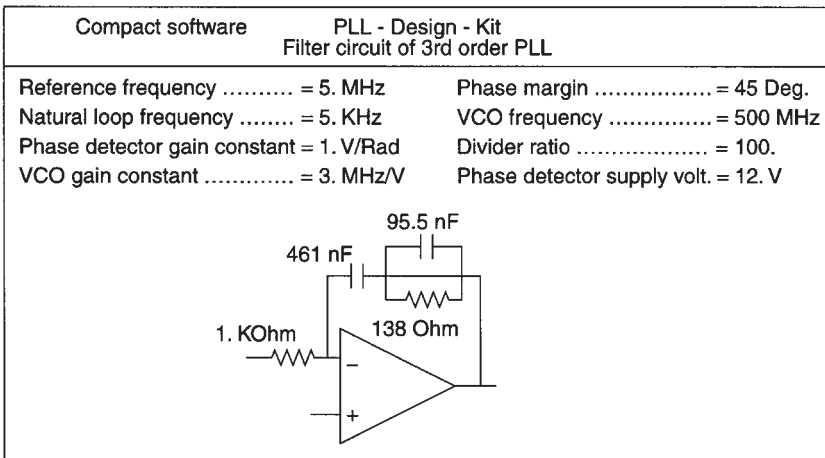

Figure 42. Loop filter for a type 2, third-order synthesizer.

Figure 43. Open-loop Bode diagram for the type 2, third-order loop. It fulfills the requirement of 45° phase margin at the 0 dB crossover point, and it corrects the slope down to -10 dB gain.

inherent comparatively poor phase noise. This cleanup has a dramatic influence on the performance.

By deviating from the ideal 45° to a phase margin of 33°, one obtains the already-mentioned ringing, as is evident from Fig. 47. The time to settle has grown from 13.3 to 62 μs.

To more fully illustrate the effects of nonideal phase margin, Figs. 48–51 show the lock-in function of a different type 2, fifth-order loop configured for phase margins of 25°, 35°, 45°, and 55°, respectively.

I have already mentioned that the loop should avoid “ears” (Fig. 31) with poorly designed loop filters. Another interesting phenomenon is the tradeoff between loop bandwidth and phase noise. In Fig. 52, the loop band-

width has been made too wide, resulting in a degradation of the phase noise, but provides faster settling time. By reducing the loop bandwidth from about 1 kHz to 300 Hz, only a very slight overshoot remains, improving the phase noise significantly. This is shown in Fig. 53.

5.4. Practical Circuits

Figure 54 shows a passive filter that is used for a synthesizer chip with constant current output. This chip has a charge-pump output, which explains the need for the first capacitor.

Figure 55 shows an active integrator operating at a reference frequency of several megahertz. The notch filter

Figure 44. Lockin function of the type 2, third-order loop for an ideal 45° phase margin.

Figure 45. Bode plot of the fifth-order PLL system for a microwave synthesizer. The theoretical reference suppression is better than 90 dB.

at the output reduces the reference frequency considerably. The notch is about 4.5 MHz.

Figure 56 shows the combination of a phase/frequency discriminator and a higher order loop filter as used in more complicated systems, such as fractional division synthesizers.

Figure 57 shows a custom-built phase detector with a noise floor of better than -168 dBc/Hz.

6. THE FRACTIONAL-N PRINCIPLE

The principle of the fractional- N PLL synthesizer was touched previously in Section 2. The following is a numerical example for better understanding.

Example 1. Considering the problem of generating 899.8 MHz using a fractional- N loop with a 50-MHz

Figure 46. Lockin function of the fifth-order PLL. Note that the phase lock time is approximately $13.3 \mu\text{s}$.

Figure 47. Lockin function of the fifth-order PLL. Note that the phase margin has been reduced from the ideal 45° . This results in a much longer settling time of $62 \mu\text{s}$.

reference frequency,

$$899.8 \text{ MHz} = 50 \text{ MHz} \left(N + \frac{K}{F} \right)$$

The integral part of the division N has to be set to 17, the fractional part K/F needs to be $\frac{996}{1000}$ (the fractional part K/F is not a integer), and the VCO output has to be divided by $996 \times$ every 1000 cycles. This can easily be implemented by adding the number 0.996 to the contents of an accumulator every cycle. Every time the accumulator overflows, the divider divides by 18 rather than by 17. Only the fractional value of the addition is retained in the phase accumulator. If we move to the lower band or try to generate 850.2 MHz, N remains 17 and K/F becomes $\frac{4}{1000}$. This method of using fractional division was first introduced by using analog implementation and noise cancellation, but today, it is implemented totally as a digital approach. The necessary resolution is obtained from the dual modulus prescaling, which allows for a well-established method for achieving a high-performance frequency synthesizer operating at UHF and higher frequencies. Dual-modulus prescaling avoids the loss of resolution in a system compared to a simple prescaler; it allows a VCO step equal to the value of the reference frequency to be obtained. This method needs an additional counter, and the dual-modulus prescaler then divides one or two values depending on the state of its control. The only drawback of prescalers is the minimum division ratio of the prescaler for approximately N^2 . The dual-modulus divider is the key to implementing the fractional- N synthesizer principle. Although the fractional- N technique appears to have a good potential of solving the resolution limitation, it is not free of having its own complications. Typically, an overflow from the phase accumulator, which is the adder with the output feedback to the input after being latched, is used to change the instantaneous division ratio. Each overflow produces a jitter at the output frequency, caused by the fractional

Figure 48. Lockin function of another type 2, fifth-order loop with a 25° phase margin. Noticeable ringing occurs, lengthening the lockin time to 1.86 ms.

Figure 49. Lockin function of the type 2, fifth-order loop with a 35° phase margin. Ringing still occurs, but the lockin time has decreased to 1.13 ms.

Figure 50. Lockin function of the type 2, third-order loop with an ideal 45° phase margin. The lockin time is 686 μs.

Figure 51. Lockin function of the type 2, fifth-order loop, for a 55° phase margin. The lock-in time has increased to 915 μs.

Figure 52. Comparison between open- and closed-loop noise prediction. Note the overshoot of around 1 kHz off the carrier.

Figure 53. Comparison between open- and closed-loop noise prediction. Note the overshoot at around 300 Hz off the carrier.

division, and is limited to the fractional portion of the desired division ratio.

In our case, we had chosen a stepsize of 200 kHz, and yet the discrete sidebands vary from 200 kHz for $K/F = \frac{4}{1000}$ to 49.8 MHz for $K/F = \frac{996}{1000}$. It will become the task of the loop filter to remove those discrete spurious components. Although in the past the removal of the discrete spurs has been accomplished by using analog techniques, various digital methods are now available. The microprocessor has to solve the following equation:

$$N^* = \left(N + \frac{K}{F}\right) = [N(F - K) + (N + 1)K] \quad (77)$$

Example 2. For $F_0 = 850.2$ MHz, we obtain

$$N^* = \frac{850.2 \text{ MHz}}{50 \text{ MHz}} = 17.004$$

Figure 54. Type 1 high-order loop filter used for passive filter evaluation. The 1-nF capacitor is used for spike suppression as explained in the text. The filter consists of a lag portion and an additional lowpass section.

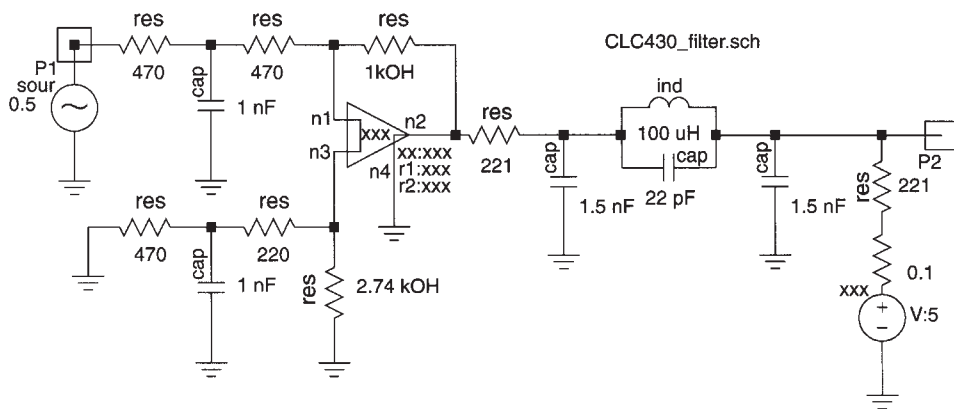

Figure 55. A type 2 high-order filter with a notch filter to suppress the discrete reference spurs.

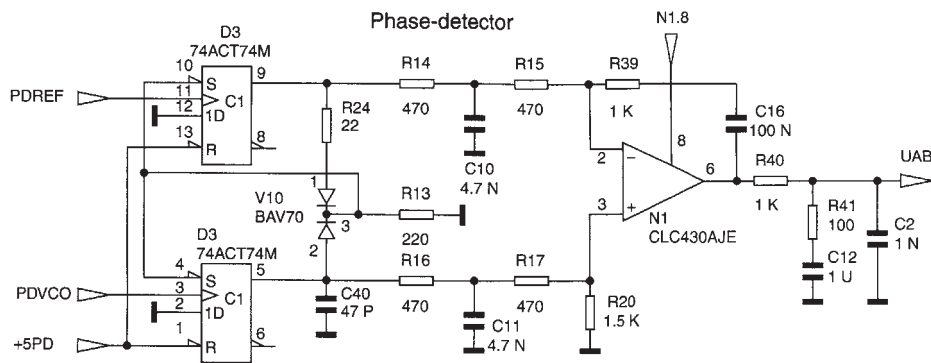

Figure 56. Phase/frequency discriminator including an active loop filter capable of operating up to 100 MHz.

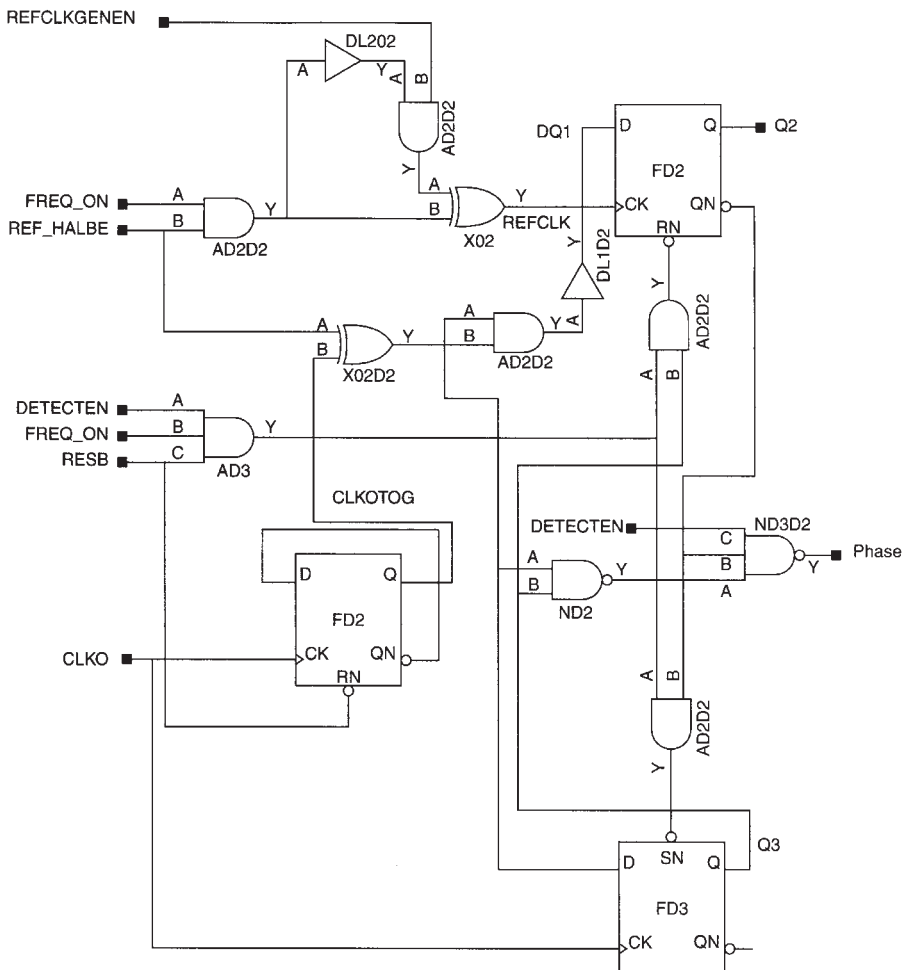

Figure 57. Custom-built phase detector with a noise floor of better than -168 dBc/Hz. This phase detector shows extremely low phase jitter.

Figure 58. The filter frequency response/phase noise analysis graph shows the required attenuation for the reference frequency of 50 MHz and the noise generated by the sigma-delta converter (three steps) as a function of the offset frequency. It becomes apparent that the sigma-delta converter noise dominates above 80 kHz unless attenuated.

Following the formula above, we further obtain

$$N^* = \left(N + \frac{K}{F} \right) = \frac{[17(1000 - 4) + (17 + 1) \times 4]}{1000}$$

$$= \frac{[16932 + 72]}{1000} = 17.004$$

$$F_{out} = 50 \text{ MHz} \times \frac{[16932 + 72]}{1000}$$

$$= 846.6 \text{ MHz} + 3.6 \text{ MHz}$$

$$= 850.2 \text{ MHz}$$

Table 2. Modern Spur Suppression Methods

Technique	Feature	Problem
DAC phase estimation	Cancel spur by DAC	Analog mismatch
Pulse generation	Insert pulses	Interpolation jitter
Phase interpolation	Inherent fractional divider	Interpolation jitter
Random jittering	Randomize divider	Frequency jitter
Sigma-delta modulation	Modulate division ratio	Quantization noise

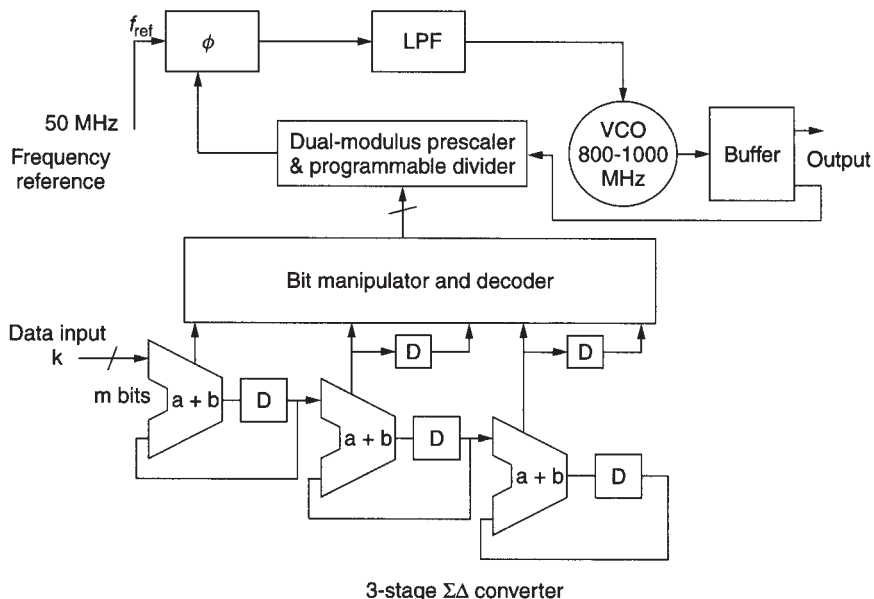

Figure 59. Block diagram of the fractional-*N* synthesizer built using a custom IC capable of operation at reference frequencies up to 150 MHz. The frequency is extensible up to 3 GHz using binary ($\div 2, \div 4, \div 8$, etc.) and fixed-division counters.

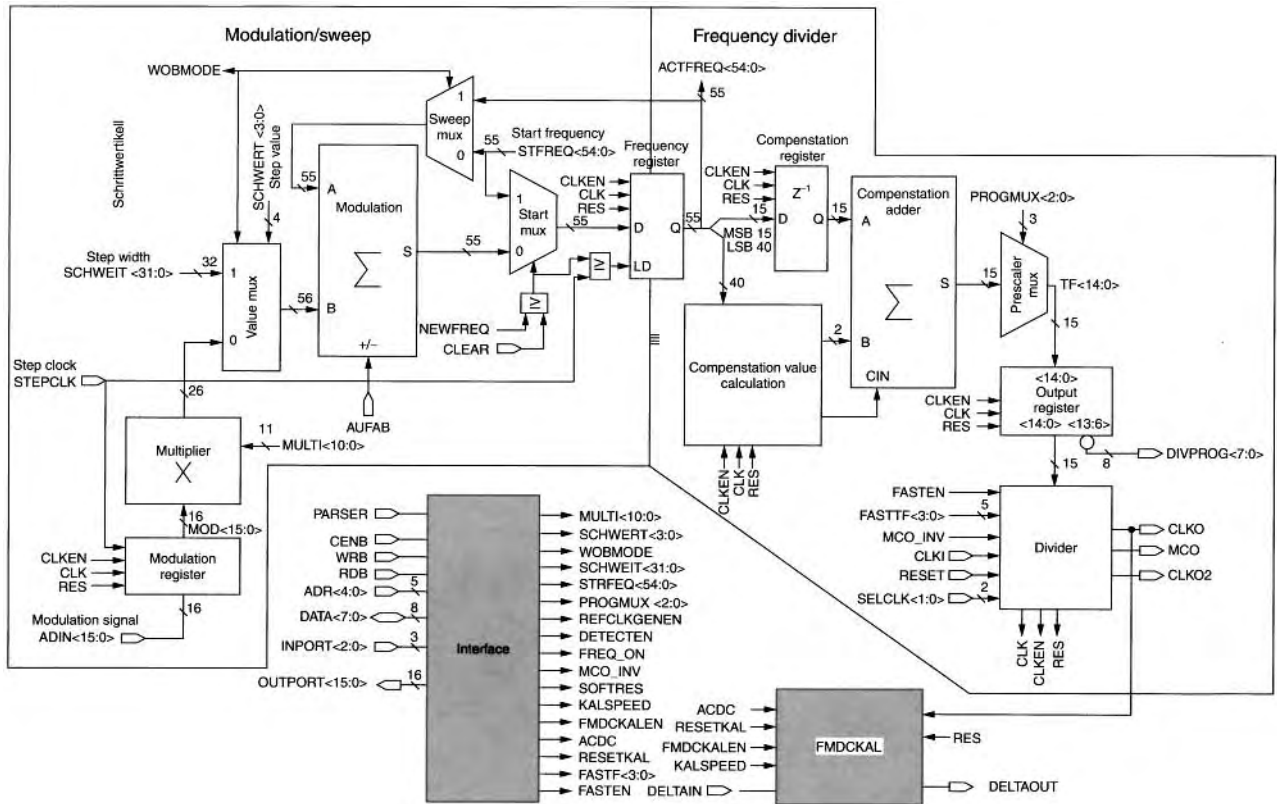

Figure 60. Detailed block diagram of the inner workings of the fractional-*N*-division synthesizer chip.

By increasing the number of accumulators, frequency resolution much below 1 Hz stepsize is possible with the same switching speed.

There is an interesting, generic problem associated with *all* fractional-*N* synthesizers. Assume for a moment that we use our 50-MHz reference and generate a 550-MHz output frequency. This means that our division factor is 11. Aside from reference-frequency sidebands (± 50 MHz) and harmonics, there will be no unwanted spurious frequencies. Of course, the reference sidebands will be suppressed by the loop filter by more than 90 dB. For reasons of phase noise and switching speed, a loop bandwidth of 100 kHz has been considered. Now, taking advantage of the fractional-*N* principle say that we want to operate at an offset of 30 kHz (550.03 MHz). With this new output frequency, the inherent spurious-signal reduction mechanism in the fractional-*N* chip limits the reduction to about 55 dB. Part of the reason why the spurious-signal suppression is less in this case is that the phase-frequency detector acts as a mixer, collecting both the 50-MHz reference (and its harmonics) and 550.03 MHz. Mixing the 11th reference harmonic (550 MHz) and the output frequency (550.03 MHz) results in output at 30 kHz; as the loop bandwidth is 100 kHz, it adds nothing to the suppression of this signal. To solve this, we could consider narrowing the loop bandwidth to 10% of the off-

set. A 30 kHz offset would equate to a loop bandwidth of 3 kHz, at which the loop speed might still be acceptable, but for a 1-Hz offset, the necessary loop bandwidth of 100 Hz would make the loop too slow. A better way is to use a different reference frequency—one that would place the resulting spurious product considerably outside the 100-kHz loop filter window. If, for instance, we used a 49-MHz reference, multiplication by 11 would result in 539 MHz. Mixing this with 550.03 MHz would result in spurious signals at ± 11.03 MHz, a frequency so far outside the loop bandwidth that it would essentially disappear. Starting with a VHF, low-phase-noise crystal oscillator, such as 130 MHz, one can implement an intelligent reference-frequency selection to avoid these discrete spurious signals. An additional method of reducing the spurious contents is maintaining a division ratio greater than 12 in all cases. Actual tests have shown that these reference-based spurious frequencies can be repeatedly suppressed by 80–90 dB.

6.1. Spur Suppression Techniques

Although several methods have been proposed in the literature, the method of reducing the noise by using a sigma-delta modulator has shown to be most promising. The concept is to get rid of the low-frequency phase error by rapidly switching the division ratio to eliminate the grad-

Figure 61. Composite phase noise of the fractional-*N* synthesizer system, including all noise and spurious signals generated within the system. The discrete spurious of 7 kHz is due to the non-linearity of the phase detector. Its value needs to be corrected by 20.58 dB to a lesser value because of the bandwidth of the FFT analyzer.

ual phase error at the discriminator input. By changing the division ratio rapidly between different values, the phase errors occur in both polarities, positive as well as negative, and at an accelerated rate that explains the phenomenon of high-frequency noise pushup. This noise, which is converted to a voltage by the phase/frequency discriminator and loop filter, is filtered out by the lowpass filter. The main problem associated with this noise shaping technique is that the noise power rises rapidly with frequency. Figure 58 shows noise contributions with such a sigma-delta modulator in place.

On the other hand, we can now, for the first time, build a single-loop synthesizer with switching times as fast as 6 μs and very little phase-noise deterioration inside the loop bandwidth, as seen in Fig. 58. As this system maintains the good phase noise of the ceramic-resonator-based oscillator, the resulting performance is significantly better than the phase noise expected from high-end signal generators. However, this method does not allow us to increase the loop bandwidth beyond the 100-kHz limit, where the noise contribution of the sigma-delta modulator takes over.

Table 2 shows some of the modern spur suppression methods. These three-stage sigma-delta methods with larger accumulators have the most potential.

The power spectral response of the phase noise for the three-stage sigma-delta modulator is calculated from

$$L(f) = \frac{(2\pi)^2}{12 \times f_{ref}} \times \left[2 \sin\left(\frac{\pi f}{f_{ref}}\right) \right]^{2(n-1)} \text{ rad}^2/\text{Hz} \quad (78)$$

where *n* is the number of the stage of the cascaded sigma-delta modulator. Equation (78) shows that the phase noise resulting from the fractional controller is attenuated to negligible levels close to the center frequency, and further from the center frequency, the phase noise is increased rapidly and must be filtered out prior to the tuning input of the VCO to prevent unacceptable degradation of spectral purity. A loop filter must be used to filter the noise in the PLL loop. Figure 58 showed the plot of the phase noise versus the offset frequency from the center frequency. A fractional-*N* synthesizer with a three-stage sigma-delta modulator as shown in Fig. 59 has been built. The

synthesizer consists of a phase/frequency detector, an active lowpass filter (LPF), a voltage-controlled oscillator (VCO), a dual-modulus prescaler, a three-stage sigma-delta modulator, and a buffer. Figure 60 shows the inner workings of the chip in greater detail.

After designing, building, and predicting the phase noise performance of this synthesizer, it becomes clear that measuring the phase noise of such a system becomes tricky. Standard measurement techniques that use a reference synthesizer will not provide enough resolution because there are no synthesized signal generators on the market sufficiently good enough to measure such low values of phase noise. Therefore, a comb generator is needed that would take the output of the oscillator and multiply this up 10–20 times.

Figure 61 shows a simulated phase noise and termination of spurious outputs for the fraction- N -division synthesizer with $\Sigma\Delta$ converter. At the moment, it is unclear if the PLL with DDS or the fractional- N -division synthesizer principle with $\Sigma\Delta$ converter is the winning approach. The DDS typically requires two or three loops and is much more expensive, while the fractional- N approach requires only one loop and is a very intelligent spurious removal circuit, and high-end solutions are typically custom built [96–111].

PHASE NOISE AND MEASUREMENTS

HENG-CHIA CHANG
RF System, Blue 7
Communications, Inc.
Fremont, California

1. INTRODUCTION TO PHASE NOISE THEORY

In modern communications phase noise has challenged the wireless communication circuits and systems on the performance. Phase noise has been known to limit the operating range, precision, and sensitivity of various communication systems, such as the radars and satellite communications. Before characterizing the phase noise and its limit on the systems, one must know some mathematical expressions and terminology of phase noise. Here we are only interested in phase noise (or phase fluctuation) and neglect amplitude fluctuation. The signal of interest can be expressed as

$$\begin{aligned} v(t) &= A \cos(\theta(t)) = A \cos(\theta_0(t) + \delta\theta(t)) \\ &= A \cos(2\pi f_0 t + \delta\theta(t)) = A \cos(2\pi(f_0 + \delta f)t) \end{aligned} \quad (1)$$

where A is the amplitude of the voltage signal, θ_0 the signal phase, and f_0 the signal frequency, respectively. $\delta\theta(t)$ and $\delta f(t)$ are the phase and frequency fluctuation of the signal around the nominal phase $\theta_0(t) = 2\pi f_0 t$ and frequency f_0 , respectively. The averaged output power of the signal expressed in (1) is $P_0 = A^2 / (2R_L)$, where R_L is the output load resistance in the measurement system.

The phase noise of the signal can be characterized in either frequency or time domain. In the frequency domain, phase noise is related to the spectral density of the phase or frequency fluctuation in the signal [2–8]. In the time domain, the phase noise is characterized by using the jitter instead, as the zero crossing of the signal is easily

measured. In the following, we characterize the phase noise only in the frequency domain.

1.1. Phase Noise Expression

Phase or frequency fluctuations in the signals can be characterized in frequency domain by using Fourier transform. From (1), one has

$$\delta\theta(t) = 2\pi\delta f(t)t \tag{2}$$

Because such fluctuations are random or stochastic in nature, one needs to calculate the power spectral density of the phase fluctuation $\delta\theta(t)$ [or frequency fluctuation $\delta f(t)$]. From the Wiener–Khintchine theorem, the autocorrelation and power spectral density of $\delta\theta(t)$ are defined as

$$R_\theta(\tau) \equiv \langle \delta\theta^*(t)\delta\theta(t + \tau) \rangle$$

$$S_\theta(\omega_m = 2\pi f_m) \equiv \int_{-\infty}^{\infty} R_\theta(\tau)e^{-j\omega_m\tau} d\tau = F_\tau[R_\theta(\tau)] \tag{3}$$

respectively, where $\langle \rangle$ is the ensemble average, (*) is the complex conjugate, and τ is the time delay. The Fourier transform of (2) is defined as

$$F_t[\delta f(t)] = \tilde{\delta f}(f_m) = \int_{-\infty}^{\infty} \delta f(t)e^{-j2\pi f_m t} dt$$

$$= F_t \left[\frac{1}{2\pi} \frac{d(\delta\theta(t))}{dt} \right] = \frac{1}{2\pi} (j2\pi f_m) \tilde{\delta\theta}(f_m) \tag{4}$$

where F_t denotes the Fourier transform of t from the time domain to the frequency domain, (\sim) the spectral variable, f_m is the noise offset frequency relative to the carrier frequency f_0 , and the subscript “m” denotes the modulation caused by the noise source.

The phase fluctuation $\delta\theta(t)$ is assumed ergodic random process, where the time average is equal to its ensemble

average. Thus, one has

$$R_\theta(\tau) = \langle \delta\theta^*(t)\delta\theta(t + \tau) \rangle$$

$$= \int_{-\infty}^{\infty} \delta\theta^*(t)\delta\theta(t + \tau) dt$$

$$= \int_{-\infty}^{\infty} \left[\int_{-\infty}^{\infty} \tilde{\delta\theta}^*(\omega_m) e^{-j\omega_m t} d\omega_m \right]$$

$$\left[\int_{-\infty}^{\infty} \tilde{\delta\theta}(\omega'_m) e^{j\omega'_m(t + \tau)} d\omega'_m \right] dt$$

$$= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \tilde{\delta\theta}^*(\omega_m) \tilde{\delta\theta}(\omega'_m) e^{j(\omega'_m - \omega_m)t} e^{j\omega'_m\tau} dt d\omega_m d\omega'_m$$

$$= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \tilde{\delta\theta}^*(\omega_m) \tilde{\delta\theta}(\omega'_m) \delta(\omega'_m - \omega_m) e^{j\omega'_m\tau} d\omega_m d\omega'_m$$

$$= \int_{-\infty}^{\infty} \tilde{\delta\theta}^*(\omega_m) \tilde{\delta\theta}(\omega_m) e^{j\omega_m\tau} d\omega_m$$

$$= \int_{-\infty}^{\infty} |\tilde{\delta\theta}(\omega_m)|^2 e^{j\omega_m\tau} d\omega_m$$

$$= F_{\omega_m}^{-1} [|\tilde{\delta\theta}(\omega_m)|^2] \tag{5}$$

where $\int_{-\infty}^{\infty} e^{j(\omega'_m - \omega_m)t} dt = \delta(\omega'_m - \omega_m)$ and $F_{\omega_m}^{-1}$ is the inverse Fourier transform of ω_m from the frequency domain to the time domain. Then the power spectral density of the phase fluctuation $\delta\theta(t)$ becomes

$$S_\theta(\omega_m = 2\pi f_m) = F_\tau[R_\theta(\tau)]$$

$$= F_\tau[F_{\omega_m}^{-1} [|\tilde{\delta\theta}(\omega_m)|^2]]$$

$$= \langle |\tilde{\delta\theta}(\omega_m)|^2 \rangle \tag{6}$$

In typical phase noise measurements, the power spectral density of the phase fluctuation (or phase noise) is measured relative to the averaged signal power P_0 at the carrier frequency $\omega_0 = 2\pi f_0$. One can obtain the spectral density of the phase fluctuations (i.e., the phase noise or

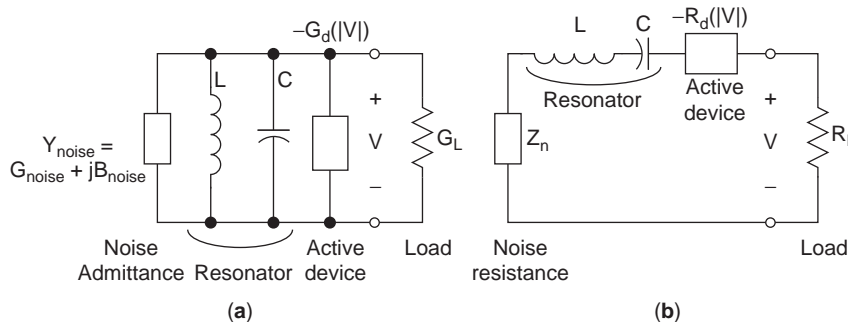

Figure 1. The oscillator phase noise model with noise admittance or resistance dependent on the oscillator equivalent circuits.

PM noise) and frequency fluctuations (i.e., FM noise)

$$S_{\theta}(f_m) \equiv \langle |\tilde{\delta}\theta(f_m)|^2 \rangle / P_0 \quad (7)$$

$$\begin{aligned} S_f(f_m) &\equiv \langle |\tilde{\delta}f(f_m)|^2 \rangle / P_0 = f_m^2 \langle |\tilde{\delta}\theta(f_m)|^2 \rangle / P_0 \\ &= f_m^2 S_{\theta}(f_m) \end{aligned} \quad (8)$$

respectively.

1.2. Free-Running Oscillator Result

The oscillator has been the driving force of modern communication systems, and it can be modeled by the equivalent circuits shown in Figs. 1a and 1b to obtain important phase noise features. The active device is modeled by a negative conductance or resistance embedded in parallel or series-resonant circuits, respectively. The negative conductance $-G_d(|V|)$ or resistance $-R_d(|V|)$ is assumed to be independent of frequency, but dependent on the oscillation signal amplitude nonlinearly. Here we only use the parallel-resonant circuit model to derive the noise as illustration. The noise source of the oscillator can be modeled by adding the noise conductance or resistance [7,8]. The same derivation can be applied to series-resonant oscillator model. The circuit equation of parallel-resonant oscillator model is

$$C \frac{dV}{dt} + \frac{1}{L} \int V dt + (G_L - G_d(|V|) + Y_n)V = 0 \quad (9)$$

The integral of this equation can be approximated by integration by parts [6] to give

$$\int V dt = -\frac{2jV}{\omega_0} + \frac{1}{\omega_0^2} \frac{dV}{dt} + \dots \quad (10)$$

By substituting (10) into (9), $\omega_0^2 = 1/(LC)$, and $Q = \omega_0 C/G_L$ (the Q factor of a parallel-resonant circuit), one can obtain

$$\frac{dV}{dt} = j\omega_0 V - \frac{\omega_0}{2Q} \left(1 - \frac{G_d(|V|)}{G_L}\right) V - \frac{\omega_0 Y_n}{2QG_L} V \quad (11)$$

where the Q factor of the oscillator is high enough so that the oscillation frequency is close to ω_0 . The output signal of the oscillator can be expressed as

$$V(t) = A(t)e^{j\theta(t)} \quad (12)$$

where $A(t)$ and $\theta(t)$ are the amplitude and phase, respectively. Then the imaginary and real parts of (11) with (12) become the phase and amplitude dynamics

$$\frac{d\theta}{dt} = \omega_0 - \frac{\omega_0}{2Q} B_n \quad (13)$$

$$\frac{dA}{dt} = -\frac{\omega_0}{2Q} \left(1 - \frac{G_d}{G_L}\right) A - \frac{\omega_0}{2Q} G_n A \quad (14)$$

respectively, where $G_n = G_{\text{noise}}/G_L$ and $B_n = B_{\text{noise}}/G_L$. The amplitude saturation constant α is modeled as

$$1 - \frac{G_d(|V|)}{G_L} \approx -\mu_p \left(1 - \frac{A^2}{\alpha^2}\right) \quad (15)$$

and the subscript ‘‘p’’ denotes the parallel-resonant oscillator model.

For noise analysis, the equations above are perturbed by substituting $A \rightarrow \hat{A} + \delta A$ and $\theta \rightarrow \hat{\theta} + \delta\theta$ into (13) and (14), where $(\hat{A}, \hat{\theta})$ are the steady-state solutions to (13) and (14) and $(\delta A, \delta\theta)$ are the amplitude and phase fluctuations, respectively. Assuming small fluctuations, the equations can be linearized around $(\hat{A}, \hat{\theta})$ to become

$$\frac{d\delta\theta(t)}{dt} = -\frac{\omega_0}{2Q} B_n(t) \quad (16)$$

$$\begin{aligned} \frac{d\delta A(t)}{dt} &= -\frac{\omega_0}{2Q} \mu_p \left(1 - \frac{3\hat{A}^2}{\alpha^2}\right) \delta A(t) \\ &\quad - \frac{\omega_0}{2Q} \hat{A} G_n(t) \end{aligned} \quad (17)$$

where $\omega_{3\text{dB}} = \omega_0/(2Q)$ is the half the full-width half-maximum frequency of the oscillator. By Fourier transforming these equations, one can obtain

$$\frac{J\omega_m}{\omega_{3\text{dB}}} \tilde{\delta}\theta = -\tilde{B}_n \quad (18)$$

$$\left[\frac{J\omega_m}{\omega_{3\text{dB}}} - \mu_p \left(1 - 3\frac{\hat{A}^2}{\alpha^2}\right) \right] \tilde{\delta A} = -\hat{A} \tilde{G}_n \quad (19)$$

Therefore, from the previous phase noise expressions one can obtain the PM noise of single free-running oscillator

$$\langle |\tilde{\delta}\theta|^2 \rangle_{\text{uncoupled}} = \frac{\langle |\tilde{B}_n|^2 \rangle}{(\omega_m/\omega_{3\text{dB}})^2} \quad (20)$$

and the AM noise

$$\langle |\tilde{\delta A}|^2 \rangle_{\text{uncoupled}} = \frac{\hat{A}^2 \langle |\tilde{G}_n|^2 \rangle}{(\omega_m/\omega_{3\text{dB}})^2 + \mu_p^2 \left(3\frac{\hat{A}^2}{\alpha^2} - 1\right)^2} \quad (21)$$

where α and \hat{A} are the free-running oscillator amplitude and the steady-state amplitude after coupling, respectively.

These results have the same form as those in Kurokawa’s and Schlosser’s papers [4,5]. Note that for most oscillators, noise close to the carrier ($\omega_m \ll \omega_{3\text{dB}}$) is dominated by phase noise. This somewhat justifies our neglect of amplitude noise and AM-to-PM conversion [8]. The result (20) features prominently in the following derivations.

1.3. Leeson's Model and Noise Admittance/Resistance

The noise admittance (or noise resistance) has been used to model the intrinsic oscillator noise sources, and the theory matches very well with the experimental results. However, Leeson's oscillator model, shown in Fig. 2, has often been used because it explains the power-law spectral density of the phase noise in real oscillators. Here we will compare our oscillator noise admittance (or resistance) model with Leeson's oscillator model and determine the equivalence between these two models.

The Leeson's model consists of an amplifier with a feedback loop. The amplifier has a noise figure F , and the feedback is a tank circuit with a transfer function

$$L(\omega_m) = \frac{1}{1 + j \left(\frac{\omega_m}{\omega_{3\text{dB}}} \right)} \quad (22)$$

where $\omega_{3\text{dB}} = \omega_0/2Q$ is the half the 3 dB bandwidth of the resonator tank circuit, and Q is the Q factor of the resonator, and ω_0 is the free-running oscillator frequency and the center resonance frequency of the resonator. The power spectral density of the ergodic internal oscillator phase uncertainty is

$$\overline{\tilde{V}_n^2}(\omega_m) = FkTB \quad (23)$$

and the phase fluctuation spectral density in Leeson's model is

$$\begin{aligned} \langle |\tilde{\delta}\theta_0(\omega_m)|^2 \rangle &= \frac{\overline{\tilde{V}_n^2}(\omega_m)}{|1 - L(\omega_m)|^2} \\ &= FkTB \left(1 + \left(\frac{\omega_{3\text{dB}}}{\omega_m} \right)^2 \right) \end{aligned} \quad (24)$$

where k is the Boltzmann constant, T is the absolute temperature of the oscillator, and $B = 1$ for a 1 Hz bandwidth. Under the standard room temperature, $kTB = -174$ dBm/Hz. In (23) $(-)$ denotes the time average of the signal. If the noise offset frequency $\omega_m < \omega_{3\text{dB}}$, the oscillator phase noise is $\overline{\tilde{V}_n^2}/(\omega_m/\omega_{3\text{dB}})^2$. If the noise offset frequency $\omega_m > \omega_{3\text{dB}}$, the oscillator phase noise becomes the thermal noise floor $\overline{\tilde{V}_n^2}$, and the feedback inside the oscillator has no effect.

Figure 2. Leeson's model for oscillator phase noise.

The phase noise of the single free-running oscillator from the oscillator noise admittance/resistance model is

$$\begin{aligned} \langle |\tilde{\delta}\theta_0(\omega_m)|^2 \rangle &= \langle |\tilde{\delta}\theta_i(\omega_m)|^2 \rangle_{\text{uncoupled}} \\ &= \frac{\langle |\tilde{\mathbf{B}}_n(\omega_m)|^2 \rangle}{\left(\frac{\omega_m}{\omega_{3\text{dB}}} \right)^2} \end{aligned} \quad (25)$$

After comparing Leeson's model with our noise admittance model, we have

$$\langle |\tilde{\mathbf{B}}_n(\omega_m)|^2 \rangle = FkTB \quad (26)$$

In the oscillator admittance/resistance model, the thermal noise floor is not included in the derivation. One can include the thermal noise floor into the noise expression by multiplying the correction factor

$$\text{Correction factor} = \frac{1 + \left(\frac{\omega_{3\text{dB}}}{\omega_m} \right)^2}{\left(\frac{\omega_{3\text{dB}}}{\omega_m} \right)^2} \quad (27)$$

with our phase fluctuation spectral density $\langle |\tilde{\delta}\theta_0(\omega_m = 2\pi f_m)|^2 \rangle$, and then we have the same results as Leeson's model. If $1/f$ flicker noise contribution is considered, one can set

$$\langle |\tilde{\mathbf{B}}_n(\omega_m)|^2 \rangle = FkTB \left(1 + \frac{\omega_c}{\omega_m} \right) \quad (28)$$

where ω_c is the corner frequency for $1/f$ flicker noise.

In the typical phase noise measurements, the normalized [in 1 Hz bandwidth (BW)] single-sideband noise power, \mathfrak{L} in dBc/Hz, is often used, and it is defined as

$$\mathfrak{L}(f_m) = \frac{N(1 \text{ Hz BW})}{P_0} \quad (29)$$

where $N(1 \text{ Hz BW})$ is the noise power with corrections at f_m (where $f_m = \omega_m/(2\pi)$ is the noise offset frequency in Hz), and P_0 is the carrier power.

The relationship between $\mathfrak{L}(f_m)$ and $\langle |\tilde{\delta}\theta_0(\omega_m)|^2 \rangle$ can be written as

$$\mathfrak{L}(f_m) = \frac{\langle |\tilde{\delta}\theta_0(\omega_m = 2\pi f_m)|^2 \rangle}{2P_0} \quad (30)$$

where the factor of 2 is used, because $\mathfrak{L}(f_m)$ is the single-sideband noise power instead of double sideband, and P_0 is the averaged oscillator power at carrier frequency. Therefore, the spectral density of phase fluctuation is

defined as

$$S_{\theta}(f_m) = \frac{\langle |\tilde{\delta}\theta_0(\omega_m = 2\pi f_m)|^2 \rangle}{P_0} \tag{31}$$

$$= 2\mathfrak{L}(f_m)$$

where S_{θ} is in the unit of rad^2/Hz .

From the preceding definitions, if the $1/f$ flicker noise and thermal noise floor are included in our oscillator model, the measured oscillator phase noise becomes

$$\mathfrak{L}(f_m) = \frac{FkTB}{2P_0} \left(1 + \frac{f_c}{f_m} \right) \left(1 + \left(\frac{f_{3\text{dB}}}{f_m} \right)^2 \right)$$

$$= \underbrace{\frac{FkTB}{2P_0}}_{\text{thermal noise floor}} + \underbrace{\frac{FkTB}{2P_0} \left(\frac{f_c}{f_m} \right)}_{\text{flicker phase noise}} \tag{32}$$

$$+ \underbrace{\frac{FkTB}{2P_0} \left(\frac{f_{3\text{dB}}^2}{f_m^2} \right)}_{\text{thermal phase noise}} + \underbrace{\frac{FkTB}{2P_0} \left(\frac{f_c f_{3\text{dB}}^2}{f_m^3} \right)}_{\text{upconverted } 1/f \text{ noise}}$$

where f_m is the noise offset frequency in Hz. The first term in this equation is thermal noise floor, the second term is flicker phase noise, the third term is thermal phase noise (which is our main concern), and the fourth term is upconverted $1/f$ noise or flicker phase noise in the oscillator phase noise. The SSB phase noise with different noise source contributions versus the noise offset frequency is shown in Fig. 3. Here one can find that the noise admittance/resistance model is consistent with Leeson’s model.

2. MEASUREMENT TECHNIQUES

Phase noise measurement is very important for testing and verifying the design of circuits and systems. However, the phase noise measurement often takes much time and money for the related expensive equipments. Many sophisticated techniques are used to obtain the phase noise results. Here the author only explains several popular methods and the related basic ideas, including the

Figure 3. The SSB (single-sideband) oscillator phase noise spectrum versus the noise offset frequency.

spectrum analyzer, frequency discriminator, and double-balanced mixer methods.

2.1. Spectrum Analyzer

The spectrum analyzer is the most direct way to measure the phase noise of the device under test. The spectrum analyzer needs to have enough dynamic range for the input signal, and its internal local oscillator phase noise of the spectrum analyzer is less than the device under test [9–12]. The output frequency of the device under test is also required to be reasonably stable during the test. The measured phase noise by spectrum analyzer can be obtained from (29)

$$\mathfrak{L}(f_m) = 10 \log_{10}(P_{\text{SSB}}) - 10 \log_{10}(P_0) \tag{33}$$

where P_{SSB} is the single-sidedband noise spectral power reading and P_0 is the carrier spectral power reading from the spectrum analyzer.

The schematic diagram of the typical spectrum analyzer is shown in Fig. 4. Several factors affect the measurement sensitivity. There is an input attenuator in the spectrum analyzer, and it should be set to minimum (or zero) in order to increase the signal-to-noise ratio (SNR) for optimum measurement sensitivity. The resolution bandwidth (RBW) also affects the SNR, and it should be set to minimum for optimum SNR of the measurement system. The RBW is the bandwidth of the intermediate-frequency (IF) filter following the first gain stage (or the mixer) of the analyzer. After setting the input attenuation and RBW to minimum, one can set the video bandwidth (VBW) to minimum in order to view the signal close to the noise level, even though the video bandwidth does not affect the noise level. The video bandwidth is the bandwidth of the video filter used to reduce or smooth out the fluctuation of the input noisy signal displayed on the screen of the analyzer.

However, Eq. (33) is not complete because several correction factors are not included. The nonideal IF filter has a filter rolloff, which affects the IF bandwidth and then the resolution bandwidth. The correction factor due to the IF filter rolloff is expressed as $-10 \log_{10}(c_1 \cdot \text{RBW})$, where c_1 is the parameter dependent on the specific spectrum analyzer. The spectrum analyzer has logarithmic IF gain stage that amplifies the noise peaks less than the rest of the noise signal. The correction factor due to the logarithm IF gain stage is c_2 . Thus, the modified phase noise is

$$\mathfrak{L}(f_m) = 10 \log_{10}(P_{\text{SSB}}) - 10 \log_{10}(P_0)$$

$$- 10 \log_{10}(c_1 \cdot \text{RBW})$$

$$+ c_2 \tag{34}$$

The factors c_1 and c_2 depend on different spectrum analyzer designs and their specifications.

2.2. Frequency Discriminator

The frequency discriminator method is a sensitive technique used to measure $S_f(f_m)$. The measurement setup of

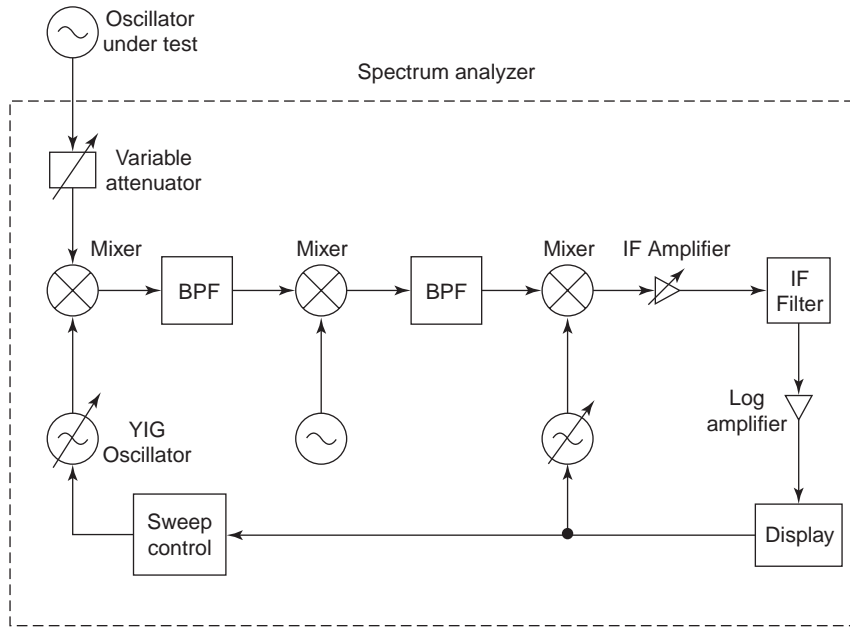

Figure 4. The spectrum analyzer method for phase noise measurement.

frequency discriminator method is shown in Fig. 5a and 5b. The signal of the oscillator under test is $V_1(t) = A_1 \cos(\omega_1 t + \delta\theta_1(t))$, and that of the reference oscillator is $V_2(t) = A_2 \cos(\omega_2 t + \delta\theta_2(t))$. These two signals are mixed and passed through the lowpass filter and the frequency discriminator. Several methods are used to implement the frequency discriminator. In Fig. 5(a) one

can use the op-amp to implement the frequency discriminator with transfer function $H(s) = -sRC$, and $s = j\omega$. The output signal of the discriminator is $V_{fd}(t) = K'(\omega_1 - \omega_2) + K'd(\delta\theta_1(t) - \delta\theta_2(t))/dt$. In Fig. 5(b) a delay-line cable, a phase shifter, a power divider, and a mixer are used as a frequency discriminator. The output signal of the discriminator is $V_{fd}(t) = K'(\omega_1 - \omega_2) + K'(\delta\theta_1(t) - \delta\theta_1(t - \tau) +$

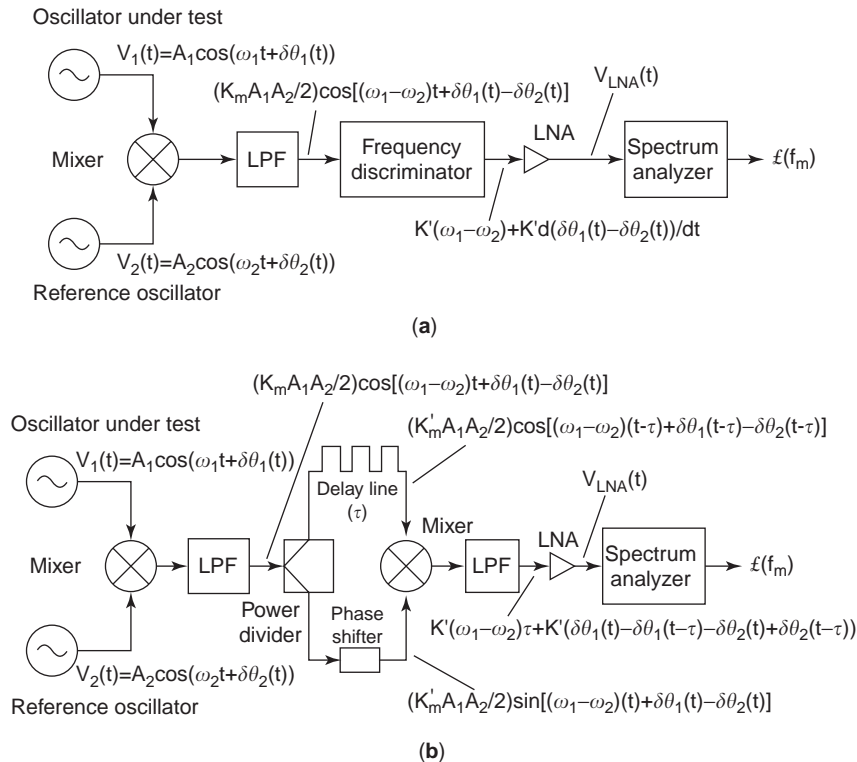

Figure 5. The frequency discriminator method for phase noise measurement.

$\delta\theta_2(t) - \delta\theta_2(t - \tau) \approx K'(\omega_1 - \omega_2) + K'\tau d(\delta\theta_1(t) - \delta\theta_2(t))/dt$, where the approximation $\delta\theta(t - \tau) \approx \delta\theta(t) - \tau d(\delta\theta(t))/dt$ is used. The delay τ of the delay-line cable can be measured by the time-domain reflectometer. The signal after the LNA can be expressed as $V_{LNA}(t) = K(\omega_1 - \omega_2) + Kd(\delta\theta_1(t) - \delta\theta_2(t))/dt$. The parameter K includes the signal amplitudes of the device under test and the reference oscillator signal, the mixer, the frequency discriminator conversion gain, and the LNA gain. The phase noise (or frequency noise) introduced by the LNA is assumed negligible as compared to the device under test or the reference oscillator signal. The signal $K(\omega_1 - \omega_2)$ can be treated as a DC offset and filtered out, as long as the output frequencies ω_1 and ω_2 are reasonably stable.

The output signal of the LNA, $Kd(\delta\theta_1(t) - \delta\theta_2(t))/dt = K(\delta f_1(t) - \delta f_2(t))$, is applied to a low-frequency spectrum analyzer. In the frequency domain, the desired signal becomes $K(\tilde{\delta f}_1(f_m) - \tilde{\delta f}_2(f_m))$, where (\sim) is a spectral variable and f_m is the noise offset frequency relative to the carrier frequency. Since the frequency fluctuations $\tilde{\delta f}_1(f_m)$ and $\tilde{\delta f}_2(f_m)$ are uncorrelated, the combined RMS (root-mean-squared) $\tilde{\delta f}_{RMS} = K\sqrt{|\tilde{\delta f}_1(f_m)|^2 + |\tilde{\delta f}_2(f_m)|^2}$. The spectrum analyzer normally displays the spectral power, and the display is $(\tilde{\delta f}_{RMS})^2 = (K)^2(|\tilde{\delta f}_1(f_m)|^2 + |\tilde{\delta f}_2(f_m)|^2)$. The phase (or frequency) fluctuation of the reference oscillator is much less than that of the device under test [i.e., $|\tilde{\delta f}_2(f_m)| \ll |\tilde{\delta f}_1(f_m)|$], and $(\tilde{\delta f}_{RMS})^2 \approx (K)^2|\tilde{\delta f}_1(f_m)|^2$. The low-frequency spectrum analyzer with more exquisite embedded functions can calculate the noise sideband power relative to the carrier power to obtain $\xi(f_m) = S_\theta(f_m)/2 = S_f(f_m)/(2f_m^2)$ from (8).

2.3. Double-Balanced Mixer

The double-balance mixer method shown in Fig. 6 is also a sensitive method used to measure the phase noise without frequency discriminator [1,9]. The frequency difference error is used to lock the reference oscillator to the device under test. The reference oscillator frequency can be tuned as close to the device frequency under test (i.e., $\omega_1 \cong \omega_2$) in order to maintain constant phase difference

between the input signal phase and the reference oscillator phase. The output signal of the lowpass filter becomes $V_{LPF}(t) = -(K_m A_1 A_2 / 2) \sin(\delta\theta_1(t) - \delta\theta_2(t)) \approx -(K_m A_1 A_2 / 2)(\delta\theta_1(t) - \delta\theta_2(t))$, where $(\delta\theta_1(t) - \delta\theta_2(t))$ is assumed very small, and K_m includes the mixer conversion gain and the filter gain. The spectrum analyzer normally displays the spectral power, and the display is $(\tilde{\delta f}_{RMS})^2 = (K_m A_1 A_2 / 2)^2 (|\tilde{\delta f}_1(f_m)|^2 + |\tilde{\delta f}_2(f_m)|^2)$. The phase (or frequency) fluctuation of the reference oscillator is much less than that of the device under test [i.e., $|\tilde{\delta f}_2(f_m)| \ll |\tilde{\delta f}_1(f_m)|$] and $(\tilde{\delta f}_{RMS})^2 \approx (K)^2|\tilde{\delta f}_1(f_m)|^2$. The reference oscillator noise can track that of the device noise under test inside the loop bandwidth. The noise of those two oscillators has no correlation outside the loop bandwidth. However, the Q factor of the stable reference oscillator is very high and its phase noise is very low from (20), so its tuning range is very small. The double-balanced mixer method is suitable for the device under test only with operating frequency as close as possible to that of the reference oscillator.

For the these measurement methods, one can find that the spectrum analyzer is the most direct method, but requires some correction factors on the test results. The frequency discriminator and double-balanced mixer methods also require good mixers, lowpass filter, bandpass filters, and LNAs (low-noise amplifiers). The double-balanced mixer method is more suitable for the input signal stable frequency as close as possible to the reference oscillator frequency. Figure 7 is the illustrated measured phase noise result of the X-band microwave oscillator fabricated in microstrip circuit, and the frequency discriminator method is used.

3. CONCLUSIONS

Phase noise has been a very important design consideration in modern communication systems. The phase noise in the oscillators has dominated the system performance and one must characterize the oscillator phase noise by theory and measurement. The brief phase noise theory

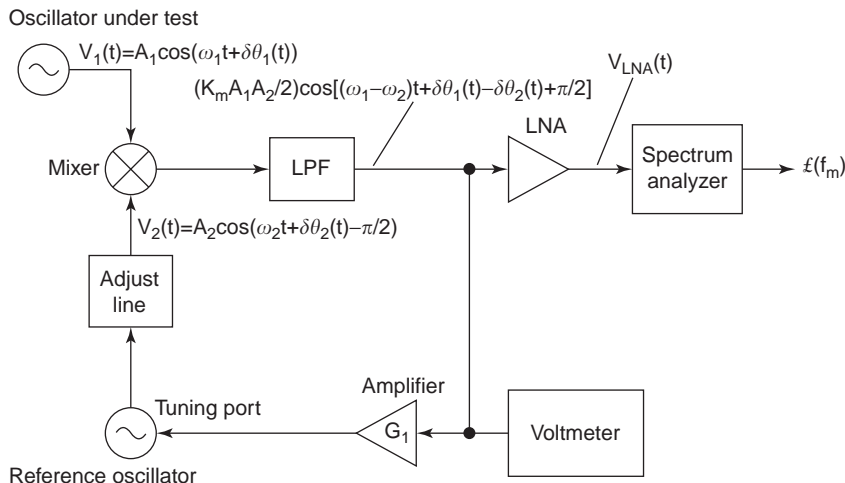

Figure 6. The double-balanced mixer method for phase noise measurement.

Figure 7. The measured phase noise result of the microwave oscillator fabricated in microstrip circuits operating at X band. The phase noise results is obtained from the frequency discriminator method.

and measurement techniques are presented in this article. The oscillator phase noise can be modeled by using either the noise conductance (or resistance) or Leeson's model [2–8], as the consistence between these two models is illustrated.

Several popular measurement methods are illustrated and explained, including the Spectrum analyzer, frequency discriminator, and double-balanced mixer method [9–13]. The advantages and disadvantages of these methods are explained. One can obtain accurate phase noise results by using one of the measurement methods described above carefully after considering the limits and requirements of each method. There are many phase noise model and theory in the literature, and the readers can find more details and references in the review and tutorial articles [1,14–18].

PHASE SHIFTERS

FRANCO DE FLAVIIS
University of California at
Los Angeles

A microwave phase shifter is a two-port device capable of producing a true delay of a microwave signal flowing through it. The produced time delay can be fixed or adjustable, and the phase shifter is accordingly called fixed phase shifter or tunable phase shifter. The geometry of the phase shifter is intimately related to the guiding structure that is used to design it and is also related to the operational frequency. Most phase shifters are realized in waveguides or in planar structures. Electrically, a phase shifter can be characterized by its scattering parameters matrix. The scattering matrix for an ideal phase shifter (see Fig. 1) takes the form

$$S = \begin{bmatrix} 0 & e^{-j\phi_1} \\ e^{-j\phi_2} & 0 \end{bmatrix} \quad (1)$$

The signal arriving at port 1 will appear at port 2 with a phase shift ϕ_1 without being reflected at port 1 and with no attenuation, while the signal arriving at port 2 will appear at port 1 with phase shift ϕ_2 and without reflection or attenuation.

In general, $\phi_1 \neq \phi_2$ and the phase shifter is called non-reciprocal, and if $\phi_1 = \phi_2$ the phase shifter is called reciprocal. In practice it is impossible to achieve perfect matching at the two ports (no reflection) and to avoid some attenuation while the signal flows through the phase shifter. For these reasons the scattering matrix of a real phase shifter can be written in general as

$$S = \begin{bmatrix} S_{11} & |S_{21}|e^{-j\phi_1} \\ |S_{12}|e^{-j\phi_2} & S_{22} \end{bmatrix} \quad (2)$$

The attenuation of the microwave signal due to the presence of the phase shifter can be calculated from its S parameters, and it is expressed in decibels as

$$(\text{Insertion loss})_1 = 20 \log |S_{21}| \quad (3)$$

$$(\text{Insertion loss})_2 = 20 \log |S_{12}| \quad (4)$$

The subscripts 1 and 2, respectively, refer to the phase shifter when the input signal is at port 1 or port 2. The mismatch is expressed as standing-wave ratio (VSWR) at

Figure 1. Phase shifter viewed as a two-port device.

each port and is given by

$$(\text{VSWR})_1 = \frac{1 + |S_{11}|}{1 - |S_{11}|} \quad (5)$$

$$(\text{VSWR})_2 = \frac{1 + |S_{22}|}{1 - |S_{22}|} \quad (6)$$

In order to evaluate the performance of a phase shifter, it is necessary to introduce a quality factor. For a phase shifter operating at a specific frequency we can define a *figure of merit* as the ratio between the maximum phase shift (in degrees) and the corresponding attenuation in dB at that frequency. This parameter can be expressed as

$$\text{figure of merit} = \frac{\Delta(\text{phase } S_{21})}{|S_{21}|} \quad (7)$$

The performance of a phase shifter can be measured using a standard S parameter setup, including a network analyzer and a test-set of calibration standards suitable for the specific guiding structure [1].

1. PHASE SHIFTER CLASSIFICATION

A first classification of a phase shifter can be based on its phase shifting capability, according to which it can be identified as fixed or adjustable. A fixed phase shifter will provide a constant phase change between the two ports, while an adjustable phase shifter will provide a phase change between the ports which can be controlled mechanically or electrically. Further classification for the adjustable type is based on electrical performance and operational principle. Within the adjustable phase shifters we can distinguish between those where the phase change is achieved through a mechanical tuning and those where the change is obtained with an electrical signal. Furthermore, for the electrically tunable type we can distinguish between those where the phase can be changed continuously (analog) and those where the phase can only be changed by discrete steps (digital). Figure 2 shows a graphical classification of different types of phase shifters.

2. PHASE SHIFTER PERFORMANCE

In the evaluation of a phase shifter performance, besides the quantities derived from its S parameters such as insertion loss, quality factor, and VSWR, other quantities are important for practical design. Below we discuss such parameters and their corresponding meaning.

- *Operational Bandwidth.* This is defined as the 3 dB bandwidth (2), which is expressed as the frequency range in which the insertion loss is contained within 3 dB change.
- *Power-Handling Capabilities.* This is expressed as the maximum power that can flow in the phase shifter without overheating its components or without introducing nonlinear phenomena due to the amplitude

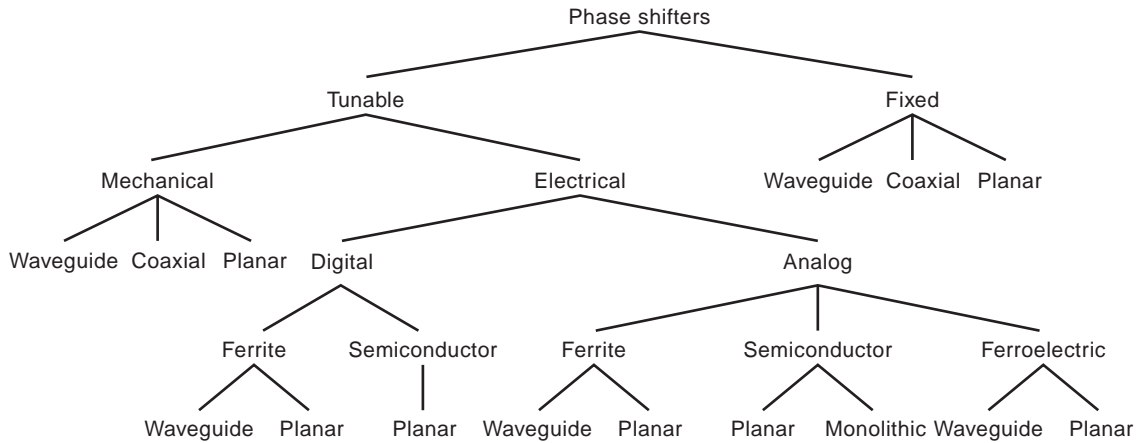

Figure 2. Phase shifter classification chart.

of the microwave field. This second limitation is particularly important for phase shifters which employ discrete devices such as field-effect transistors (FETs) or diodes.

- *Switching Speed.* This is the time needed by the phase shifter to switch between two different states, usually at the two ends of the achievable phase shift (larger allowable jump).
- *Temperature Sensitivity.* This expresses the sensitivity in terms of degree of phase shift degradation per °C change. This parameter should be small to avoid the necessity to adopt thermal compensation.
- *Physical Size.* This parameter can be very important, especially when the phase shifter is employed in a radar system where thousands of units are required. Physical dimensions and weight must be minimized even at the cost of other parameters. As an example, think of a radar system that needs to be mounted on the frontside of a jet fighter.

3. FIXED PHASE SHIFTERS

A fixed phase shifter must provide a constant phase change between its two ports. Theoretically any transmission line would be suitable for producing such a function as illustrated in Fig. 3. For instance, in the X band [1] a coaxial cable could be used as a fixed phase shifter, while in the Ku band a waveguide can be employed for the same purpose. In many applications, it is desirable to achieve a differential phase shift between two lines having the same

Figure 3. Transmission line acting as a phase shifter.

length. For this purpose, lines with different time delays must be used. A possible approach to this problem is to change the propagation constant of the line, loading it with lumped or distributed elements. So if β_1 is the propagation constant of the unloaded line and β_2 is the propagation constant of the loaded one, the achieved differential phase shift will be given by [3]

$$\Delta\phi = (\beta_1 - \beta_2)x \tag{8}$$

where x is the length of the line. So the basic idea in the realization of this type of phase shifter is to change the propagation constant of the transmission line by properly loading it. As an example, consider the realization of a fixed phase shifter in circular waveguide geometry. The waveguide is loaded with metal inserts as shown in Fig. 4. The equivalent circuits for the loaded and unloaded cases, assuming that the guide is operating with the fundamental mode TE_{11} [4], are reported in Fig. 5. Both lines have the same length, and the differential phase shift between the two TE_{11} modes is related to the normalized suscep-

Figure 4. Loaded circular waveguide.

Figure 5. Equivalent circuits for loaded and unloaded circular waveguides operating with the fundamental mode.

tance of the loads [5] by the following equations:

$$\bar{B}_B = \frac{B_B}{Y_0} = \frac{\sin 2\beta x - \sin(2\beta x + \Delta\phi)}{\sin^2 \beta x} \quad (9)$$

$$\bar{B}_A = \frac{B_A}{Y_0} = \frac{\sin \Delta\phi \cos \beta x - (1 - \cos \Delta\phi) \sin \beta x}{\sin \beta x \sin(2\beta x + \Delta\phi)} \quad (10)$$

The use of Eqs. (9) and (10) allows one to design the loads necessary to achieve a desired phase shift. Using a similar concept, depending on the transmission line geometry, different type of loads can be devised as shown in Fig. 6. A quarter-wave transformer is used to avoid reflection at the load interface. Figures 6a and 6b show realization in circular waveguide geometry using dielectric or metallic loads, while Figs. 6c and 6d are rectangular waveguide geometry using dielectric loads.

4. MECHANICALLY TUNED PHASE SHIFTERS

Mechanically tunable phase shifters are capable of varying the signal delay in a transmission line using some

moving parts. The specific geometry depends on the operational frequency and on the guiding structure. As an example, three classical implementations—a coaxial cable, a waveguide, and a microstrip line, respectively—are outlined below.

4.1. Coaxial Cable Phase Shifter

In a coaxial cable the dominant mode is TEM (see ELECTROMAGNETIC FIELD MEASUREMENT) [6], so the phase of the signal propagating over a length between two cable endpoints is given by

$$\phi = \frac{\omega\sqrt{\epsilon_r}}{c} x \quad (11)$$

where x is the cable length, ω is the operating frequency, ϵ_r is the dielectric constant of the inner core of the cable, and c is the speed of light in free space. A Δx change in its length will produce a change in phase ($\Delta\phi$) between the two cable endpoints expressed by

$$\Delta\phi = \frac{\omega\sqrt{\epsilon_r}}{c} \Delta x \quad (12)$$

Figure 7 illustrates a section view of this type of phase shifter. To allow for the stretch, the coaxial cable has concentric airlines which can slide one into another, maintaining the characteristic impedance of the cable constant while changing length.

4.2. Waveguide Phase Shifter

In waveguide geometry, one way of obtaining a tunable phase shift without changing its length is to change the effective dielectric constant in some region of the guide, inserting a movable dielectric slab. Figure 8 illustrates one version of this mechanical tunable phase shifter. The insertion of the flap in the center of the waveguide, where the electric field is maximum assuming that the fundamental mode is propagating, will delay the signal, producing a phase shift. This type of device is only usable with some restrictions, since the thickness of the flap and its dielectric constant must be calculated to avoid the propagation of higher-order modes (i.e., TE_{30}). A simple equation for the design of this type of phase shifter, which avoids higher modes, was proposed by Gardiol [7] and leads to the following relation:

$$\sqrt{\epsilon_r} \tan[\pi(a - d)/\lambda_c] = \cot(\pi\sqrt{\epsilon_r}d/\lambda_c) \quad (13)$$

Based on the same concept, it is possible to have a movable dielectric inside a rectangular waveguide operating with

Figure 6. Different types of loaded transmission line.

Figure 7. Mechanically tuned coaxial phase shifter.

the fundamental mode TE_{10} as shown in Fig. 9, where the interaction of the field with the dielectric will be maximum when the plate is in the center of the guide (maximum delay corresponding to maximum phase shift) and minimum when it is on the sidewalls. Proper design of the $\lambda/4$ transformer [8] is necessary to avoid reflections at the phase shifter interface.

4.3. Microstrip Phase Shifter

For the microstrip geometry a mechanically tuned phase shifter was proposed by Joines [9]. In this geometry it is possible to achieve a phase shift by changing the dielectric constant of the substrate above and below the strip as depicted in Fig. 10.

The change in the dielectric constant will induce a change in the propagation constant, and consequently different phase shifts will be achieved. This structure is attractive because it yields a continuous phase shift while maintaining the characteristic impedance constant. If we observe its section view depicted in Fig. 10, we notice that by a proper design of the thicknesses t_1 and t_2 , accordingly with the dielectric constant [9], it is possible to keep the characteristic impedance of the strip constant while changing its propagation constant.

These are just a few examples of mechanically tunable phase shifters; of course, many others are possible, but the basic concept on which they operate is the same and can be summarized as follows. In order to obtain a phase shift, it is necessary to delay the electric signal independently from the type of guiding structure used. This can be achieved in two ways; one way is to change the *physical length* of the transmission line Δx that produces a delay of

the signal at the output port, inducing a phase shift change given by $\Delta\phi = \beta\Delta x$. In the second case, a change of the *wave propagation velocity* obtained by changing the propagation constant of the line $\Delta\beta$ will produce a phase shift at the output port given by $\Delta\phi = \Delta\beta x$.

5. ELECTRICALLY TUNED PHASE SHIFTERS

In electrically tuned phase shifters the phase change is controlled by an electric signal (driving signal) such as a voltage or a current. Since no moving parts are involved in the phase control process, electrically controlled phase shifters can achieve faster phase shift compared to mechanical ones. They can be subdivided into two major categories—*digital* and *analog*—depending on the type of control on the phase shift they provide. One of the most important application of electrically tuned phase shifters is the so-called phased-array system. A phased-array system is an array of antennas of which by electronically controlling the phase of the electromagnetic signal at each antenna element one can change its pointing direction. As an example, let us consider a linear array of antenna as illustrated in Fig. 11. If all the elements are excited with the same phase signal, the radiated signal adds coherently and forms a wave front parallel to the array direction (line joining all the elements). The beam pointing direction is perpendicular to the wavefront, so the radiated beam will point in a broadside direction. In a phased array, this direction is adjustable by acting on the phase of the electromagnetic signal at the aperture of each radiating element. In a linear array with equispaced elements the beam can

Figure 9. Dielectric loaded rectangular waveguide phase shifter.

Figure 8. Mechanically tuned waveguide phase shifter.

Figure 10. Microstrip mechanically tuned phase shifter.

be steered by introducing a progressive phase shift between successive elements. If θ_0 is the scan angle with respect to the broadside direction, then the phase delay to be introduced between adjacent antenna apertures can be calculated from

$$\Delta\phi = \frac{\omega}{c} d \sin \theta_0 \tag{14}$$

where d is the element spacing and c is the free space light speed. For scanning the beam continuously, $\Delta\phi$ is varied by analog phase shifters; and for switching the beam from one scan angle to another, $\Delta\phi$ is varied in discrete steps by digital phase shifters. The same principle applies to planar array for achieving three-dimensional scanning and switching.

5.1. Digital Phase Shifters

Digital phase shifters use electronic devices such as pin diodes or FETs as switching elements; this allows the digital phase shifter to direct the microwave signal through paths of different length, obtaining in this way the phase shift. The use of a pin diode as a switching circuit allows biasing of the diode forward (to obtain a trough) or reverse (to obtain an open circuit) by means of a dedicated bias circuitry. In a similar way, an FET channel can be switched

on or off by proper bias [10]. The use of FETs and diodes allows four basic designs. The simplest one is shown in Fig. 12, where the shift is obtained by switching the signal between two different length transmission lines; Fig. 12 also shows a microstrip implementation of this type. The phase shift is proportional to the difference between the length of the two lines and is given by $\Delta\phi = \Delta x\beta$. In a similar way, as shown in Fig. 13, the use of different loads on the transmission lines, which are switched on and off by the diodes, allows a phase change between the biased and unbiased condition ($\Delta\phi$) related to the impedance of the line (Z_0) and to the susceptance of the loads (B) according to the relation [5]

$$\Delta\phi = 2 \arctan \left(\frac{B_n}{1 - B_n^2/2} \right) \tag{15}$$

where $B_n = Z_0 B$. A microstrip implementation of this circuit is also shown in Fig. 13; the reactive and inductive loads are obtained using open stubs of different length, and their values can be calculated for a given susceptance using [11]

$$B = Z_s \cot \left(\frac{2\pi f \sqrt{\epsilon_r} l_s}{c} \right) \tag{16}$$

Figure 11. Beamsteering concept using a phase shifter at each radiating element.

where Z_s is the stub impedance, f is the operation frequency, ϵ_r is the relative dielectric constant, l_s is the stub length, and c is the speed of light in free space. Another design using a pin diode in combination with a 90° hybrid circuit is illustrated in Fig. 14. In this case the differential phase shift obtained between the biased and unbiased condition is given by

$$\Delta\phi = \beta \frac{x}{2} \tag{17}$$

The bias circuit must be designed carefully here, in order to avoid degradation of performance and direct-current (DC) leaks. The bias circuit must allow biasing of all the active devices independently, while insulating the DC biasing signal from the radiofrequency (RF) signal. A simple design for a microstrip topology is illustrated in Fig. 15. The two DC blocks are acting as series capacitors for the RF signal, allowing the RF to go through the diode while stopping the DC component from the rest of the circuit. The two $\lambda/2$ high-impedance microstrip lines are operating as an open stub [11]. At the microstrip junction they will result in an open circuit transparent to the microwave

signal while allowing the DC signal to provide the necessary bias for the diode. The high impedance of the open stub makes it look like an open circuit for a larger bandwidth [11].

The use of FETs as a switching element is similar to that of the pin diode: The source and drain are grounded (only for the DC signal). In the off state, the gate-source and the gate-drain capacitances are equal. Because of this, the drain is not isolated from the gate terminal. In real circuits, the bias network is configured so as to provide high impedance for the RF at the gate terminal. This is achieved by using a lowpass filter such that it presents an effective RF open at the gate. This arrangement is shown in Fig. 16.

Because digital phase shifters only allow discrete phase jumps, a cascade of them must be used when high resolution in the phase change is desired. Figure 17 shows a typical arrangement and the corresponding phase shift states for a 4-bit phase shifter, capable of giving phase jumps with an increment of 22.5° and a maximum phase shift of 360° . By increasing the number of phase shifters, higher resolution is achievable. The maximum achievable resolution will obviously depend on the number of phase

Figure 12. Pin diode type of electrically controlled digital phase shifter.

shifters and is expressed by the relation

$$\Delta\phi_{\min} = \frac{2\pi}{2^n} \quad (18)$$

where n is the number of discrete phase shifters.

5.2. Analog Phase Shifters

Analog phase shifters allow time-delay control of a microwave signal by using an electric driving signal. They differ from digital phase shifters due to their capability to pro-

Figure 13. Loaded pin diode electrically tuned digital phase shifter.

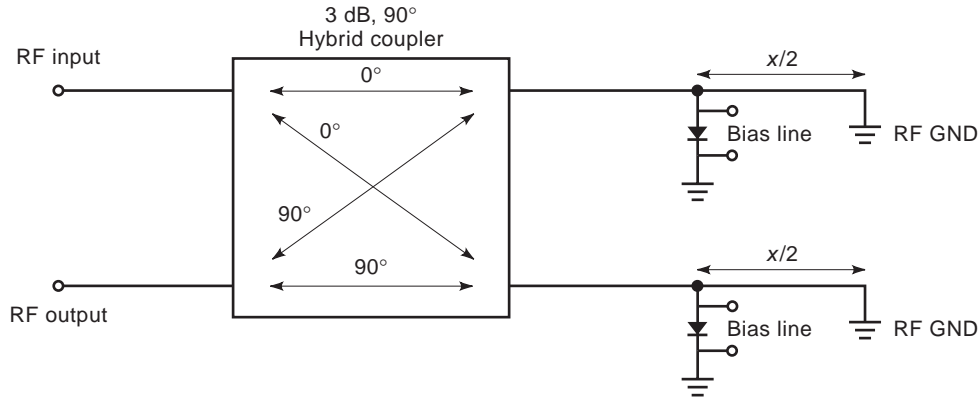

Figure 14. Pin diode and 90° hybrid circuit type of electrically controlled digital phase shifter.

vide continuous phase delay control. This characteristic is very attractive when a fixed phase resolution is impractical to use. Consider as an example the received signal coming from a broadcast TV, as illustrated in Fig. 18. Because a multiple reflection path exist, a double image is received. One possible solution to overcome the problem is to use two receiving antennas and by proper adjustment of the phase difference between them eliminate the reflected signal. Because of the random nature of the delay, only a continuous adjustable phase shifter can be employed.

Electrically analog tunable phase shifters can be subdivided in three major subcategories as illustrated in Fig. 2. A description of the operational principle for each of them is provided below.

5.3. Ferrite Phase Shifters

Ferrite phase shifters are employed in a waveguide or a planar structure. They operate using the ferrite property of nonlinear dependence between magnetization (B) and magnetic field (H). Ferrites are nonlinear and nonreciprocal magnetic materials composed of a mixture of divalent metal and iron oxide having the general chemical structure

where M is a divalent metal such as manganese, magnesium, nickel, or iron. They exhibit a hysteresis $B-H$ dependence as reported in Fig. 19. To explain how ferrites are used in phase shifters, it is not necessary to describe in detail the material properties, which are well documented in Refs. 12 and 13. The nonlinear $H-\mu$ dependence will be exhibited as shown in Fig. 19. The permeability at specific magnetization value (H^*) can therefore be calculated as

$$\mu = \mu_0 + \left. \frac{\partial B}{\partial H} \right|_{H=H^*} \tag{20}$$

In general the ferrite permeability takes the form of a tensor because of the nonreciprocal behavior. The elements of this tensor are a function of the applied magnetic field. When the magnitude or direction of the magnetic field is changed, the permeability of the ferrite changes, thereby changing the propagation constant of the electromagnetic wave. Phase shift is a consequence of the change in the propagation constant brought about by electronically controlling the applied magnetic field. For a more extensive and complete treatment of ferrite properties at microwave frequencies, see Refs. 14 and 15. As direct application of this concept, a waveguide ferrite loaded phase shifter is described. The geometry of the device is shown in Fig. 20, the magnetization of the ferrite is achieved using a

Figure 15. Bias circuit of pin-diode-type phase shifter.

Figure 16. Bias circuit for an FET type of phase shifter.

current loop around the ferrite slab (with the aid of a biasing wire). The ferrite is placed in the waveguide in such a way to maximize the interaction with the existing magnetic field in the guide. For waveguide operating with the fundamental mode (TE_{10}), the magnetic field will be maximum at $\frac{1}{4}$ and $\frac{3}{4}$ of the longitudinal section of the guide [6] as illustrated in Fig. 20. Because the magnetic field has opposite direction at those sections, an asymmetric bias (see Fig. 20) will be necessary in order to obtain a phase shift. This is done using a current flowing in the two wires in opposite directions. Another concept is to use different geometries as illustrated in Fig. 21. The cross section depicted in Fig. 21a is an extension of the one shown in

Fig. 20; the difference is that the ferrite is placed where the maximum magnetic field exists at the bottom and top of the guide. This allows a reduction of the mismatch with the empty waveguide, making easier the design of the matching circuit. Also in this case as illustrated in the figure, a differential bias of the ferrite must be used. Figure 21b is also based on a similar concept; but the asymmetric bias is replaced by an asymmetric geometry, so the ferrite is only placed on one side of the guide. Further improvement toward the matching for this structure is obtained in the case of Fig. 21c. Several versions of a planar structure that employ ferrites as tunable elements have been proposed [16–18]. Even though in principle

those structures work, most ferrite phase shifters currently constructed use waveguide geometry.

Another operational principle for the ferrite reciprocal phase shifters is to use Faraday rotation to produce time delay of microwave signal. This type of phase shifter was at first proposed by Reggia and Spencer [19] and is illustrated in Fig. 22. Several modifications of the original form were proposed later, but the basic operative principle remains the same. In this phase shifter a longitudinal ferrite toroid is placed in the longitudinal section of a rectangular waveguide (see Fig. 22). The magnetic biasing field is produced by an external magnetization circuit. It is well known that when a linearly polarized wave propagates in a ferromagnetic rod, the plane of polarization of the wave in the rod rotates. Now if the rod is placed inside a rectangular waveguide with one of its dimension at cutoff, then the rotational effect is suppressed (for small-size rod). Reggia and Spencer have demonstrated large changes in insertion phase with external magnetic field bias for the transmitted power. They also demonstrated that the phase variations are independent of the propagation

Figure 20. Nonreciprocal waveguide ferrite phase shifter.

direction. Many other authors investigated the theory beyond this effect [20,21]. Practical design of the Reggia-Spencer phase shifter is mostly based on approximate equations [22] that consider the phase shift as a consequence of a small perturbation in the effective permeability.

5.4. Ferroelectric Phase Shifters

In ferroelectric phase shifters the phase shift capability of ferroelectric materials results from the fact that if we are below their Curie temperature [23,24] (see FERROELECTRICS), the dielectric constant of such a material can be modulated under the effect of an electric bias field. Particularly, if the electric field is applied perpendicularly to the direction of propagation of the electromagnetic signal, the propagation constant ($\beta = 2\pi/\lambda$) of the signal will depend on the bias field since $\beta = 2\pi\sqrt{\epsilon_r}/\lambda_0$ and $\epsilon_r = \epsilon_r(V_{\text{bias}})$. The total wave delay will become a function of the bias field, and therefore this will produce a phase shift $\Delta\phi = \Delta\beta l$, where l is the length of the line. Two major implementations of a ferroelectric phase shifter have been used: waveguide geometry and planar structures. In waveguide geometry the ferroelectric material is placed inside a waveguide as illustrated in Fig. 23. A voltage is applied to the center conductor, creating a vertical electric field to the grounded flange. The matching layer must be placed on either side of the sample to couple the RF energy in and out of the material. These rectangular layers of dielectric are needed in the design of the phase shifter because of the impedance mismatch between air and the high permittivity ferroelectric. One problem in the use of this type of setup is the high bias required (typically 1–2kV) due to the thickness of the material. Ferroelectrics require a bias

Figure 19. Nonlinear $B-H$ dependence and correspondent $\mu-H$ dependence.

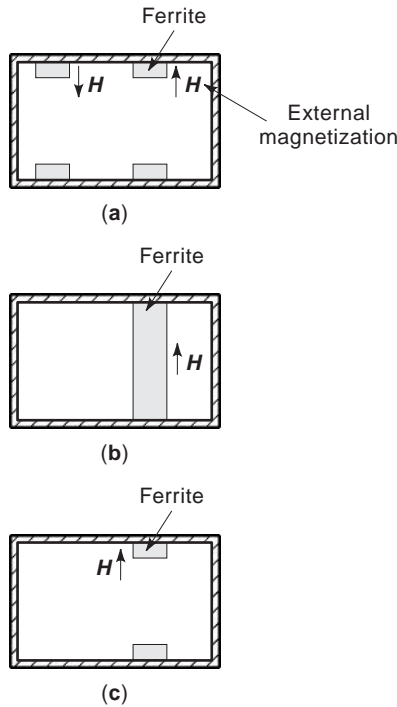

Figure 21. Different types of nonreciprocal waveguide ferrite phase shifter.

voltage of the order $2\text{--}4\text{V}/\mu\text{m}$ in order to significantly change their dielectric constant [25,26].

Use of the planar type of ferroelectric material in microstrip geometry avoids this problem as demonstrated in Ref. 27. The geometry is illustrated in Fig. 24. The active part of the device consists of a microstrip line printed on a ferroelectric substrate whose dielectric constant is changed by bias. The length of the strip determines the maximum phase shift achievable for a fixed change of the propagation constant ($\Delta\beta$), associated with the maximum bias voltage. The complete design of this type of phase shifter is reported in Ref. 28. To reduce the required bias, the ferroelectric material has a thickness of the order of $0.1\text{--}0.2\text{ mm}$, allowing bias voltage of a few hundred volts. As in the case of the pin-diode phase shifter, attention must be dedicated to the design of the biasing circuit, to avoid leakage of the DC voltage in the RF circuit.

Figure 23. Waveguide ferroelectric type of analog phase shifter.

Figure 22. Reggia-Spencer reciprocal ferrite phase shifter.

5.5. Varactor Diode Phase Shifter

In varactor diode phase shifters a varactor diode is used as a variable-capacitance element. This variable capacitance is obtained through a voltage-tuned capacitance of the diode under a reverse-bias condition [24]. The varactor diode is used in combination with a hybrid coupled circuit as illustrated in Fig. 25a. The $3\text{ dB } 90^\circ$ hybrid circuit is symmetrically terminated with the diodes. If X is the reactance of the diode, the reflection coefficient can be calculated as [11]

$$\Gamma = \frac{jX/Z_0 - 1}{jX/Z_0 + 1} \tag{21}$$

and the corresponding phase of the reflection coefficient is given by

$$\phi = \pi - 2 \arctan(X/Z) \tag{22}$$

Figure 24. Microstrip ferroelectric type of analog phase shifter.

where Z_0 is the characteristic impedance of the transmission line ($50\ \Omega$ typically). We notice that in order to obtain a phase variation in the range going from 0 to 2π , the reactance of the diode must go from $-\infty$ to 0 to $+\infty$ and the maximum change of phase is obtained when $X=0$. Hence, in order to obtain a maximum phase shift, the diode must be connected in series with an inductive load to allow resonance ($X=0$); this can be achieved with a stub as illustrated in Fig. 25b for a microstrip realization. The

impedance of the reflecting termination (diode and stub) is given by

$$Z = R_d + j\left(Z_s \tan \beta l_s - \frac{1}{\omega C_d}\right) \quad (23)$$

where R_d and C_d are the equivalent parameters of the diode, and Z_s and l_s are the stub characteristic impedance and length, respectively. The associated reflection coefficient is calculated from

$$\Gamma = \frac{R_d - Z_0 + jX}{R_d + Z_0 + jX} \quad (24)$$

As the bias voltage changes from 0 to a negative value, C_d goes from $C_{d,max}$ to $C_{d,min}$, giving a change of X expressed by

$$\Delta X = \frac{1}{\omega C_{d,min}} - \frac{1}{\omega C_{d,max}} \quad (25)$$

For such change of X the correspondent phase change can be obtained as

$$|\Delta\phi| = 4 \arctan\left(\frac{\Delta X}{2Z_0}\right) \quad (26)$$

Also at $X=0$ (resonance condition) a maximum insertion loss due to R_d will occur. The corresponding attenuation in

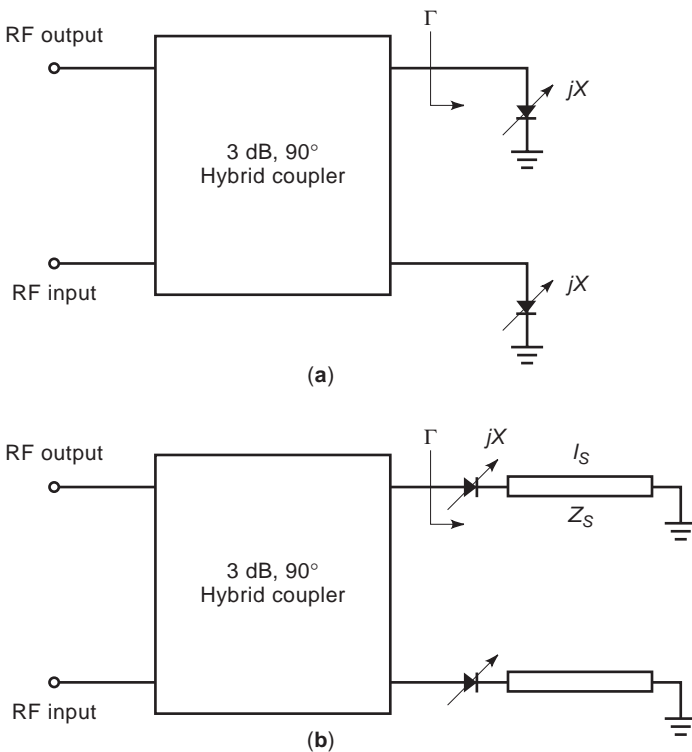

Figure 25. Varactor-based tunable phase shifter.

Figure 26. Active FET-type phase shifter.

this circumstance is

$$\alpha_{\text{dB}} = 20 \log_{10} \left(\frac{1 + R_d/Z_0}{1 - R_d/Z_0} \right) \quad (27)$$

The figure of merit (F) for the analyzed structure is calculated as

$$F = \frac{|\Delta\phi|_{\text{deg}}}{\alpha_{\text{dB}}} \quad (28)$$

A possible improvement of the presented structure can be obtained using two series varactor diodes as presented in Ref. 29. the operational principle remains the same, but a larger change in the capacitance is obtained.

5.6. Active Phase Shifter

Use of FET in an analog phase shifter [30] allows one to take advantage of the gain of the FET at microwave frequencies, while producing the time delay at the same time. Figure 26 shows the topology of this kind of phase shifter. The phase variation in the transmission coefficient (S_{21}) is achieved by controlling the bias voltage at the gate of the FET. The bias voltage is applied on the second gate of the FET, while a fixed inductive load is connected to it. The bias voltage will change the capacitance between the first gate (G_1) and the source, and this will change the amplitude and phase of the S_{21} . One limitation of this topology is the narrow bandwidth that is achieved. Use of more complicated topologies as reported in Ref. 31 will allow larger bandwidth and larger phase shifting capabilities.

PHOTONIC BAND GAP (PBG)

1. INTRODUCTION

In 1987, E. Yablonovitch suggested that a dielectric medium with a periodic index of refraction in the three dimensions would make it feasible to inhibit the spontaneous emission from an excited atom, provided a sufficient refractive index contrast was achieved [1]. This phenomenon occurs because the periodicity of the medium gives rise to a frequency region where electromagnetic (EM) radiation is suppressed regardless of the wavevector (direction of incidence). This frequency region is usually called the *photonic bandgap* (PBG) as it is the classical wave equivalent to the electronic bandgap for electrons in semiconductors. Since this seminal work, the number of publications related to PBG materials and applications has doubled every year.

The first step after the publication of the Yablonovitch's work was intended to find a three-dimensional (3D) composite that could allow a complete 3D PBG. The microwave regime was chosen to fabricate the first 3D structures because they can be more easily manufactured and tested than their optical counterparts, taking into account that the fundamental length is on the order of millimeters instead of micrometers. The first choice was a face-centered cubic (fcc) lattice of air spheres in a high-index ($n = 3.5$) dielectric material as the rounded shape of the Brillouin zone of the fcc lattice contributes to the appearance of a full 3D PBG [2]. Following this approach, a number of structures with different filling factors and refractive indices were fabricated and tested owing to the lack of numerical tools that could ease the design. For one of these structures (86% filling factor), Yablonovitch was

able to identify experimentally a 1-GHz-width 3D PBG centered at 15 GHz between the first two bands [2], which validated his own theoretical predictions 2 years earlier. These experimental results were confirmed by two theoretical works in which the photonic band diagram of the structure measured in Ref. 2 was calculated by employing a plane-wave expansion (PWE) method with a scalar approximation of the EM fields [3,4]. However, after this apparent success several authors pointed out that if a full-vector approximation were used to obtain the photonic bands by means of the PWE approach, the PBG observed experimentally would be merely a pseudo-PBG [5,6], due to degeneracy of the first bands near the W and U symmetry points. These disappointing theoretical results gave rise to some controversy but, at the end of 1990, the first structure possessing a complete 3D PBG was discovered: the diamond lattice of dielectric spheres [7]. From this discovery until the present the investigation field related to PBG materials has experienced such a growing interest that many authors have pointed out that these materials could give rise to a technological revolution similar to that caused by semiconductors in the mid twentieth century [8].

2. FUNDAMENTALS OF PHOTONIC BANDGAP

PBG materials can be classified as one-dimensional (1D), two-dimensional (2D), or (3D) depending on the directions of periodicity of the index of refraction. A 3D PBG structure is necessary to achieve a complete PBG. However, 2D PBG structures such as planar photonic crystals that can have an in-plane PBG [9] have attained great success as they are easier to fabricate (use of conventional techniques employed in microelectronics) and to test than 3D ones such as inverted opals [10] or woodpile structures [11,12].

As mentioned above, PBG materials can be designed to work in any spectral regime, from microwaves to infrared frequencies, due to the scaling properties of the Maxwell equations [13]. The materials must have only an appropriate index of refraction and low absorption losses in the selected spectral regime. For example, materials such as silica, silicon, or III–V composites are commonly used to implement PBG circuits working at optical frequencies [9–12,14]. On the other hand, in the microwave regime the most extensive choice has been the use of alumina (Al_2O_3) because of its high refractive index and low absorption losses [15]. 2D and 3D lattices of alumina rods have been widely used to study PBG-based phenomena [16–20] that have been demonstrated experimentally first in the microwave domain and then in the optical domain, for the reasons explained previously. For example, the existence of localized modes and the guiding of light through linear defects were first demonstrated in the microwave regime using 2D lattices of alumina rods [12,21]. Some years later, these same phenomena were measured in the optical domain using more sophisticated procedures [22].

The two most important EM properties of PBG structure are (1) the existence of the PBG where no propagation states exist owing to the destructive interaction between multiple EM waves reflected and refracted in all interfaces

of the composite and (2) the existence of EM modes that can propagate without scattering through the periodic composite despite the high-index contrast at the materials interfaces. These modes propagate in the form of Bloch waves [23]: a plane wave modulated by a periodic function with a periodicity the same as that of the PBG structure. Because of the property of wavevector conservation, a Bloch wave can propagate losslessly through a perfectly periodic dielectric structure. The photonic bands of a PBG composite show all the Bloch modes that can propagate in the composite and thus fully characterize the EM behavior of the PBG structure. The photonic bands of a given PBG structure can be obtained from the so-called master equation [13]

$$\nabla \times \left(\frac{1}{\varepsilon(\mathbf{r})} \nabla \times \mathbf{H}(\mathbf{r}) \right) = \left(\frac{\omega}{c} \right)^2 \mathbf{H}(\mathbf{r}) \quad (1)$$

where $\varepsilon(\mathbf{r})$ is the permittivity in the region under consideration, $\mathbf{H}(\mathbf{r})$ is the magnetic field, ω the optical frequency, and c the light speed in vacuum. A detailed procedure on how to obtain Eq. (1) can be found in Ref. 13.

To better understand the EM properties of PBG composites, let us analyze a typical PBG structure: a 2D arrangement of high-index cylinders with radius r in air forming a hexagonal lattice with lattice constant a , such as that shown in Fig. 1a. The structure is formed by the periodic repetition of the unit cell (see Fig. 1b) in a plane. The high-symmetry directions are denoted as ΓM and ΓK . Figure 1c depicts the first Brillouin zone in the reciprocal space corresponding to the hexagonal lattice, including the high-symmetry points and the irreducible Brillouin zone (highlighted triangle). All these concepts are similar to those employed in solid-state physics to describe the electronic properties of crystals [24]. In a 2D PBG structure such as that depicted in Fig. 1a, EM modes can be classified into transverse electric (TE) and transverse magnetic (TM) polarizations as the system is invariant under reflections through the plane perpendicular to the cylinders' axes [13]. In general, it is assumed that the waves are confined in the plane of periodicity, so the wave vector in the normal direction is zero. For TM (TE) modes the electric (magnetic) field is parallel to the rods' axes and the magnetic (electric) field is in the periodicity plane. The behavior of TM and TE modes is quite different; a PBG may exist for TE modes and not for TM ones, or vice versa. Furthermore, a periodic structure of high-index cylinders in air (such as that shown in Fig. 1) benefits the appearance of PBGs for TM modes, whereas a 2D lattice of air-holes in a high-index material has PBGs mainly for TE modes [13]. Figure 2a shows the photonic bands of the structure described in Fig. 1 for TM modes. The bands have been obtained by employing the PWE method to solve Eq. (1) [7]. The parameters have been chosen as $r = 0.133a$ and $\varepsilon = 10.3$, as in the PBG circuits described below. On the horizontal axis (abscissa) the wavevector at the boundary of the irreducible Brillouin zone is represented; on the vertical axis (ordinate) the frequency of the modes is represented in normalized units of a/λ , where λ is the wavelength in vacuum. It is usual to represent the

Figure 1. (a) Schematic of a 2D PBG structure consisting of high-index cylinders in air distributed in a hexagonal arrangement; (b) hexagonal lattice of the PBG structure, showing the unit cell, the lattice constant a , and the high-symmetry directions ΓM and ΓK ; (c) Brillouin zone of the hexagonal lattice in the reciprocal space, with the high-symmetry points (Γ , M , and K) and the irreducible Brillouin zone (highlighted triangle). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

photonic bands in terms of these normalized dimensionless units, as this representation is independent of the frequency regime where the PBG structure works. From the band diagram and properly selecting a , the PBG

Figure 2. (a) Photonic bands of a 2D hexagonal PBG structure of cylinders ($\epsilon = 10.3$, $r = 0.133a$) in air (PWE method); (b) transmission response of the previous PBG structure along the ΓM direction (seven layers) obtained with an FDTD method. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

structure can be designed to have a PBG in a given frequency range (from microwaves to the infrared). Figure 2a shows a frequency range of $0.37\text{--}0.55 [a/\lambda]$ where no photonic bands exist regardless of the wavevector. Then, in this region there exists a PBG for TM-polarized waves. This can also be demonstrated by obtaining the transmission spectrum of the proposed PBG structure. To this end, the finite-difference time-domain (FDTD) method [25] can be employed. This method allows one to resolve numerically the Maxwell equations in the time domain in a finite spatial region. Figure 2b shows the transmission spectrum of a PBG structure such as that whose photonic bands are shown in Fig. 2a. The wave propagates along the ΓM direction and the crystal has a thickness of seven layers in this direction (see inset of Fig. 2b). It can be observed that there is a low-transmission region corresponding to the TM PBG shown in Fig. 2a. The ripple in the transmission region between 0.55 and $0.63 [a/\lambda]$ (where the second photonic band is excited) is due to the reflectivity at both facets of the PBG structure that behaves as a Fabry–Perot cavity. There are two other low-transmission regions ($0.63\text{--}0.76 [a/\lambda]$ and $0.86\text{--}0.95 [a/\lambda]$) corresponding to pseudo-PBGs in the ΓM direction, that is, PBGs that exist for wavevectors along ΓM but not along ΓK , which can also be identified in the photonic bands. The total transmission in a PBG or a pseudo-PBG is not actually zero because the PBG structure has a finite thickness and modes with frequencies inside the PBG are evanescent inside the crystal and their amplitudes decrease exponentially as they enter the crystal. This can be observed in more detail in Fig. 3, which shows the distribution of the electric field component parallel to the cylinder axis when a plane wave impinges on the PBG structure under study. Two different cases are taken into account; in Fig. 3a the frequency of the wave is $0.58 [a/\lambda]$, so there exists an allowed Bloch mode (see Fig. 2a) that is excited when the

Figure 3. Distribution of the vertical component of the electric field (TM polarization) for a 2D hexagonal PBG structure of cylinders ($\epsilon = 10.3$, $r = 0.133a$) in air when a monochromatic wave impinges from above and is directed upward along the ΓM direction: (a) $0.58 [a/\lambda]$ (guided band); (b) $0.5 [a/\lambda]$ (inside the PBG). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

plane wave enters the crystal; in Fig. 3b the frequency is $0.5 [a/\lambda]$, inside the PBG, so the incident wave cannot enter the crystal as there is no mode that can be excited and the wave is mainly reflected backward whereas a exponentially attenuated signal penetrates inside the crystal in the form of an evanescent wave.

Most of the applications related to PBG composites are related to the insertion of defects inside the otherwise periodic structure, as occurs with the doping of impurities in semiconductors. For example, the insertion of a point defect in a 3D PBG composite breaks the 3D periodicity and can give rise to the presence of a localized EM mode with frequency inside the PBG. This phenomenon was first investigated by Yablonovitch et al., who developed a PBG structure known as a *Yablonovite*, which was the first structure to experimentally demonstrate a complete 3D PBG [21]. Yablonovitch et al. inserted impurities in this composite by adding (acceptor modes) and removing (donor modes) a given quantity of high-index material and noticed that a narrow peak appeared in the transmission spectrum due to the existence of a localized mode inside the defect [26]. Such defects can be used as optical microcavities (or photon boxes) and allow the confinement of light in volumes on the order of $(\lambda/2)^3$.

Linear defects can also be inserted giving rise to EM modes (which can also be classified as acceptors and donors) confined along a line. This fact can be used to implement optical waveguides with a field transverse width of about $\lambda/2$ [13]. In contrast to conventional optical integrated waveguides, in which light confinement is achieved by index guiding (a dielectric core is sandwiched between claddings with a refractive index lower than that of the core material), using PBG linear defects, it becomes feasible to guide light through air waveguides. This has several advantages over guiding light through dielectric materials: reduction of absorption losses, reduction of nonlinear effects, and higher power transmission. However, the most important characteristic of PBG waveguides is that they allow bending of light through sharp bends with negligible losses as the radiation outside the line defect is suppressed because of the existence of the PBG [17,27]. In this way, PBG structures are considered as the main candidates to miniaturize optical components to the order of several wavelengths, which could give rise to the development of nanophotonics technology, in the same way that semiconductors made feasible the widely known microelectronics technology.

3. PHOTONIC BANDGAP IN THE MICROWAVE REGIME: PROPERTIES AND APPLICATIONS

As stated previously, PBG composites can be designed to have a PBG in the microwave regime if the lattice constant ($a \sim \lambda/2$) and the dielectric material are properly chosen. A number of PBG structures, components, and functionalities have been analyzed in the microwave regime, due the relatively easy mode of fabrication (sizes of the order of centimeters) and test (mature measure instruments in the megahertz and gigahertz ranges). The first experiments were aimed at demonstrating the exis-

tence of a 2D PBG for in-plane wavevectors (as in Ref. 16) or a complete 3D PBG (as in Ref. 21). The following target was to demonstrate the existence of localized defect modes, as done in Ref. 26 for cavities and in Ref. 17 for linear waveguides. The demonstration of the feasibility of guiding EM waves through line defects was a key step as a great number of devices and components (in both microwave and optical regimes) are implemented making use of waveguides.

Among all the passive components and applications that have been proposed to implement functionalities of use in optical devices and networks, the Y junction, the directional coupler, and the Mach-Zehnder interferometer (MZI) can be considered as the key building blocks because they enable almost all the applications necessary in these networks (filters, routers, demultiplexers, power combiners/splitters) to be implemented. All these components can be created in a PBG lattice of alumina cylinders and tested using conventional microwave instruments, such as horn antennas and a network analyzer, in order to characterize their performance. In the following paragraphs, these components, as well as two kinds of conventional PBG waveguides that can be used to implement them, are separately described and analyzed.

3.1. PBG Waveguides

As mentioned above, a waveguide can be created in a PBG structure by inserting a line defect that alters the otherwise periodic structure. For example, a ΓK -oriented row of rods can be removed in a 2D hexagonal lattice of high-index cylinders in air, as shown schematically in Fig. 4a. This kind of waveguide is usually referred to as W1 waveguide. In this case, the line defect arises from the removal of high-index dielectric material, so it gives rise to a decreased-index waveguide. Insertion of the defect produces that a single donor mode appears inside the PBG [13]. On the other hand, if the defect is created by adding high-index material, then an increased-index waveguide is obtained, which is inherently multimode. Decreased-index waveguides are preferred as they are single-mode and allow a high efficiency in processes such as guiding through sharp bends or power splitting in Y junctions [27,28]. On the other hand, increased-index waveguides are inherently multimode, which gives rise to undesired phenomena when the translational symmetry of the waveguide is broken (bends, cavities, Y junctions) because higher-order

Figure 4. Schematics of (a) a W1 waveguide and (b) a CCW inserted along the ΓK direction in a hexagonal lattice of high-index cylinders in air. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

modes become excited, degrading the performance of the structure [29].

A waveguide can also be created by inserting a chain of evenly spaced strongly confined microcavities, a structure which is commonly referred to as *coupled-cavity waveguide* (CCW) [18,30,31]. A CCW can be created in a PBG lattice by removing one of each of two cylinders along a certain direction, as shown schematically in Fig. 4b. Light propagation in CCWs can be explained as photon hopping between nearby cavities, due to overlapping of the tightly confined modes. The separation d between cavities must be large enough to ensure that the modes are weakly coupled and the eigenmode of the field in the waveguide remains essentially the same as in an isolated cavity (in Fig. 4b, $d = 2a$). This picture is exactly the classical wave analogous of the tight-binding (TB) approach employed in solid-state physics to describe the electronic properties of solids. From the TB formalism and taking into account that interaction occurs only between consecutive defects along the waveguide, the dispersion relation of a CCW can be expressed as [30]

$$\omega(k) = \Omega[1 + \kappa \cos(kd)] \quad (2)$$

where ω is the angular frequency, k is the wavevector along the direction of the waveguide, Ω is the angular eigenfrequency of an isolated cavity, and κ is the hopping parameter. Owing to the periodicity of the structure along the waveguide direction, the wavevector k is folded into the region $[0, \pi/d]$, so the TB model of the CCW band [Eq. (2)] depends on only two parameters: Ω and κ . The width of the CCW band $\Delta\omega$ may be obtained as $\Delta\omega = 2|\kappa|\Omega$. The most promising features of CCWs are the feasibility of tuning the central frequency of the CCW guided band by modifying the cavities and the 100% transmission of light through sharp bends over their entire bandwidth if the cavity mode has a proper symmetry [30].

Figure 5 shows the measured TM-polarized transmission response (normalized with respect to free-space

Figure 5. Experimental TM-polarized transmission response (normalized with respect to free-space transmission) of a bulk hexagonal crystal of alumina cylinders, a W1 waveguide, and a CCW (parameters: $\epsilon = 10.3$, $r = 0.133a$, $a = 1.5$ cm).

transmission) of a ΓK -oriented bulk structure composed of alumina rods (with the same parameters considered above: $\epsilon = 10.3$, $r = 0.133a$, and $a = 1.5$ cm), and both a W1 waveguide and a CCW inserted in such a structure as shown in Fig. 4. When no defects are inserted, a PBG appears between approximately 7.4 and 13 GHz for in-plane propagation and ΓK incidence. However, if the line defects are introduced, a passband appears inside the rejected band. It can be noticed that the passband is wider and has more amplitude in the case of the W1 waveguide. This is because the dispersion relation of a W1 waveguide is wider and has a higher slope (which means a higher group velocity), so the coupling efficiency from free space is higher and the insertion loss smaller. When bends are introduced, a CCW shows a better behavior than a W1 waveguide, due to the propagation mechanism. In any case, 120° sharp bends can be introduced with high efficiency of power transmission. A more detailed analysis of the performance of bending in these waveguides can be found in Refs. 27 and 29 for a W1 waveguide and in Ref. 31 for a CCW. Both kinds of waveguides are used to implement the structures described below.

3.2. Directional Coupler

A directional coupler (DC) can be created by setting closely two parallel 2D PBG waveguides [32,33]. The main advantage of this approach relies on achieving strong coupling due to the narrow separation between both waveguides. Figure 6 shows a scheme of a 1×2 DC implemented on a 2D hexagonal lattice of alumina rods, as that considered previously in the study of the PBG waveguides. Both waveguides are of the W1 kind. Because of the close proximity between waveguides, the guided mode of an isolated waveguide splits up into two guided modes with even and odd symmetries with respect to the plane equidistant from both waveguides [32]. These modes have different propagation constants β_{even} for the even mode and β_{odd} for the odd mode respectively, which gives rise to an EM power interchange between both waveguides as an EM wave travels along the structure. In order to quantify this effect, the coupling coefficient of the structure is defined as $\kappa = |\beta_{\text{even}} - \beta_{\text{odd}}|/2$. Thus, a higher mismatch of the propagation constants produces a higher κ , which means a stronger mode coupling. This also yields a shorter coupling length, which is defined as $L_c = 2\pi/|\beta_{\text{even}} - \beta_{\text{odd}}|$ and represents the length that light needs to jump from one

Figure 6. Schematic layout of the directional coupler. The waveguides are created along the ΓK direction of the hexagonal structure. The total coupling length is l , and the lattice constant is a .

waveguide to the other and return back to the first one. The transmission response of the coupler depends on the coupling coefficient and the overall length of the coupling region l (see Fig. 6). The normalized power related to the power injected into the input port at both output ports can be written as $P_{o1}/P_i = \cos^2(\kappa l)$ and $P_{o2}/P_i = \sin^2(\kappa l)$, respectively. Figure 7a shows both β_{even} and β_{odd} as a function of the frequency for the directional coupler shown in Fig. 6 and assuming the parameters previously considered. Both propagation constants were obtained by employing the PWE method. Figure 7b shows the calculated normalized coupling coefficient $\kappa \cdot a$ of the proposed coupler. From Fig. 7b it is observed that very high coupling coefficients are obtained mainly in the range between 8.2 and 8.6 GHz, so very short coupling lengths are achieved [34]. For example, at a frequency of 8.5 GHz ($\lambda = 3.53$ cm) the normalized coupling coefficient is $\kappa \cdot a = 0.38$, so the coupling length becomes as short as $3.5\lambda = 12$ cm. Since an overall length of $L_c/4$ is needed to distribute the signal equally between both waveguides, it becomes clear that 3-dB power splitters with a length in the order of the wavelength of the propagating signal can be achieved using PBG technology [34]. It should be emphasized that the same principles may be used to implement ultrashort couplers at

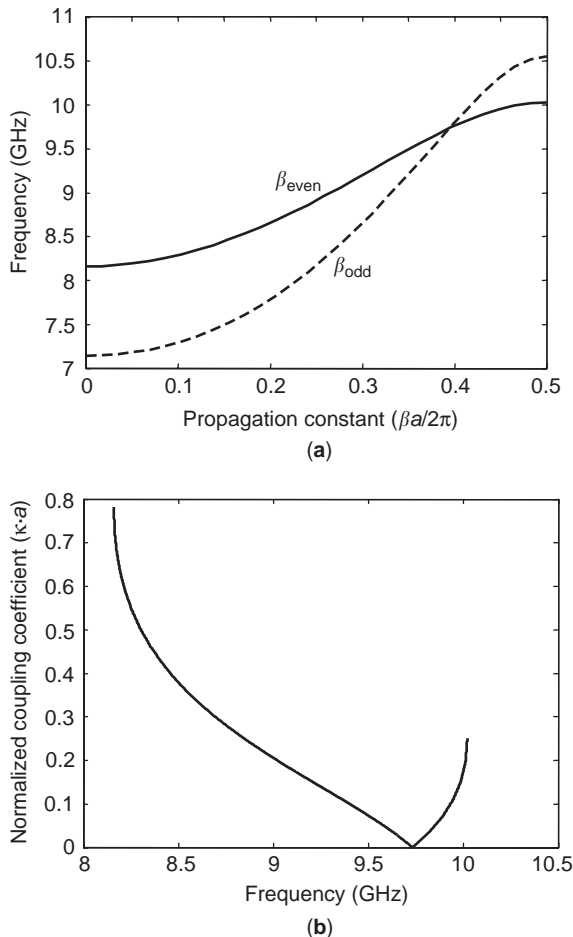

Figure 7. (a) Propagation constant of the even (solid line) and odd (dashed line) modes of the PBG coupler; (b) normalized coupling coefficient ($\kappa \cdot a$) as a function of frequency.

Figure 8. Simulated (dashed line) and measured (solid line) transmission frequency response at output port 1 (a) and output port 2 (b).

optical frequencies, so, in principle, it would be feasible to achieve 3-dB power splitters in the optical domain ($\lambda = 1550$ nm) with lengths around $2 \mu\text{m}$.

The coupler structure was measured and also simulated using the FDTD method. Figure 8a shows the simulated and measured transmission responses at output port 1 of the coupler. From Fig. 8a, it can be observed that the simulated transmission notches inside the guided transmission band appear at 8.7008 and 9.3717 GHz whereas the measured ones appear at 8.723 and 9.383 GHz, respectively. On the other hand, Fig. 8b shows the simulated and measured transmission responses at output port 2 of the coupler. In this case, and from Fig. 8b, the simulation notches appear at 8.44, 9.04, and 9.718 GHz whereas the measured notches appear at 8.475, 9.005, and 9.743 GHz, respectively. A very good agreement between simulation and experimental results is observed in both cases. In addition, it can be noticed that the maximum transmission points in one waveguide correspond to minimum ones in the other one, as expected from the coupler behavior. The small differences observed between simulated and measured results are due mainly to the limitations arising from the experimental setup (undesired reflections, small variations of the rod diameter) and the spectral resolution (4 MHz) of the employed network analyzer. These results confirm that PBG waveguide DCs in the optical domain could be used for wavelength-dependent applications such as demultiplexers or interleavers.

3.3. Y Junction

Power splitters are key building blocks in photonic multifunctional devices and systems. There are mainly two different approaches to equally split up the power of an incoming signal into two output ports: using either a DC

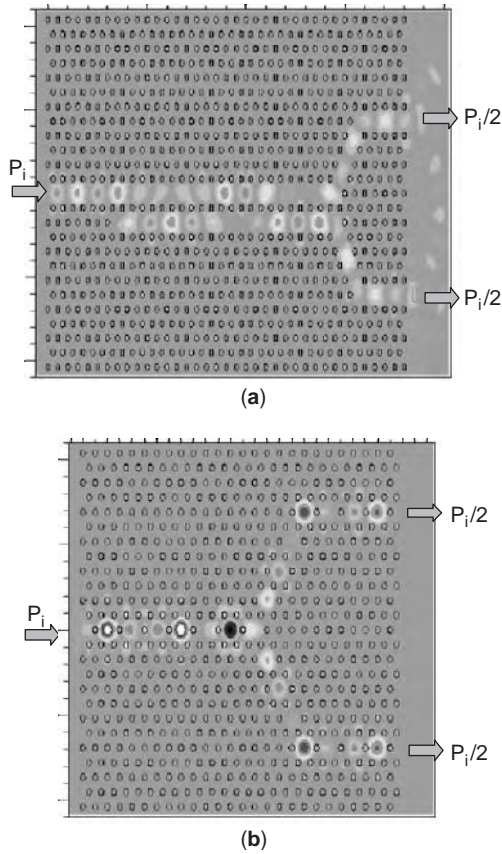

Figure 9. Distribution of the vertical component of the electric field (TM polarization) in two different PBG structures that allow 3 dB power splitting: (a) DC; (b) Y junction. The results are obtained by means of the FDTD method. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

or a Y-junction structure [35]. The performance of both structures is schematically shown in Fig. 9, which depicts the distribution of the vertical components of the electric field (TM polarization) in a 3-dB splitter based on (a) a DC and (b) a Y junction obtained by means of the FDTD method. It should be noted that in the first approach (Fig. 9a) the relative phase shift between output signals is 90° whereas in the latter (Fig. 9b) both output signals are in phase. The performance of a Y junction working as 3 dB power splitter implemented in a PBG structure (120° and 180° between output waveguides) has been demonstrated in the microwave regime using CCWs [18]. As the mode in the input waveguide has even symmetry (assuming that the fundamental mode of this waveguide is excited), the even supermode of the system formed by the two output waveguides is excited, so there is no phase shift between outputs. However, an alternative structure can be implemented that allows a 180° phase shift between output ports [34]. Figure 10 shows a schematic of this alternative power splitter implemented on a hexagonal lattice of alumina rods in air, as in the previous examples. The coupler section (dashed rectangle in Fig. 10) consists of two CCWs as those shown in Fig. 4b. Thereby, this section of the overall splitter structure can be seen as a CCW coupler. Each CCW forming the coupler consists of N cavities

Figure 10. Schematic of the proposed 180° phase shift power splitting structure implemented on a hexagonal PBG lattice of high-index cylinders.

(in Fig. 10, $N = 5$ cavities) with a d spacing between adjacent ones. A single CCW is used to inject signal into one of the CCWs comprising the coupler, whereas two CCWs are used as output ports. The proximity between CCWs in the coupler section gives rise to the splitting of the guided mode of an isolated CCW into two modes with even and odd symmetries, as in the case of the DC previously analyzed. The band structures of an isolated CCW and the CCW coupler obtained by using the PWE method for TM modes are shown in Fig. 11. The parameters are the same as the previously considered. From Fig. 11 it can be seen that the splitting of the isolated mode when the coupler is created is very strong and the modes of the coupler are almost completely separated in two frequency ranges, which can be explained by considering that the coupling strength in the transverse direction of the waveguides (ΓM) is of similar order as the coupling strength in the longitudinal direction, (ΓK), due to the propagation caused by photon hopping between cavities. Periodic power transfer between waveguides in DCs can be achieved only for the frequency range where both coupler modes coexist and have different propagation constants, so in the

Figure 11. Band structure of the guided modes for an isolated CCW (dashed curve) and the CCW coupler (solid curves).

proposed CCW coupler power interchange is achieved only in a very narrow frequency range around $0.446 [a/\lambda]$, which drastically limits its operation as a conventional DC. However, the behavior of the CCW coupler may be exploited to implement a power splitter as that shown in Fig. 10. From Fig. 11 it may be observed that in the frequency range between 0.4076 and $0.4454 [a/\lambda]$ only the odd mode can propagate through the CCW coupler. If this mode is excited by means of an external CCW as shown in Fig. 10, the frequency working range of the splitter is restricted to the dotted rectangle depicted in Fig. 11. Signals propagating through the output CCWs have a relative phase shift of 180° because of the odd symmetry of the mode. As both signals travel through the same length, they are synchronized and there is no time delay between them, which results in a technique suitable for high-speed signals.

Figure 12 shows the distribution of the electric field component parallel to the rods of a monochromatic wave with frequency $0.44 [a/\lambda]$ in the proposed structure with $N = 6$ obtained by means of the FDTD method. In Fig. 12 it can be seen that there is a 180° phase shift between the field in each CCW coupler branch because maxima (white) in the upper cavities correspond to minima (black) in the lower cavities, and vice versa. CCWs provide the added advantage of implementing sharp bends with negligible losses, which allows spatial separation of the branches of the coupler. Simulated transmission spectra for different lengths demonstrated that the power splitting occurs regardless of the coupler length (even for $N = 1$), although, for example, for $N = 2$ the response was slightly impaired because of the strong interaction between input and output CCWs. Anyway, it can be stated that the overall splitter length can be very small (e.g., for $N = 4$ the total length of the coupling section is $\sim 4a < 2\lambda$), resulting in a very compact structure.

The splitting structure depicted in Fig. 10 was experimentally characterized in the microwave regime using the same procedure that in the DC case. Figure 13 shows the measured transmission (a) amplitude and (b) phase for a splitter with $N = 4$ cavities. Different spectral regions

Figure 12. Distribution of the vertical component of the electric field of a monochromatic wave in the splitter ($N=6$) for a frequency $0.44 [a/\lambda]$ obtained with a 2D FDTD simulation.

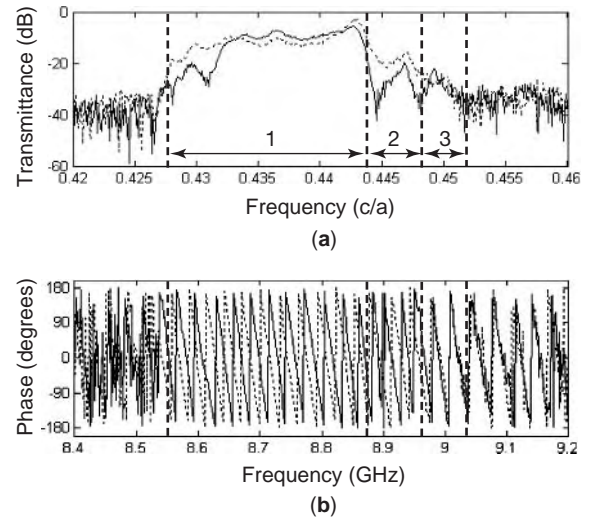

Figure 13. Experimental transmission of the 180° phase shift power splitting structure: (a) amplitude and (b) phase for both output ports 1 (solid curves) and 2 (dashed curves).

are separated by vertical dotted lines in Fig. 13. Region 1 highlights the 180° phase shift power splitting range, where only the odd mode exists and the input power is equally split up between the outputs, in good agreement with the theoretical results and confirming the feasibility of employing the proposed structure as a 3-dB power splitter. In region 2, the difference on transmitted power between the two output ports is attributed to the interaction between the odd and the even modes, so the structure does not work any longer as a splitter. Finally, in region 3 only the even mode is excited and both outputs are balanced again, so this structure can also work as a conventional Y-junction-based 3-dB power splitter. The different power transmission at the outputs observed in Fig. 13a is due mainly to external reflections, finiteness of the structure in the vertical direction, and inaccuracies in the implementation of the physical structure, as in the DC case. In Fig. 13b a phase difference near 180° between output ports is observed in region 1, confirming the theoretical and simulation results. The EM splitting covers a spectral range over 300 MHz, which means a relative splitter operational range of 3.45%. In region 3, around 9 GHz, only the even mode is excited so the outputs are in phase, as shown in Fig. 13b. The low transmittance in region 3 compared to region 1 can be explained by taking into account the flatness of the dispersion relation of the even mode. It should be highlighted that a 50% power splitting over the frequency range indicated in Fig. 11 is achieved, which contrasts clearly with splitters implemented using DCs in which perfect 50% splitting is possible in only a limited frequency range, due to the frequency-dependent behavior of the coupling coefficient (see Figs. 7 and 8).

3.4. Mach-Zehnder Interferometers

Mach-Zehnder interferometers (MZIs) have been widely used to implement a huge variety of optical devices such as filters, demultiplexers, switches, and intensity

modulators. A MZI makes use of two interfering paths of different lengths to resolve different wavelengths at the outputs. The reduction of the overall size of an interferometric structure can be achieved by using PBG waveguides and in particular, CCWs because the effective length of these waveguides can become very large for a reduced number of cavities because of their small group velocity [36].

Figure 14a shows a scheme of a 2×2 MZI consisting of two 3-dB DCs connected through two optical waveguides with different lengths, L and $L + \Delta L$. Assuming that optical power is injected only into input port 1, the transfer function of the MZI may be basically expressed as

$$\begin{pmatrix} T_{11}(f) \\ T_{21}(f) \end{pmatrix} = \begin{pmatrix} \sin^2 \frac{\beta \Delta L}{2} \\ \cos^2 \frac{\beta \Delta L}{2} \end{pmatrix} \quad (3)$$

where β is the propagation constant of the guided mode in the waveguides. As mentioned previously, guided modes in CCWs have very low group velocities, even one or two orders of magnitude lower than in conventional index-guiding waveguides, reaching their maximum at the band center and decaying to zero at both band edges [37]. This means that light propagates slowly through the CCW and the effective length of the guide becomes very large compared to its actual length, so very large phase shifts between both paths can be attained using very short CCWs. Furthermore, one can accurately control the transmission properties of these guides by using the TB approach expressed in Eq. (2), from which the propagation constant of the guided mode in a CCW may be written as

$$\beta(f) = \frac{1}{d} \arccos \left(\frac{f - f_0}{\kappa f_0} \right) \quad (4)$$

where f_0 is the eigenfrequency of an isolated cavity and f is the frequency.

Figure 14. (a) Scheme of a 2×2 MZI; (b) scheme of a MZI employing DCs and CCWs in a 2D PBG structure of alumina cylinders.

Figure 14b depicts the scheme of a MZI implemented using CCWs. Input and output DCs are formed by two parallel PBG waveguides and should be properly designed to achieve 3 dB power splitting, using the procedure explained in Section 3.2. CCWs are implemented as two chains consisting of N and $N + \Delta N$ d -spaced coupled cavities, respectively. Then the path difference can be written as $\Delta L = \Delta N d$ and the MZI transfer function can be expressed as

$$\begin{pmatrix} T_{11}(f) \\ T_{21}(f) \end{pmatrix} = \begin{pmatrix} \sin^2 \left(\frac{\Delta N}{2} \arccos \left(\frac{f - f_0}{\kappa f_0} \right) \right) \\ \cos^2 \left(\frac{\Delta N}{2} \arccos \left(\frac{f - f_0}{\kappa f_0} \right) \right) \end{pmatrix} \quad (5)$$

The transfer function of the CCW-based MZI given by (5) depends on only three parameters: the eigenfrequency of an isolated cavity (f_0), the hopping parameter (κ), and the difference in the number of cavities (ΔN). Both f_0 and κ depend on the physical structure of the CCW and may be easily obtained from band structure calculations. Thereby, ΔN may be considered as a design parameter of the interferometric effect that may be chosen to achieve the requirements of a specific MZI-based functionality.

Figure 15 shows the amplitude responses of CCW-based MZIs with different ΔN values obtained from Eq. (5). To emphasize the interferometric effect, the intrinsic CCW transmission response is not considered in Fig. 15. It should be noticed that in the frequency region around f_0 , the $\arccos(\cdot)$ function has an almost linear response, which gives rise to evenly spaced channels at the MZI outputs. In this frequency range the spacing $\Delta \nu$ between demultiplexed channels may be obtained from (5) as $\Delta \nu = \pi \kappa f_0' \Delta N$, so as the parameters f_0 and κ depend on the CCW

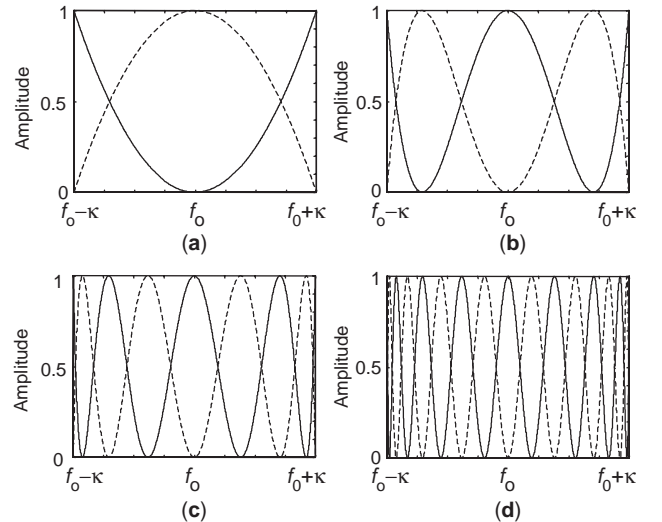

Figure 15. Theoretical CCW-based MZI transmission responses for (a) $\Delta N = 2$, (b) $\Delta N = 4$, (c) $\Delta N = 8$, and (d) $\Delta N = 16$ resulting from the theoretical model. Dotted and solid lines stand for output ports 1 and 2, respectively.

structure, the MZI response for demultiplexing applications may be designed by properly choosing ΔN .

A CCW-based MZI such as that shown in Fig. 14b was implemented on the 2D hexagonal lattice of alumina rods in air and tested, as in the case of the previously mentioned structures. Y junctions instead of 3-dB DCs were used to both divide and combine the input signal due to the difficulty in implementing DCs in the experimental structure. In this case, the transfer function of the 1×1 MZI can be expressed as $T_{11}(f) = \cos^2(\beta\Delta L/2)$. From this transfer function it can be noticed that $\Delta N/2$ transmission notches appear at the MZI output due to the interference between different paths. Figure 16 shows the experimental transmission responses for (a) $\Delta N=2$ and (b) $\Delta N=4$. The MZI response is depicted as solid line, whereas the transmission response of one of the CCWs forming the corresponding MZI is shown as dotted line. In addition, in Fig. 16 the frequencies of the transmission notches expected from theoretical calculations are set in dotted vertical lines. A very good agreement is observed between theoretical and experimental results. From Fig. 16, for $\Delta N=2$ the calculated value of the transmission notch is

Figure 16. Experimental transmission response of the CCW-based MZI (solid line) and one of two CCWs constituting the MZI (dashed line) for (a) $\Delta N=2$ and (b) $\Delta N=4$. The theoretical frequencies of the transmission notches are shown as vertical dotted lines.

8.79 GHz and the measured frequency is 8.802 GHz, while for $\Delta N=4$ the theoretical notches are 8.6066 and 8.9734 GHz and the experimental notches appear at 8.594 and 8.978 GHz, respectively. The small differences observed are also due mainly to the limitations arising from the experimental setup and the spectral resolution of the network analyzer.

4. PHOTONIC BANDGAP IN MICROSTRIP LINES

4.1. Brief Introduction to PBG Structures Implemented in Microstrip Technology

PBG structures have also been demonstrated at microwave frequencies but employing microstrip or coplanar technologies instead of 2D and 3D lattices of high-index rods. The first approach to implement PBG structures in microstrip technology consisted of creating periodic structures by drilling a periodic pattern of rods through the substrate [38,39]. In 1998, Radisic et al. demonstrated a convenient way to implement PBG microstrip structures by etching a three-rod periodic pattern of circles in the ground plane of a microstrip line [40]. Later, it was demonstrated that only one-rod of etched circles could be employed to develop high quality PBG structures due to the high confinement of the electric field above the microstrip line [41]. This property allows one to design meander PBG microstrip structures with improved behavior and reduced size as demonstrated in Ref. 42.

A periodic PBG microstrip line can be considered and studied as a 1D grating. This correspondence allows us to employ Bragg condition and coupled-mode theory [43] to control the physical parameters of the designed PBG structure in order to obtain a bandgap with desired parameters in terms of central frequency and bandwidth. Further equivalencies between physical parameters of the PBG microstrip line and those of the grating were reported [44]. Furthermore, this equivalency led to novel PBG microstrip approaches, including apodized [44–46] and chirped [47] structures. On the other hand, circuital models based on the modification of the microstrip-line inductance introduced by the periodic patterns can also be employed to characterize and design periodic PBG structures in microstrip technology as reported in Ref. 48.

Other etched geometries besides circles have also been suggested to implement PBG microstrip structures with better performances and further applications [50–52]. Furthermore, continuous etched patterns in the ground plane of the microstrip lines were proposed to achieve PBG microstrip structures, avoiding the formation of spurious bandgaps that typically appears in PBG structures based on discrete patterns. In this way, Laso et al. [49] demonstrated that the combination of several raised sinus patterns etched in the ground plane of a microstrip line could be employed to obtain PBG microstrip structures with multiple-frequency-tuned bandgaps at desired frequencies.

Finally, PBG microstrip structures with an unperturbed ground plane have been also proposed. In this kind of structure the bandgap is achieved by varying the microstrip-line impedance, which is wide relative to the linewidth [47,53]. These concepts can be easily translated

to other planar technologies as reported in Ref. 54, where PBG structures are achieved using coplanar technology.

4.2. Nonperiodic Structures

All the patterns described in Section 4.1, which are employed for the implementation of PBG microstrip structures, are periodic. However, it is interesting to analyze the behavior and properties of nonperiodic patterns. So, in Ref. 55 nonperiodic patterns of etched circles in the ground plane of a 50-Ω microstrip line were proposed in order to obtain multiple tuned frequency bandgaps and new PBG microstrip circuit applications. These nonperiodic PBG topologies are based on breaking the etched circles periodicity (defects insertion) as shown in Fig. 17, which depicts the three nonperiodic structures that were studied in Ref. 55. When a single defect is inserted in the periodic pattern, a resonance appears inside the initial bandgap of the unperturbed PBG structure [56]. The frequency of this resonance depends on the defect size, referred to as *ad* in Fig. 17. As this basic structure (defect) is repeated along the microstrip ground plane, a splitting of the single defect resonance into *n* resonances takes place, where *n* is the number of introduced defects. This splitting effect may be explained by using the TB theory, as it can be considered that there is a CCW formed by *n* cavities along the microstrip line [19]. In addition, it may be demonstrated that this splitting effect depends mainly on the spacing between defects *d* in Fig. 17, obtaining a higher frequency splitting by increasing the coupling between defect modes when the defects are closely placed.

Figure 18 shows respectively the *S*₂₁ parameter obtained experimentally (thick line) and by FDTD simulation (thin line) for the three structures depicted in Fig. 17. As can be observed in Fig. 18, the maximum frequency splitting (Fig. 18c) corresponds to the closer defect inser-

Figure 17. Microstrip PBG ground-plane topologies with two defects and (a) weak coupling, (b) medium coupling, and (c) high coupling between defect modes.

Figure 18. Simulated (thin line) and measured (thick line) *S*₂₁ parameter for topologies in Fig. 14.

tion as expected. The results shown in Fig. 18 report on a verification of the TB theory applied to PBG microstrip technology, and its application for multiple tuned bandgap structures has been demonstrated. Other applications of CCWs in microstrip lines are envisaged, such as bandpass filters, channelizers, or phase shifters.

4.3. PBG Microstrip Structures Applied to Harmonic Suppression in Bandpass Filters

PBG-microstrip structures have been employed for spurious suppression in bandpass filters based on coupled line sections [52,57–59]. Furthermore, a PBG-microstrip circuit based on etching a circle pattern in the circuit ground plane has been proposed to reject second-order harmonics in multistage coupled ring bandpass filters [60]. As shown in Fig. 19, two topologies were employed for harmonic suppression: PBG inside and out of microstrip-coupled rings. The topology depicted in Fig. 19a incorporates a PBG microstrip structure at the output feeding line. This PBG microstrip structure based on etching a periodic pattern of circles in the ground plane was designed to obtain a bandgap centered at the second harmonic of the coupled ring bandpass filter. Conversely, Fig. 19b depicts the filter topology when the PBG structure is etched in the ground plane of one of the two bandpass filter rings. In such a structure harmonic suppression is achieved by cascading two rings, one of which is an embedded PBG ring to obtain a lower frequency-shifted second-harmonic (slow-wave effect) in comparison to a simple ring as reported in Ref. 60. Both filters shown in Fig. 19 were physically implemented

Figure 19. Microstrip ring filter layouts with electromagnetic bandgap (EBG) structures out of the rings (a) and inside a ring (b).

on a fiberglass substrate with a relative permittivity of 4.41 and a substrate dielectric height of 1.6 mm.

Figure 20a shows the S_{11} and S_{21} parameters of the filter topology depicted in Fig. 19a, obtained by FDTD simulation (dashed line) and experimental measurements (solid line). It can be observed that a second-harmonic suppression of nearly 30 dB is achieved. On the other hand, Fig. 20b depicts the scattering parameters of the filter topology shown in Fig. 19b, obtained by FDTD simulation (dashed line) and measurements (solid line). From Fig. 20b it can be observed that a second-harmonic suppression ratio higher than 20 dB is now achieved without any size penalty of the overall composed circuit. In addition, insertion losses lower than 3 dB (a lower figure may be obtained by using better dielectric substrates) and return losses of nearly 12 dB with a flat passband and a sharp rejection band are also obtained. Finally, it should be pointed out that other PBG microstrip structures have also been employed for harmonic suppression in microstrip multistage coupled ring bandpass filters [61].

5. PBG STRUCTURES IN THE OPTICAL REGIME

Although extensive work has been done most recently on PBG structures in the microwave regime, it is in the op-

tical regime (infrared, near infrared, visible) where these systems can find real applications that justify the interest that they have received. In this way PBG materials are expected to be the main candidates for the realization of high-density photonic integrated circuits. Microscale photonic integrated circuits are expected to become key components in all-optical networks in order to address the increasing data traffic, which is currently limited by components performed in the electronic domain. Most of the processing functionalities, such as routing and switching, are still performed in the electrical domain, limiting the maximum data transmission rate in this kind of network. Current photonic integrated circuits are limited to replacing microelectronics circuits because of their large size and relative simplicity. More recent results show that key components in photonic integrated circuits as directional couplers and Mach-Zehnder devices have still lengths in the order of millimeters [62–64]. However, a large variety of functionalities based on compact PBG structures have also been reported and experimentally demonstrated, thus proving its advantages with respect to conventional photonic devices.

Resonant cavities and waveguides have been the subject of a significant research effort as they are the basic components in photonic integrated circuits. On the basis of these components, different passive functionalities have been proposed and demonstrated, such as sharp bends [22,65], Y junctions [66–68], add drop filters [14,69], or demultiplexers and multiplexers [70,71], and also active ones, such as all-optical switches [72], ultra-low-threshold lasers [73,74], or high-efficiency light-emitting diodes (LEDs) [75,76]. Transmission through CCWs has also been demonstrated in the optical regime [77] in 2D planar PBG structures. Figure 21a–21c shows SEM micrographs of a sharp bend, a Y junction, and a CCW fabricated on an 8-in silicon-on-insulator (SOI) wafer (220 nm top silicon with 1 μm of silica) using 248-nm-

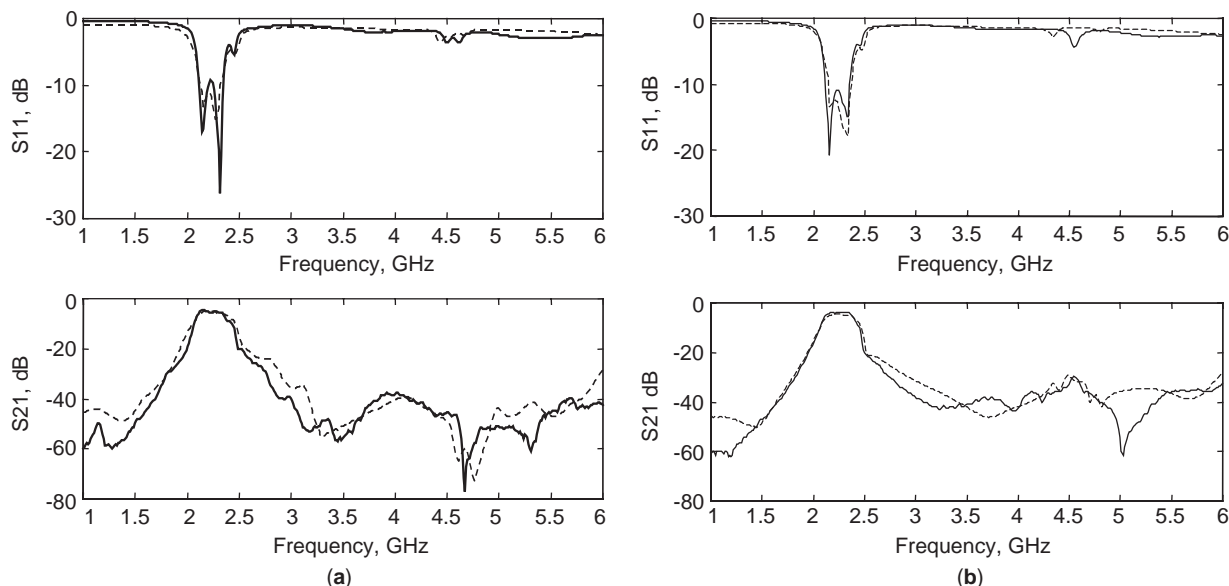

Figure 20. Simulated (dashed line) and measured (solid line) S -parameter results: (a) for the topology in Fig. 17a; (b) for topology in Fig. 17b.

Figure 21. SEM micrographs of (a) sharp bend, (b) Y junction, (c) CCW, and (d) optimized PBG waveguide taper which were fabricated on a silicon-on-insulator (SOI) substrate.

deep UV lithography [78], as examples of PBG structures fabricated to work in the optical regime.

On the other hand, efficient coupling into and out of PBG circuits is a key step in the way to a definitive commercial deployment of this technology. Coupling losses are due to the mode mismatch between the PBG and external waveguides. In PBG waveguides, light propagation is determined by Bloch modes, whereas in conventional dielectric waveguides this method relies on index contrast guiding. A large variety of coupling techniques and structures have been proposed for efficient interfacing fiber and wide-dielectric waveguides to the narrower PBG waveguides [79–86]. It is important to highlight the PBG waveguide tapers, which are a promising approach because of their small coupling length and high coupling efficiencies achieved in a broad frequency range [87–91]. Figure 21d shows a SEM micrograph of an optimized PBG waveguide taper where a localized defect is inserted within the taper, significantly increasing the transmission efficiency [92,93]. It is also worth mentioning the importance of an efficient coupling between different blocks or functionalities inserted in a PBG optical circuit. Thereby, crosstalk reduction, particularly in waveguide intersections, are of interest to reduce the circuit size. Broadband bandwidth and low crosstalk intersections have been proposed as a means to effectively utilize the interesting properties derived from PBG structures [94,95]. In addition, efficiency coupling into and out of CCWs is also mandatory in order to eliminate the undesired resonances of the transmission spectrum, which generate ripples in the group velocity that may distort the transmission of ultrashort pulses [96–98].

Finally, it is important to mention the role of the third dimension in 1D and 2D PBG structures. In these structures, the confinement of light in the vertical direction is usually achieved by total internal reflection, as in conventional integrated waveguides. However, diffraction losses appear in practical PBG circuits because of the presence of roughness and other impairments [99,100]. Therefore, a thorough understanding of out-of-plane losses as well as techniques to eliminate them is important for enabling commercial device applications.

1. INTRODUCTION

Tunable microwave circuits can be realized in many techniques, but whatever the method of tuning may be, they

must conserve as much as possible their original S -parameter magnitudes or output characteristics over a tuning range [1]. Most tunable microwave circuits and antennas described in the literature fall into four basic types [2]: mechanically [3–5], magnetically [6–10], electrically [11–15], and optically [16,17] tunable circuits. In addition, the most recently reported are microelectromechanical systems (MEMS) [18,19], providing mechanical tuning with electrically controlled methods using electrostatic forces. The MEMS with movable metal overlays seems to have a low loss and wide tuning range for limited circuit applications such as phase shifters and switches. A new method introduced in this article is also a kind of electromechanical tuning method using a piezoelectric transducer (PET) or actuator [20–22]. The PET is a piezoelectric ceramic, deflected by an applied voltage [23]. A dielectric or metal perturber attached to the PET can introduce wide tunability, low loss, low cost, and easy fabrication for various microwave circuits. Advantages of the PET tuning method will be demonstrated for the largest tuning range to date in a bandpass filter, resonator, and dielectric resonator oscillator (DRO) based on a low-loss PET-controlled phase shifter concept.

A wideband, low-loss phase shifter is an important component in a phased array for beamsteering and beamforming, timing recovery circuits, phase equalizers for data channels, and other applications. Published results [10,14,16] were narrowband, lossy, or providing small phase shift. A new phase shifter has been presented using dielectric perturbation on the microstrip line, electrically controlled by the PET [20]. The PET-controlled dielectric layer perturbs the electromagnetic fields of the microstrip line. The dielectric perturber attached to the PET can be easily moved in the z -axis direction, as shown in Fig. 1a. In this article, an optimized PET phase shifter will be presented with the largest phase shift and the lowest loss to date. In addition, from the PET-controlled phase shifter idea, a new tunable bandpass filter and ring resonator are presented on the microstrip line with simulation and measurement data. The dielectric perturber produces shielding effect on the microstrip line for reducing the radiation loss [24].

One-dimensional (1D) photonic bandgap (PBG) resonators have been reported using varactors for electronic tuning [25]. This resonator is based on the Fabry–Perot resonator consisting of a center resonant line with two sides of PBG reflectors. Even though a flip-chip varactor having very small parasitic effects was used, the quality (Q) factor was still degraded. In this article a new electronically tunable 1D PBG resonator is proposed using the PET-controlled perturber over the resonant line. The dielectric or metal perturber attached under the PET can perturb the electromagnetic fields at the center of the resonant line. This changes the line capacitance, which produces exactly the same effect as with a varactor. Thus the distance of the airgap between the perturber and resonant line determines the operating frequency. This new method is successfully demonstrated with wideband tuning of the resonant frequency with little Q -factor degradation.

The dielectric resonator oscillator (DRO) is widely used for stable microwave sources because of its good temper-

1. INTRODUCTION

Tunable microwave circuits can be realized in many techniques, but whatever the method of tuning may be, they

must conserve as much as possible their original S -parameter magnitudes or output characteristics over a tuning range [1]. Most tunable microwave circuits and antennas described in the literature fall into four basic types [2]: mechanically [3–5], magnetically [6–10], electrically [11–15], and optically [16,17] tunable circuits. In addition, the most recently reported are microelectromechanical systems (MEMS) [18,19], providing mechanical tuning with electrically controlled methods using electrostatic forces. The MEMS with movable metal overlays seems to have a low loss and wide tuning range for limited circuit applications such as phase shifters and switches. A new method introduced in this article is also a kind of electromechanical tuning method using a piezoelectric transducer (PET) or actuator [20–22]. The PET is a piezoelectric ceramic, deflected by an applied voltage [23]. A dielectric or metal perturber attached to the PET can introduce wide tunability, low loss, low cost, and easy fabrication for various microwave circuits. Advantages of the PET tuning method will be demonstrated for the largest tuning range to date in a bandpass filter, resonator, and dielectric resonator oscillator (DRO) based on a low-loss PET-controlled phase shifter concept.

A wideband, low-loss phase shifter is an important component in a phased array for beamsteering and beamforming, timing recovery circuits, phase equalizers for data channels, and other applications. Published results [10,14,16] were narrowband, lossy, or providing small phase shift. A new phase shifter has been presented using dielectric perturbation on the microstrip line, electrically controlled by the PET [20]. The PET-controlled dielectric layer perturbs the electromagnetic fields of the microstrip line. The dielectric perturber attached to the PET can be easily moved in the z -axis direction, as shown in Fig. 1a. In this article, an optimized PET phase shifter will be presented with the largest phase shift and the lowest loss to date. In addition, from the PET-controlled phase shifter idea, a new tunable bandpass filter and ring resonator are presented on the microstrip line with simulation and measurement data. The dielectric perturber produces shielding effect on the microstrip line for reducing the radiation loss [24].

One-dimensional (1D) photonic bandgap (PBG) resonators have been reported using varactors for electronic tuning [25]. This resonator is based on the Fabry–Perot resonator consisting of a center resonant line with two sides of PBG reflectors. Even though a flip-chip varactor having very small parasitic effects was used, the quality (Q) factor was still degraded. In this article a new electronically tunable 1D PBG resonator is proposed using the PET-controlled perturber over the resonant line. The dielectric or metal perturber attached under the PET can perturb the electromagnetic fields at the center of the resonant line. This changes the line capacitance, which produces exactly the same effect as with a varactor. Thus the distance of the airgap between the perturber and resonant line determines the operating frequency. This new method is successfully demonstrated with wideband tuning of the resonant frequency with little Q -factor degradation.

The dielectric resonator oscillator (DRO) is widely used for stable microwave sources because of its good temper-

ature stability, small size, compactness, low price, and other advantages. In addition, the electronically tunable DRO or voltage-controlled DRO (VCDRO) has many applications in communication and radar systems, and frequency-hopping spread-spectrum circuits. Several methods have been used to tune the resonant frequency of DR [2] and DRO: mechanical [5], ferrite, varactor [12,13], PIN diode, and optical [17]. The mechanical method using a dielectric disk perturbation was able to maintain good performance over a wide tuning range [2]. The DRO oscillation frequency can be tuned by perturbing the DR's electromagnetic fields. This tuning can be achieved by varying the airgap between the DR and the dielectric (or metallic) disk above the DR, using the PET. The PET-controlled VCDRO is demonstrated to obtain the largest tuning range up to date.

2. DESIGN AND EXPERIMENTS

2.1. Tunable Phase Shifter

The new phase shifter of Fig. 1a consists of microstrip-line substrate (dielectric constant of ϵ_{r1}), airgap ($\epsilon_{r2} = 1$), and perturber (ϵ_{r3}). To calculate the capacitance of perturbed microstriplike transmission lines, the variational method was used [26]. The capacitance variations correspond to variations in effective dielectric constant, characteristic impedance (Z_c), and propagation constant. A dispersion formula is found from curve fitting [27,28], which is used for optimizing the PET-controlled phase shifter to reduce the control voltage with smaller size and larger phase shift. The substrate optimized for the microstrip line is RT/duroid 6010.8 with a dielectric constant of 10.8, thick-

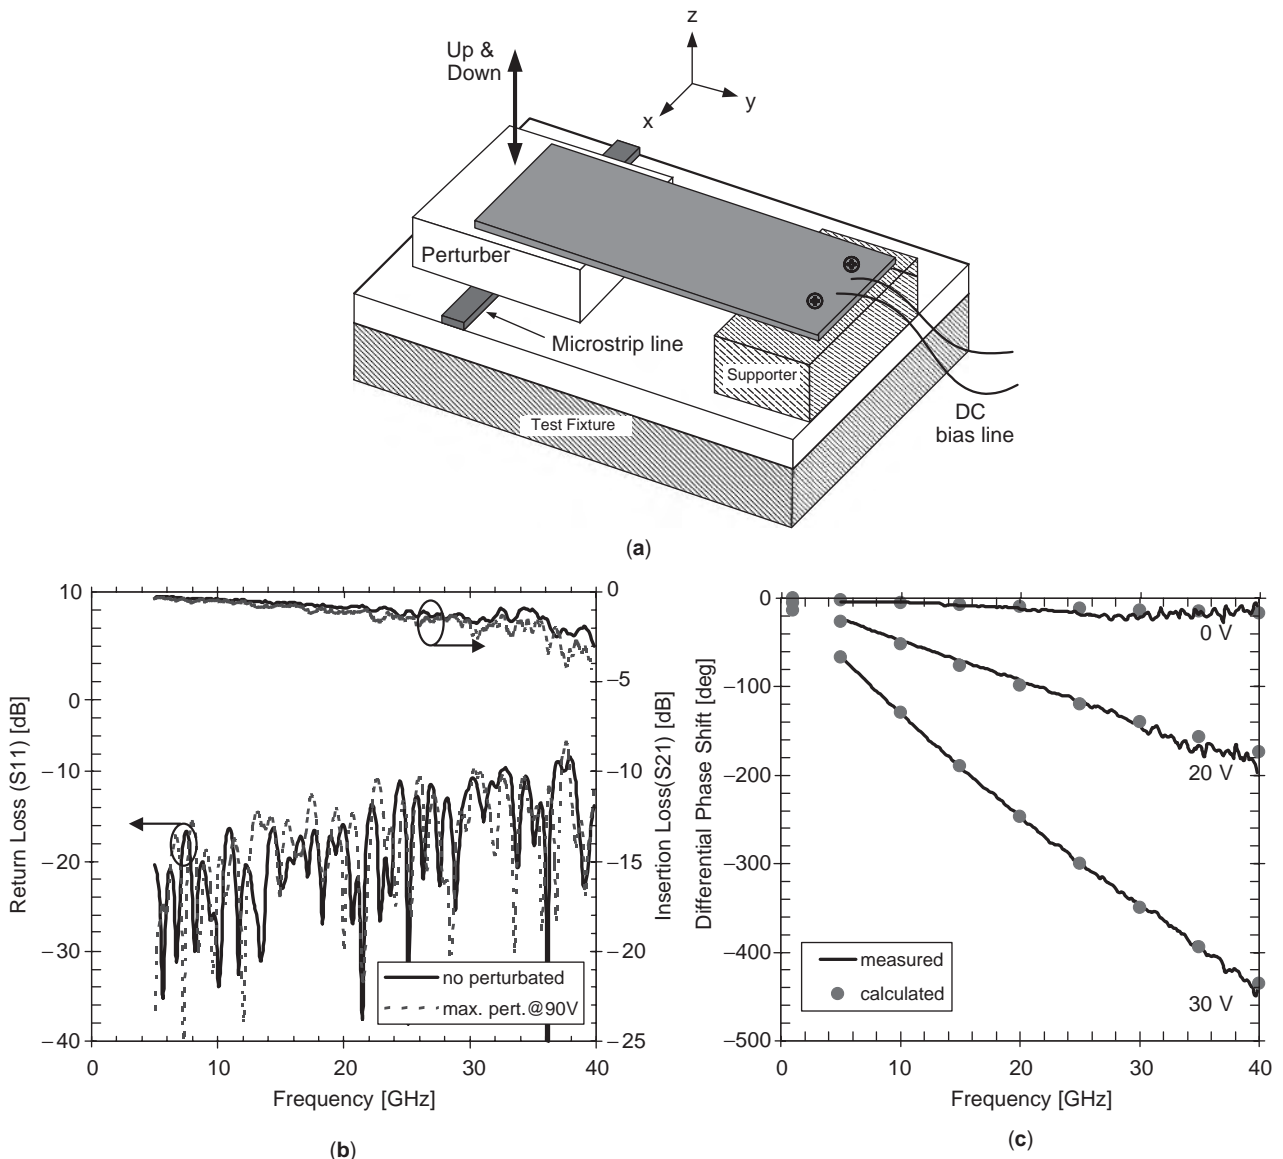

Figure 1. A PET-controlled phase shifter: (a) configuration; (b) S parameters; (c) phase shifts versus frequencies with different PET voltages, with a substrate of $\epsilon_r = 10.8$, thickness = 10 mil, microstrip width = 5 mil, and perturber of $\epsilon_r = 10.8$ and length = 1.2 in. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

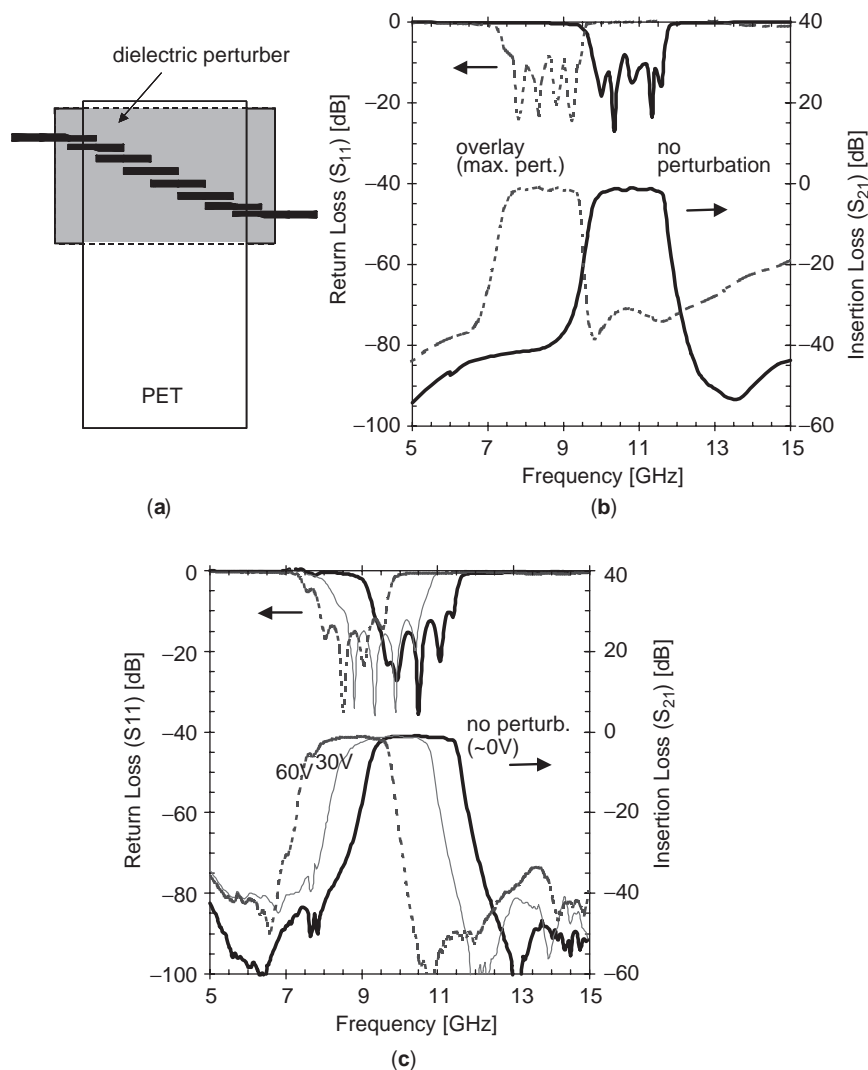

Figure 2. A tunable bandpass filter: (a) configuration—top view; (b) simulated S parameters; (c) measured S parameters with different PET voltages, with a substrate of $\epsilon_r = 10.8$, thickness = 25 mil, microstrip width = 22 mil, and perturber of $\epsilon_r = 10.8$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

ness of 10 mil, and width of 5 mil. The dielectric perturber has a dielectric constant of 10.8, height of 50 mil, and length of 1.2 inch. The microstrip-line width of 5 mil is designed for a high Z_c of $64\ \Omega$ at 40 GHz to compensate for the decreased Z_c by dielectric perturbation. At maximum perturbation, when the dielectric perturber is placed on the microstrip line, Z_c is close to $50\ \Omega$. This will maintain good impedance matching without any external matching circuit. The PET measures 2.75 in (length) \times 1.25 in (width) \times 0.085 in (thickness including a supporter) with a composition of lead zirconate titanate. This size makes a large capacitance of 290 nF and a relatively slow response time of 5 ms. Smaller size can be used to make a compact unit and improve the tuning time.

“Thru reflect line” (TRL) calibration was used to remove the coaxial connector-to-microstrip-line transition effect for S -parameter measurement of HP8510. But an imperfect calibration and/or surface-wave generation caused a fluctuation in the insertion loss (S_{21}) near 37 GHz, as shown in Fig. 1b. Except for the fluctuation of S_{21} , the maximum perturbation-added loss is less than 2 dB, and

thus the total loss is less than 4 dB up to 40 GHz. The return loss (S_{11}) is less than -15 dB over all frequency range and about -10 dB near 40 GHz. S -Parameter magnitudes are not much affected by the dielectric perturbation.

Figure 1c shows measured differential phase shifts with varying frequencies and PET voltages and how S_{21} of the microstrip line with a PET-controlled perturber exhibits a phase shift from -450° to -20° at 40 GHz with respect to the unperturbed condition. The amount of phase shift depends on PET deflection, which is controlled by varying the applied voltage from 0 to 30 V. There is no deflection (or no perturbation) at 0 V and full downward deflection (or maximum perturbation) at 90 V. This is called a *top-down alignment*, the reverse of the *bottom-up alignment* used in Refs. 20–22. The calculated phase shift agrees very well with measured data at each PET-controlled voltage. Between 30 and 90 V of the control voltage, the additional phase shifts becomes small. The phase shift at 90 V is almost saturated and shows -480° . Thus the DC bias is required only up to 30 V. This DC voltage can be further decreased if the alignment is

improved or a narrower microstrip line and thinner substrate are used.

The optimized PET phase shifter has three advantages compared with the previously reported results [20,22]; the bias voltage range is reduced from 90 to 30 V, the size is reduced from 1.8 to 1.2 in, and the phase shift curves are more linear with respect to frequency, even though the S parameters and phase shifting performance are similar. In addition, a phase shift/insertion loss ratio of 229°/dB at 25 GHz and 287°/dB at 35 GHz are achieved. The results are better than those reported in Refs. 15 and 19.

2.2. Tunablebandpass Filter and Ring Resonator

A seven-section, parallel-coupled microstrip bandpass filter was designed, as shown in Fig. 2a. The dielectric perturber is large enough to cover the whole filter and is attached under the PET. Details of design parameters for

the filter are not described here but can be found in Ref. 29. The hand-calculated design is confirmed using IE3D, a moment method full-wave electromagnetic simulator produced by Zeland Software. In Fig. 2b, multilayer simulation results of S parameters are shown with and without perturbation, near the center frequency of 10 GHz. A wide tuning range of 2.315 GHz or 24% was achieved in the simulation without S -parameter degradation. The measured results are shown in Fig. 2c and agree very well with the simulation. The slight difference of filter responses between simulation and measurement may be caused by fabrication inaccuracy and long, bent 50 Ω input/output microstrip lines to balance two ports on a test fixture that were not considered in the simulation. A measured tuning range is 1.675 GHz or 17.5%, which is slightly smaller than the simulated result because of nonperfect overlay or perturbation. The tuning range should be increased if the filter substrate is designed using a lower dielectric con-

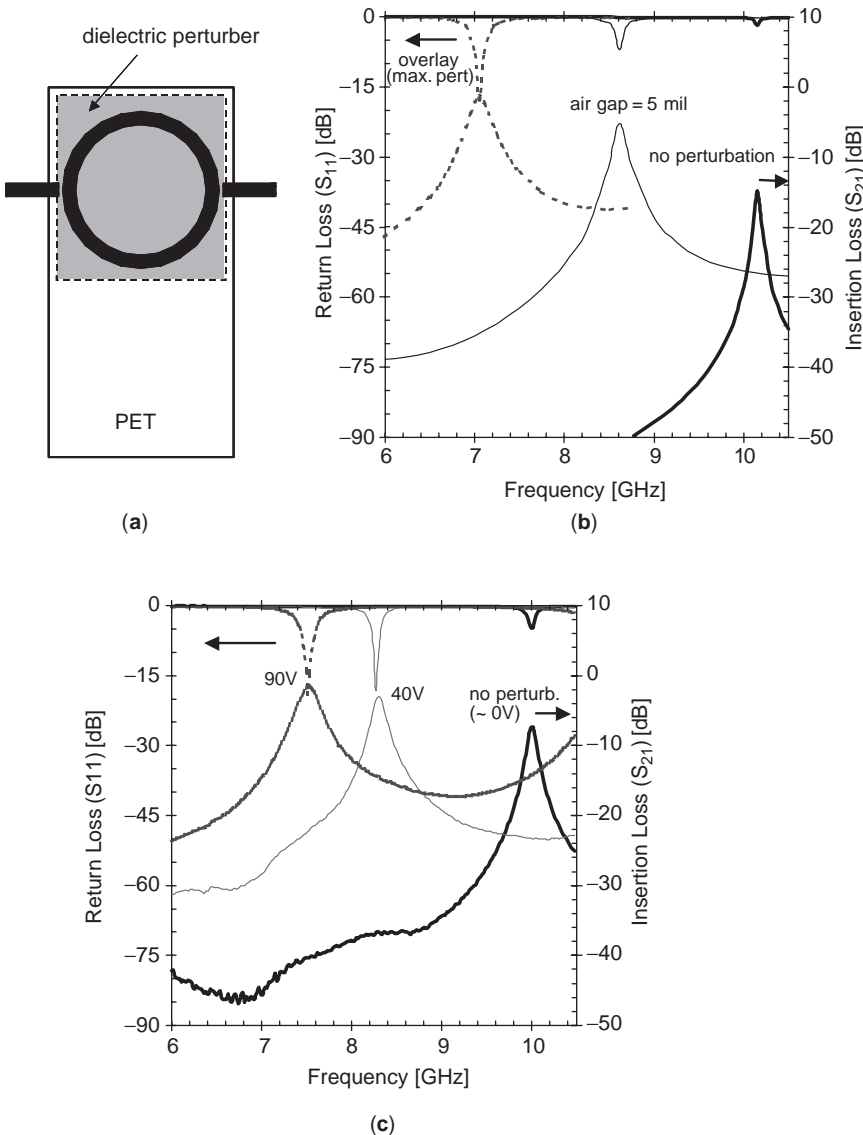

Figure 3. A tunable ring resonator: (a) configuration—top view; (b) simulated S parameters; (c) measured S parameters with different PET voltages, with a substrate of $\epsilon_r = 2.33$, thickness = 20 mil, microstrip width = 50 mil, ring coupling gap = 5 mil, and perturber of $\epsilon_r = 10.8$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

stant material. This idea is demonstrated in the following PET-tuned ring resonator.

In Fig. 3, the PET tuning feasibility for the microstrip ring resonator is demonstrated with simulation and measurement. As mentioned above, a lower dielectric constant of $\epsilon_r = 2.33$ was used for the microstrip substrate to increase the tuning range. The second resonant frequency of the ring resonator was designed near 10 GHz and tuned over 3.1 GHz or 36% with maximum perturbation in the simulation, as shown in Fig. 3b. The measured results in Fig. 3c show a tuning range of 2.5 GHz or 28.5%; the range is greatly improved by using the lower-permittivity-material substrate. Although not shown, experiments indicated a tuning range of 1.35 GHz or 14.7% with a microstrip substrate of $\epsilon_r = 10.8$. Note that the radiation and mismatch losses are gradually reduced by overlaying of dielectric perturber, as shown in Figs. 3b and 3c and as suggested in Ref. 24.

2.3. Tunable One-Dimensional (1D) Photonic Bandgap (PBG) Resonator

The 1D PBG structure consists of a 50-Ω microstrip conductor line and etched square holes on the ground plane,

(a)

(b)

Figure 4. Tunable 1D PBG resonator configurations: (a) varactor-tuned; (b) PET-tuned.

as shown in Fig. 4a. This has results similar to those obtainable for an alternately high low characteristic impedance line or air holes drilled through the substrate along the microstrip line [25]. When a varactor is mounted in a resonant line, the variable capacitance is used to change the resonant frequency (f_0). The substrate used is a RT/duroid 6010.5 with dielectric constant 10.5, length 2 in., thickness 25 mil, and linewidth 22 mil. Slot size ($a = b$) 100 mil, spacing (d) 200 mil, and resonant-line length ($L_R = 1.5d$) of 300 mil are chosen. As a result of the varactor-tuned PBG resonator, a wideband tuning capability of ~20% near 10 GHz is measured with a maximum loaded $Q(Q_L)$ of only 77. The low intrinsic Q of the varactor near 10 GHz is the main reason for the low Q_L . With the same structure as that of the 1D PBG resonator, the PET is used instead of the varactor to change the resonant frequency by perturbation of the electromagnetic fields on the resonant line, as shown in Fig. 4b. The airgap distance between the perturber and the resonant line is controlled by varying the DC bias of the PET from 0 to 90 V.

Both metal and dielectric perturbations can be used to tune the 1D PBG resonator. To investigate effects of metal and dielectric perturbers on the resonant frequency, a variational analysis [26] was developed and compared with measured results as shown in Fig. 5. A micrometer head was used for measuring the accurate distance of the airgap. The resonant frequency depends on the effective length of resonant line, which can be easily calculated from the line capacitance and effective dielectric constant obtained from variational analysis. As can be seen from Fig. 5, metal perturbation increases the resonant frequency whereas dielectric perturbation decreases the resonant frequency. This is because metal perturbation decreases the effective dielectric constant and dielectric perturbation increases the effective dielectric constant of the perturbed resonant. The calculated and measured results of dielectric perturbation agree very well. But metal perturbation

Figure 5. Micrometer-head-controlled perturbation on 1D PBG resonator, to compare measurement with calculation data.

Figure 6. A PET-controlled tunable 1D PBG resonator, measured S parameters with different PET voltages, with a substrate of $\epsilon_r = 10.8$, thickness = 25 mil, microstrip width = 22 mil, perturber of $\epsilon_r = 10.8$, and thickness = 50 mil. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

results are somewhat different. This discrepancy can be attributed to the distortion that occurs in the quasi-TEM field of the microstrip line when the metal perturber is very close to the resonant line. The above variational analysis may not be accurately predicting this situation.

Insertion loss (S_{21}) and return loss (S_{11}) are measured for the PET-controlled metal and dielectric perturbation on the 1D PBG resonator, as shown in Fig. 6. In order to avoid short-circuiting the metal perturber and microstrip line at 0 V, an airgap of ~ 0.1 mm is added for the metal perturbation. Tuning capability is from -8.2% to $+9\%$ at 10.6 GHz. A maximum insertion loss increase is 1.6 dB and Q_L is larger than 100 for both perturbations. Measured Q_L is 148.5 at 10.6 GHz for the unperturbed condition under 90 V applied bias.

2.4. Tunable Dielectric Resonator Oscillator (DRO)

As shown in Fig. 7a, the DRO consists of a MESFET feedback-type oscillator with a DR. To perturb electromagnetic fields of the DR and thereby tune the oscillation frequency, a dielectric or metal perturber disk attached to the PET moves vertically above the DR puck as the DC bias voltages is varied from 0 to 90 V. A commercial DR (Trans-Tech) of $\epsilon_r = 30.09$ and a MESFET (Agilent, ATF-26836) are used. To obtain an optimum power level and a more

Figure 7. A PET-controlled VCDRO: (a) configuration; (b) photograph.

stable oscillation, the DR locations between two microstrip lines and bias conditions are adjusted. DC biases of $V_{GG} = -0.8\text{ V}$, $V_{DD} = 12\text{ V}$, and $I_{DS} = 30\text{ mA}$ are applied. A drain resistor of $100\ \Omega$ is used. The dielectric perturber has a dielectric constant of 10.8, diameter of 0.3 in, and thickness of 0.1 in. The perturber's size affects the tuning bandwidth. So as not to change the normal circuit operation, the perturber diameter is chosen very similarly with the DR puck diameter. Figure 7b shows a photograph of the PET-controlled VCDRO.

Measured results are shown in Fig. 8. A bottom-up alignment method was used, which means a minimum perturbation and deflection at 0 V and a maximum perturbation and deflection at 90 V. The use of dielectric and metal perturbation results in the tuning of the oscillation frequency from 11.54 to 11.97 GHz or -2.0 to $+1.7\%$ about the center frequency of 11.78 GHz. There is a gap

Figure 8. PET-controlled VCDRO results with the dielectric and metal perturbation: (a) spectrum analyzer display of tuning the oscillation frequency; (b) oscillation frequencies versus PET-controlled voltages.

Figure 9. A photograph of mechanical tuning using a micrometer-head-controlled DRO.

without tuning from 11.7 to 11.87 GHz as shown in Fig. 8b because the DRO was not designed for PET tuning and it was difficult to align the PET exactly on the DR. The metal perturbation may increase the stored magnetic energy in the DRO with respect to the electrical energy, which results in increased oscillation frequency. Increase in resonant frequency can be also explained by a metal cavity wall movement inward. The dielectric perturbation effect can, in contrast, also be explained [2]. Material with a dielectric constant of >10.8 for the perturber may produce a wider tuning range [5]. Ideally the VCO output power level remains constant, but all practical purposes the PET and metal or dielectric perturber cause the output power level to fluctuate from -5 to $+2.9\text{ dBm}$. The output power level without perturbation is $+1.45\text{ dBm}$.

For comparison, a mechanical tuning using a micrometer head was set up as shown in Fig. 9, and the results are given in Fig. 10. The micrometer-head-controlled DRO produces more ideal perturbation results due to better alignment and the smaller effect on the circuit by the micrometer head movement. A tuning bandwidth ranging from -3.1 to $+1.6\%$ with a power level variation of 4.5 dB has been achieved. The results are slightly better than with the electronic tuning.

3. DISCUSSION

Although PET-controlled microwave circuits are a new technology with much promise, for use in any commercial systems, certain practical considerations need to be investigated such as uniformity, reproducibility, survivability,

Figure 10. Mechanically micrometer-head-controlled DRO results with the dielectric and metal perturbation: (a) spectrum analyzer display of tuning the oscillation frequency; (b) measured oscillation frequencies versus PET-controlled voltages.

temperature stability, and sensitivity to acceleration or sudden movement (jolts, jerks, etc.).

As in other applications, the piezoelectric material can be used to actuate antennas [30,31]. In addition, the single-line PET phase shifter is easily expanded to a multi-line PET phase shifter, which will be particularly useful for simple and low-priced phased-array antenna systems [22,32]. The coplanar waveguide (CPW) line, instead of the microstrip line, can be also perturbed to be another type of PET phase shifter [33].

4. CONCLUSIONS

New piezoelectric transducer (PET)-controlled tunable microwave circuits have been successfully demonstrated. Theoretical results agreed well with measured data. A

new analog PET-controlled phase shifter using perturbed microstrip line showed the largest phase shift with low loss over ultrawide bandwidth up to 40 GHz. The new phase shifter should be helpful for beamsteering and beamforming of antenna arrays. In addition, new PET-tuned bandpass filter, ring resonator, one-dimensional (1D) photonic bandgap (PBG) resonator, and dielectric resonator oscillator (DRO) have been demonstrated with the largest tuning range to date. The proposed tuning method should have many applications in monolithic and hybrid microwave integrated circuits.

PIEZOELECTRICITY

YUKIO ITO
 KENJI UCHINO
 The Pennsylvania State
 University

Certain materials produce electrical charges on their surfaces as a consequence of applied mechanical stress. The induced charges are proportional to the mechanical stress. This is called the direct piezoelectric effect and was discovered by Jacques and Pierre Curie in 1880. Materials showing this phenomenon also conversely have a geometric strain proportional to an applied electric field. This is the converse piezoelectric effect. The root of the word “piezo” means “pressure”; hence the original meaning of the piezoelectricity implied “pressure electricity” [1,2].

Piezoelectric materials provide coupling between electrical and mechanical parameters. The materials used earliest for its piezoelectric properties was single-crystal quartz. Quartz crystal resonators for frequency control appear today at the heart of clocks and are also used in TVs and computers. Ferroelectric polycrystalline ceramics such as barium titanate and lead zirconate titanate exhibit piezoelectricity when electrically poled. Since these ceramics possess significant and stable piezoelectric effects, that is, high electromechanical coupling, they are capable of producing large strains/forces and hence are extensively used as transducers. Piezoelectric polymers, notably polyvinylidene difluoride and its copolymers with trifluoroethylene and piezoelectric composites combining a piezoelectric ceramic with a passive polymer, have been developed that offer a high potential. More recently, thin films of piezoelectric materials have received attention because of their potential utilization in microsensors, microtransducers, and microactuators.

Piezoelectricity is being extensively utilized in the fabrication of various devices such as transducers, actuators, surface acoustic wave devices, and frequency control. In this article we discuss the piezoelectric effect, a brief history of piezoelectricity followed by present-day piezoelectric materials that are used, and finally various potential applications of piezoelectric materials.

1. PIEZOELECTRICITY

1.1. Relationship between Crystal Symmetry and Properties

All crystals can be classified into 32 point groups according to their crystallographic symmetry. These point groups are divided into two classes; one has a center of symmetry, and another lacks it. There are 21 noncentrosymmetric point groups. Crystals belonging to 20 of these point groups exhibit piezoelectricity. The cubic class 432, although lacking a center of symmetry, does not permit piezoelectricity. Of these 20 point groups, there are 10 polar crystal classes containing a unique axis, along which an electric dipole moment is oriented in the unstrained condition.

Pyroelectric effect appears in any material that possesses a polar symmetry axis. As a result of this the material develops an electrical charge on the surface owing to change in magnitude of the dipole moment with changing temperature. Among the pyroelectric crystals whose spontaneous polarization are reorientable by application of an electric field of sufficient magnitude (not exceeding the breakdown limit of the crystal) are ferroelectrics [3,4]. Table 1 shows the crystallographic classification of the point groups.

1.2. Piezoelectric Coefficients

Materials are deformed by stresses and the resulting deformations are represented by strains ($\Delta L/L$). When the stress \mathbf{T} (force per unit area) causes a proportional strain \mathbf{S}

$$\mathbf{S} = \mathbf{s}\mathbf{T} \quad (1)$$

where all quantities are tensors; \mathbf{S} and \mathbf{T} are second-rank and \mathbf{s} is fourth-rank. Piezoelectricity creates additional strains by applied field \mathbf{E} . The piezoelectric equation is given by

$$\mathbf{S}_{ij} = \mathbf{s}_{ijkl}\mathbf{T}_{kl} + \mathbf{d}_{ijk}\mathbf{E}_k \quad (2)$$

where \mathbf{E} is the electric field and \mathbf{d} is the piezoelectric constant which is the third-rank tensor. This equation can be also expressed in a matrix form such as given for the case in a poled ceramics:

$$\begin{bmatrix} S_1 \\ S_2 \\ S_3 \\ S_4 \\ S_5 \\ S_6 \end{bmatrix} = \begin{bmatrix} s_{11} & s_{12} & s_{13} & & & \\ s_{12} & s_{11} & s_{13} & & & \\ s_{13} & s_{13} & s_{33} & & & \\ & & & s_{44} & & \\ & & & & s_{44} & \\ & & & & & 2(s_{11} - s_{12}) \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ T_6 \end{bmatrix} + \begin{bmatrix} 0 & 0 & d_{31} \\ 0 & 0 & d_{31} \\ 0 & 0 & d_{33} \\ 0 & d_{15} & 0 \\ d_{15} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} E_1 \\ E_2 \\ E_3 \end{bmatrix} \quad (3)$$

Another frequently used piezoelectric constant is g , which gives the electric field produced when a stress is applied ($\mathbf{E} = \mathbf{g}\mathbf{T}$). The \mathbf{g} constant is related to the \mathbf{d} constant

through the permittivity ϵ :

$$\mathbf{g} = \mathbf{d}/\epsilon \quad (4)$$

A measure of the effectiveness of the electromechanical energy conversion is the electromechanical coupling factor k which measures the fraction of the electrical energy converted to mechanical energy when an electric field is applied or vice versa when a material is stressed [5]. The relationship is in terms of k^2

$$k^2 = \frac{\text{electrical energy converted to mechanical energy}}{\text{input electrical energy}} \quad (5)$$

or

$$k^2 = \frac{\text{mechanical energy converted to electrical energy}}{\text{input mechanical energy}} \quad (6)$$

which can also be expressed by

$$k^2 = \mathbf{d}^2/(\epsilon \cdot \mathbf{s}) \quad (7)$$

k is always less than 1, because k^2 is below 1. Typical values of k are 0.10 for quartz, 0.4 for BaTiO₃ ceramic, 0.5–0.7 for PZT (lead zirconate-titanate) ceramic, and 0.1–0.3 for PVDF [poly(vinylidene difluoride)] polymer. Another important material parameter is the mechanical quality factor Q_m , which determines the frequency characteristics. The Q_m is given by

$$Q_m = 2\pi \times \frac{\text{energy stored over one cycle}}{\text{energy dissipated per cycle}} \quad (8)$$

2. HISTORY OF PIEZOELECTRICITY

As stated already the discovery of piezoelectricity in quartz (which is not ferroelectric) was done by Pierre and Jacques Curie in 1880. Ferroelectricity can provide the creation of useful piezoelectric materials. Rochelle salt was the first ferroelectric discovered in 1921. Until 1940 only two types of ferroelectrics were known, Rochelle salt and potassium dihydrogen phosphate and its isomorph. From 1940 to 1943, unusual dielectric properties such as the abnormally high dielectric constant of barium titanate BaTiO₃ were discovered independently by Wainer and Salmon, Ogawa, and Wul and Golman. After the discovery, compositional modifications for BaTiO₃ led to improvement in the temperature stability or the high-voltage output. Piezoelectric transducers based on BaTiO₃ ceramics were becoming well established in a number of device applications.

In the 1950s Jaffe and coworkers established the lead zirconate-lead titanate system (called PZT system) as suitable for inducing strong piezoelectric effects. The maximum piezoelectric response was found for PZT compositions near the morphotropic phase boundary, that is, the composition-dependent and temperature-independent

Table 1. Crystallographic Classification in Terms of Polarity and Centrosymmetry

Polarity	Symmetry	Crystal System										
		Cubic		Hexagonal		Tetragonal		Rhombohedral		Orthorhombic	Monoclinic	Triclinic

rhombohedral–tetragonal phase change. Since then, the PZT system with various additives has become the dominant piezoelectric ceramics for potential applications. Other ferroelectric perovskite compounds were also extensively examined. The discovery of PZT solid solution systems was rapidly followed by its exploitation in a number of practical piezoelectric applications.

Kawai et al. discovered in 1969 that certain polymers, notably polyvinylidene difluoride, are piezoelectric when stretched during fabrication. Such piezoelectric polymers are also useful for some transducer applications. In 1978 Newnham et al. improved composite piezoelectric materials by combining a piezoelectric ceramic with a passive polymer whose properties can be tailored to the requirements of various piezoelectric devices.

There is another class of ceramic material which recently has become important; relaxor-type electrostrictors such as lead magnesium niobate (PMN), typically doped with 10% lead titanate (PT), which are potentially used for applications in piezoelectric actuator field. More recent breakthroughs in the growth of high quality large single crystal relaxor piezoelectric compositions have brought interest in these materials for wide applications ranging from high strain actuators to high frequency transducers for the medical ultrasound devices because of their superior electromechanical characteristics. More recently, thin films of piezoelectric materials such as zinc oxide (ZnO), or PZT have been extensively investigated and developed for use in microelectromechanical device applications.

3. PIEZOELECTRIC MATERIALS

This section summarizes the current status of piezoelectric materials: single crystal materials, piezoceramics, piezopolymers, piezocomposites, and piezofilms. Table 2

shows the material parameters of some representative piezoelectric materials described next [6,7].

3.1. Single Crystals

More recently, the piezoelectric ceramics have been widely used for a large number of applications. However, single crystal materials retain their utility, being essential for application fields such as frequency stabilized oscillators and surface acoustic devices. The most popular single-crystal piezoelectric materials are quartz, lithium niobate (LiNbO₃) and lithium tantalate (LiTaO₃). The single crystals are anisotropic, which gives different material properties depending on the cut of the materials and the direction of bulk or surface wave propagation.

Quartz is a well-known piezoelectric material. α -quartz belongs to triclinic crystal system with point group 32 and has a phase transition at 537°C to β type, which is not a piezoelectric. Quartz has the cut with a zero temperature coefficient. For instance, quartz oscillators using a thickness shear mode of AT-cut are extensively used for clock sources in computers, and frequency stabilized ones in TVs and VCRs (videocassette recorders). On the other hand, an ST-cut quartz substrate with *X*-propagation has a zero temperature coefficient for surface acoustic waves (SAWs) and so are used for SAW devices with high-stability frequencies. The other distinguishing characteristic of quartz is that it has an extremely high mechanical quality factor $Q_m > 10^5$.

Lithium niobate and lithium tantalate belong to an isomorphous crystal system and are composed of oxygen octahedron. The Curie temperatures of LiNbO₃ and LiTaO₃ are 1210 and 660°C, respectively. The crystal symmetry of the ferroelectric phase of these single crystals is 3 *m* and the polarization direction is along the *c* axis. These mate-

Table 2. Properties of Piezoelectric Materials

Parameter	Quartz	BaTiO ₃	PZT 4	PZT 5H	(Pb,Sm)TiO ₃	PVDF-TrFE

Figure 1. Perovskite structure ABO_3 . This ideal structure consists of a simple cubic unit cell with a large cation A on the corner, a smaller cation B in the body center, and oxygen O in the centers of the faces.

rials have high electromechanical coupling coefficients for surface acoustic waves. In addition, large single crystals can easily be obtained from their melt using the conventional Czochralski technique. Thus, both materials occupy very important positions in the surface acoustic wave device application field.

3.2. Ceramics

3.2.1. Perovskite Structure. Most of the piezoelectric ceramics have perovskite structure ABO_3 , as shown in Fig. 1. This ideal structure consists of a simple cubic unit cell with a large cation A on the corner, a smaller cation B in the body center, and oxygen O in the centers of the faces. The structure is a network of corner-linked oxygen octahedra surrounding B cations. Piezoelectric properties of perovskite-structure materials can be easily tailored depending on their applications by incorporating various cations in the perovskite structure.

3.2.2. Barium Titanate. Barium titanate ($BaTiO_3$) is one of the most thoroughly studied and most widely used piezoelectric materials. Figure 2 shows the temperature dependence of dielectric constants in $BaTiO_3$ demonstrating

the phase transition in $BaTiO_3$ single crystals. Three anomalies can be observed. The discontinuity at the Curie point (130°C) is due to a transition from a ferroelectric to a paraelectric phase. The other two discontinuities are accompanied with transitions from one ferroelectric phase to another. Above the Curie point the crystal structure is cubic and has no spontaneous dipole moments. At the Curie point the crystal becomes polar and the structure changes from a cubic to a tetragonal phase. The tetragonal axis is in the direction of dipole moment and thus along the spontaneous polarization. Just below the Curie temperature, the vector of the spontaneous polarization points in the $[001]$ direction (tetragonal phase), below 5°C it reorients in the $[011]$ (orthorhombic phase) and below -90°C in the $[111]$ (rhombohedral phase). The dielectric and piezoelectric properties of ferroelectric ceramics $BaTiO_3$ can be affected by its own stoichiometry, microstructure, and by dopants entering into the A and B site solution. Modified ceramic $BaTiO_3$ with dopants such as Pb or Ca ions have been used as commercial piezoelectric materials.

3.2.3. Lead Zirconate–Lead Titanate. Piezoelectric $Pb(Zr,Ti)O_3$ solid solutions (PZT) ceramics have been widely used because of their superior piezoelectric properties. The phase diagram of the PZT system ($PbZr_xTi_{1-x}O_3$) is shown in Fig. 3. The crystalline symmetry of this solid-solution system is determined by the Zr content. Lead titanate also has a tetragonal ferroelectric phase of perovskite structure. With increasing Zr content x , tetragonal distortion decreases and when $x > 0.52$ the structure changes from tetragonal $4mm$ phase to another ferroelectric phase of rhombohedral $3m$ symmetry. This transition is rather independent of temperature. The line dividing the two phases is called morphotropic phase boundary, that is, the change of symmetry occurs only as a function of composition. This composition is considered to have both phases. Figure 4 shows the dependence of several d constants on composition near the morphotropic phase boundary. The d constants have their highest values near the morphotropic phase boundary. This enhancement in piezoelectric effect is attributed to the increased ease of reorientation of the polarization under electric field. Doping the PZT material with donors or acceptors changes the

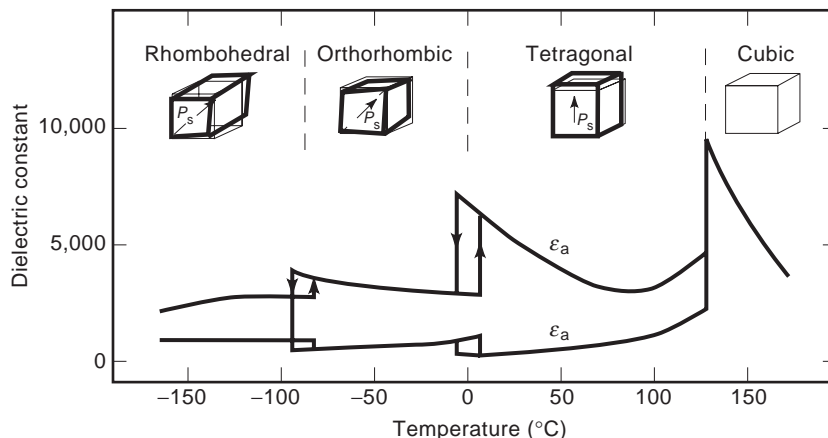

Figure 2. Dielectric constants of $BaTiO_3$ as a function of temperature. Three anomalies accompanied with phase transitions can be observed.

Figure 3. Phase diagram of the PZT system. The crystalline symmetry of this solid-solution system is determined by the Zr content. The line dividing the two, tetragonal and rhombohedral phases is called morphotropic phase boundary.

properties dramatically. Donor doping with ions such as Nb^{5+} or Ta^{5+} provides soft PZTs like PZT-5, because of the facility of a domain motion due to the resulting Pb vacancy. On the other hand, acceptor doping such as Fe^{3+} or Sc^{3+} leads to hard PZTs such as PZT-8, because oxygen vacancies will pin the domain-wall motion.

3.2.4. Lead Titanate. Lead titanate has a large crystal distortion. PbTiO_3 has tetragonal structure at room temperature with its tetragonality approximately equal to 1.063. The Curie temperature is 490°C . Densely sintered PbTiO_3 ceramics cannot be obtained easily, because they break up into a powder when cooled through the Curie temperature. This is due to the large spontaneous strain that occurs at the transition. Lead titanate ceramics modified by adding small amounts of additives exhibit a high piezoelectric anisotropy. Either $(\text{Pb}, \text{Sm})\text{TiO}_3$ [8] or $(\text{Pb}, \text{Ca})\text{TiO}_3$ [9] has extremely low planar coupling, that is,

Figure 4. Several piezoelectric d strain coefficients versus composition near the morphotropic phase boundary for the PZT system. The d coefficients have their highest values near the morphotropic phase boundary.

large k_t/k_p ratio. Here, k_t and k_p are thickness-extensional and planar electromechanical coupling factors, respectively. $(\text{Pb}, \text{Nd})(\text{Ti}, \text{Mn}, \text{In})\text{O}_3$ ceramics with a zero temperature coefficient of surface acoustic wave delay have been developed as a superior substrate materials for SAW device applications [10].

3.3. Polymers

Poly(vinylidene difluoride), PVDF or PVF2, is piezoelectric when stretched during fabrication. Thin sheets of the cast polymer are then drawn, stretched, in the plane of the sheet in at least one direction, and frequently also in the perpendicular direction, to make the material into its microscopically polar phase. Crystallization from melt forms nonpolar α -phase, which can be converted into another polar β -phase by a uniaxial or biaxial drawing operation; these dipoles are then reoriented through electric poling. Large sheets can be manufactured and thermally formed into complex shapes. The copolymerization of vinylidene difluoride with trifluoroethylene (TrFE) results in random copolymer (PVDF-TrFE) with a stable, polar β phase. This polymer need not be stretched; it can be poled directly as formed. The thickness-mode coupling coefficient of 0.30 has been reported. Such piezoelectric polymers are used for directional microphones and ultrasonic hydrophones.

3.4. Composites

Piezocomposites composed of a piezoelectric ceramic and polymer are promising materials because of excellent and tailored properties. The geometry for two-phase composites can be classified according to the connectivity of each phase (1, 2, or 3 dimensionally) into 10 structures; 0-0, 0-1, 0-2, 0-3, 1-1, 1-2, 1-3, 2-2, 2-3 and 3-3 (11). A 1-3 piezocomposite or PZT-rod/polymer-matrix composite, is identified as a most promising candidate. The advantages of this composite are high coupling factor, low acoustic impedance, good matching to water or human tissue, mechanical flexibility, broad bandwidth in combination with low mechanical quality factor, and the possibility of making undiced arrays by only structuring the electrodes. The thickness-mode electromechanical coupling of the composite can exceed the k_t (0.40-0.50) of the constituent ceramic, almost approaching the value of the rod-mode electromechanical coupling, k_{33} (0.70 to 0.80) of that ceramic (12). Acoustic impedance is the square root of the product of its density and elastic stiffness. The acoustic match to tissue or water (1.5 Mrayls or $\text{kg m}^{-2} \text{s}^{-1}$) of the typical piezoceramics (20-30 Mrayls) is significantly improved by forming a composite structure, that is, by replacing heavy and stiff ceramic by light and soft polymer. Piezoelectric composite materials are especially useful for underwater sonar and medical diagnostic ultrasonic transducer applications.

3.5. Thin Films

Both zinc oxide (ZnO) and aluminium nitrate (AlN) are simple binary compounds with a Wurtzite-type structure, which can be sputter-deposited in a c -axis-oriented thin film on a variety of substrates. ZnO has large piezoelectric

coupling and its thin films are widely used in bulk acoustic and surface acoustic wave devices. The fabrication of highly c-axis oriented ZnO films has been extensively studied and developed. The performance of ZnO devices is, however, limited due to their small piezoelectric coupling (20–30%). PZT thin films are expected to exhibit higher piezoelectric properties. At present, the growth of PZT thin film is being carried out for use in microtransducers and microactuators.

3.6. Relaxor-Type Ferroelectric Materials

Relaxor ferroelectrics differ from normal ferroelectrics in terms of having broad phase transition from paraelectric to ferroelectric state, strong frequency dependence of dielectric constant (i.e., dielectric relaxation) and weak remanent polarization. Lead-based relaxor materials have complex disordered perovskite structures with a general formula $\text{Pb}(\text{B}_1, \text{B}_2)\text{O}_3$ ($\text{B}_1 = \text{Mg}^{2+}, \text{Zn}^{2+}, \text{Sc}^{3+}, \text{B}_2 = \text{Nb}^{5+}, \text{Ta}^{5+}, \text{W}^{6+}$). The B site cations are distributed randomly in the crystal. The characteristic of relaxors is a broad and frequency dispersive dielectric maximum. Relaxor-type electrostrictive materials such as lead magnesium niobate $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ –lead titanate PbTiO_3 solid solution (PMN–PT) are very suitable for application in actuators. This relaxor ferroelectrics can also provide an induced piezoelectric effect. That is, the electromechanical coupling factor k_t varies with the applied dc bias field. As the DC bias field increases, the coupling increases and saturates. This behavior is reproducible. These materials would be applied for ultrasonic transducers that can be tunable by the bias field [13].

Single-crystal relaxor ferroelectrics have been developed that show very promising results in ultrasonic transducers and electromechanical actuators. Single crystals of $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PMN), $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PZN) and binary systems of these materials combined with PbTiO_3 (PMN–PT and PZN–PT) exhibit extremely large electromechanical coupling factors [14,15]. Large coupling coefficients and large piezoelectric constants have been found for these solid-solution crystals with morphotropic phase boundary compositions. PZN-8%PT single crystals were found to possess high k_{33} value of 0.94 for (001) crystal cuts. The k_{33} value of the conventional PZT ceramics is usually 0.70–0.80.

More recently, it was reported that these relaxor based ferroelectric single crystals also exhibit ultrahigh strain levels not available with current piezoelectric ceramics [16]. Pseudocubic (001)-oriented relaxor based rhombohedral crystals such as $(1-x)\text{PZN}-x\text{PT}$ ($x < 0.09$) and $(1-x)\text{PMN}-x\text{PT}$ ($x < 0.35$) were reported to have \mathbf{E} -field-induced strains up to 0.6% with negligible hysteresis. Ultrahigh strain levels more than 1.5%, nearly an order of magnitude higher than polycrystalline PZTs or electrostrictive PMN, could be achieved being related to an \mathbf{E} -field-induced phase transformation.

4. APPLICATIONS OF PIEZOELECTRIC MATERIALS

Piezoelectric materials can provide coupling between electrical and mechanical energy and thus have been exten-

sively used in a variety of electromechanical device applications. The direct piezoelectric effect is most obviously used in the generation of charge at high voltage such as for the spark ignition of gas in space heaters, cooking stoves, and cigarette lighters. Using the converse effect, mechanical small displacements and vibrations can be produced for actuators by applying a field. Acoustic and ultrasonic vibrations can be generated by an alternating field tuned at the mechanical resonance frequency of a piezoelectric device, and can be detected by amplifying the field generated by vibration incident on the material, which is usually used for ultrasonic transducers. The other important application field of piezoelectricity include the control of frequency. The application of piezoelectric materials ranges over many technology fields including ultrasonic transducers, actuators and ultrasonic motors, electronic components such as resonators, wave filters, delay lines, SAW devices and transformers, and high-voltage applications; gas ignitors, ultrasonic cleaning, and machining. Piezoelectric-based sensors, for instance, accelerometers, automobile knock sensors, vibration sensors, strain gages, and flow meters have been developed, because pressure and vibration can be directly sensed as electric signals through piezoelectric effect. Examples of these applications are given in the following sections.

4.1. Ultrasonic Transducers

One of the most important applications of piezoelectric materials is based on ultrasonic echo field [17,18]. Ultrasonic transducers convert electrical energy into mechanical form when generating an acoustic pulse and convert mechanical energy into an electrical signal when detecting its echo. Currently, piezoelectric transducers are being used in medical ultrasound for clinical applications ranging from diagnosis to therapy and surgery. They are also used for underwater detection, such as sonar and fish finding, and nondestructive testing.

The ultrasonic transducers often operate in a pulse-echo mode. The transducer converts electrical input into acoustic wave output. The transmitted waves propagate into a body, and echoes are generated which travel back to be received by the same transducer. These echoes vary in intensity according to the type of tissue or body structure, thereby creating images. An ultrasonic image represents the mechanical properties of the tissue, such as density and elasticity. We can recognize anatomical structures in an ultrasonic image since the organ boundaries and fluid-to-tissue interfaces are easily discerned. The ultrasonic imaging process can also be done in real time. This means we can follow rapidly moving structures such as the heart without motion distortion. In addition, ultrasound is one of the safest diagnostic imaging techniques. It does not use ionizing radiation like X rays and thus is routinely used for fetal and obstetrical imaging. Useful areas for ultrasonic imaging include cardiac structures, the vascular systems, the fetus, and abdominal organs such as liver and kidney. In brief, it is possible to see inside the human body by using a beam of ultrasound without breaking the skin.

There are various types of transducers used in ultrasonic imaging. Mechanical sector transducers consist of single, relatively large resonators and can provide images by mechanical scanning such as wobbling. Multiple-element array transducers permit discrete elements to be individually accessed by the imaging system and enable electronic focusing in the scanning plane to various adjustable penetration depths through the use of phase delays. Two basic types of array transducers are linear and phased (or sector). A linear array is a collection of elements arranged in one direction, producing a rectangular display. A curved linear (or convex) array is a modified linear array whose elements are arranged along an arc to permit an enlarged trapezoidal field of view. The elements of these linear type array transducers are excited sequentially group by group in a sweep of the beam in one direction. These linear array transducers are used for radiological and obstetrical examinations. On the other hand, in a phased-array transducer the acoustic beam is steered by signals that are applied to the elements with delays, creating a sector display. This transducer is useful for cardiology applications where positioning between the ribs is necessary.

Figure 5 shows the basic ultrasonic transducer geometry. The transducer is composed mainly of matching layers, piezoelectric material and backing [19]. One or more matching layers are used to increase sound transmissions into tissues. The backing is added to the rear of the transducer in order to damp the acoustic backwave and to reduce the pulse duration. Piezoelectric materials are used to generate and detect ultrasound. In general, broadband transducers should be used for medical ultrasonic imaging. The broad bandwidth response corresponds to a short pulse length, resulting in better axial resolution. Three factors are important in designing broad bandwidth transducers. The first is acoustic impedance matching, that is, effectively coupling acoustic energy to the body. The second is a high electromechanical coupling coefficient of the transducer. The third is electrical impedance matching,

Figure 5. Prototype transducer geometry. The transducer is mainly composed of matching layer, piezoelectric material and backing.

Table 3. Comparison of Ultrasonic Transducer Materials

	PZT Ceramic	PVDF Polymer	PZT- Polymer Composite	ZnO Film
k_t	0.45–0.55	0.20–0.30	0.60–0.75	0.20–0.30
$Z(\text{Mrayls})$	20–30	1.5–4	4–20	35
$\epsilon_{33}^T/\epsilon_0$	200–5000	10	50–2500	10
$\tan\delta$ (%)	<1	1.5–5	<1	<1
Q_m	10–1000	5–10	2–50	10
ρ (g/cm^3)	5.5–8	1–2	2–5	3–6

that is, effectively coupling electrical energy from the driving electronics to the transducer across the frequency range of interest. These pulse echo transducers operate based on the thickness mode resonance of the piezoelectric thin plate. The thickness-mode coupling coefficient k_t is related to the efficiency of converting electric energy into acoustic and vice versa. Further, a low-planar-mode coupling coefficient, k_p , is beneficial for limiting energies being expended in non-productive lateral mode. A large dielectric constant is necessary to enable a good electrical impedance match to the system, especially with tiny piezoelectric sizes.

Table 3 compares the properties of ultrasonic transducer materials [7,20]. Ferroelectric ceramics, such as lead zirconate titanate and modified lead titanate, are today almost universally used as ultrasonic transducers. The success of ceramics is due to their very high electromechanical coupling coefficients. In particular, soft PZT ceramics such as PZT-5A and 5H type compositions are most widely used because of their exceedingly high coupling properties and because they can be relatively easily tailored, for instance, in the wide dielectric constant range. On the other hand, modified lead titanates such as samarium doped materials have high piezoelectric anisotropy: the planar coupling factor k_p is much less than the thickness coupling factor k_t . This absence of lateral coupling leads to reduced interference from spurious lateral resonances in longitudinal oscillators. This is very useful in high-frequency array transducer applications. One disadvantage to PZT and other lead-based ceramics is their large acoustic impedance (approximately 30 Mrayls) compared to body tissue (1.5 Mrayls). Single or multiple matching layers with intermediate impedances needed to be used in the case of PZT to improve acoustic matching.

On the other hand, piezoelectric polymers, such as poly(vinylidene)-difluoride-trifluoroethylene, have much lower acoustic impedance (4–5 Mrayls) than the ceramics and thus provide better matching with soft tissues. However, piezopolymers are less sensitive than the ceramics and they have relatively low dielectric constants, requiring large drive voltage and giving poor noise performance due to electrical impedance mismatching.

An alternative to ceramics and polymers is piezoelectric ceramic/polymer composites. Piezocomposites having 2–2 or 1–3 connectivity are commonly used in ultrasonic medical applications. These combine the low acoustic impedance advantage of polymers with the high sensitivity and low electrical impedance advantages of ceramics.

The design frequency of a transducer depends on the penetration depth imposed by the application. Resolution is improved with increasing frequency. Although a high-frequency transducer is capable of producing a high-resolution image, higher frequency acoustic energy is more readily attenuated by the body. A lower frequency transducer is used as a compromise when imaging deeper structures. Most medical ultrasound imaging systems operate in the frequency range from 2 to 10 MHz and can resolve objects approximately 0.2–1 mm in size. At 3.5 MHz, imaging to a depth of 10–20 cm is possible, while at 50 MHz, increased losses limit the depth to less than 1 cm. Higher-frequency transducers (10–50 MHz) are used for endoscope-based imaging and for catheter-based intravascular imaging. At higher frequencies over 100 MHz applications are used in the field of ultrasound microscopy. The operating frequency of the transducer is directly related to the thickness and velocity of sound in the piezoelectric materials employed. As frequency increases resonator thickness decreases. For a 3.5-MHz transducer, PZT ceramic thickness needs to be roughly 0.4 mm. Most conventional ceramic transducers, such as PZT, are limited to frequencies below nearly 80 MHz because of the difficulty of fabricating thinner devices [21]. For microscopic applications at frequencies over 100 MHz, corresponding to the thickness of less than 20 μm , piezoelectric thin-film transducers such as ZnO have to be used [22].

The design of ultrasonic transducers with piezoelectrics used in the medical field was mentioned above. Another major ultrasonic transducer application is the underwater sonar transducer employed as both acoustic source and hydrophone. Sonar (sound navigation and ranging) is used to explore the ocean and underwater objects. Hydrophones are underwater microphones for detecting sound in water and under hydrostatic pressure. The representative transducers widely used for high-power and low-frequency active sonar include the Tonpiliz and flextensional structures. The design of the Tonpiliz transducer typically involves head and tail masses that are configured for impedance matching and a central piezoceramic section, whose shape roughly resembles a mushroom [23]. This transducer is made from stacks of rings electroded on the flat surfaces and electrically connected in parallel and are electrically insulated for each other held together with a stress rod. On the other hand, the flextensional transducer uses a mechanical shell, generally made of metal such as steel or brass, to convert hydrostatic stress to a stress along one or more of the sensitive axes of a stack of piezoelectric ceramic plates or rings [24]. The flextensional transducers with different shapes of the outer shell have been designed to achieve an extremely high sensitivity.

4.2. Actuators and Motors

4.2.1. Actuators. Currently the other important applications of piezoelectric materials exist in actuator fields [25]. Actuators are defined as transducers capable of transferring input energy into a mechanical output energy. Using the converse piezoelectric effect, small displacement can be produced by applying a field to piezoelectric

materials. Vibrations can be generated by applying an alternating field. In advanced precision engineering, the demand for a variety of types of actuators that can adjust positions precisely (micropositioning devices), suppress noise vibrations (dampers), or drive objects dynamically (ultrasonic motors) exist. These devices are used in broad areas including optics, astronomy, fluid control, and precision machinery. For actuator applications, piezoelectric strain and electrostriction induced by an electric field are used. Electrostrictive materials such as lead magnesium niobate (PMN) ceramics are especially preferred because of their small degradation under severe operating conditions. The PMN is easily electrically poled when an electric field is applied around the transition temperature and depoled completely without any remanent polarization. This provides extraordinarily large apparent electrostriction though it is a secondary phenomenon of the electromechanical coupling. Figure 6 shows the longitudinal induced strain curve at room temperature in 0.9PMN–0.1PT [26]. The magnitude of the electrostriction is 10^{-3} , and this material has almost no hysteresis.

Figure 7 shows the design classification of ceramic actuators. Simple devices composed of a disk and multilayer type directly use the strain induced in a ceramic by the applied electric field. Complex devices do not use the induced strain directly but use the magnified displacement through a special magnification mechanism such as unimorph, bimorph, and moonie. The most popularly used multilayer and bimorph types have the following characteristics. The multilayer type does not show a large displacement (10 μm), but has advantages in generation force (1000 N), response speed (10 μs), lifetime (10^{11} cycles), and the electromechanical coupling factor k_{33} (0.70). The bimorph type exhibits a large displacement (300 μm), but shows disadvantages in generation force (1 N), response

Figure 6. Longitudinal induced strain curve at room temperature in 0.9PMN–0.1PT as a function of electric field. The magnitude of the electrostriction is 10^{-3} and this has almost no hysteresis.

Figure 7. Structures of ceramic actuators. There are three representative types: multilayer, bimorph, and moonie types.

speed (1 ms), lifetime (10^8 cycles) and the electromechanical coupling factor k_{eff} (0.10). For instance, in a 0.65 PMN–0.35 PT multilayer actuator with 99 layers of 100- μm thick sheets ($2 \times 3 \times 10 \text{ mm}^3$), an 8.7 μm displacement is generated by a 100 V voltage, accompanied by a slight hysteresis. The transmit response of the induced displacement after the application of a rectangular voltage is as quick as 10 μs . In conclusion, the multilayer exhibits the field induced strain of 0.1% along the length.

Unimorph and bimorph devices are defined by the number of piezoelectric ceramic plates: only one ceramic plate is bonded onto an elastic shim, or two ceramic plates are bonded together simultaneously. The bimorph causes bending deformation because each piezoelectric plate bonded together produces extension or contraction under an electric field. In general, there are two types of piezoelectric bimorph: antiparallel polarization type and parallel polarization type, as shown in Fig. 8. Two poled piezoelectric plates with $t/2$ in thickness and L in length are bonded with their polarization directions opposite or parallel to each other. In cantilever bimorph configuration whose one end is clamped, the tip displacement δ_z under an applied voltage V is provided as follows:

$$\delta_z = 3/2 \cdot d_{31} (L^2/t^2) V \text{ (antiparallel type)} \quad (9)$$

$$\delta_z = 3d_{31} (L^2/t^2) V \text{ (parallel type)} \quad (10)$$

Figure 8. Two types of piezoelectric bimorphs: (a) antiparallel polarization type; (b) parallel polarization type.

The resonance frequency f_r for both types is given by

$$f_r = 0.16t/L^2 (\rho S_{11}^E)^{-1/2} \quad (11)$$

where ρ is density and S_{11}^E is elastic compliance. A metallic sheet (called a shim) is occasionally sandwiched between the two piezoelectric plates to increase the reliability, that is, the structure can be maintained even if the ceramics fracture. Using the bimorph structure, a large magnification of the displacement is easily obtainable. However, the disadvantages include a low response speed (1 kHz) and low generative force.

A composite actuator structure called moonie has been developed to amplify the small displacements induced in a piezoelectric ceramic. The moonie consists of a thin multilayer element and two metal plates with a narrow moon-shaped cavity bonded together. This device has intermediate characteristics between the conventional multilayer and bimorph actuators; this shows an order of magnitude larger displacement (100 μm) than the multilayer, and much larger generative force (100 N) with quicker response (100 μs) than the bimorph.

Some examples of applications of piezoelectric and electrostrictive actuators mentioned already are described next. The piezoelectric impact dot-matrix printer is the first mass-produced device using multilayer ceramic actuators. The advantage of the piezoelectric printer head compared to the conventional magnetic types are: low energy consumption, low heat generation, and fast printing speed. The longitudinal multilayer actuators do not exhibit a large displacement and thus a suitable displacement magnification mechanism is necessary. The displacement induced in a multilayer actuator pushes up the force point, and its displacement magnification is carried out through hinge levers so as to generate a large wire stroke. When the displacement in the piezoactuator is 8 μm , the wire stroke of 240 μm can be obtained, that is the magnification rate is 30 times.

Bimorph structures are commonly used for VCR head tracking actuators, because of their large displacements. An autotracking scan system uses the piezoelectric actuators so that the head follows the recording track even while driven at both still and quick modes. As can be anticipated, the bimorph drive is inevitably accompanied by

a torsional motion. To obtain a perfect parallel motion a special mechanism has to be employed. Piezoelectric bimorphs have also been used in phonograph pickup cartridges, and cantilever bimorphs with small masses attached to their free end can be used as accelerometers. Piezoelectric pumps for gas or liquid utilizing an alternating bending motion of bimorph have been developed for intravenous drip injection in hospitals and for medication dispensers in chemotherapy, chronic pain, and diabetes. Piezoelectric fans for cooling electronic circuits are made from a pair of bimorphs that are driven out of phase so as to blow effectively. Furthermore, piezobimorph-type camera shutters have been widely commercialized.

In optical control systems, lenses and mirrors require micropositioning and even the shapes of mirrors are adjusted to correct image distortions. For instance, a space qualified active mirror called articulating fold mirror utilizes six lead magnesium niobate (PMN) electrostrictive multilayer actuators to precisely position a mirror tip and tilt in order to correct the focusing aberration of the Hubble Space Telescope.

Piezoelectric actuators are also useful for vibration suppression systems of an automobile. An electronically controlled shock absorber was developed by Toyota. The piezoelectric sensors detecting road roughness is composed of 5 layers of 0.5 mm thick PZT disks. The actuator is made of 88 layers of 0.5 mm thick disks. Applying 500 V generates about 50 μm displacement, which is magnified by 40 times through a piston and plunger pin combination. This stroke pushes the change value of the damping force down, then opens the bypass oil route, leading to decrease in the flow resistance. This electronically controlled shock absorber has both controllability and comfortability simultaneously.

4.2.2. Ultrasonic Motors. An ultrasonic motor is an example of piezoelectric actuators using a resonant vibration. In ultrasonic motors linear motion is obtained from the elliptical vibration through frictional force. The motor basically consists of a high-frequency power supply, a vibrator, and a slider. The vibrator is composed of a piezoelectric driving component and an elastic vibrator part, and the slider is composed of an elastic moving part and a friction coat. The characteristics of the ultrasonic motors are low speed and high torque compared to the conventional electromagnetic motors with high speed and low torque [25,27].

The ultrasonic motors are classified into two types: a standing-wave type and a propagating-wave type. The standing wave is expressed by

$$V_s(x, t) = A \cos(kx) \cdot \cos(\omega t) \tag{12}$$

while the propagation wave is given by

$$\begin{aligned} V_p(x, t) &= A \cos(kx - \omega t) \\ &= A \cos(kx) \cdot \cos(\omega t) \\ &\quad + A \cos(kx - \pi/2) \cdot \cos(\omega t - \pi/2) \end{aligned} \tag{13}$$

Figure 9. Vibratory coupler type ultrasonic motor. A vibratory piece is attached to a rotor or a slider with a slight cant angle.

A propagating wave can be generated by superimposing two standing waves whose phases differ by 90° to each other both in time and in space. The standing-wave type is sometimes known as a vibratory-coupler or a “woodpecker” type, where a vibratory piece is connected to a piezoelectric driver and the tip portion generates flat elliptic movement. Figure 9 shows a vibratory coupler type motor. A vibratory piece is attached to a rotor or a slider with a slight cant angle. The standing-wave type has high efficiency, up to 98% theoretical. However, a problem of this type is lack of control in both clockwise and counterclockwise directions. The principle of the propagation type is shown in Fig. 10. In the propagating-wave type, also called “surfing-type,” a surface particle of the elastic body draws an elliptic locus due to the coupling of longitudinal and transverse waves. This type generally requires two vibration sources to generate one propagating wave, leading to low efficiency (not more than 50%), but is controllable in both the rotational directions. An ultrasonic rotatory motor is successfully used in autofocusing cameras to produce precise rotational displacements. The advantages of this motor over the conventional electromagnetic motor are: silent drive (inaudible), thin motor design, and energy saving.

4.3. Resonators and Filters

When a piezoelectric body vibrates at its resonant frequency it absorbs considerably more energy than at other frequencies resulting in the fall of impedance. This phenomenon enables piezoelectric materials to be used as a

Figure 10. Principle of the propagating wave type ultrasonic motor. A surface particle of the elastic body draws an elliptic locus due to the coupling of longitudinal and transverse waves.

wave filter. A filter is required to pass a certain selected frequency band or to stop a given band. The bandwidth of a filter fabricated from a piezoelectric material is determined by the square of the coupling coefficient k , that is, nearly proportional to k^2 . Quartz crystals with very low k value of about 0.1 can pass very narrow frequency bands of approximate 1% of the center resonance frequency. On the other hand, PZT ceramics with a planar coupling coefficient of about 0.5 can easily pass a band of 10% of the center resonance frequency. The sharpness of the passband is dependent on the mechanical quality factor Q_m of the materials. Quartz has also a very high Q_m of about 10^6 which results in a sharp cutoff to the passband and well-defined frequency of the oscillator.

A simple resonator is a thin disk type, electroded on its plane faces and vibrating radially for applications in filters with a center frequency ranging from 200 kHz to 1 MHz and with a bandwidth of several percent of the center frequency. For a frequency of 455 kHz the disk diameter needs to be about 5.6 mm. However, if the required frequency is higher than 10 MHz, other modes of vibration such as the thickness extensional mode are exploited, because of its smaller-size disk. The trapped-energy type filters made from PZT ceramics have been widely used in the intermediate frequency range (at 10.7 MHz) for devices such as for FM radio receivers and transmitters. By employing the trapped-energy phenomena, the overtone frequencies are suppressed. The plate is partly covered with electrodes of a specific area and thickness. The fundamental frequency of the thickness mode beneath the electrode is less than that of the unelectroded portion, because of the extra inertia of the electrode mass. The longer wave characteristic of the electrode region cannot propagate in the unelectroded region. The higher-frequency overtones can propagate away into unelectroded region. This is known as trapped-energy principle. Figure 11 shows a schematic drawing of trapped-energy filter. In this structure the top electrode is split so that coupling between the two parts will only be efficient at resonance. More stable filters suitable for telecommunication systems have been made from single crystals such as quartz or LiTaO_3 .

4.4. SAW Devices

A surface acoustic wave (SAW; also called a Rayleigh wave) is composed of a coupling between longitudinal and shear waves in which the SAW energy is confined near the surface. An associated electrostatic wave exists

Figure 11. Trapped-energy-type filter. The top electrode is split so that coupling between two parts will be efficient only at resonance.

for a SAW on a piezoelectric substrate, which allows electroacoustic coupling via a transducer. The advantages of SAW technology are that the wave can be electroacoustically accessed and tapped at the substrate surface and its velocity is approximately 10^4 times slower than an electromagnetic wave. The SAW wavelength is on the same order of magnitude as line dimensions which can be photolithographically produced and the lengths for both short and long delays are achievable on a reasonable size substrates [28,29].

There are a very broad range of commercial system applications which include front-end and IF (intermediate frequency) filters, CATV (community antenna television) and VCR (video cassette recorder) components, synthesizers, analyzers, and navigators. In SAW transducers, finger electrodes provide the ability to sample or tap the wave and the electrode gap gives the relative delay. A SAW filter is composed of a minimum of two transducers. A schematic of a simple SAW bidirectional filter is shown in Fig. 12. A bidirectional transducer radiates energy equally from each side of the transducer. Energy that is not received is absorbed to eliminate spurious reflection.

Various materials are currently being used for SAW devices. The most popular single-crystal SAW materials are lithium niobate and lithium tantalate. The materials have different properties depending on the cut of the material and direction of propagation. The fundamental parameters considered when choosing a material for a given device applications are SAW velocity, temperature coefficients of delay (TCD), electromechanical coupling factor, and propagation loss. Surface acoustic waves can be generated and detected by spatially periodic, interdigital electrodes on the plane surface of a piezoelectric plate. A periodic electric field is produced when a radiofrequency (RF) source is connected to the electrode, thus permitting piezoelectric coupling to a traveling surface wave. If an RF source with a frequency f is applied to the electrode having periodicity d , energy conversion from an electrical to mechanical form will be maximum when

$$f = f_0 = V_s/d \tag{14}$$

V_s is the SAW velocity and f_0 is the center frequency of the device. SAW velocity is an important parameter determining the center frequency. Another important parameter for many applications is temperature sensitivity. For example, the temperature stability of the center frequency of

Figure 12. Typical SAW bidirectional filter consisting of two interdigital transducers. The input transducer generates surface acoustic waves in either direction and the output transducer converts the acoustic energy back to an electrical signal.

SAW bandpass filters is a direct function of temperature coefficient for the velocity and delay for the material used. The first-order temperature coefficient of delay is given by

$$(1/\tau) \cdot (d\tau/dT) = (1/L) \cdot (dL/dT) - (1/V_s) \cdot (dV_s/dT) \quad (15)$$

where $\tau = L/V_s$ is the delay time and L is the SAW propagation length. The surface wave coupling factor k_s^2 is defined in terms of the change in SAW velocity that occurs when the wave passes across a surface coated with a thin massless conductor, so that the piezoelectric field associated with the wave is effectively shorted-circuited. The coupling factor k_s^2 is expressed by

$$k_s^2 = 2(V_f - V_m)/V_f \quad (16)$$

where V_f is the free surface wave velocity and V_m is the velocity on the metallized surface. In actual SAW applications, the value of k_s^2 relates to the maximum bandwidth obtainable and the amount of signal loss between input and output, determining the fractional bandwidth versus minimum insertion loss for a given material and filter. Propagation loss is one of the major factors that determine the insertion loss of a device and is caused by wave scattering at crystalline defects and surface irregularities. Materials that show high electromechanical coupling factors combined with small temperature coefficients of delay are likely to be required. The free surface velocity V_0 of the material is a function of cut angle and propagation direction. The TCD is an indication of the frequency shift expected for a transducer due to a temperature change and is also a function of cut angle and propagation direction. The substrate is chosen based on the device design specifications and includes consideration of operating temperature, fractional bandwidth, and insertion loss.

Piezoelectric single crystals such as 128° -Y-X (128° -rotated-Y-cut and X-propagation)—LiNbO₃ and X- 112° -Y (X-cut and 112° -rotated-Y-propagation)—LiTaO₃ have been extensively employed as SAW substrates for applications in VIF (video intermediate frequency) filters. A *c*-axis-oriented ZnO thin film deposited on a fused quartz, glass, or sapphire substrate is also commercialized for SAW devices. Table 4 shows some important material parameters for some SAW materials.

Table 4. SAW Material Properties

	Material	Cut Propagation Direction	k^2 (%)	TCD (ppm/C)	V_0 (m/s)	ϵ_r
Single crystal	Quartz	ST-X	0.16	0	3158	4.5
	LiNbO ₃	128° -Y-X	5.5	-74	3960	35
	LiTaO ₃	X 112° -Y	0.75	-18	3290	42
	Li ₂ B ₄ O ₇	(110)-(001)	0.8	0	3467	9.5
Ceramic	PZT-In(Li _{3/5} W _{2/5})O ₃		1.0	10	2270	690
	(Pb,Nd)(Ti,Mn,In)O ₃		2.6	<1	2554	225

	ZnO/Sapphire		1.0	-30	5000	8.5

Figure 13. Fundamental Rosen-type structure of piezoelectric transformer. Two differently-poled parts coexist in one piezoelectric plate.

4.5. Delay Lines

A delay line can be formed from a slice of glass such as PbO- or K₂O-doped SiO₂ glass in which the velocity of sound is nearly independent of temperature. PZT ceramic transducers are soldered on two metallized edges of the slice of glass. The input transducer converts the electrical signal to a shear acoustic wave that travels through the slice. At the output transducer the wave is reconverted into an electrical signal delayed by the length of time taken to travel around the slice. Such delay lines are used in color TV sets to introduce a delay of approximately 64 μ s and are also employed in videotape recorders.

4.6. Piezoelectric Transformer

The transfer of vibration energy from one set of electrodes to another on a piezoelectric ceramic body can be used for voltage transformation. This device is called a piezoelectric transformer. Office automation equipment with liquid crystal displays have been successfully commercialized into such products as notebook type personal computers and car navigation systems. This equipment with a liquid crystal display requires a very thin, non-electromagnetic-noise transformer to start the glow of a fluorescent backlamp. This application has accelerated the development of piezoelectric transformers. Figure 13 shows a fundamental structure where two differently poled parts coexist in one piezoelectric plate. The plate has electrodes on half its major faces and on an edge, which is then poled in its thickness direction at one end and parallel to the long axis over most of its length. A low-voltage AC supply is applied to the large-area electrodes at a frequency that excites a length extensional mode resonance. A high-voltage output can then be taken from the small electrode and one of the larger electrodes. After the proposal by C. A. Rosen, piezoelectric transformers with several different structures

have been reported. A multilayer type transformer is proposed in order to increase the voltage rise ratio. The input part is of the multilayer structure with internal electrodes and the output electrodes are formed at the side surface of the rectangular plate. This transformer uses piezoelectric transverse mode for the input and output parts.

PIN DIODES

ALY E. FATHY

University of Tennessee
Knoxville, Tennessee

ARYE ROSEN

Drexel University
Philadelphia, Pennsylvania

A PIN diode is a semiconductor device that operates at RF and microwave frequencies as a variable resistor in the forward direction. The resistance value of the PIN diode can be varied over a range of approximately 1 Ω –100 K Ω through the use of a DC or low-frequency control current. A unique feature of the PIN diode is its ability to control large amounts of RF power with relatively much lower DC levels.

The PIN diode is useful for leveling, limiting, and amplitude modulating an RF signal, when the control current is varied continuously. However, the device can be used for pulse modulating, attenuating, switching, and phase shifting of an RF signal if the control current is turned ON or OFF, or in discrete steps. In addition, the PIN's small size, weight, high switching speed, and minimized parasitic elements make it ideally suited for miniature, broadband RF signal applications.

1. PIN-DIODE MODEL

A PIN diode is a PN junction with a doping profile tailored so that an intrinsic layer I is sandwiched between the P region and the N region [1]. A model of a PIN diode chip is shown in Fig. 1. The chip is prepared with a wafer of almost pure intrinsic silicon, with high resistivity and long lifetime. A P region is then diffused into one diode surface and an N region is diffused into the other surface. Both regions are heavily doped, so we will call them P⁺ and N⁺, to indicate the heavy doping. The resulting intrinsic or I region of width W is sandwiched between P⁺- and N⁺-type regions. The width of the I-region is a function of the original thickness of the wafer, and its area A depends on how many small sections are defined across the wafer.

When a PIN diode is forward-biased, holes and electrons are injected from the P and N regions into the high-resistivity I region. These charges do not immediately recombine, and the average recombination time is called the *carrier lifetime* τ . Both τ and W in large part determine approximately the low-frequency limit of useful applications. The lifetime of PIN diode is determined by the design and is based on the required switching speed and is typically in the range of 5 ns to over 100 μ s [2,3].

The conductance of the diode is proportional to the stored charge, and the charge, in turn, is related to the

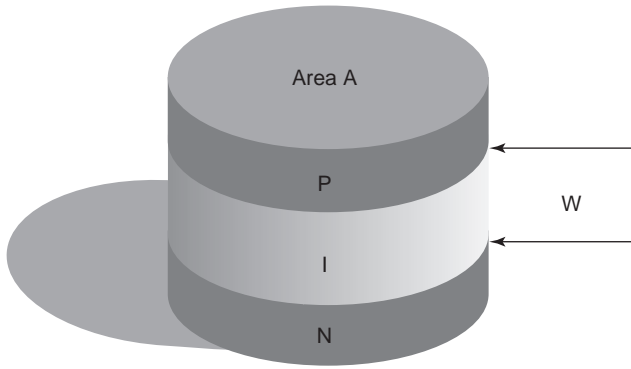

Figure 1. PIN-diode chip outline.

diode forward bias current I_F as follows [4,5]:

$$I_F = \frac{dQ}{dt} + \frac{Q}{\tau}$$

If the diode is biased only with a constant current, that is, in steady state, then the stored charge is constant and is equal to $Q = I_F \tau$. However, if the bias consists of both a constant current and a low-frequency RF, specifically, a time-varying signal, then the charge will be modulated, and the degree of modulation will depend on the AC and DC signal levels and frequency of operation as given by [4]

$$Q(\omega) = \frac{I_F \tau}{1 + j\omega\tau}$$

where ω is $2\pi f$ and f is the operating frequency. This charge frequency dependence is plotted in Fig. 2, and illustrates the fact that if the signal frequency is less than $f_c = 1/2\pi\tau$, then the signal modulation cannot be neglected; however, beyond that the modulation effect should decrease by about 6 dB/octave, and eventually disappears. In other words, at frequencies well below f_c , the PIN diode behaves as an ordinary PN junction diode, while in the vicinity of f_c , the diode will start to behave as a linear resistor with a small nonlinear component, and the signal will suffer from a measure of distortion. But, at frequencies beyond f_c , the diode appears essentially as a pure resistance controlled by a DC or a low-frequency control signal.

Figure 2. PIN diode charge response as function of frequency. (After [4].)

2. DETAILED PIN DIODE STRUCTURE

The ideal PIN structure will have a high-resistivity undoped I region. In practice, no silicon material is without impurities. A PIN diode consists of an extremely high-resistivity P or N region between low-resistivity highly doped P and N regions at its boundaries. For nomenclature, we will use the following notation: for heavily doped P and N materials we will use P^+ and N^+ , but for high-resistivity P and N material we will use the Greek notation π -type and ν -type, for P and N, respectively. Figure 3 shows a P^+ , ν , N^+ diode structure; the few impurity atoms of the I region will be ionized (assuming high-resistivity I layer), and the depletion region will extend through the P^+ and N^+ regions. For all practical purposes, the small penetration of the depletion region in the P^+ and N^+ regions can be neglected and the width of the depletion region will essentially be constant, equal to the I-region width, W_I . The same is true if the device is P^+ , π , N^+ ; however, the former structure is the most commonly manufactured one.

3. PUNCHTHROUGH VOLTAGE

Thus far, we have assumed that the I region has a very high resistivity, and that the depletion region extends to the P^+ and N^+ interfaces, even with no applied bias. Under these circumstances, the width of the I layer is almost constant and C_j is practically independent of the applied voltage. In other words, at zero voltage the depletion region has already extended through the I region. This type of device is called a *zero-punchthrough diode*, as the depletion region has punched through to the high-conductivity region even before bias was applied.

This is again, an ideal situation, the practical PIN diode with ionized impurity profiles is as shown in Fig. 4. At zero bias, a large portion, but not necessarily all, of the I region is depleted, and the width of the depletion region $W(0)$ is most likely less than the I-region width W . Applying a reverse bias, the depletion region spreads further, until it reaches the N^+ region (as shown in Fig. 4), and is called the *punchthrough voltage* V_{PT} .

The reverse bias potential required for punchthrough is given by [4,5]

$$V_{PT} = \frac{eN_D W^2}{2\epsilon_r \epsilon_0}$$

where N_D is the impurity concentration in the ν region. Obviously, if N_D equals zero (ideal case), then V_{PT} is zero.

V_{PT} can be used to measure the resistivity of the I region. Where the resistivity is related to the donor impurity as given by

$$\rho = \frac{1}{N_D e \mu_N}$$

where μ_N is the electron mobility, and combining the preceding two equations will result in the following expres-

Figure 3. Profiles for the ν and π PIN types diodes. (After [4].)

sion that can be used to accurately estimate ρ [4,5]:

$$\rho = \frac{W^2}{2V_{PT}\epsilon_0\epsilon_r\mu_N} = \frac{(2.4 \times 10^8)W^2}{V_{PT}} (\Omega \cdot \text{cm})$$

where W unit is cm.

Example 1. A particular silicon diode has an I-region width of 0.0025 cm, and is found to have punchthrough voltage of 5 V. Evaluate its resistivity:

$$\rho = \frac{(2.4 \times 10^8)W^2}{V_{PT}} = \frac{(2.4 \times 10^8)(0.0025)^2}{5} = 300 \Omega \cdot \text{cm}$$

4. LOW-FREQUENCY EQUIVALENT-CIRCUIT MODEL

The equivalent circuit of a PIN diode depends on the operating frequency. At frequencies much lower than f_c , the equivalent circuit of just below the punchthrough case, is as shown in Fig. 5a, and the portions of the P^+ and the I regions, which were partially depleted, are represented by a depletion, or “swept”, region. While the remainder of the I region is unswept, and its overall characteristics are very similar to those of a normal PN junction diode.

At low frequencies (say, < 1 MHz), most of the current goes through the unswept capacitance C_{US} , while at higher frequencies (e.g., > 1 GHz), the current almost bypass it. And for all practical purposes, the total capacitance can

Figure 4. Practical PIN and reversed punchthrough characteristics. (After [4].)

be represented by the series combination of C_{SW} and C_{US} , which is approximately equal to C_j ; the full capacitance of the I region. To identify high and low frequencies, we define a frequency called the dielectric relaxation frequency f_R , given by [4,5]:

$$f_R = \frac{1}{2\pi R_{US} C_{US}}$$

where $R_{US} = \rho L/A$ and $C_{US} = \epsilon_0 \epsilon_r A/L$, where L is the width of the unswept region and A is its cross sectional area. Therefore

$$f_R = \frac{1}{2\pi \epsilon_0 \epsilon_r \rho} = \frac{153}{\rho(\Omega \cdot \text{cm})} \text{ GHz}$$

Usually an I layer has a resistivity of at least $100 \Omega \cdot \text{cm}$. A rule of thumb, is that for frequencies beyond $3f_R$ (also $> 10f_c$), the diode can be assumed to be a constant capacitance, that is, having constant depletion width W . Hence,

if we assume a $100 \Omega \cdot \text{cm}$ I layer, then for frequencies beyond 4.59 GHz, we need to use the microwave circuit model.

5. MICROWAVE EQUIVALENT CIRCUIT

The microwave equivalent circuit for the unpackaged PIN diode chip is shown in Fig. 6. In most applications the PIN diode is used as a switch; therefore, it is a better open circuit, for a lesser capacitance in the reverse-bias state. Also, the diode will have a better short circuit, for lower forward resistance, where decreasing R_F and R_R will lower the device insertion loss in the ON state. A figure of merit is generally used to relate to the PIN switching effectiveness. This is the switching cutoff frequency f_{CS} , expressed as follows:

$$f_{CS} = \frac{1}{2\pi c_J \sqrt{R_R R_F}}$$

In principle, the values of R_F and R_R can be evaluated and f_{CS} can be specified. The term *switching cutoff* is not intended to imply that a particular device can be used for designing a switching circuit at frequencies as high as f_{CS} . But it gives an upper limit as PIN diodes are typically used in a frequency range around $\frac{1}{100}$ th– $\frac{1}{50}$ th of f_{CS} . Meanwhile, in switching and phase shifting applications, the overall losses are proportional to the ratio of switching cutoff frequency to the operating frequency.

A more general representation of figure of merit for two impedance state switching devices has been proposed by Kurokawa and Schlosser [6], and the figure of merit is written as

$$Q = \frac{\sqrt{(r_1 - r_2)^2 + (x_1 - x_2)^2}}{\sqrt{r_1 r_2}}$$

where the impedances of the two states are $z_1 = r_1 + jx_1 = R_F$, and $z_2 = r_2 + jx_2 = R_R + 1/j\omega C_j$. Hence

$$Q = \frac{\sqrt{(R_F - R_R)^2 + (1/\omega C_j)^2}}{\sqrt{R_F R_R}} \approx \frac{1}{2\pi f C_j \sqrt{R_F R_R}}$$

when $|R_F - R_R| \ll 1/\omega C_j$, then this above expression can be simplified as

$$Q \approx f_{CS}/f$$

where f_{CS} is the switching cutoff frequency. Typical Q values are in the range of 100–200, and for f_{CS} are in the range of 350–800 GHz, respectively.

6. EVALUATION OF R_F

To determine the microwave properties of a diode when forward-biased, let us calculate the conductivity and

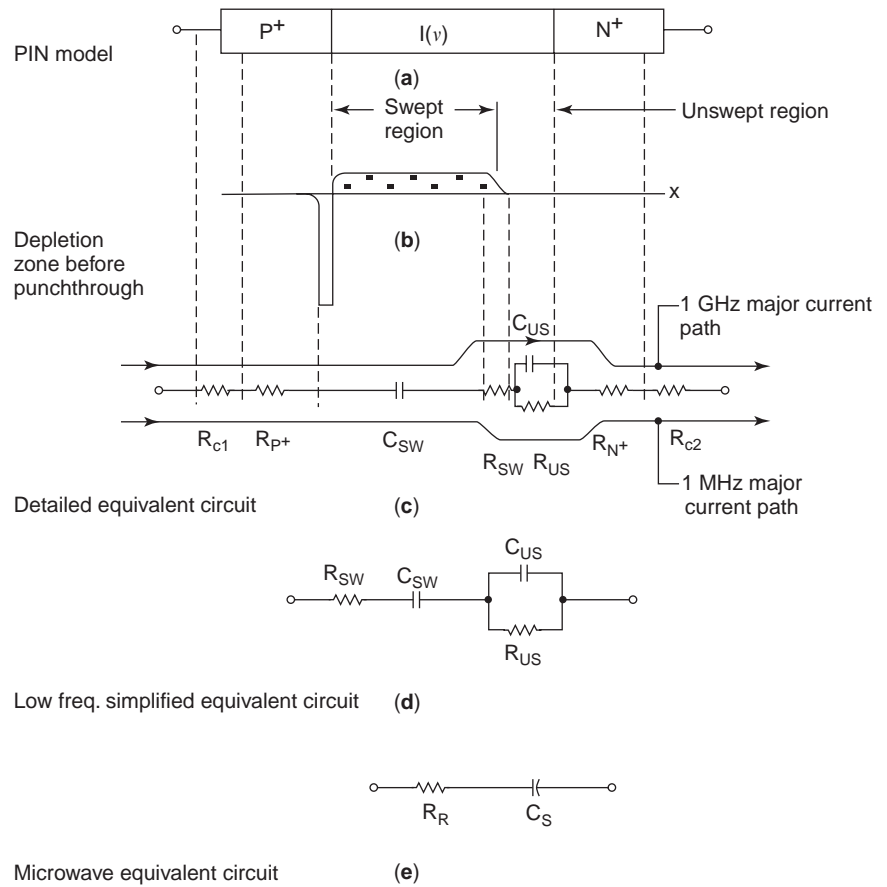

Figure 5. Reverse-bias PIN equivalent circuit: (a) PIN model; (b) depletion region before punchthrough; (c) detailed equivalent circuit; (d) equivalent circuit at low frequencies; (e) microwave equivalent circuit R_{C1} = contact resistance at left; R_{C2} = contact resistance at right; R_{P+} = semiconductor resistance of P⁺ region; R_{N+} = semiconductor resistance at N⁺ region; C_{SW} = capacitance of swept region; R_{US} = capacitance of the unswept region, R_{US} resistance of the unswept region; C_j junction capacitance = $C_{SW} + C_{US}$, $R_R = R_{C1} + R_{C2} + R_{P+} + R_{N+}$. (After [4].)

resistance of the I region under a forward-bias condition. We will first assume that the I region as a whole is electrically neutral (the injected carriers; $n=p$), and that the bias current injects both types of carrier, which recombine with one another in the I region after “long lifetime.” We will assume also that the average lifetime of these carriers before combining is sufficiently long to allow both the holes and the electrons to be uniformly distributed within the I-region.

Then, the conductivity of the I region is related to the ratio of the current density to the applied field strength $\sigma = J/E$, where J is the directed average rate of flow of electric charge. Hence the current J can be expressed as the sum of the current due to the two carriers in the I region and is given by

$$J = (ev_p p + ev_n n)E$$

where v_p and v_n are the average directed velocities of the n and p carriers, respectively, and where e , the magnitude of electron’s charge, is 1.6×10^{-19} C, and (p,n) are the respective injected hole and electron densities in the I region. Thus, the conductivity in terms of the mobility μ , which is defined as the average carrier velocity per unit of

applied electric field, and is given by

$$\sigma = e(\mu_p p + \mu_n n)$$

Hence, for a diode with thickness W and cross-sectional area A , its I-region resistance R_I is given by

$$R_I = \frac{W}{\sigma A} = \frac{W}{eA(\mu_p p + \mu_n n)}$$

Now, under the assumption of $n = p$, and $\tau_p = \tau_n$, the diode I region resistance is

$$R_I = \frac{W}{2eA\mu_{AP}p}$$

where $2\mu_{AP} = (\mu_p + \mu_n)$ is the ambipolar mobility [4], and is defined as the effective average of the hole and electron mobilities ($610 \text{ cm}^2/\text{V} \cdot \text{s}$ in silicon). But the stored charge, if the diode is injected, with fixed (i.e., constant) current is given by

$$Q_p = I_F \tau_p = I_F \tau = epAW$$

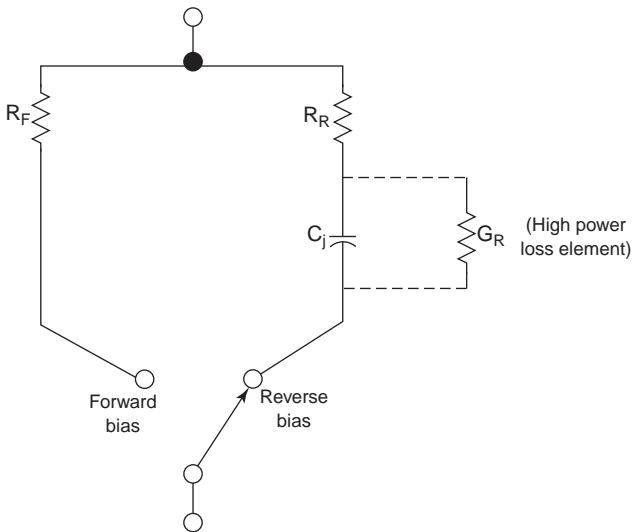

Figure 6. PIN diode chip equivalent circuit (C_j = reverse bias junction capacitance; R_F = forward-bias resistance; R_R = sum of semiconductor P^+ and N^+ resistances, and any contact resistance, i.e., $R_{C1} + R_{C2} + R_{P^+} + R_{N^+}$).

Then, the I-region resistance is [4]

$$R_I = \frac{W^2}{2\mu_{AP}\tau I_F}$$

Example 2. Find R_I for a silicon diode that has an I-region width of $W = 100 \mu\text{m}$, and a $4 \mu\text{s}$ τ lifetime that is injected by $I_F = 100 \text{ mA}$ in the forward bias.

Solution:

$$R_I = \frac{(100 \times 10^{-4})^2 \text{cm}^2}{\left(2 \times 610 \frac{\text{cm}^2}{\text{V} \cdot \text{s}}\right) \cdot (4 \times 10^{-6} \text{ s}) \cdot (100 \cdot 10^{-3} \text{ A})} = 0.21 \Omega$$

It is important to recognize that R_I does not depend on the cross-sectional area A , and is inversely proportional to the bias current I_F .

7. PRACTICAL RF RESISTANCE

The resistance R_I , which practically can be expressed by $R_I = K/I_F^x$ [7], governs the diode ON characteristics at RF frequencies, where R_I is the effective high-frequency resistance and I_F is the DC bias current in mA. The dependence of R_I on DC is similar in form to the dependence of the previously defined R_I on I_F in the low-frequency equivalent circuit; however, the constant K and the exponent x are different. Due to a variety of mechanisms that exist in the diode at RF frequencies, both K and x must be deter-

mined empirically. For a specific diode design, the exponent x is usually constant, very close to 1. Meanwhile, the constant K is highly dependent on the fabrication and process control, and its value can vary by as much as 3–1 from diode to diode. Fortunately, for switching or pulse operation, the variation of R_I between diodes at a given bias point is not significant since the diode is usually switched between a very high value and a very low value of resistance by the control current. For analog applications such as attenuating and modulating, the variation of R_I from unit to unit this could be troublesome.

8. R_R AND C_j REVERSE-BIASED CIRCUIT MODEL

At microwave frequencies, and under reverse bias, the I region is depleted of carriers and the PIN appears as an essentially constant capacitance to a microwave signal. Either series or parallel resistance can account for the presence of dissipative losses in the equivalent circuit (see Fig. 6). In a high-quality PIN diode, the I region has extremely high resistance, and most of the dissipation under RF occurs in the ohmic contacts (R_{C1} , R_{C2}), and in the resistance of P^+ and N^+ regions. Hence, a fixed resistance R_R is used to represent the overall losses.

Meanwhile, the I region is represented by a junction capacitance C_j , which is expressed approximately by the following simple parallel-plate capacitance formula

$$C_j \approx \frac{\epsilon_0 \epsilon_r \pi D^2}{4W}$$

where $\epsilon_0 = 8.85 \times 10^{-14} \text{ F/cm}$ is free-space permittivity, $\epsilon_r = 11.8$ equals the relative dielectric constant for silicon, D is the junction diameter, and W is the I region thickness.

9. EQUIVALENT CIRCUITS OF PACKAGED PIN DIODES

Packages typically introduce additional reactive elements in the form of package inductance L_p and package capacitance C_p . These elements are shown in Fig. 7.

Examples of these available packages, are given in Fig. 8, which shows typical HP PIN-diode packages, with package HP OUTLINE 15 having $L_p = 2.5 \text{ nH}$ and a C_p of 0.10 pF .

10. PIN-DIODE APPLICATIONS

10.1. Design of Reflective SPST Switches

10.1.1. Ideal Case. The PIN diode is ideally suited for use in attenuating or switching of RF signals. In an ideal

case, when the diode is connected in series as shown in Fig. 9a, the attenuation will increase by increasing the RF resistance, which is controlled by the DC bias current. The opposite is true if the diode is connected in shunt as shown in Fig. 9b.

For switching applications, the bias will change abruptly between two states, high and low values. When the diode is ON and connected in series configuration, it should pass the RF signal with minimal loss, and when it's OFF it should isolate the RF signal from the load, by highly attenuating the RF signal.

Ideally the diode is assumed to be purely resistive at RF, and the attenuation for each circuit is given as

$$\alpha_{(series)} = 20 \log \left(1 + \frac{R_1}{2Z_0} \right)$$

$$\alpha_{(shunt)} = 20 \log \left(1 + \frac{Z_0}{2R_1} \right)$$

where $R_S = R_L = Z_0$ generator and load resistance respectively, and R_1 is the diode forward resistance at the specified DC bias current (i.e., $R_1 = R_F$).

In this ideal case, the attenuation does not depend on frequency and is a function of the ratio of the circuit characteristic impedance Z_0 and the diode resistance R_1 . The power dissipation in these types of switches is due partially to absorption, and partially to reflection, and they are classified as reflective switches.

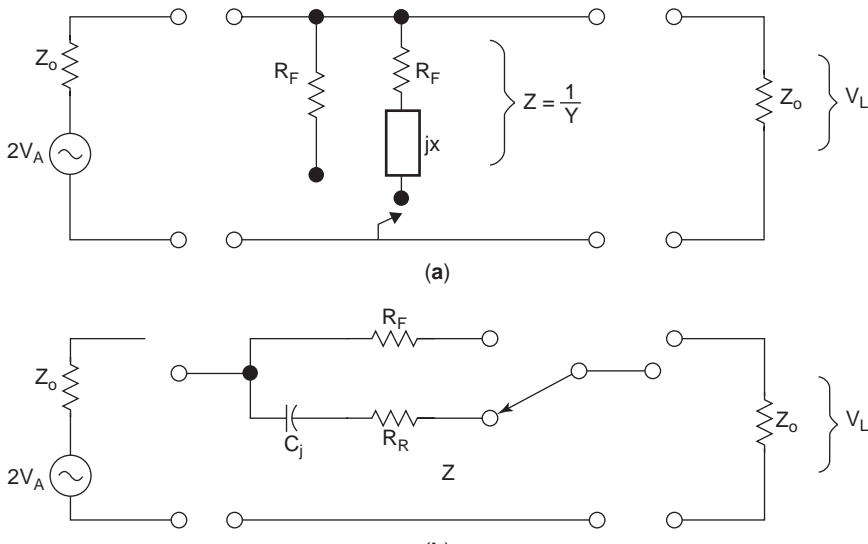

Figure 9. The diode is connected in shunt (a) and series (b), where the source and load impedances are equal to Z_0 .

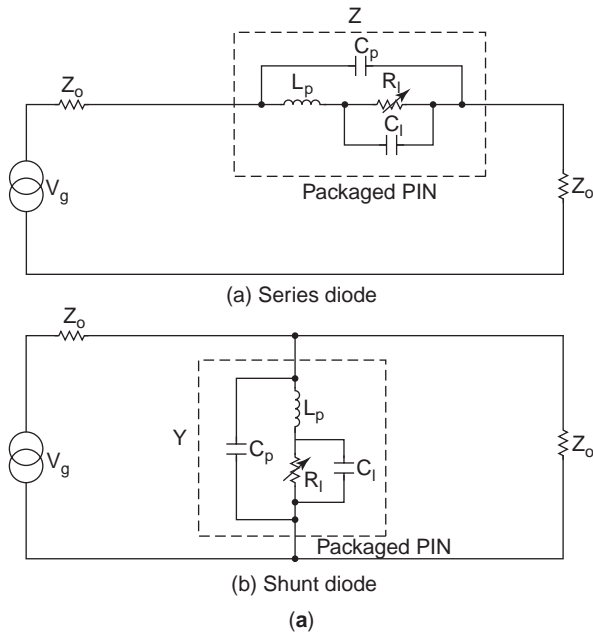

Figure 10. Packaged diodes used as reflective attenuators or switches.

switch in both series and shunt cases is

$$\alpha_{(\text{series})} = 20 \log(|1 + ZY_0/2|)$$

$$= 20 \log \left| 1 + RY_0 + \frac{(RY_0)^2}{4} + \frac{(XY_0)^2}{4} \right|$$

$$\alpha_{(\text{shunt})} = 20 \log(|1 + Z_0Y/2|)$$

$$= 20 \log \left| 1 + GZ_0 + \frac{(GZ_0)^2}{4} + \frac{(BZ_0)^2}{4} \right|$$

where the real device model is presented either by its impedance $(Z = R + jX)$ when connected in series, or by its admittance Y when connected in shunt where $(Y = G + jB)$.

In this practical case, it is obvious that the losses will be a function of frequency, and it is expected that the parasitic elements will degrade the performance quite significantly, and limit their operation at relatively higher frequency. However, some packages can be tailored to a

certain extent to extend the operating frequency range of these switches.

10.2. Design of Resonant SPST Switches

A packaged diode performance can be improved at high frequency by adding external reactance(s) to tune out the parasitic elements. These switches, called *resonant switches*, generally will be limited to <10% bandwidth. Where changing the state of the switch will be used to change the circuit topology from series resonance to parallel resonance. For example, when the switch is ON, it will have pure resistance (series resonance), and when the switch is OFF, it will have high resistance (parallel resonance).

For example, the circuit in Fig. 11a represents a diode connected in shunt. We externally add a shunt capacitance C_1 and a series inductance L_1 . When the diode is ON, it represents a pure resistance at microwave frequency, and L_1 and C_1 are adjusted to have parallel resonance based on L_1 and C_1 , and the points between A and B appear as high impedance. Meanwhile, when the diode is in the OFF state, it will present a capacitance C_j , and it will resonate with the inductance L_2 , and then at points A and B appear to have series resonance [8]. In both cases, if $L_1 = L_2$, then the resonant frequency is

$$f_0 \cong \frac{1}{2\pi\sqrt{L_1C_1}}$$

while in the ON state, there will be another series resonant frequency due to L_2 and C_1 , which will occur at about f_2 —that is, by appropriate design, it will be located approximately at $1.4f_0$.

11. MEASURING DIODE LIFETIME

A conventional method for measuring PIN-diode lifetime τ consists of injecting a known amount of charge Q_0 , into the I region and measuring the time τ_s required to extract it using a constant reverse-bias current. Figure 12 shows the equivalent circuit and charge–time profile. We first provide a forward-bias current I_F to flow for a long period of time (much longer than the expected lifetime) to store a charge Q_0 , which is given by $Q_0 = I_F\tau$. We then turn ON the switch S to provide a reverse current I_R , where the diode current I_D reverses direction and reaches a magnitude

Figure 11. Resonant PIN switches realized by adding external parasitics L_1 , L_2 , and C_1 (After Ref. 8.)

Figure 12. Evaluation of carrier lifetime (After [4].)

$(I_R - I_F)$, where $I_R > I_F$, by proper design of the circuit configuration. Due to the negative current, the stored energy Q_0 will be removed until it is completely depleted. Assuming that the discharge time τ_s is short compared to the lifetime ($\tau_s \ll \tau$), then the total charge time τ_s will be given by $Q_0 = I_F \cdot \tau = (I_R - I_F) \tau_s$, and the lifetime τ , will be found from [4,5]

$$\tau \approx \tau_s \left(\frac{I_R}{I_F} - 1 \right)$$

where $\tau_s \ll \tau$. Typical PIN diode lifetime may range from 0.1 to 100 μ s, which would require very fast switching speeds to satisfy the requirements that τ_s be small. In practice τ_s should be $\frac{1}{10}$ th of τ at most, which can be easily achieved with today's technology. It is imperative, however, that the experiment described above be repeated for different circuit settings to change the value of I_R and evaluate τ independent of τ_s .

12. PIN-DIODE POWER LIMITS

The maximum RF signal that a PIN diode can handle is limited by either the diode's breakdown voltage or its power dissipation capability. In most cases, power dissipation

capability sets limits on RF power-handling capability.

PIN diodes are usually operated in a reflective mode, and the amount of signal power that can be handled by a PIN diode in a circuit is usually much larger than the actual power dissipated in the diode. The ratio of the power dissipated in the diode to the incident power depends on the impedance of the diode relative to the circuit impedance, the number of diodes, and their relative interspacing.

Under forward bias, a PIN diode chip has an RF resistance of 1 Ω or less. Failure of the diode in this state will occur if the dissipative heating ($I^2 R_F$) is sufficient to cause the diode temperature to rise sufficiently to introduce metallurgical changes, and for silicon, as an example, it is about 1000°C. However, metal contacts at the silicon boundaries introduce failure mechanisms in the vicinity of 300–400°C.

Failure of a diode does not occur instantaneously when an overstress is applied unless the resulting temperature significantly exceeds 300°C. However, a mean lifetime can be expressed empirically based on the operating temperature and how close it is to the burnout temperature [4].

Since power handling can be many times greater than the power dissipated in the diode, the latter should be minimized and carefully controlled in high-power applications. The maximum power that a PIN diode can dissipate is given by [8,9]

$$P_{max} = \frac{T_{j(max)} - T_A}{\theta_{jc} + \theta_{jA}}$$

where

- $T_{j(max)}$ = maximum operating diode junction temperature
- T_A = ambient temperature
- θ_{jc} = thermal resistance—junction to case
- θ_{jA} = thermal resistance—case to ambient

The junction to diode is dictated by diode and package manufacture design, while the case to ambient is determined by how well the diode is thermally mounted. For a given diode, the maximum power dissipation limit can be obtained from its datasheet from the absolute maximum ratings. Designers can use a chart based on diode resistance to calculate a multiplier factor to evaluate the maximum power-handling capability of that device. For example, if the diode ON resistance is 1 Ω , and it is used in a series configuration, then the multiplying factor is 80 (as seen in Fig. 13), and if the maximum dissipated power is 1 W, then the RF power handling capability can be up to 80 W.

However, if the PIN operation is limited by reverse voltage breakdown, then we need to check the circuit performance under high voltage as shown below

$$P_A(max) = \frac{(V_{BR} - V_{bias})^2}{400} \text{ (Watts)}$$

Figure 13. (a) Continuous-wave (CW) power multiplier versus diode resistance; CW multiplier versus series or shunt attenuation. (After Ref. 8.)

and for shunt circuit this is the same as

$$P_A(\text{max}) = \frac{(V_{BR} - T_{\text{bias}})^2}{100} \text{ (Watts)}$$

where V_{BR} is breakdown voltage and P_A can be optimized when we utilize devices with zero turn on voltages. However, in general, the maximum field E_{max} in Si at lower dopings is about 2.5×10^5 V/cm, which corresponds to a

Figure 14. Vertical PIN diode structure.

breakdown voltage of [1]

$$V_{BR} \approx E_{\text{max}}W \approx 25W(\text{Volt})$$

where W is in micrometers.

13. DEVICE FABRICATION

There are two distinct structures for PIN diodes, vertical or lateral (see Figs. 14, 15). There are various methods for diode fabrication. In the following, we will describe only two typical processes used in Si PIN fabrication: chemical vapor deposition (CVD) and ion implantation.

13.1. CVD Process

The PIN diodes are fabricated from v -type high-resistivity, (111)-oriented silicon crystal wafers with resistivity in the range of 1500–5000 $\Omega \cdot \text{cm}$ [10]. The wafer thickness is about 450 μm . Boron and phosphorus are diffused into opposite surfaces of the wafer from doped oxide layers. Diffusion depths of 1–2 μm for the $P^+ - v$ junction and 1–2 μm for the $N^+ - v$ junction are carefully permitted through extensive measurement testings.

Then a bimetal chrome–gold coating is sputter-deposited onto the silicon contact surfaces, followed by a gold plating 10 μm thick. A photoresist pattern of dots is then formed on the gold surface covering the N^+ layer, and the exposed gold is etched down to the chrome layer. The gold dots act as a mask layer, and the exposed chrome layer is removed by an aqueous etchant. Finally, the silicon surface is passivated with SiO_2 , Si_3N_4 by the sputtering technique, followed by a cured resin coating [10].

A cross section of PIN-diode structure is shown in Fig. 15, and the PIN-diode fabrication process is shown in Fig. 16.

The lateral PIN diode

Figure 15. Lateral PIN diode structure.

Figure 16. Step-by-step PIN-diode fabrication process. (After Ref. 10.)

13.2. Ion Implantation Process

Starting wafers are the same as those in the CVD process. Wafers are ion-implanted using a beam current of approximately 1 mA [10]. A $1 \times 10^{16} \text{ cm}^{-2}$ dose of B atoms impinges on one surface of the wafer at an implant energy of 150 keV, and the other side receives a $1 \times 10^{16} \text{ cm}^{-2}$ dose of P atoms at an implant energy of 150 keV. The sources are then driven for 15 minutes at 1200°C to form N⁺ and P⁺ contact layers. The concentration profile is shown in Fig. 17.

14. GaAs PIN DIODES

Undoped (100) liquid-encapsulated Chelchroski-grown GaAs substrate can be used to fabricate PIN diodes. In

Figure 17. Concentration profile for a PIN diode. (After Ref. 10.)

the case of a vertical diode structure, A P⁺ layer and N⁺ layer are formed by ion implantation into the wafer of Be and Si, respectively, on top and bottom of the surface of the semiinsulating GaAs substrates (see Fig. 18). Then, wafers are annealed in the furnace under ASH₃/H₂ atmosphere. The N⁺ layer is formed first, followed by the P⁺ layer, as the Si implant in GaAs requires an annealing temperature for dose activation much higher than that for Be implantation [11]. Then, AuZn ohmic contacts are formed on the P side of the wafer using photolithography and liftoff. Finally, an AuGe–Ni–Au ohmic contact is formed on the back (v) of the wafer. The wafer is then diced for evaluation [11].

GaAs PIN diodes offer high switching speeds, high breakdown voltage, and a variable resistance with bias. In silicon, the electron and hole mobilities are almost the same.

1. INTRODUCTION

Since the birth of radio in 1895, there has been a very rapid growth of radiocommunication technology. To obtain higher information transmission rates over larger distances, there has been a steady demand for using higher frequency bands and larger amounts of transmitted power. The most significant progress in these two directions took place during World War II and afterward. This led to the emergence and development of microwave (1–30 GHz frequency band) and millimeter wave (30–300 GHz frequency band) communication technologies. Key systems that operate now at microwave and millimeter-wave frequencies include terrestrial and satellite links, and radar. These systems use active and passive circuits, which fulfill a number of fundamental functions related to signal generation, modulation, launching, reception, and detection.

Prior to 1948, the year when the transistor was invented, the only semiconductor element that was used in microwave communication circuits was a crystal detector diode. At that time, microwave signal generation and amplification were dominated by vacuum tubes including magnetron, klystron, and traveling-wave tubes (TWTs) [1]. These devices still remain in use at kilowatt levels, where solid-state devices cannot yet compete. Since the late 1960s the situation with the dominance of microwave

power generation by tubes has changed dramatically. This was due to the introduction of microwave semiconductor devices such as the Gunn diode, avalanche diodes, and bipolar and field-effect transistors [1], which were able to produce considerable power levels and gain at microwave frequencies. With the invention and introduction of these new devices, there has been growing interest in developing techniques to obtain higher power levels by combining power from individual modules. The motivation for such techniques has been due to a number of reasons. For example, in the mid-1970s it became clear that the combination of even a modest number of IMPATT (impact avalanche transit-time) diodes could lead to the manufacture of a pulsed radar transmitter offering a significant reduction in size and weight, which required only tens of volts for its operation. This was in contrast to tubes that often required 1000 V supplies and a considerable warm-up time. Since the inception of the concept of power combining, in the late 1960s, many power-combining schemes have been tried and developed. These schemes often include the two tasks of power division and combination and therefore the terms *power combining* and *power dividing* often appear simultaneously.

Power-combining schemes involve different technologies and media. These range from metal waveguides and cavities, microstrip, and striplines for which the power is confined to a finite region. Alternatively, open space configurations are used. In that case, power is launched by a set of radiating elements, antennas, at the transmit side and is intercepted by another set of antennas at the receive side. The choice of technology and medium depends on the type of solid-state device involved in the power-combining scheme, operational frequency and bandwidth, and the type of application in which the combined power is required. The devices involved in power combining/dividing are known as *power combiners/dividers*. Because of their reciprocal character, the same circuits can alternatively be viewed as power combiners or power dividers. This designation depends on the nomination of their input and output ports. In most cases the configuration of power combiner/divider is fixed. However, there is a category of these devices whose configuration and operation is variable. These devices have a redundant number of input/output ports, only selected ones of which are activated at a given instance of time. This function is performed using various types of RF switches.

Power combining/dividing structures are the subject of this article. The presentation commences with an introduction of categories of power combiners followed by the fundamental characteristics of these structures. Methods of analysis and applications of power combiner/dividers are described next.

2. MICROWAVE AND MILLIMETER-WAVE POWER COMBINING TECHNIQUES

2.1. Power-Combining Principles

Power combining can be achieved in a variety of manners, but they can be generalized to two situations, shown in Fig. 1.

Figure 1. General configurations for power combining: (a) oscillators; (b) amplifiers.

In Fig. 1a, there are a number of individual oscillators, and the task is to combine them into a more powerful synchronized signal source. This is achieved via a suitable combining circuit. This circuit with some modifications can be used for injection-locked oscillators and reflection amplifiers. In that case, the output port is used as an input port for injection of an external signal.

Figure 1b shows a single low-power source that is split and applied to the inputs of amplifiers. In turn, the outputs of these amplifiers are combined into a common port to produce a more powerful source. In this case, both dividing and combining circuits are employed to obtain the function of power combining.

The proper functioning of a power combiner is related to the efficient utilization of individual oscillators or amplifiers that appear within its structure. First, the combined source has to function in a reliable manner. This means that it has to have stable and longlasting performance. The term *stability* may also refer to the purity of the frequency spectrum generated by the combined devices. The combining circuit should be able to synchronize individual sources and suppress any instability that can lead to multimode operation of multiple solid-state devices present in the combiner. Reliability is often associated with graceful degradation of performance of the combiner. It means that if one of the oscillators or amplifiers fails, the remaining devices should not be affected. Consequently, the power produced by the combiner should be only slightly reduced because of the absence of the failed unit. Graceful degradation has always been regarded as the most important aspect of the power-combining techniques in the competition of solid-state sources with tubes, for which failure is usually catastrophic. One additional aspect, in conjunction with graceful degradation, is feasibility of the “hot” replacement of a failed unit. A suitable provision in the power-combining/dividing structure is necessary to accomplish this task.

2.2. Classification of Power Combiners/Dividers

A systematic grouping of power combiners has been accomplished by Russell [2] and Chang and Sun [3]. As a result of this classification, three major categories of combiners have been introduced: chip-level, circuit-level, and

spatial-level. In addition to these three major groups, multiple-level and other types of combining schemes have also been identified [3]. This classification is not unique; however, it helps distinguish combiner/divider configurations in the context of their use. Chip-level combiners [4–7] can be viewed as a subcategory of circuit-level combiners. They utilize very small distances (a small fraction of a wavelength) between individual solid-state devices. As such, although they increase the generated power, they do not offer graceful degradation. This is because the failure of one chip usually leads to the destruction or prevention of operation of the remaining chips and thus to the catastrophic failure of the combined source. Other problems with this type of combiners concern low effective impedance and adverse thermal interactions. Standard circuit-level combiners utilize larger distances between individual solid-state devices and therefore they allow for the introduction of counter measures against a catastrophic failure of the combiner. Because of the marginal importance of chip-level combiners, Fig. 2 shows the reduced classification of combiners, which include only circuit-level and space-level combiner categories, with chip-level combiners omitted.

Circuit-type combiners [2,3] confine power within a finite region often enclosed by a conducting surface such as a cavity or a waveguide. Radiation into a free space is considered an undesired phenomenon due to power loss. In space-level combiners, power combining takes place in an unbounded [8] or partially bounded region [9]. In the latter case, the combining region often forms a space resonator. The combining process is accomplished using transmitting and receiving radiating elements (antennas). The relative dimensions, in terms of wavelength, of the spatial combiner structure are usually much larger than those of its circuit-type equivalent. Consequently, the quality factor that is achieved with space resonators is usually much larger than that obtained with circuit-type resonant cavities. Because of this feature, circuit-type combiners are employed at the lower end of microwave and millimeter-wave frequencies while the space-type combiners are aimed for use at the upper millimeter-wave frequency bands.

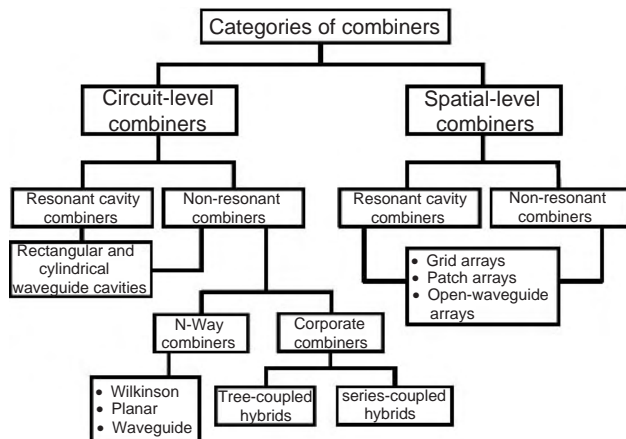

Figure 2. Categories of power combiners.

As shown in Fig. 2, circuit-level combiners are divided into resonant and nonresonant combiners. Resonant combiners use resonant cavities that exhibit a high quality factor Q and, as a result, feature small operational bandwidth. Because of this property, they serve the purpose of synchronizing multiple oscillators. Nonresonant combiners utilize structures with low quality factor and offer an increased operational bandwidth.

It has to be emphasized that similar-in-shape structures may appear in both resonant and nonresonant types of combiners [2,3]. For example, a cylindrical cavity with N coaxial ports including IMPATT or Gunn diode oscillators with a central port for power extraction is considered a resonant cavity combiner [10]. On the other hand, the same cylindrical cavity, but with peripheral coaxial probes and a central probe, can be considered a non-resonant, N -way radial combiner [11,12]. The difference lies in the Q factor that the cylindrical cavities provide [13]. The division into resonant and nonresonant cavity combiners may be less apparent for those structures for which it is difficult to identify whether they are resonant in operation. The proper identification of the Q factor may require solving an electromagnetic field problem to fully characterize a given structure. This is not always feasible.

Nonresonant combiners are generally divided into N -way and corporate-type combiners. Again, this classification is not unique and conforms to some earlier accepted terminology [2,3]. N -way combiners use a structure with N input ports and one output port. Corporate combiners use a tree of M -way combiners, where M is a small number, to create a combiner with a large number of input ports. The case of $M = 2$ leads to the binary-type corporate combiner. As has been indicated earlier, all the nonresonant combiners discussed here can also be regarded as power dividers. This is accomplished by designating input ports of an N -way combiner as output ports of a divider, and by renaming the common output port of the combiner to the input port of the N -way divider.

Similar to circuit-level combiners, spatial combiners can be divided into resonant (open-resonator cavity) and nonresonant structures [14]. Because of their similarities with Fabry–Perot cavity lasers [1], resonant-type spatial combiners using a space resonator with frontward and backward reflection mirrors are also termed *quasioptical power combiners* [9,14].

3. RESONANT AND NONRESONANT CAVITY COMBINERS/DIVIDERS

For the purpose of power combining and dividing, rectangular and cylindrical cavities are often used. Both resonant and nonresonant power combining structures can employ such cavities. As has been explained earlier, the identification of the resonant or nonresonant behavior can be distinguished by the quality factor that a given cavity structure offers. This factor depends on the method of launching and extracting the power and therefore on the cavity loading conditions. Resonant and nonresonant combiners/dividers using cavities are described in the following sections.

3.1. Rectangular Cavity Combiners/Dividers

The most popular configurations of rectangular cavities, which have been used for the purpose of power combining, are shown in Figure 3. The first structure, shown in Fig. 3a, is known as the *Kurokawa rectangular waveguide cavity combiner* [15,16]. It is considered as a resonant-type combiner. In this combiner, solid-state devices (IMPATT or Gunn diodes) operating as oscillators or amplifiers are connected to the lower coaxial lines. The upper coaxial lines are loaded with an absorber to stabilize the operation of the multiple-oscillator structure. They are also used to provide bias to solid-state devices. Please note that for the proper operation, pairs of coaxial lines are located close to waveguide walls, at the maximum of the magnetic field, and are spaced approximately at a half-waveguide wavelength along the waveguide. The waveguide short circuit is located a quarter-wavelength from the first adjacent coaxial pair. The bottom coaxial lines often include impedance-transforming circuits to obtain suitable impedance conditions for the proper operation of solid-state devices.

Figure 3b shows one variation of the basic Kurokawa combiner [17,18]. In this case, the bottom parts of the coaxial lines are removed and replaced by open-ended posts. In this configuration, solid-state devices are located in the gaps between the bottom waveguide floor and the tips of the posts. The rectangular waveguide in this configuration can be of a standard or oversized format.

Figure 3c shows a rectangular waveguide with coaxial probes [19]. In contrast to the Kurokawa-type combiner, individual amplifiers including active devices (diodes or

Figure 3. Rectangular waveguide cavity combiner/dividers: (a) cross-coupled coaxial lines; (b) posts; (c) disk-ended probes.

transistors) are connected externally to this structure via coaxial ports. These in turn couple power to the common rectangular cavity. Depending on the method of launching and extracting power, this basic configuration with some modifications can be used in ladder-type [19,20] and traveling-wave-type combiners/dividers [21]. In this case, coaxial probes or waveguide apertures can be used as combining ports. To combine power, reflection (single unit) and transmission (using dividing and combining units) configurations can be explored.

3.2. Cylindrical Cavity Combiners/Dividers

The principles of using cylindrical cavities for the purpose of power combining or dividing are analogous to those already presented for rectangular cavities. This is because both types belong to the same family of parallel-plate waveguides. The obvious differences are in the cross-sectional shapes, which consequently lead to their various uses. Figure 4 shows typical configurations of combiners/dividers that use a cylindrical cavity as a combining structure.

For the purpose of combining, it is usually assumed that the cavity operates in its TM_{0N0} mode whose field is constant with the cavity height and axially (azimuthally) symmetric. Power is extracted or launched by the centrally located probe (Figs. 4a–4c) or by the rectangular wave-

guide port (Fig. 4d). An important feature of the cylindrical cavity combiner/divider is that, since the mode of operation assumes fields azimuthally symmetric, in theory there is no minimum spacing between peripheral probes or coaxial lines. This is in contrast to the rectangular cavity combiner/divider in which the peripheral ports have to be spaced at half-waveguide wavelengths along the waveguide for proper operation.

3.3. Radial, Conical, and Hemispherical Cavity Combiners/Dividers

The cylindrical cavity with symmetrically located peripheral coaxial probes or lines and a single central coaxial probe, described above, can also be regarded as a radial cavity combiner/divider. This designation, instead of *cylindrical cavity combiner*, has been used in a number of references. Variations of this structure include shaping of the radial cavity and concern the use of different types of central and peripheral ports. Standard designs include a uniform-height radial cavity, which is fed by the central probe. However, some designs include a non-uniform-height cavity [29,30]. At the periphery, rectangular waveguide ports or coaxial probes are used. For the central port, full-waveguide-height coaxial probe [31,32] disk-ended [33,34], conical [35–37], or dielectric coated probes [38] are used. Similarly, peripheral probes can be formed by full-height coaxial probes [29,30], dielectric coated probes [37], conical probes [36], disk-ended probes [34], balun loops [39], continuous annular balun sections [35], or rectangular waveguide ports [33,38], instead of straight coaxial probes. Various configurations of radial cavity combiner/dividers are shown in Fig. 5.

Conical [2,3] and hemispherical cavity combiner/dividers [40,41], shown in Fig. 6, exhibit axial symmetry and utilize posts or coaxial probes for connecting solid-state sources or amplifiers. Posts or probes can also be used for signal launching and collecting.

4. NONRESONANT N-WAY COMBINERS

4.1. Cavity-Type Nonresonant N-way Combiners

N -way combiners form a single structure with N input ports and one output port. Some examples of these types of combiners have already been discussed and include radial, hemispherical, and conical cavities. In these structures, an azimuthally symmetric field is exploited in the power-combining/dividing process. In this case, the device operation is equivalent to N parallel transmission lines connected to one port. To support this mode of operation, input ports are excited in phase. Since in practice, the signals launched at the input ports may have different phases, dielectric beads or rods [40] of variable length or height may be used for tuning purposes to equalize the signal phases. An out-of-phase excitation of ports leads to the generation of higher-order modes that feature azimuthal (angular) dependence. To suppress higher-order asymmetric modes, slits [24,26] and resistive absorbers [24,25] are used. These components help increase the isolation between peripheral ports, which in turn improves

Figure 4. Cylindrical cavity combiner/divider configurations: (a) cross-coupled coaxial lines [10,12,22] and a central coaxial probe; (b) posts and disk-ended coaxial central probe [23,24]; (c) coaxial probes [25,26]; (d) posts and a waveguide aperture [27,28].

Figure 5. Various configurations of radial cavity combiners/dividers.

the graceful degradation performance of the combiner. This action is explained as follows.

In general, failure of a source, or an amplifier connected to a given port, results in a change of the load presented to this port. This new condition affects the performance of the remaining active devices. The extent of influencing the performance of other active devices depends on the isolation between the failed port and the remaining ports. Radially symmetric cavity combiners have a built-in isolation

that usually increases with the number of ports, and is equal to $1/N$ on average. This value may be considered insufficient in some applications, and this is why the resistive elements are introduced to increase isolation. When the slits or resistive vanes are located along the lines of the surface electric current of the dominant symmetric cavity mode, their effect on the fundamental mode is negligible. However, they cut lines of the currents that are associated with higher-order azimuthally varying

Figure 6. (a) Hemispherical and (b) conical cavity combiner/divider configurations.

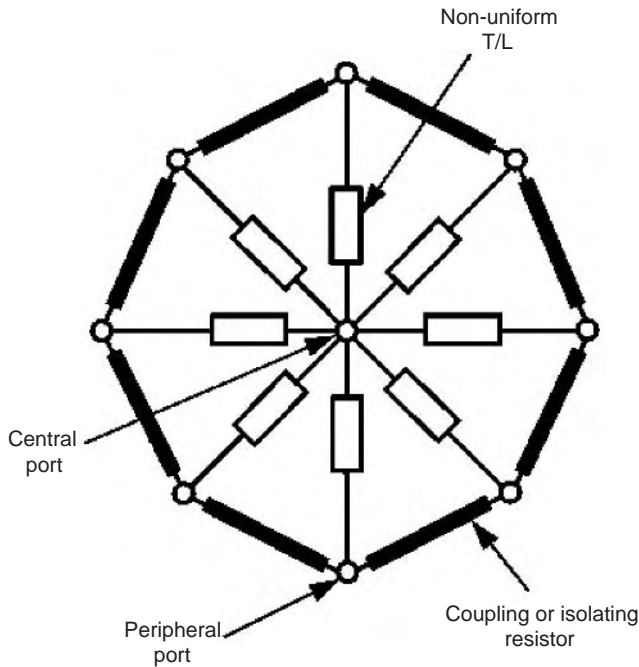

Figure 7. An equivalent circuit for a radial combiner under assumption of the dominant mode of operation.

fields. This results in absorption of higher-order modes and consequently improves the isolation between the peripheral ports.

An equivalent circuit for the radial (also hemispherical and conical) combiner under the condition of the dominant (symmetric, in-phase) mode of operation is shown in Fig. 7.

As can be seen in Fig. 7, a number of transmission lines of equal length (not necessarily quarter-wavelength), which meet at a common port, form this circuit. These lines are nonuniform as their characteristic impedance varies with distance. In this case, they operate as impedance tapers and provide suitable impedance transformation between the peripheral ports and the central port. This is to counter the parallel loading effect at the common port. The peripheral ends are connected via resistors. These resistors represent mutual coupling between the lines. These equivalent resistors may incorporate isolation resistors purposely introduced in the combiner.

4.2. Nonresonant Planar Radial-Line Combiners

Radial combiners do not necessarily have to be realized in waveguide. Their planar equivalents have also been investigated [42–47]. In these cases, a planar disk with a coaxial line at its center and N microstrip lines connected at its periphery form the combiner structure. A planar version of a radial combiner is shown in Fig. 8.

Depending on the design, nonuniform (tapered) or uniform (constant width) microstrip lines can be used to form this type of radial combiner. Additionally, resistors can be connected between the neighboring lines to improve isolation [42,43,46] and hence the graceful degradation performance of this device.

Figure 8. Planar version of a radial combiner with a coaxial central port and microstrip transmission lines connecting peripheral ports.

4.3. Wilkinson N -Way Combiners

Wilkinson's N -way combiner is one of the oldest power combining structures. It was introduced by Wilkinson in 1960 [48]. The device resembles in its concept the radial-line combiner and is synthesized using M sections of N uncoupled transmission lines of equal length with isolation resistors. A similar concept was also followed by Yee et al. [49]. The equivalent circuit of the N -way Wilkinson divider, which includes one-section transmission lines, is shown in Fig. 9. The difference, in comparison with an N -way radial-line combiner, is that in the present case the lines are uniform and are quarter-wavelength long. To meet the impedance matching conditions, the characteristic impedance of the lines is equal to $\sqrt{N} Z_0$, where Z_0 is the characteristic impedance of input and output transmission lines. Isolation between peripheral ports is improved using resistors between adjacent lines. Note that when N is greater than 2, the use of resistors in an N -way Wilkinson divider requires a crossover arrangement to effect connection between first and last output ports. The most well known version of the Wilkinson's divider is the two-way divider, as shown in Fig. 9b. It is used as a basic building block in a corporate-type combiner, which is discussed later.

Generalizations or variations of the standard Wilkinson divider were presented in Refs. 50–53. In particular, the synthesis of N -way dividers using M sections of N -wire uncoupled or coupled transmission lines was described in Ref. 50. To avoid multilayer construction of the standard Wilkinson N -way divider, for $N > 2$, new planar solutions concerning fork-type power dividers were presented in Ref. 51. Practical designs of four-way and seven-way dividers with isolation exceeding 20 dB between ports over a fractional bandwidth of 40% were demonstrated. The new structures presented in Ref. 52 feature an increased power-handling capability. The work in Ref. 53 concerns the design procedures for unequal power split-tee junctions.

4.4. Sectorial Radial Combiners

One problem with the N -way planar radial divider/combiner is that it uses hybrid (coaxial and planar) technology

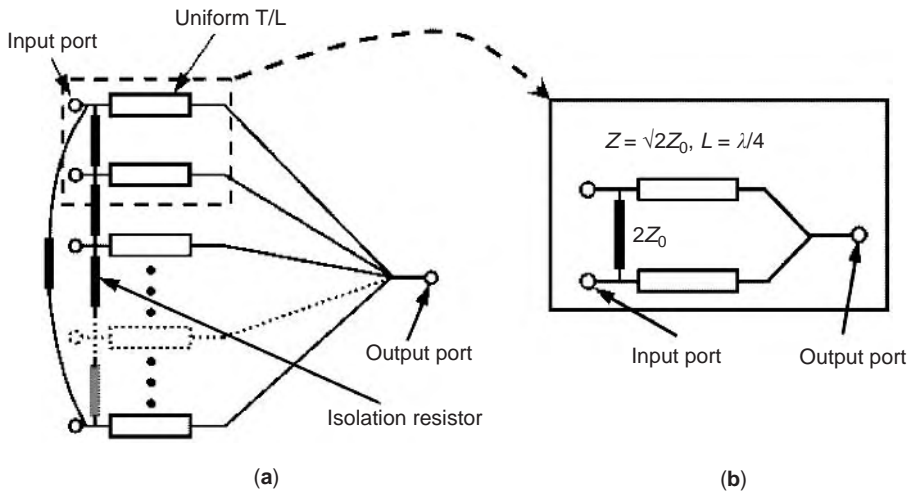

Figure 9. (a) An equivalent circuit of Wilkinson’s N -way power combiner; (b) its two-way version.

for its construction. This shortcoming can be avoided using a sectorial M -way planar combiner [54]. Variations of this structure are shown in Fig. 10.

Used as dividers, these structures can provide approximately equal power split with equal phase distribution. To increase the isolation between the peripheral ports, lumped resistors, as in the case of Wilkinson’s type combiner, can be used. In order to make output ports parallel as well as to provide equal phase division, exponential taper and purposely created holes can be used [55–57].

4.5. Corporate Combiners

Combiners with a large number of ports can be built using a tree of identical or similar hybrid devices with a small

Figure 10. Sectorial planar combiners: (a) without isolation resistors; (b) with isolation resistors; (c) with holes for phase and amplitude equalization.

number of input/output ports. These combiners can include binary or generally M -ary basic building blocks. As a result, the number of input ports in such combiners is not arbitrary but given by 2^L or M^L , where L is the number of section in the longitudinal direction. Basic building blocks for the binary tree-type combiners are shown in Fig. 11.

These basic structures include the two-way Wilkinson’s combiner, the 3-dB quadrature hybrid and the rat-race hybrid [58]. Other possibilities include other types of couplers (e.g., coupled-line directional coupler) and the Gysel power combiner [52,59]. These hybrids can be built in waveguide or planar (e.g., microstrip) technologies. These structures have built-in isolation between their input ports, exceeding 20 dB, and feature an increased operational bandwidth, typically 20% or more.

The common property of the Wilkinson 3-dB quadrature and rat-race hybrids is that they can provide equal power division when they operate as dividers. Please note,

Figure 11. Basic blocks used in tree-type power combiners: (a) Wilkinson two-way divider; (b) 3-dB branchline coupler; (c) rat-race hybrid.

however, that alternative designs of these dividers can also offer unequal power division [53]. The differences between these building blocks concern the number of ports and phase relationships. The Wilkinson's hybrid is a three-port device and provides equal in-phase power split. The rat-race hybrid is a four-port device and is capable of in-phase and out-of-phase (180° phase difference) equal power split. The 3-dB branch coupler is a four-port device and provides equal power split with a 90° phase difference between its output ports. Because of the four-port arrangement, the subtracting port of the rat-race hybrid and the isolated port of the 3-dB coupler need be match-terminated prior to their use in the tree-type combiners.

Figure 12 shows examples of corporate (tree-type) combiners with two-way Wilkinson's combiners and 3-dB couplers. As can be seen in Fig. 12, assembling of the binary corporate structure using two-way Wilkinson or rat-race hybrids is straightforward. The use of the 3-dB coupler requires an extra care to account for the 90° phase difference in its output ports. This is accomplished using suitable connection arrangements, which compensate for 90° phase difference.

Major advantages of corporate combiners are that their designs are straightforward. Their disadvantages are due to losses. Heatsinking for isolation resistors also creates problems. Because each section includes quarter-wavelength transmission lines, the corporate combiner becomes less compact than the radial combiner does with a similar number of ports. As a result of losses and large size, corporate combiners with many branches can be inconvenient, especially at the lower end of microwave frequencies. An interesting discussion regarding the use of corporate and radial combiners has been presented in Refs. 59 and 39. The inconvenience of the corporate combiner due to its large dimension is diminished at upper microwave or millimeter-wave frequency bands, because its size is scaled. However, considerable conduction losses

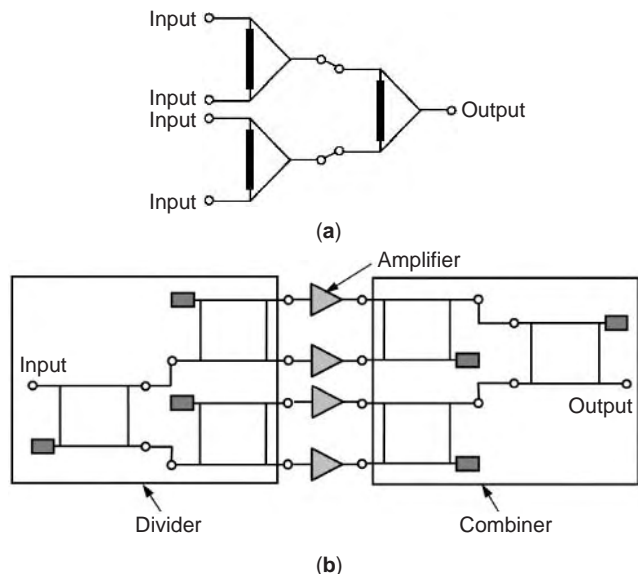

Figure 12. Typical configurations of corporate power combiners: (a) Wilkinson combiners; (b) 3-dB branchline couplers.

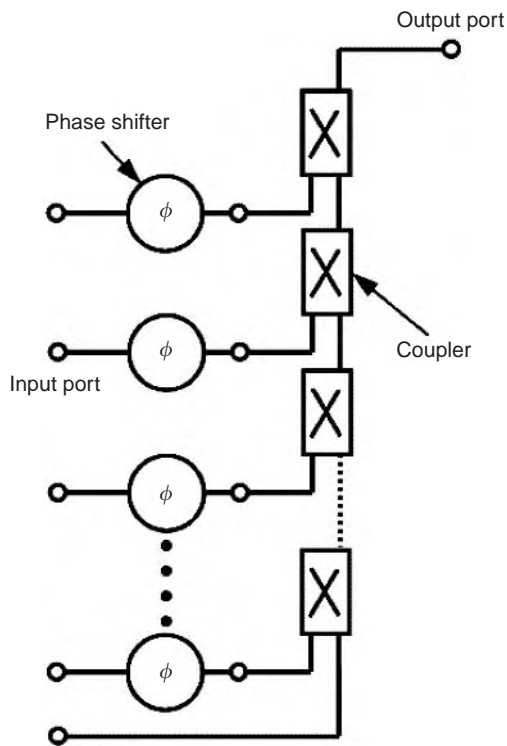

Figure 13. Chain-type combiner using couplers with unequal coupling coefficients.

occurring in these bands still restrict their use to only a few stages.

Similar to binary corporate combiners, M -ary corporate combiners can be built using M -way combiners [54]. However, they have not found many practical applications and therefore are not discussed here.

As shown in Fig. 13, combiners can also be built using hybrid circuits in the chain or serial configuration [2]. Using this approach, combiners with arbitrary number of input ports can be produced. These structures are easy to realize in practice. Usually, couplers with progressively increasing values of coupling are used in the chain. Because of the use of nonidentical couplers, phase shifters have to be included to compensate for unequal phases that can occur for input signals. As the phase equalization is not easy to accomplish at upper microwave frequencies, these circuits have not found wide acceptance at this particular frequency band.

4.6. Switchable Power Combiners

There a number of applications in which power division or combination have to be performed with regard to M selected ports of an N -port network (in which N is greater than M). Such a situation is met, for example, in a switched circular array antenna system for mobile satellite communication [60,61]. In this antenna system, only a few elements of a circular array facing a satellite need to be activated, while the remaining ones have to be deactivated. The function of activating and deactivating antenna elements is performed by a switched radial power

combiner/divider. The design and development of such a divider/combiner, which employs pin diodes as RF switches was described by Bialkowski and colleagues [60,62].

The concept of a switched radial divider/combiner for use with a mobile satellite circular antenna system is presented in Fig. 14. As seen in Fig. 14, the antenna array is formed by circular patches positioned on a truncated cone. These antenna elements are coupled via apertures to a switched radial divider/combiner. Beside RF switches, which activate and deactivate elements, 1-bit phase shifters are included to provide additional beams for this array. A switched radial divider with 14 output ports, with any three adjacent ports being active, was presented by Bialkowski et al. [60]. A device with eight total output ports, two of which were active, was described by Karmakar and Bialkowski [62]. A photograph of the fully developed 8-2-ON radial switch (including 1-bit phase shifters) is shown in Fig. 14b.

Another concept of switchable combiner is shown in Fig. 15. The device is a combination of a Wilkinson power combiner and a switching network. The combiner can operate in one-, two-, three-, and four-way modes, which means that up to four input signals can be combined to one output. In Fig. 15, the $\lambda/4$ transmission lines become open-ended stubs when they are turned off. The $\lambda/2$ lines are used to allow for obtaining an extra space required for incorporating multiple RF switches.

Characteristic impedances of transmission lines are optimized for minimum insertion loss and high return loss in all modes of operation.

5. SPATIAL POWER COMBINERS

5.1. General Considerations

Spatial combiners use arrays of radiating elements to combine power in an unbounded or partially bounded free space. The major difference with circuit-type combiners is that besides an active device and its biasing/impedance-matching circuit, an antenna is an integral part. Because of the integration of an active element with an antenna, spatial power combiners are often regarded as an extension of what is known as an *active-array antenna*. Different types of antennas, including dipoles, patch antennas, notch antennas, and open-ended waveguides, can be used to this purpose. This blending leads to a wide range of spatial combiner structures. Irrespective of the choice of particular antenna elements, they can be classified into one of the two types of configurations: *tile* or *tray*. In the tile configuration, which seems to be the most popular, active devices and antenna elements appear in one plane. The desired direction in which the radiated wave is produced is broadside direction. In the tray configuration active stages and radiating elements are supported by

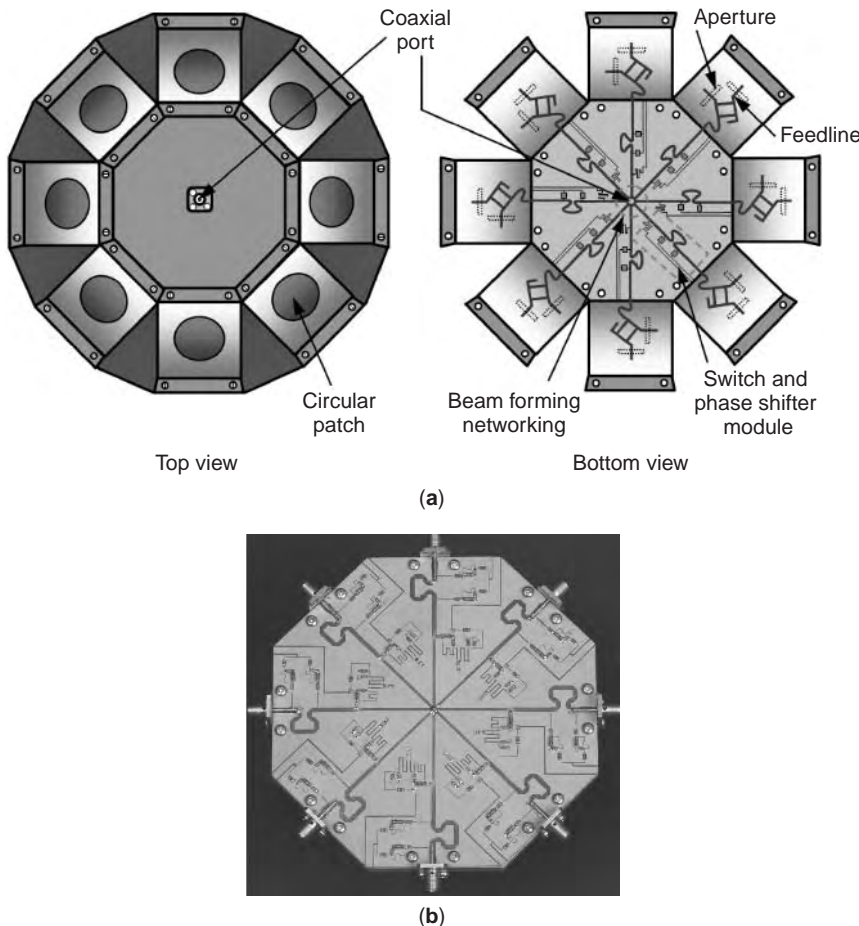

Figure 14. (a) Configuration of a switched circular array antenna (top and bottom views) showing the use of a switched radial divider/combiner; (b) photograph of a 8-2-ON radial divider combiner developed for use in a mobile satellite antenna system.

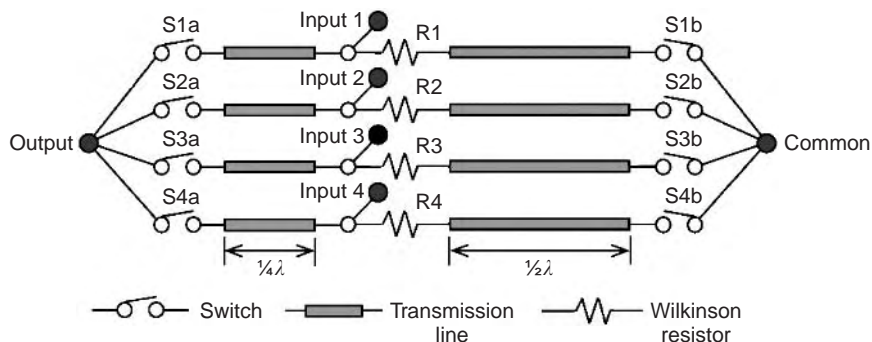

Figure 15. Configuration of a switchable power combiner divider utilizing a Wilkinson divider and a switching network.

separate ground planes that are stacked in vertical direction. In this configuration, antenna elements are chosen to radiate in an endfire direction. This configuration is also known as a *brick* configuration.

Similar to their circuit counterparts, spatial combiners can combine power due to individual oscillators or amplifiers. Thus the general principles for the combining schemes introduced earlier (in Fig. 1) also apply to this type of combiners. The difference is that now the combining has to take place in a given direction in space, which eventually can be collected by a horn antenna located in far- or near-field region of the active array. In the power-combining process dielectric lenses can also be used to focus the produced wave onto a power collecting antenna. When the active stages radiate in free space, the beam pointing at an undesired direction is considered as a loss in combining efficiency. This is a new aspect in comparison with the circuit-level combiners.

Most of the initially reported work on spatial combiners has been related to oscillators [63]. However, at subsequent stages work concerning amplifiers, frequency multipliers, detectors, mixers, and modulators were also developed [63]. Most of the more recent research work focusses on amplifiers instead of oscillators mainly because amplifiers do not need synchronization mechanism as do oscillators. Problems associated with synchronization relate mainly to the difficulties in maintaining oscillations, which are prone to electrical, thermal, and mechanical disturbances. In amplifier combiners, one (initial) source is required to be stable and to undergo an amplification process. This task is much easier to accomplish than synchronizing a multiple-source array.

Synchronizing of spatial oscillators, similar to their circuit counterparts, can be achieved using internal or external means. A preferable option is to use a high-*Q* resonator such as a spatial cavity resonator [64–68]. In contrast to a circuit-type cavity resonator, this resonator, in addition to its synchronizing role, has to enable power radiation in a desired direction. Because of this requirement, one of its mirrors usually has to be semitransparent. Signals reflected from the resonator’s walls (or mirrors) cause the self-injection of oscillators. Because of the high *Q* of the resonator, an electromagnetic field and consequently a signal having high spectral purity can be established. The resulting frequency of the spatially combined oscillators is closely related to the resonant

frequency of a field (mode) that can exist in the cavity. Note, however, that because the spatial cavity is partially enclosed, it can also support a continuous spectrum of modes. This is in contrast to the enclosed conducting cavities that exclusively support a discrete spectrum of modes. One inconvenience is that a spatial resonator occupies considerable volume, making the combiner’s design less compact. This disadvantage is of secondary importance at a millimeter frequency band due to a frequency scaling of the structure’s size. Frequency synchronization is also achieved internally through the self-signal injection in the combiner structure [69–72]. The mechanisms contributing to this phenomenon are due to mutual coupling of individual elements. This coupling can be accomplished by free-space or surface waves [69–74], resulting in the weak coupling mechanism, or via specially arranged transmission-line-type connecting circuits [75] or close spacing of active devices in grid-type combiners [76,77], which produce strong coupling between individual oscillators. If successfully accomplished, this synchronization approach makes the combiner’s design compact and low-profile. An alternative method for synchronizing individual oscillators is to inject an external high-purity signal [77,78]. An antenna can be used to illuminate the combiner array. Different mechanisms for synchronizing spatially combined oscillators are shown in Fig. 16.

The synchronization mechanism in the spatially combined oscillator array is not easy to explain. The general answer to this problem is given by Adler’s theory [79]. This theory provides general conditions for synchronization, which are related to the amplitudes and frequencies of the free-running oscillators and the injected signal. In particular, this theory provides the information on the locking (synchronization) bandwidth of the externally injected oscillator. The extension of this theory in relation to linear arrays of spatially combined oscillators has been presented [69–75]. The most recent contributions in this area are covered by Pogorzelski and colleagues [80,81].

The two parameters involved in the synchronization process are the frequency and the phase. Because of a large number of competing mechanisms whose parameters are not precisely known, the synchronization process may often be difficult to theoretically predict. The problem concerns a number of individual oscillators whose free-running frequencies may be different. These differences are due to various characteristics of individual solid-state

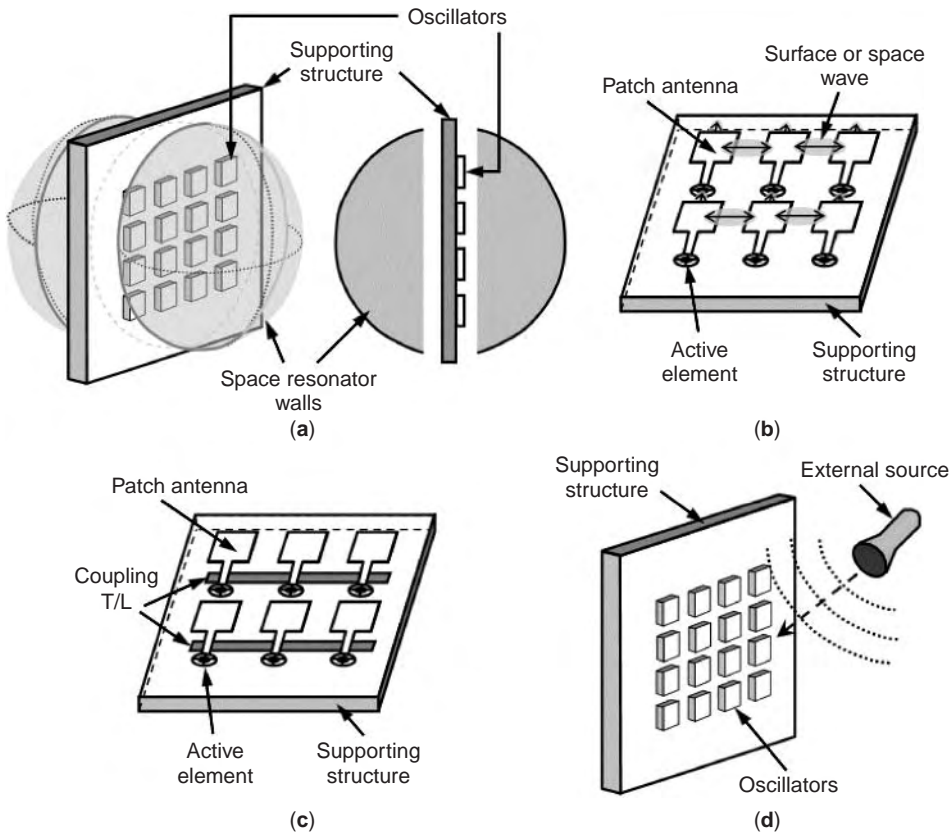

Figure 16. Methods of synchronizing spatially combined oscillators: (a) spatial resonator; (b) surface of space waves (weak coupling mechanism); (c) connecting transmission lines (strong coupling mechanism); (d) external source.

devices as well as the different environments they experience. Middle elements in the array observe similar environments. However, this is not the case for end elements in a finite-size array. Because of different environment and individual characteristics, the synchronized (in frequency) oscillators may feature different phases, which may generally have random values or can exhibit a progressive shift. Random phase differences lead to power-combining losses, as the signals, in a given direction, add out of phase. This phenomenon is similar to that observed in circuit-level combiners using N -way Wilkinson or radial combiners. On the other hand, the constructive (progressive) phase shift can result in an endfire beam launching or beam squint. These phenomena were explained in Refs. 72–74. It was shown that the phase shift could intentionally be controlled by end elements in the finite array [73,74]. It was also shown that by varying the free-running frequency of the oscillator at one end of the linear array, beam scan could be obtained. Larger scan angles could be obtained for strongly coupled arrays of elements.

The formation of the beam in the broadside direction usually improves with the use of a space resonator [71]. However, a comprehensive answer to the problem of synchronization of individual oscillators to achieve efficient directional combining is a challenging problem. Nevertheless, a number of relatively well synchronized spatial oscillators with good radiation characteristics have been demonstrated. Frequency tuning of such oscillators

using mechanical and electronic means has also been shown [63]. Features such as gradual degradation of spatially combined arrays have also been demonstrated [63].

The fundamental structures of spatially combined amplifiers are similar to those used in spatially combined oscillators. Their design often becomes less complicated than for oscillators. This is because the solid-state devices used in such amplifying arrays usually operate at their small-signal or linear amplification mode, for which characteristics are more feasible to obtain. However, coupling mechanisms due to surface or space waves and circuit connections still have to be taken into account to obtain a successful design. Reflection and transmission types of spatially combined amplifiers can be designed following a methodology similar to that already established for circuit-type combiners. The approach concerns the design of single-cell amplifiers. This design relies on knowledge of load conditions as presented by antenna elements that are connected to the input/output ports of individual amplifier modules. Assuming that various cells of the active array exhibit similar loading conditions due to the presence of other active stages, the task is to design and develop a single amplifier and replenish this design to form an array. Design of the entire combiner is facilitated when the individual cells are weakly coupled and the interactions with the remaining active cells can be neglected. This is often the practical case.

In contrast to spatially combined oscillators, the amplifier combiners require both the signal launching and combining devices (as shown in Fig. 1). These can be in the form of horn antennas or combinations of lenses and horns.

In general, these signal-launching/collecting devices require producing uniform illumination of individual amplifying cells while providing minimum insertion loss. The need for excitation uniformity is to have all the active stages equally contributing to the output port of the combiner. This condition is also required to obtain a large dynamic range of the entire amplifier combiner before saturation of individual active stages in the array can occur. Meeting the condition of uniformity of the active array and low insertion loss is a challenging task. This is explained as follows.

A uniform plane wave illuminating a planar active array is not so difficult to obtain by using a horn antenna located at a far-field zone. However, this arrangement suffers from considerable insertion losses due to spillover. In order to eliminate or reduce spillover losses, the horn should be located in the near field of the array. In order to meet the requirement of uniform amplitude illumination, a special type of horn (such as a hard horn) has to be

employed. However, because of near-field interactions between the array elements and the conducting walls a reduced operational bandwidth is usually obtained.

5.2. Classification of Spatial Power Combiners

The spatial combining structures can be classified in a variety of ways. One approach, which has already been introduced, is to group them in terms of tile and tray active-array configurations. An alternative grouping is in terms of resonant and nonresonant structures. However, as has already been indicated for circuit-level combiners, this classification may not be an easy task because estimation of the Q factor of a given structure can be difficult. A more convenient way is to classify spatial combiners in terms of their radiating elements. Using this approach, grid-type, patch (or slots), and open-ended rectangular waveguide types of power-combining structures can be introduced. These three types are shown in Fig. 17.

5.3. Grid Combiners

The grid-type combiner is one of very early structures introduced for the purpose of spatial power combining. The term *grid* was introduced as early as the 1960s [82,83] and

Figure 17. Basic configurations of spatial combiners: (a) grid structure; (b) microstrip patch antennas; (c) open-ended parallel-plate waveguides.

is related to wire antennas and selective periodic surfaces. The use of solid-state devices using grid structures was also reported at that time [84,85]. The first grid oscillators for quasioptical power combining were introduced in 1988 [86,87].

As shown in Fig. 17, the grid combiner is formed by an array of identical units that are called *cells*. Unit cells are densely spaced (approximately quarter-free-space-wavelength or less). This spacing creates a strong coupling mechanism between adjacent units. The vertical conducting strips in the grid structure act as dipole antennas. These can be fed by active elements such as diodes [86] or transistors [76,77,87]. The horizontal conducting strips or bars serve the purpose of biasing as well as heatsinking.

For the case of in-phase operation, which results in broadside radiation, the considerations of an infinite array are often reduced to that of a single cell. Assuming that the array operates in its dominant mode, as established by in-phase excitation of the identical unit cells, the structure can be regarded as an assembly of parallel rectangular waveguides with top and bottom walls formed by an electric conductor and sidewalls formed by magnetic conductors. In practice, the arrays are of finite size. However, an infinite array approach permits reasonable design rules.

As grid arrays are equivalent to densely packed dipoles, these arrays form inefficient radiators, as their equivalent radiation apertures are small, resulting in low directional gains. To obtain higher radiation efficiencies, antenna elements with a larger directional gain have to be used. This task can be accomplished with patch antennas that feature gain higher than that in dipole antennas. This statement concerns the situation when the active grid operates as an active planar array directly radiating in free space.

5.4. Spatial Combiners with Patch Antennas

One problem with grid-type combiners is that the design of the array has to be accomplished in a single step with all elements present, as there are almost no means for tuning or trimming. The available options for tuning include changing the bias conditions, use of transparent and non-transparent mirrors, and injection of an external signal. Consequently, the design has to be very predictable, as the design error can be costly. Although design of the passive grid structure can be accomplished in a very accurate and

repeatable manner, variations in performance of individual active devices may lead to design uncertainties in the active array.

Weakly coupled arrays of active patch antenna elements provide a better alternative to make the design more feasible. This is because single elements can be designed and tested before being assembled into the array. As has already been mentioned, a variety of antenna elements including different integration techniques with different types of active elements (diodes or transistors) can be used to this purpose. Figure 18 shows some typical arrangements that have already been explored.

As patch antennas and active devices take usually a larger space than do dipoles in grid arrays, special care has to be taken to minimize their dimensions to avoid undesired grating lobes or nulls in the radiation pattern, if the combiner operates as an active array radiating in free space. This requires minimization of the interelement spacing to a value smaller than one wavelength. As active devices require biasing lines and pads, which consume considerable space, this task may become a challenge. In some cases, a triangular lattice instead of the usual rectangular lattice may provide a solution to this problem [93].

Spatial oscillators or amplifiers integrated with patches can also be strongly coupled. This can be arranged using circuit connections between active elements [85]. To avoid multimode problems, resistors in transmission lines that connect adjacent active elements can be used [72].

Microstrip or patch antennas or printed dipoles in active arrays usually are arranged in the tile configuration. This is because these antennas radiate in the broadside direction. Depending on the layout, the resulting spatial power combiner can be of transmission or reflection type and the associated array is termed *transmitarray* or *reflectarray*, respectively. In the amplifier combiner, which uses the transmitarray configuration, an antenna positioned some distance from one side of the array launches an electromagnetic (EM) wave onto the active array. The array intercepts the incident wave, amplifies and phases (or delays) it by active delay circuitry, and then retransmits it. Another antenna located on the other side of the array intercepts and combines the amplified signal. For the reflectarray configuration a single antenna, for example, an orthomode horn capable of receiving dual-polarized

Figure 18. Different integration techniques used in spatially combined active array antennas: (a) Gunn or IMPATT diode beneath the patch [88,89]; (b) Gunn diode integrated with the feedline of the aperture coupled patch [90]; (c) FET transistor integrated with the patch [91,92].

signals, and appearing some distance away from one side of the array is used to both distribute and combine the signal.

5.5. Spatial Combiners Using Waveguides

Although spatial combiners with patch antennas seem to be more advantageous than grid-type combiners in terms of better integration with active elements and superior qualities for heatsinking, they still have a number of deficiencies. As with grids, they feature a limited tuning range and wide power output deviations. At millimeter-wave frequencies patch dimensions may become too small to accommodate an active device. In this case, patches can be replaced by waveguides [67], rectangular horns, or their equivalents such as notch antennas [94,95].

The use of open-ended parallel-plate waveguides for spatial power combining has been demonstrated [67,96]. In this case, each parallel-plate region consists of a number of equispaced Gunn diodes. The backshorts in the grooves are adjusted to provide the simultaneous frequency tuning. The parallel-plate guides are stacked in the vertical direction. This is equivalent to having a grooved mirror. For synchronization purposes, a spherical mirror with a waveguide aperture is positioned in the front of the grooved section, creating a Fabry–Perot resonator. The array of parallel-plate identical oscillators can be modeled in an analogous manner as the grid-type oscillator array, described earlier. For the dominant mode of operation (established by its symmetric arrangement and in-phase excitation), an infinite array of these oscillators is equivalent to an infinite array of unit cells having electric walls at the top and bottom walls and the magnetic walls on its sides. The difference with the planar grid is that this symmetry is enforced instead of being assumed. Perhaps because of this enforced mode of operation, the parallel-plate waveguide offers better stability in comparison with the planar grid.

A radial equivalent of the parallel-plate groove concept for the Fabry–Perot resonator operation has been presented [97]. In this case, instead of using parallel-plate regions, a circular groove was used to accommodate Gunn diodes to enable them to operate in an axially symmetric mode. As in the parallel-plate guide case, a ray-collimating window, which also served the purpose of frequency synchronization, was used. High combining efficiency close to 100% was obtained.

One very interesting alternative option to open-ended waveguides is a tapered-slot antenna, also known as a *notch antenna*, whose basic configuration is shown in Fig. 19.

This antenna is considered a planar equivalent of a horn antenna. Their variations include Vivaldi and antipodal antennas. Belonging to the class of traveling-type antennas, they feature an increased, often multiband, frequency operation. This is a significant advantage over the patch, which can barely obtain a 50% operational bandwidth. In contrast to the patch, which is used in the tile-type array, the notch antenna allows for the brick array construction, providing more space for inclusion of active devices. These are usually placed at the nonradiative end

Figure 19. Configuration of a standard notch antenna fed by a microstrip coupled to the slot.

of the notch antenna. Examples of spatially combined oscillators and amplifiers using notch antennas have been presented in Refs. 95 and 98. Because of their large scope of operation, they are a suitable choice for broadband electronically tunable oscillators and multiband amplifiers. The use of tapered slot antennas to build the tray-type amplifier power combiner has been demonstrated [99]. The configuration of this amplifier is shown in Fig. 20.

It is worthwhile to note that tapered-slot antennas are not the only types of antennas that can be utilized in the tray-type power combiners. Other types of antenna elements that can be used in the tray-type power combiners are presented in Fig. 21.

Figure 21a shows quasi-Yagi antennas [100] as elements of tray power combiner. These elements feature an approximately 1-octave return loss bandwidth enabling a similar bandwidth for an entire combiner. Figure 21b shows a hybrid tray–tile combiner [101]. In this case, active stages are assembled using the tray configuration, while the coupling to pyramidal horns is achieved using passive patch arrays arranged in a tile configuration. Figure 21c shows a hybrid slab-beam combiner, with amplifiers positioned between focusing lenses [102].

6. ANALYSIS METHODS FOR POWER COMBINERS/DIVIDERS

Knowledge of equivalent-circuit parameters of power combiners/dividers is of paramount importance in their design process. This is often a nontrivial task, as it requires solving a three-dimensional electromagnetic field problem. In the past, many simplified methods were developed to tackle these complicated problems. Using these simplified methods, ample design rules for varieties of combiners/dividers were obtained. This situation has changed dramatically in the 1990s with a number of commercial, general-purpose electromagnetic (EM) field solvers being developed. Examples of commercial EM field software packages include IE3D of Zeland Software [103], Ansoft Ensemble [104], and High Frequency Structure Simulator [105], Agilent ADS [106], and CST Microwave Studio [107], to name just a few. In general, EM field solvers are based on integral or finite difference methods, in frequency or time do-

Figure 20. Configuration of a tray amplifier combiner using tapered-slot antennas.

main, and are capable of accurately analyzing arbitrarily shaped passive structures. Some of these software packages are also able to simultaneously analyze assemblies of passive and active devices in real time. One problem with the general-purpose EM field solvers is that they require large computing resources and long computational times. This may be inconvenient in cases when combining structures have to be optimized. This is because the optimization process usually requires much iteration time. Because of these shortcomings, it is advantageous to have alternative approximate ways for the analysis of combiners/dividers. In many cases, these methods can provide a relatively good approximation to the optimal design using less computing resources than the general-purpose commercial software. Nevertheless, the design process can be finalized using more accurate general-purpose software.

The following sections present examples of approximate methods for the analysis of selected power-combining/dividing structures, beginning with one-dimensional transmission-line-type combiners and then two- and three-dimensional structures.

6.1. Analysis of Transmission-Line-Type Combiners

As has been demonstrated earlier, a number of basic power-combining/dividing structures can be built using sections of transmission lines. For example, the Wilkinson power combiner/divider, 3-dB branchline coupler, and Gysel power combiner/divider can be built using microstrip or stripline transmission lines. The design equations for such structures using the transmission-line approach are straightforward and can be found in standard microwave books [58,108,109]; thus they are not repeated here. In practice, these simple design equations are not accurate enough as they neglect discontinuities in the form of tee junctions, mitered bends, and impedance steps, which real combining structures incorporate. To obtain a more accurate design, these discontinuities have to be taken into

account. Modern-day commercial software [103–107,110] not only provides this solution but also offers a necessary optimization before etching of the circuit takes place. This software can also take into account the presence of active devices in these structures [106].

6.2. Analysis of Planar Two-Dimensional Power-Combining Structures

Many planar power combiners cannot be represented by simple connections of transmission lines. Examples include microstrip planar circular disk combiners [45], sectorial dividers [54,55], and planar dividers with holes [56,57]. Also included in this list are combiners exploiting microstrip disk and annular ring-type couplers [111–113].

Analysis of these structures can be handled by a number of commercial software packages, which have been developed for the purpose of analyzing arbitrarily shaped 2- and 2.5D multilayer microstrip configurations. One example of such software is presented in Ref. 104. Full-wave analysis methods in real or spectral domains in association with the moment method can be employed to accomplish this task. The use of these software packages may lead to time-consuming computations due to their general-purpose nature.

For single-layer microstrip structures, an alternative boundary-element method can be used [112–114]. In this method, an arbitrarily shaped microstrip structure is modeled as a cavity, with top and bottom plates formed by a perfect electric conductor and their sidewalls formed by a perfect magnetic conductor. The electric field at the cavity's wall is assumed to be uniform with height but varying along the perimeter. In the combiner/divider, this cavity can incorporate a number of microstrip and coaxial ports. For coaxial ports, equivalent strips can be introduced to make the analysis approach uniform. To determine the equivalent circuit parameters, one of the ports is excited while the remaining ones are left open-circuited. At the excitation port the electric current is assumed to be

Figure 21. (a) Stacked-tray combiner including planar quasi-Yagi antennas; (b) waveguide-based aperture-coupled patch amplifier array; (c) hybrid slab-beam combiner.

known. The unknown is the electric field along the structure's perimeter, which has to be determined. As can be seen, using the magnetic wall model, a 2D problem is replaced by a 1D problem. This is in contrast to the usual full-wave analysis method in which the distribution of electric currents on an arbitrarily shaped conducting surface has to be determined to obtain equivalent parameters of planar single-layer circuits.

For an irregularly shaped microstrip structure, the wall surface is divided into a number of sections, each with a constant value of the electric field. Using field equations for a parallel-plate guide, a set of linear algebraic equations is generated that can be solved using standard methods. Having determined the electric field

distribution for the case of excitation of each single section of the boundary, an equivalent impedance matrix for the N port formed by N sections of the perimeter is determined [113,114]. For some regular microstrip structures, such as a circular disk or an annular ring, an alternative method of determining the impedance matrix of the equivalent N port can be employed. This time, the field in the cavity is expressed in terms of radial waves. The problem again reduces to a 1D problem, in which field expansion coefficients are determined. This alternative approach has been demonstrated in Refs. 45, 46, and 113.

One deficiency of the magnetic wall approach is the negligence of radiation. This leads to erroneous results at frequency points at which the structure becomes resonant

and radiating. Nevertheless, this approach generates reasonably accurate results for equivalent circuit parameters for many planar structures. The advantage of this approach is that these parameters are determined in a reasonably short time using an ordinary personal computer (PC), unlike general-purpose commercial software packages where the computational time becomes longer even using more powerful workstations.

6.3. Analysis of Waveguide and Cavity-Type Combiners

As has been shown in the preceding sections, many circuit-type power combining/dividing structures are formed by parallel-plate waveguides with coaxial probes or cylindrical posts perpendicular to the plates. Rectangular cavity, cylindrical, and radial cavities belong in this category.

Equivalent-circuit parameters of these structures can be derived assuming that rectangular waveguide entries, coaxial entries, or gaps in the posts form input/output ports of these structures. The usual assumption about these ports is that they support only single-mode operation. This includes the TEM mode for the coaxial line, the TE_{10} mode for the rectangular waveguide, and the TEM mode, having uniform dependence with height and axial symmetry, in the cylindrical gap in the post. Equivalent circuits of these structures, as viewed from their ports, can be determined by solving an electromagnetic field problem in which single ports are excited while the remaining ports are terminated. Depending on the chosen type of equivalent (admittance, impedance, or scattering matrix) parameters to be determined, a short circuit, an open circuit, or a match load is used as a termination. The choice depends on the configuration of the analyzed structure.

A major difficulty in finding a solution to this problem is due to arbitrarily positioned cylindrical posts and coaxial entries with respect to the walls of a rectangular or a cylindrical cavity, which do not allow for simple approximations. The analysis of these structures can be handled by a number of commercial software packages that have been developed for the purpose of analysis of arbitrarily shaped 3D passive structures such as the HFSS [105]. This approach is usually time-consuming, especially when the performance of these structures has to be optimized. This is why it is desirable to have approximate fast analyses. For this purpose, the problem can be simplified by assuming that the field in an adjacent cylindrical region containing a post or a coaxial probe (including the coaxial aperture) is axially symmetric. By making this assumption, the field in these cylindrical regions can be represented in terms of radial TM modes having only vertical component of the electric field and the azimuthal component of the magnetic field. These fields can generally vary in the vertical direction. The fields outside the cylindrical regions containing the probes or posts can be expressed as sums of waveguide modes. Special accelerating routines can be applied to achieve their fast convergence [115–117]. For a given excitation, the field within the combiner can be determined using, for example, a field-matching method. Using this approach, a number of elegant solutions to single or multiple probes in rectangular or radial guide have been presented in the microwave literature. The solutions

for rectangular waveguides include single and double coaxial probe [115,116], cylindrical posts and equivalent strip [117,118], and single and dual disk-ended probes [119]. Note that the problems of coaxially driven probes can also be solved in an alternative manner by replacing coaxial entries with equivalent gaps in post [119]. Excellent insights into the operation of a variety of coaxial-to-waveguide transitions with practical solutions have been presented in Ref. 120.

As in rectangular waveguide cavities, electromagnetic problems involving radial cavities with various types of posts and probes can be solved. Field-matching solutions for radial cavities with different types of probes were demonstrated in Refs. 34 and 38.

Radial or coaxial cavities with rectangular waveguide ports connected in their E or H plane were modeled in Refs. 121–123.

On the described basis of the analyses above, a number of computer programs have been developed. These programs can be run on any PC. They are able to determine equivalent-circuit parameters for a rectangular or radial cavity combiner with a moderate (<20) number of coaxial or waveguide ports at a single frequency point in a matter of seconds of central processing unit (CPU) time assuming at least a 100-MHz clock. Because of this feature, these programs are very useful in the analysis and design of many power-combining structures.

The developed analyses of parallel-plate type, rectangular, and radial cavity combiners with coaxial probes and cylindrical posts can also be useful in the design of conical and hemispherical cavity combiners. In this case, the design is divided into separate designs of central and peripheral probes. The design of the central probe is similar to the design of a good transition between a coaxial line and an infinite radial guide. The design of peripheral probes is equivalent to the design of probes in a rectangular waveguide with electric bottom and top walls and magnetic sidewalls. This design strategy was presented in Ref. 123.

6.4. Analysis of Spatial-Type Power Combining Structures

Similarly as for a circuit-type combiner, in order to obtain a predictable design of a space-type combiner it is important to know its equivalent circuit parameters as observed from the terminals of active devices. For example, knowledge of these parameters is necessary to obtain suitable impedance conditions for proper operation of active devices. Since some forms of space-level combiners represent active-array antennas, obtaining their radiation pattern through a suitable analysis is also of great importance. According to the classification presented in the preceding section, grids, arrays of patches, or assembly of open-ended waveguides have to be analyzed for characterizing these structures. Determining equivalent circuit parameters for such arrays is not a trivial task, usually due to a large number of elements, that require large computing resources. To ease the complexity of the problem, approximate and simplifying analyses can be applied to this purpose. In particular, these analyses may exploit symmetries

of power-combining structures to ease computational difficulties.

For large arrays of identical radiating elements with perfect symmetry in two planes, the analysis can often be confined to the unit cell problem. For example, this concept is explored in planar grid combiners, which is explained as follows. By assuming that the grid is infinite and active devices are matched and synchronized in magnitude, frequency, and phase, an identical environment is experienced by each one of these elements. Consequently, the analysis reduces to a single element cell. The unit cell often resembles the post or strip waveguide diode mounting structure that was initially analyzed in the 1970s [118]. The difference with the present case is that a perfect magnetic conductor, instead of an electric conductor, forms sidewalls of the equivalent rectangular waveguide. Using this equivalent-waveguide approach, grids including straight, bowtie, and double-vee strips can be analyzed [124,125].

For finite arrays, this approximate analysis can result in a relatively accurate equivalent circuit for elements in the center section of the array. This is because the elements in this section experience an environment similar to that in an infinite array. This is not the case for the end-array elements.

The absence of identical environment in a finite array makes the in-phase, unit cell analysis less accurate with respect to the array's radiation pattern. Because of the different neighboring environments, active elements may be out of phase. This results in effective combined power losses. Additionally, the progressive phase shift between adjacent elements that can unintentionally be established may result in an endfire operation of the array. To cause the elements to radiate in the broadside direction, the elements, particularly at the array's end, may require some means of tuning.

This example shows that for a finite-size grid array a strict EM field analysis is required to predict its real performance. This task can be accomplished with present-day software for the analysis of multilayer microstrip patch antennas such as those described in Refs. 104 and 105. This statement also applies to spatial combiners using patch antennas in so-called strong-coupled configurations.

For weakly coupled arrays of patches, the analysis of a single element may be sufficient for an ample design of the array. This is because impedance characteristics of the patch are only slightly affected by their placement in an array. However, the prediction of radiation performances of both weakly and strongly coupled patch arrays may still require a strict electromagnetic field analysis. For finite arrays, commercial software packages such as those described in Refs. 104 and 105 may be the best answer.

Spatial combiners with open-ended rectangular waveguides can be handled by approximate analyses, which have already been described for circuit-type rectangular waveguide combiners [123]. One extension, which is required in the present application, is to include open-space conditions at the apertures of these waveguides. An alternative way is to use commercial software packages, that are able to analyze three-dimensional open-ended waveguide diode mounting structures. The required tasks are

within the reach of the present day commercial packages using powerful workstations [126].

In order to accelerate the solution to the electromagnetic characterization of power-combining structures, it is advantageous to analytically preprocess a given problem or divide into smaller-scale problems that can be solved separately. The solution to the original problem is then found by connecting solutions of these smaller-scale electromagnetic problems into one solution. For example, spatial power combiners, including active stages and signal launching and collecting antennas, such as horn antennas, can be viewed as a cascade of waveguiding structures. These structures can be divided into sections, and each section can be modeled as a waveguide using a multimode approach. Such an approach has been applied to model the performance of conventional and special types of horn antennas and waveguide sections carrying the active stages of a power combiner. Examples of work in this field include Refs. 127 and 128.

7. APPLICATIONS

The preceding sections discussed the classification and analysis methods of various power-combining/dividing structures. This section discusses the application of circuit-level and space-level combiners to build powerful solid-state sources. Much of this discussion is concerned with the circuit-level power combining structures. The discussion concludes with examples of the most impressive circuit- and space-level combiners.

7.1. Solid-State Power Amplifiers (SSPAs) Using Circuit-Level Combiners

As can be gathered from the available literature concerning circuit-level power-combining capability of solid-state devices, the early structures dealt predominantly with two-terminal devices such as the Gunn or IMPATT diodes, whose outputs were combined to produce a more powerful source [2,3]. Waveguide cavities were used mainly as combining structures. The reason was that the early stage solid-state power combiners operated as oscillators. In this case, high- Q waveguide cavities were used for synchronization purposes.

Later developments in the field had seen the emergence of powerful three-terminal solid-state devices: transistors. These devices not only were able to produce a higher output level but also had higher DC-to-RF conversion efficiency, which was an extra advantage over their two-terminal counterparts. While the Gunn diode could achieve a few percent and the IMPATT diode could reach several percent, the transistor was able to achieve a 20–50%, DC-to-RF conversion rate.

As a three-terminal device, the transistor is better suited to planar rather than waveguide technology. Because of its likely broadband operation, the amplifier-mode rather than the oscillator mode of operation is preferred. Using the planar approach, cascaded amplifiers with tens of watts of output power can be built. However, even at this power level, these amplifiers require a good heatsink arrangement. This in turn requires a suitable substrate

with good thermal properties. Proper mounting of transistors including good-quality heatsinks is also necessary.

The cascade configuration has one advantage in that a large amplifying factor can be achieved using even a moderate number of amplifying stages. Its deficiency is that if one of the intermediate transistors fails, the entire amplifier may also record the failure. Thus this configuration does not exhibit graceful degradation. For to this reason, cascaded amplifiers are used in preamplification stages. A resilient strategy is required in the high-power stages to avoid catastrophic failure. Suitable power-combining techniques can be used to achieve this goal.

If one decides to continue with the planar technology to build the next amplifying stages, hybrid combiners are a good choice [39,130]. At the early stage of amplification process, two-way Wilkinson combiners can be used to build a corporate combining network [39]. This usually involves up to $N = 4$ individual modules. The configuration of Fig. 1b is employed in this process. A corporate divider splits the input signal into N ways. These in turn are input to N amplifying modules. A corporate combiner, identical to the divider, sums outputs of these amplifiers. As the next-size corporate combiner/divider handles $2^3 = 8$ amplifiers, it is often avoided because of its considerable size. It should be mentioned that some designers prefer to use 3-dB quadrature couplers instead of Wilkinson's dividers to build a corporate network [130] at this amplification stage.

Following this amplifying stage, the use of the corporate network faces some problems. This is due to the parasitics of isolating resistors [39] and general power losses that corporate networks incur. Dissipation of a considerable level of power in isolating resistors creates extra problems as well; thus, a preferable option is to share the failure between larger numbers of dissipating units. A waveguide radial divider/combiner and its like (hemispherical and conical combiners) provides a suitable solution [39,130]. The advantages of this device are a relatively large operational bandwidth (almost 1 octave), low insertion losses, good amplitude and phase balance as well as good isolation, which generally increase with the number of ports. Fine examples of radial divider/combiner employed in the last stages of solid-state transmitters have been demonstrated [33,39–42]. A 110-way radial divider/combiner was used in a 100-kW pulse L-band transmitter [39]. A 50-way radial divider/combiner was applied in a 22-kW pulse S-band transmitter [130]. A 20-way hemispherical divider/combiner was used in 60- and 80-Watt CW (continuous-wave) Ku-band SSPAs [40,41]. Similarly, a 30-way radial divider/combiner was employed in a 26-W CW X-band SSPA [42]. The design of a 60-GHz, 16-way power divider/combiner was presented in Ref. 33.

7.2. Solid-State Sources Using Space-Level Combiners

In Section 7.1 we showed that circuit-level combiners can offer the design of very reliable high-level power solid-state amplifiers at microwave frequencies and the lower end of millimeter waves. However, the extension of this type of combiner to upper millimeter-wave frequencies faces some difficulties. This is due to the tight manufac-

turing tolerances required at these frequency bands. For example, miniature coaxial probes are difficult to manufacture in some waveguide-type combiners. Other problems are associated with increased conductive and dielectric losses. For example, the quality factor for a resonant conductor cavity becomes low, making it less attractive for oscillator synchronization purposes.

The requirement for low conductive and dielectric losses demands that a new generation of millimeter-wave combiners should to a greater extent exploit a low-loss combining medium such as free space. At this frequency range, transversal dimensions of combining structures, in terms of multiples of wavelength, do not lead to a large physical size as is the case for their low-frequency counterparts. This means that a planar approach to building spatial combiners becomes a very feasible option. To reduce transversal dimensions, cascades of planar active stages can be explored [131]. However, at this stage of research, this solution has not found much success because of the reduced combining efficiency [131].

As mentioned earlier in this article, a lot of early work on spatial power combiners was concerned with oscillators. However, most of the more recent investigations concentrate on amplifiers. The reason is that amplifiers offer a larger instantaneous operational bandwidth. In addition, the amplifier design seems to be less critical, as compared to the oscillator, as knowledge of large-signal parameters of the solid-state device may be not necessary. The required small-signal parameters are easier to obtain from measurements or the manufacturer's data, making the design more feasible.

Although a large number of space-level combiners have been introduced, as summarized in three monographs [63,132,133], some of them have to be critically viewed. This is because the space-level combining concept is still in the exploration stage. For example, many of the structures presented are only low-cost prototypes. Often, they are formed by small-size arrays operating at the microwave frequency band.

Contrary to some expectations, spatial combiners may suffer from problems similar to those of their circuit-type counterparts. For example, in spatial resonators solid-state devices have to be properly spaced. Otherwise, a sudden drop in the combining efficiency is observed [65]. Patch oscillators with a strong coupling mechanism may suffer from the multimoding problem unless special configurations including resistive elements are used [75]. In addition, due to some undesired radiation mechanisms, spatial combiners face problems that have not been known for circuit-level combiners. For example, a random phase distribution in weakly or strongly coupled oscillators may be responsible for significant reduction in power-combining efficiency, while progressive phase shift can lead to an undesired beam squint [71,73–75] that effectively is regarded as power loss in the broadside direction.

The most impressive examples of spatial combiners, that have been accomplished so far concern structures with the largest number of passive or active elements. In this case, grid structures have a leading role. Examples include 100-element MESFET and HBT amplifiers or oscillators [77,134,135], a 464 element pin diode switch

[136], and a 4800 Schottky diode transmittance controller [136], to name only a few. Another example utilizing a large number of active stages involves a 137-element X-band amplifier reflectarray [137]. Other achievements in the field of space-level combining can be grouped in terms of the level of combined power and the frequency range in which a given level of power was reached. These include a 120-W X-band amplifier using the tray configuration of tapered-slot antennas [99], a 25-W Ka-band 45-element quasi-optical amplifier array using the tile configuration with through-plate coaxial transition [138] and a 5-W 37-GHz monolithic grid amplifier [139]. A 36-W V-band 272-element tray-type power combiner utilizing waveguide horns with focusing lenses, as described in Ref. 140, is a very impressive example with regard to the highest frequency of operation that has been achieved so far for space-level combiners.

Many of the above mentioned space-level combiners have been designed and developed with a considerable involvement of commercial companies. The interest and involvement of such institutions clearly indicates that the space-level power combining is not a purely academic research, but has a great potential to deliver new products to communication industries.

University of Pavia

The essential task of sensors, detectors, and transducers is to convert the characteristics of the physical world (e.g., light, sound, pressure, displacement, temperature) into electrical signals, which are then suitably processed for the required application. Before being processed, these electrical signals must be conditioned by appropriate electronic circuitry.

Despite the improvements carried out in recent years, all sensors have a common characteristic: a weak signal delivered and a limiting noise level. Therefore, the front end of the sensor-associated electronic system must be an amplifier, usually called a *preamplifier*. Two main requirements must be satisfied for preamplifiers. First, they must raise the signal level adequately over a certain frequency range (linear amplification is very often requested). Second, they must contribute only a minimum amount of additional noise. Depending on the specific application, other features such as high linearity, large output swing, wide-band operation, and large output drive capability may be needed, but these requirements do not differ substantially from those of normal amplifiers. What is specifically important for preamplifiers is to optimize their noise performance. This is because, although the noise performance of a generic electronic system [which is made up of a preamplifier, signal conditioning and processing circuitry, and output interface (Fig. 1)] depends on the noise behavior of all these subsystems, in practice, in a well-designed system the noise performance is entirely dominated by the noise characteristics of the front-end circuit (preamplifier). This is true if the preamplifier gain is sufficiently high to allow the subsequent processing to be performed with negligible degradation in the signal-to-noise ratio. Hence, low-noise system design is focused mainly on low-noise preamplifier design.

The essential task of sensors, detectors, and transducers is to convert the characteristics of the physical world (e.g., light, sound, pressure, displacement, temperature) into electrical signals, which are then suitably processed for the required application. Before being processed, these electrical signals must be conditioned by appropriate electronic circuitry.

Despite the improvements carried out in recent years, all sensors have a common characteristic: a weak signal delivered and a limiting noise level. Therefore, the front end of the sensor-associated electronic system must be an amplifier, usually called a *preamplifier*. Two main requirements must be satisfied for preamplifiers. First, they must raise the signal level adequately over a certain frequency range (linear amplification is very often requested). Second, they must contribute only a minimum amount of additional noise. Depending on the specific application, other features such as high linearity, large output swing, wide-band operation, and large output drive capability may be needed, but these requirements do not differ substantially from those of normal amplifiers. What is specifically important for preamplifiers is to optimize their noise performance. This is because, although the noise performance of a generic electronic system [which is made up of a preamplifier, signal conditioning and processing circuitry, and output interface (Fig. 1)] depends on the noise behavior of all these subsystems, in practice, in a well-designed system the noise performance is entirely dominated by the noise characteristics of the front-end circuit (preamplifier). This is true if the preamplifier gain is sufficiently high to allow the subsequent processing to be performed with negligible degradation in the signal-to-noise ratio. Hence, low-noise system design is focused mainly on low-noise preamplifier design.

1. BASIC CONCEPTS RELATED TO PREAMPLIFIERS

Some basic concepts useful in analyzing preamplifiers from the noise standpoint, namely, equivalent input noise,

noise factor and noise figure, and noise matching, are introduced in this section.

1.1. Equivalent Input Noise

In the characterization of many nonideal electrical quantities, which are generated by a plurality of sources or mechanisms within a circuit, it is a common practice to replace all by one equivalent input source. This equivalent source has the same effect at the circuit output as the global effect of all the individual internal sources and, therefore, the circuit can be considered free of such mechanisms [1], which greatly simplifies circuit analysis and design. Offset voltage and noise are representative examples of what has been discussed.

A network, such as an amplifier, is made up of many components. Any electrical component has its own internal mechanisms of noise generation. As a result, the output of any real amplifier exhibits noise, which depends on factors such as internal noise sources, circuit topology, gain, and measurement bandwidth. The amplifier’s output noise power spectral density can be found by multiplying the noise power spectral density of each source by the squared module of its particular transfer function and then superposing all the individual noise contributions. This procedure must be followed for any frequency of interest.

Rather than by the noise measured at its output, an amplifier is best characterized by the minimum signal applied to its input, which is still detectable at the output of the signal processor. This signal may be conveniently regarded as equivalent to a virtual noise source located at the input. This is known as *equivalent input noise* or *input-referred noise* of the amplifier, and allows one to easily compare the total noise generated by the amplifier with the input signal. From the considerations above, the equivalent input noise power of an amplifier coincides with the output noise power divided by the squared module of the amplifier gain [2].

A similar idea is applied to the noise model of a generic sensor. Starting from its small-signal equivalent circuit, including all impedances and current/voltage signal generators, a noise equivalent circuit is derived by including the noise sources associated with resistances (or, better, with the real parts of impedances) and signal generators. From this equivalent noise circuit, an expression for small-signal gain and equivalent input noise is derived.

Figure 2a represents the equivalent noise circuit of a generic system consisting of a sensor and a preamplifier. The sensor is described by its signal voltage generator V_s , its internal series impedance Z_s , and a noise voltage generator $V_{n,s}$, which includes the contributions by all sensor noise sources. The preamplifier, having voltage gain A_v and input impedance Z_i , is represented from the noise point of view, by a noise voltage generator $V_{n,a}$ and a noise current generator $I_{n,a}$ placed in series and in parallel, respectively, with the input port. These noise generators, whose magnitude is specified in units of $V/(\text{Hz})^{1/2}$ and $A/(\text{Hz})^{1/2}$, respectively, are in general frequency-dependent, and are very often represented in terms of their mean-square voltage, $V_{n,a}^2 (V^2/\text{Hz})$, and mean-square current, $I_{n,a}^2 (A^2/\text{Hz})$. The two generators can be statistically correlated or not, depending on the specific case. For example, they are practically 100% correlated and totally uncorrelated, respectively, when modeling a metal oxide semiconductor (MOS) field-effect transistor or a bipolar junction transistor (BJT) in the midfrequency range [3]. When combining the effects of different noise sources, one must remember that noise is a random signal. Therefore, when summing two noise variables A_n and B_n , the result is $C_n^2 = A_n^2 + B_n^2 + 2 \text{Re}\{A_n^* B_n\}$, where $\text{Re}\{A_n^* B_n\}$ represents the real part of the cross-correlation spectrum of A_n and B_n . For ease of use, the correlation effect between two variables is very often expressed by using the so-called correlation coefficient γ , which is a normalized factor having a value between 0 (no correlation) and 1 (100% correlation). Using this approach, one has $C_n^2 = A_n^2 + B_n^2 + 2\gamma A_n B_n$.

Although the number of noise sources in Fig. 2a has been reduced to three, further simplifications are usually carried out to represent them just by one equivalent input noise voltage generator, $V_{n,eq}$, at the signal source location [2]. To derive an expression for the equivalent input noise, the total noise at the amplifier output, $V_{n,o}$, must be first derived. Assuming $V_{n,a}$ and $I_{n,a}$ to be statistically uncorrelated, one obtains:

$$V_{n,o}^2 = (V_{n,a}^2 + V_{n,s}^2) \cdot |A_v|^2 \cdot \left| \frac{Z_i}{Z_i + Z_s} \right|^2 + I_{n,a}^2 \cdot |A_v|^2 \cdot \left| \frac{Z_i \cdot Z_s}{Z_i + Z_s} \right|^2 \tag{1}$$

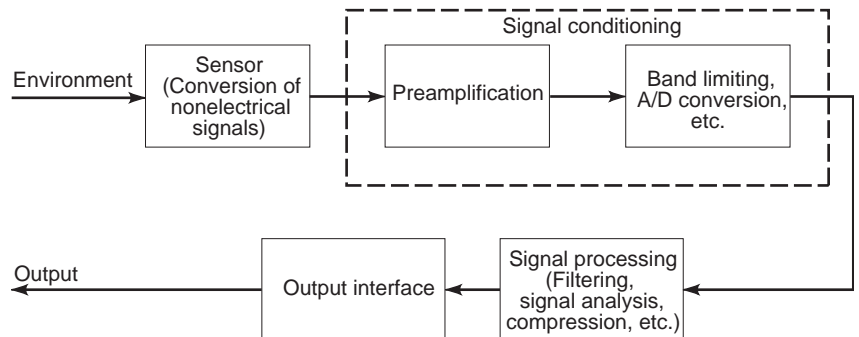

Figure 1. The electronic chain associated with a sensor includes a preamplifier, signal conditioning and processing circuitry, and output interface. The stages cascaded to the preamplifier may provide additional gain.

The system gain from the signal source location is

$$A'_v = A_v \frac{Z_i}{Z_i + Z_s} \tag{2}$$

Therefore, the equivalent input noise voltage, $V_{n,eq}$, which is equal to the total output noise divided by the squared module of the system gain, is given by

$$V_{n,eq}^2 = \frac{V_{n,o}^2}{|A'_v|^2} = V_{n,a}^2 + V_{n,s}^2 + I_{n,a}^2 \cdot |Z_s|^2 \tag{3}$$

After combining and reflecting all noise sources to the signal source location, the resulting equivalent circuit is as shown in Fig. 2b. The noise source $V_{n,eq}$ will generate exactly the output noise given by Eq. (1).

$V_{n,eq}^2$ can also be obtained from Fig. 2a by disconnecting the noiseless amplifier and evaluating the voltage across the noise generator $I_{n,a}$, which results Eq. (3). This operation corresponds to finding the equivalent dipole connected at the input of the noiseless amplifier (Thevenin theorem). In practice, the dipole in Fig. 2a constituted by

V_s , $V_{n,s}$, Z_s , $V_{n,a}$, and $I_{n,a}$, is exactly equivalent to the dipole in Fig. 2b constituted by V_s , $V_{n,eq}$, and Z_s .

Observe that, as indicated in Eq. (3), the equivalent input voltage noise does not depend on the amplifier gain and input impedance, although the effect of any noise generated at Z_i is implicit in $I_{n,a}$. However, $V_{n,eq}$ depends on the impedance of the signal source, as well as on the noise generated by the sensor (hence, the design approach for noise optimization will also depend on the kind of sensor impedance, that is resistive, capacitive, inductive, as will be shown below). Output noise will obviously depend on both the gain and the input impedance of the amplifier.

Following similar steps, an equivalent noise circuit of the system can also be derived in terms of an equivalent input noise current generator $I_{n,eq}$ (Fig. 2c)

$$I_{n,eq}^2 = I_{n,a}^2 + I_{n,s}^2 + \frac{V_{n,a}^2}{|Z_s|^2} \tag{4}$$

where $I_{n,s}^2 = V_{n,s}^2/|Z_s|^2$.

Either equivalent noise circuit can be used; however, it is generally more appropriate to characterize the system

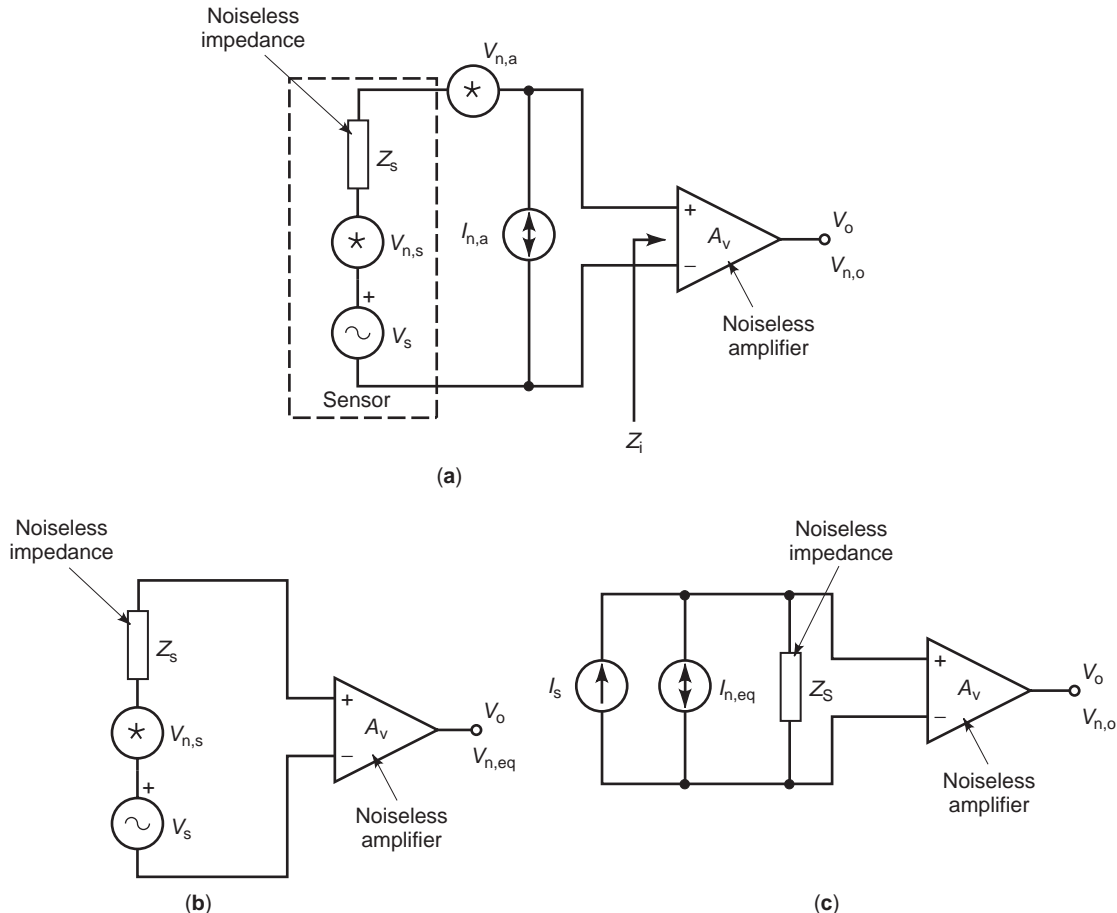

Figure 2. A generic system noise model (a) can be reduced to an equivalent circuit with an equivalent input noise voltage generator (b), or to an equivalent circuit with an equivalent input noise current generator (c).

noise in the same terms as the source signal (voltage or current).

If the amplifier noise voltage and current generators $V_{n,a}$ and $I_{n,a}$ are not statistically independent, as occurs when they contain some components arising from a common phenomenon, the scheme of Fig. 2b must include another noise voltage generator in series with $V_{n,eq}$. The power spectral density of this generator is a function of their correlation coefficient: $V_n^2 = 2\gamma|V_{n,a}I_{n,a}Z_s|$. In the same way, an additional noise current generator $I_n^2 = 2\gamma|V_{n,a}I_{n,a}/Z_s|$ has to be placed in parallel with $I_{n,eq}$ in the scheme of Fig. 2c.

1.2. Equivalent Input Noise in Cascaded Stages

Consider the network in Fig. 3, which consists of n cascaded stages having respective voltage gains $A_{v1}, A_{v2}, \dots, A_{vn}$ and equivalent input noise voltage sources $V_{n,eq1}, V_{n,eq2}, \dots, V_{n,eqn}$. It should be pointed out that a “stage” in this figure can be a complex circuit or even a single active device. Moreover, for each stage i ($i = 1, 2, \dots, n$), A_{vi} and $V_{n,eqi}$ are evaluated taking the value of input and output impedances into account. Assuming that noise sources of different stages are uncorrelated, as is the usual case, the total output noise power is

$$V_{n,o}^2 = V_{n,eq1}^2 \cdot |A_{v1}|^2 \cdot |A_{v2}|^2 \cdot \dots \cdot |A_{vn}|^2 + V_{n,eq2}^2 \cdot |A_{v2}|^2 \cdot \dots \cdot |A_{vn}|^2 + \dots + V_{n,eqn}^2 \cdot |A_{vn}|^2 \tag{5}$$

which corresponds to an equivalent input noise for the whole network equal to

$$V_{n,eq}^2 = \frac{V_{n,o}^2}{|A_{v1}|^2 \cdot |A_{v2}|^2 \cdot \dots \cdot |A_{vn}|^2} = V_{n,eq1}^2 + \frac{V_{n,eq2}^2}{|A_{v1}|^2} + \dots + \frac{V_{n,eqn}^2}{|A_{v1}|^2 \cdot |A_{v2}|^2 \cdot \dots \cdot |A_{vn-1}|^2} \tag{6}$$

From this equation, one concludes that the noise behavior of the whole network can be dominated by the first stage, provided that its voltage gain is large enough. In this case, in fact, noise contributions by the following stages can be neglected. The same conclusion also holds when considering current noise, obviously referring to the current gain rather than to the voltage gain of the stages.

1.3. Noise Factor and Noise Figure

Noise factor F is one of the most traditional parameters used to characterize the noise performance of an amplifier. It is defined as the ratio of the total available output noise power per unit bandwidth to the portion of that output noise power caused by the noise associated with the sensor, measured at the standard temperature of 290 K [4]. To emphasize that this parameter is a point function of frequency, the term “spot noise factor” may be used. Since the noise factor is a power ratio, it can be expressed in decibels. In this case, the ratio is referred to as noise figure (NF). Thus, taking Fig. 2 and Eq. (3) into account, we obtain

$$NF = 10 \cdot \log \frac{V_{n,o}^2}{V_{n,s}^2 \cdot |A_v'|^2} = 10 \cdot \log \frac{V_{n,eq}^2}{V_{n,s}^2} \tag{7}$$

An alternative expression for the noise figure can be derived from Eq. (7), obtaining

$$NF = 10 \cdot \log \frac{V_s^2 V_{n,o}^2}{V_{n,s}^2 \cdot (V_s^2 \cdot |A_v'|^2)} = 10 \cdot \log \frac{(V_s^2 / V_{n,s}^2)}{(V_o^2 / V_{n,o}^2)} = 10 \cdot \log \frac{(SNR)_i}{(SNR)_o} \tag{8}$$

where $(SNR)_i$ is the signal-to-noise ratio (SNR) available at the sensor output, and $(SNR)_o$ is the SNR at the output of the real (i.e., noisy) amplifier. This result indicates that NF accounts for the signal-to-noise power degradation caused by the preamplifier. Thus, for an ideal amplifier, which does not add any noise, the output signal-to-noise ratio is kept equal to its input counterpart, and $NF = 0$ dB. Alternatively, an NF of 3 dB means that half the output noise power is due to the amplifier.

As will be shown later, NF by itself is not always an appropriate figure of merit to characterize the noise performance of an amplifier. As stated above, NF is valid only to indicate how much noise is added by a preamplifier to a given input source resistance, and is therefore useful to compare noise behavior of different preamplifiers with a determined signal source. However, it is not a useful tool for predicting noise performance with an arbitrary source.

Figure 3. Schematics for evaluating the noise performance of an n -stage voltage amplifier.

1.4. Noise Matching

Let us now consider the particular case where the internal impedance of the signal source is a resistor R_s . This corresponds to one of the most frequently used types of sensors, which can be represented by a signal source generator V_s in series with its internal resistance and a thermal noise generator $V_{n,s}$, whose power spectral density is

$$V_{n,s}^2 = 4KTR_s \tag{9}$$

where K is Boltzmann's constant ($1.38 \times 10^{-23} \text{ W} \cdot \text{s/K}$) and T is the absolute temperature (K). According to Eq. (7), the noise figure for this resistive signal source is given by

$$\text{NF} = 10 \cdot \log \frac{4KTR_s + V_{n,a}^2 + I_{n,a}^2 R_s^2}{4KTR_s} \tag{10}$$

By differentiating this expression with respect to R_s , one obtains the so-called optimum source resistance, for which NF is minimum:

$$R_{\text{opt}} = \frac{V_{n,a}}{I_{n,a}} \tag{11}$$

From Eqs. (10) and (11), NF can be written as

$$\text{NF} = 10 \cdot \log \left[1 + \frac{V_{n,a} \cdot I_{n,a}}{4KT} \left(M + \frac{1}{M} \right) \right] \tag{12}$$

in which $M = R_s/R_{\text{opt}}$ is the matching factor. For a given $V_{n,a} \cdot I_{n,a}$ product, NF is minimum for $M = 1$.

The effect of the source resistance variation on NF for amplifiers having different values of the noise sources product $V_{n,a} \cdot I_{n,a}$, is illustrated in Fig. 4 [2, p. 46]. The minimum value of the noise figure, NF_{opt} , occurs at $R_s = R_{\text{opt}}$. As the product $V_{n,a} \cdot I_{n,a}$ increases, the noise figure also increases and is more sensitive to source resistance variations.

In the more general case where the correlation factor γ is different from zero, the optimum value F_{opt} of the noise factor corresponding to the optimum source resistance is easily calculated as

$$\begin{aligned} F_{\text{opt}} &= 1 + \frac{2 \cdot (1 + \gamma) \cdot I_{n,a}^2 \cdot R_{s,\text{opt}}^2}{V_{n,s}^2} \\ &= 1 + \frac{(1 + \gamma) \cdot I_{n,a} \cdot V_{n,a}}{2KT} \end{aligned} \tag{13}$$

F_{opt} defines the best performance obtainable when the source resistance can be selected to match R_{opt} . Equation (13) also clearly shows that, for any given source resistance and temperature, the best noise performance, obtained when perfect matching is achieved, depends on the product $V_{n,a} \cdot I_{n,a}$ of the amplifier [5,6].

Noise matching is based on the idea of modifying the amplifier equivalent input noise sources as seen at the

Figure 4. NF reaches its minimum value for $R_s = R_{\text{opt}}$. NF increases with increasing value of the product $V_{n,a} \cdot I_{n,a}$.

signal source location, to meet the condition $R_s = R_{\text{opt}}$, so as to minimize the total equivalent input noise [5]. This condition, which indicates that the preamplifier input stage is matched to the sensor, is considered as the essence of low-noise design. Of course, to keep the noise low, the rest of the amplifier must also be designed so that its noise contributions are low compared with those of the input stage.

A very simple and illustrative way to modify the amplifier equivalent input noise consists of coupling the sensor to the amplifier by means of a transformer with a primary-to-secondary turns ratio of $1 : N$ (Fig. 5 shows this for the case of a resistive sensor). The amplifier noise sources are reflected to the primary as $V'_{n,a} = V_{n,a}/N$ and $I'_{n,a} = NI_{n,a}$. The ratio of these reflected parameters is

$$R'_s = \frac{V'_{n,a}}{I'_{n,a}} = \frac{R_{\text{opt}}}{N^2} \tag{14}$$

Matching R'_s to R_s , one can derive the turns ratio required in the coupling transformer:

$$N = \sqrt{\frac{R_{\text{opt}}}{R_s}} \tag{15}$$

When this condition is met, the amplifier sees the optimum source resistance and, hence, the equivalent input

Figure 5. Noise matching by coupling transformer minimizes the total equivalent input noise.

noise is minimized. It has to be pointed out that a real transformer has its own internal noise sources and stray impedances, which have to be taken into account in an accurate low-noise design. Moreover, the use of a transformer requires a suitable shield to external electromagnetic fields, which can induce spurious currents in the transformer itself.

According to the results above, it appears that the noise figure NF can be alternatively improved by adding a series or shunt resistance to a given source resistance R_s (or, by correspondingly changing the sensor resistance), to make its final value equal to R_{opt} . However, due to the addition of an extra resistor, the signal-to-noise ratio gets worse. On the other hand, for $R_s = 0$, NF goes to infinity, although the actual output noise is less than that corresponding to any other value of source resistance, including R_{opt} . This contradictory situation arises from the fact that reducing NF improves the output SNR only if the SNR at the source remains constant. This condition is not met when matching is achieved by modifying the source resistance, but it is satisfied when using a coupling transformer. For the same reason, only when increasing sensor resistance increases the signal proportionally, should it be modified so as to match the amplifier optimum noise source resistance. When choosing or designing a preamplifier, the best noise performance is obtained by achieving the minimum equivalent input noise rather than the lowest noise figure.

Noise matching can also be achieved in the case of narrowband signal sources. By exploiting the resonance of a suitable LC group, the amplifier equivalent input noise as seen at the signal source location, can be optimized at the required center frequency. It is possible to follow this approach for both resistive and reactive narrowband sources [6].

Since transformers, as well as other coupling techniques using discrete components, are not compatible with solid-state circuits, noise matching for monolithic preamplifiers has to be obtained by appropriate choice of transistor sizes and bias conditions [7]. In particular, when $V_{n,a}$ is the dominant noise source of the preamplifier, noise matching can be obtained by using n input transistors connected in parallel rather than a single input transistor. Indeed, this technique reduces input noise voltage by a factor of \sqrt{n} and increases input noise current by the same factor, which from the noise standpoint, is equivalent to using a coupling transformer with a turns ratio of $1 : \sqrt{n}$ [5]. Similar techniques can also be adopted for discrete preamplifiers, even though much less flexibility is obviously available.

2. DESIGN CONSIDERATIONS FOR PREAMPLIFIERS

Designing or selecting a preamplifier for a specific application involves many specifications and choices. The procedure starts by considering sensor characteristics, such as signal source type, noise, impedance, and frequency response. As a function of that, the preamplifier must be designed so as to achieve the lowest value of equivalent input noise.

According to the discussion above, the ultimate limit of equivalent input noise is determined by the sensor impedance Z_s and the amplifier noise generators $V_{n,a}$ and $I_{n,a}$, where all these parameters may generally be frequency-dependent. Therefore, the signal source impedance and frequency range are decisive when choosing the type of preamplifier input device, as in a well-designed amplifier, noise performance is heavily affected by this element. To assist in this task, Fig. 6 [2, p. 210] can serve as a general guide. In this figure, the different ranges of source impedance values are covered by the different types of active or coupling devices. Low values of source resistance usually require the use of a coupling transformer for noise matching, while, for matching the highest source resistance range, the extremely low noise current $I_{n,a}$ of field-effect transistors is exploited.

With respect to the frequency range, in the simplest case of a resistive source, matching the amplifier optimum source resistance R_{opt} to the source resistance, minimizes the equivalent input noise at a given frequency. However, if the preamplifier must operate over a large frequency band, the designer's task is to minimize the noise integrated over this interval. Then, if the source impedance is reactive and/or the equivalent amplifier noise sources are functions of frequency, the use of a circuit simulator is often necessary to perform this integration over the whole bandwidth and optimize noise performance. With respect to this, it is important to note that the preamplifier bandwidth has to match, as much as possible, the signal spectrum needed in the specified application, since increasing the bandwidth increases the integrated output noise. Once the low and high amplifier cutoff frequencies of the preamplifier have been adjusted, the computer analysis may show that noise requirements are not fulfilled and, then, another operating point or different device sizes must be chosen. In extreme cases, different amplifiers or circuit topologies must be used.

Finally, needless to say, any noise injection from external source must be minimized. For example, in case electrical and/or magnetic shielding has to be provided against electromagnetic interference, power supply filtering can be required to ensure a quiet supply voltage, ground connections have to be carefully studied, and noise injection from digital sections has to be minimized. However, these considerations regard general system design, and are not specific to preamplifier design.

Next, the abovementioned design considerations are particularized for three types of source impedance (i.e., resistive, capacitive, and inductive), with emphasis on amplifiers for monolithic implementations. For this

Figure 6. Guide for selection of input devices.

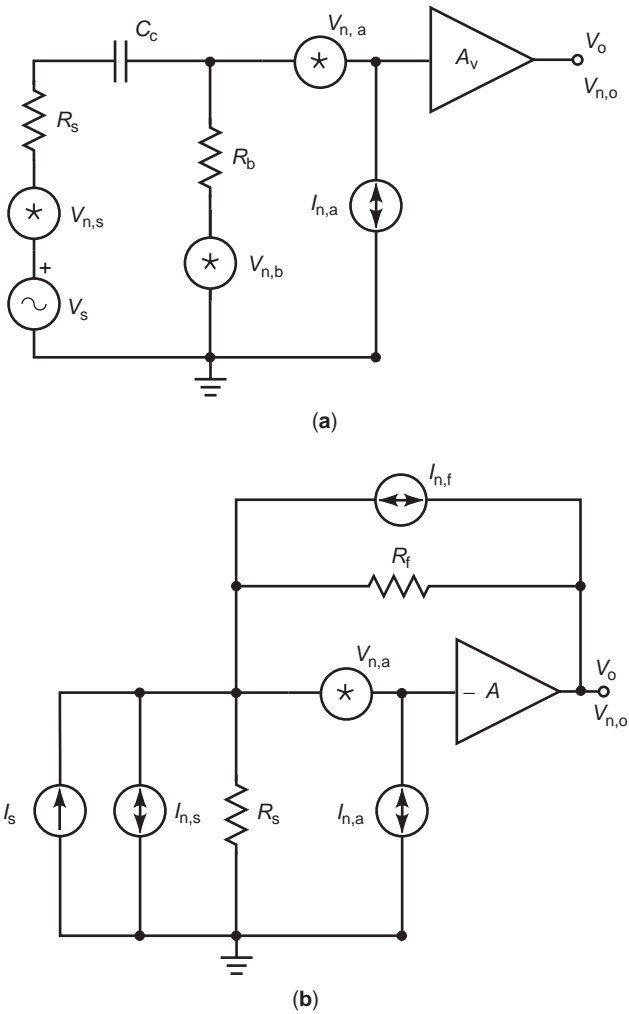

Figure 7. Preamplifiers with resistive sources: (a) voltage amplifier with coupling capacitor; (b) wideband transimpedance preamplifier.

reason, mainly bipolar and MOS transistors will be considered as amplifier devices.

2.1. Preamplifiers with Resistive Sources

The simplest type of source impedance is a resistance. Among sensors with this type of source impedance, some (i.e., voltaic sensors, such as thermocouples, thermopiles, infrared detectors, etc.) generate a voltage signal, while others (e.g., photoconductive detectors used in optoelectronic applications) produce a current signal. Figure 7 shows two generic preamplifiers with a resistive source (the noise sources, i.e., the resistor thermal noise generators and the equivalent amplifier input noise generators, are also included in both schemes). In Fig. 7a, a sensor voltage source is coupled to a voltage amplifier by means of a coupling capacitor C_c , while a resistor R_b is added for biasing the amplifier input device, which corresponds to a very usual situation. Instead, a resistive sensor, which provides a current signal, has been assumed in Fig. 7b. In this case, a transimpedance amplifier is used to amplify

the signal from the high-impedance source. The transimpedance gain of the amplifier V_o/I_s is determined by the feedback resistor R_f , provided that the loop gain is high enough.

Referring to the voltage amplifier in Fig. 7a, a highpass response is caused by the coupling capacitor C_c along with the equivalent series resistance of the input network. C_c must be chosen in such way that its reactance can be neglected in the frequency range of interest. Thus, the voltage gain in the input network is substantially independent of frequency. Moreover, the contribution of $I_{n,a}$ to the equivalent input noise voltage $V_{n,eq}^2$ [see Eq. (3)] yields results equal to $(I_{n,a}R_s)^2$.

Assuming a much higher amplifier input impedance than R_s and R_b , the equivalent input noise voltage of the system turns out to be

$$V_{n,eq}^2 \cong V_{n,s}^2 + V_{n,b}^2 \frac{R_s^2}{R_b^2} + V_{n,a}^2 \frac{(R_s + R_b)^2}{R_b^2} + I_{n,a}^2 \cdot R_s^2 + 2\gamma V_{n,a} I_{n,a} (R_s + R_b) \frac{R_s}{R_b} \tag{16}$$

In the remainder of this article, the generally accepted assumption that the amplifier noise is dominated by its input device will be adopted. In addition, single-ended input stages, which as a general rule allow the designer to minimize the noise contribution of the amplifier, will also be assumed.

First consider the case when the input transistor is a bipolar device. Neglecting $1/f$ noise and frequency-dependent terms in the frequency band of interest, the equivalent input noise sources can be approximated as [6]:

$$V_{n,a}^2 = 4KT r_b + \frac{2 \cdot (KT)^2}{qI_E} \tag{17a}$$

$$I_{n,a}^2 = 2qI_B = 2q \frac{I_C}{\beta} \tag{17b}$$

where r_b is the base resistance; q is the electron charge; I_E , I_B , and I_C are the DC emitter, base, and collector currents, respectively; and $\beta = I_C/I_B$ is the DC current gain. This operating region of the BJT is known as *short noise region* [2], since the shot noise mechanisms are the dominant ones. In this operating region, the correlation effects between the input voltage and current noise sources can usually be neglected ($\gamma \cong 0$). Here and in the following, it shall also be assumed that the noise contribution by the base resistance is negligible, as can be achieved with adequate layout, that is, by making r_b sufficiently small. The optimum noise resistance can be expressed as a function of the design parameters of the input transistor:

$$R_{opt} = \frac{V_{n,a}}{I_{n,a}} \cong \frac{KT}{qI_C} \sqrt{\beta} \tag{18}$$

The equivalent input noise of the system is minimum when the noise matching condition is fulfilled, that is, when R_{opt} as from Eq. (18) is made equal to the equivalent

resistance of the input network, $R_s || R_b$. This is achieved for the following biasing collector current:

$$I_{C,opt} = \frac{KT}{q} \frac{1}{(R_s || R_b)} \sqrt{\beta} \tag{19}$$

Obviously, the same result is achieved by differentiating $V_{n,eq}$ with respect to I_C for $V_{n,eq}$, as given by Eq. (16).

Replacing Eq. (19) into Eq. (16), the total equivalent input noise for the optimum biasing collector current can be derived:

$$V_{n,eq}^2 = 4KTR_s \left(1 + \frac{R_s}{R_b}\right) \cdot \left(1 + \frac{1}{\sqrt{\beta}}\right) \tag{20}$$

The first term, $4KTR_s(1 + R_s/R_b)$, is due to the thermal noise contribution of the source and biasing resistances, while the second term, $4KTR_s(1 + R_s/R_b)\beta^{-1/2}$, arises from the amplifier noise. It is apparent that the noise contributed by the amplifier is lower than the thermal noise by a factor of $\beta^{1/2}$. Also, the noise contribution of the biasing resistor can always be kept lower than that of R_s , by choosing $R_b > R_s$. Therefore, the noise performance of voltage amplifiers with bipolar input devices and resistive sources can be made to be dominated by the resistive source itself, if I_C can be chosen equal to $I_{C,opt}$. An alternative interpretation of Eq. (19) consists in considering the term $(1 + \beta^{-1/2})$ as the factor by which the preamplifier increases the thermal noise of the source and biasing resistances. In other words, this term is the lowest value of the optimum noise factor F_{opt} of a BJT working in the shot noise region used as the input device of an amplifier, which is obtained when the value of $I_{C,opt}$ corresponds to a sufficiently small collector current density [2].

Very similar conclusions are obtained when considering transimpedance amplifiers with resistive sources [3]—see Fig. 7b. Following the procedure above, one finds that the bias collector current of the input bipolar transistor for minimum noise is $I_{C,opt} = (KT/q)\beta^{1/2}/(R_s || R_f)$, and that the corresponding total equivalent input noise current is $I_{n,eq}^2 = [4KT/(R_s || R_f)] \cdot (1 + \beta^{-1/2})$. Again, in a well-designed bipolar preamplifier, noise performance can be made to be dominated by the resistive source, if R_f can be chosen sufficiently large. The choice of the feedback resistor R_f will result as the best tradeoff between noise, transimpedance gain, and bandwidth requirements.

Now refer to the case when an MOS transistor is used as the input device of the preamplifier in Fig. 7a. The equivalent input noise generators of an MOS device in the midfrequency range can be approximated as [3]

$$V_{n,a}^2 = \frac{8KT}{3g_m} + \frac{A_f}{WLf} \tag{21a}$$

$$I_{n,a}^2 = |j\omega C_{i1}|^2 V_{n,a}^2 \tag{21b}$$

where A_f is a suitable technology-dependent constant; W and L are the width and length, respectively, of the transistor; g_m is its transconductance; and C_{i1} , its input capacitance. As the noise voltage source is placed in series with

the signal source, the only way to minimize its contribution to the total equivalent input noise voltage $V_{n,eq}^2$ is to minimize the noise source itself. To reduce thermal noise, a large transistor transconductance must be used, which means a large aspect ratio and a large bias current. To reduce the $1/f$ term, a large gate area is required. The contribution of the noise current source to $V_{n,eq}^2$ is equal to $V_{n,a}^2[\omega(R_s || R_b)C_{i1}]^2$, and is, therefore, negligible with respect to $V_{n,a}^2$ in the frequency band of interest ($\omega < [(R_s || R_b)C_{i1}]^{-1}$).

When transimpedance amplifiers in MOS technology are considered, the contribution of the term $V_{n,a}^2$ to the total equivalent input noise current is given by $V_{n,a}^2/(R_s || R_f)^2$. This should be compared with the noise current $4KT/(R_s || R_f)$ contributed by the source and feedback resistances. Therefore, in the presence of a very large source resistance, the noise contribution of the amplifier can be made negligible provided that a sufficiently large feedback resistor is used. In this case, MOS amplifiers should be preferred to bipolar ones [3]. By contrast, in the case of a small source resistance, the source $V_{n,a}^2$ must be minimized to ensure low-noise performance of the preamplifier. This can be obtained with the same techniques as seen above for the case of the voltage amplifier. Again, the contribution due to the amplifier input current noise can be neglected in the frequency band of interest.

2.2. Preamplifiers for Optical Receivers

A very popular preamplifier application is for optical receivers. An optical receiver is a circuit able to detect and process a signal coming from an optical source. Basically, it is made up of an optical sensor followed by a preamplifier and a processing section. The optical sensor (photodetector), which in its simplest form, is a reversed-biased diode, converts the optical signal into an electrical current. The photodetector is modeled as a current source with an ideally infinite output resistance and a capacitance in parallel. As the input electrical signal can be very small (e.g., down to the nA range), it must be amplified with a preamplifier to a level suitable for the following processing. Therefore, low noise, high gain and, in many cases, high bandwidth and adequate dynamic range, are key amplifier requirements in this kind of application.

The basic principle of a preamplifier for optical receivers is to convert the current signal provided by the photodetector I_s into a voltage signal having a suitable amplitude. The most popular configuration consists of a transresistance amplifier, as illustrated schematically in Fig. 8a [8], where noise generators are not shown. The current I_s generated by the photodetector flows through the feedback resistor R_f , which, in turn, produces an amplifier output voltage $V_o = -I_s R_f$, provided that the loop gain is large enough. The required current-to-voltage conversion can also be achieved by feeding the signal current directly to a grounded resistor R_g (Fig. 8b) [9]. A suitable active stage is cascaded to provide decoupling between the input section and the following stages and, in this case, additional voltage gain. The choice of R_g results as a tradeoff between gain (V_o/I_s) and low thermal noise added to the signal current ($4KT/R_g$) on the one hand, and band-

Figure 8. Preamplifiers for optical receivers. A transresistance preamplifier (a) is generally preferred to the use of a grounded resistor followed by an active stage (b).

width, which is limited to $1/(2\pi R_g C_p)$, on the other, where C_p includes the photodetector capacitance in parallel with the amplifier input capacitance. For this reason, an equalizer stage (substantially, a parallel group RC) is very often cascaded to the active stage when R_g has a large value [9]. The use of a large R_g also causes a limited input dynamic range, as the whole voltage signal $R_g I_s$, is applied to the input of the active stage.

The transresistance configuration of Fig. 8a provides the best tradeoff in terms of noise and gain on one hand and bandwidth on the other, and also gives no problems regarding input dynamic range. The achievable signal bandwidth (assuming that the amplifier has an ideal frequency behavior) is now equal to $1/[2\pi R_f(C_f + C_p/A)]$, where C_f is the parasitic capacitance around the amplifier ($C_f \ll C_p$). The actual bandwidth of the system is limited either by parasitic capacitances in the feedback network or by the bandwidth of the amplifier. The former is a common case in high-gain applications, when a large value of R_f is used, while the latter is more typical in lower-gain applications. In any case, attention must be paid to achieving frequency stability, as a closed-loop configuration is adopted. Neglecting the feedback parasitic capacitance, the equivalent input current noise of the system in the frequency band of interest is

$$I_{n,eq}^2 = 4 \frac{KT}{R_f} + I_{n,s}^2 + I_{n,d}^2 + I_{n,a}^2 + V_{n,a}^2 \left| \frac{1 + \omega R_f C_p}{R_f} \right| \tag{22}$$

where $I_{n,s}$ and $I_{n,d}$ account for shot noise of signal and dark currents of the photodetector, respectively. From this equation, one can observe that the contribution of $V_{n,a}$ to the total equivalent input noise increases at high frequencies, even though at low frequencies, it can be negligible if $V_{n,a}$ is sufficiently small (“noise gain peaking” effect [8]). However, at very high frequencies, the contribution of $V_{n,a}$ is limited by the ratio C_p/C_f and then rolls off due to the amplifier open-loop response.

2.3. Preamplifiers with Capacitive Sources

A capacitive sensor source can be modeled, in its useful frequency range, as a voltage source in series with a capacitor or as a current source in parallel with a capacitor (the case where the sensor signal is delivered in the form of a charge packet will be briefly addressed at the end of this section). The output signal of the sensor is taken either as the open-circuit voltage or the short-circuit current, respectively. Sensor capacitance and signal frequency depend on the application, and can vary by several orders of magnitude (from picofarad up to nanofarad and from hertz to megahertz ranges, respectively). Typical examples are capacitive antennas (e.g., for radio receivers), electret microphones, some piezoelectric sensors such as hydrophones, optical detectors, and so forth. In this section, wideband monolithic preamplifiers, specifically, will be considered. In the case of narrowband applications, noise optimization can be achieved by adding a suitable series or parallel inductance in the input network, using a technique very similar to that used for narrowband preamplifiers with inductive sources [6] (see the next section). The basic principle is to determine a proper resonance that ideally makes the effects of the amplifier input current or voltage noise source disappear at the frequency of interest, thereby minimizing the system equivalent input noise.

Two basic topologies of wideband preamplifiers for capacitive signal sources are depicted in Fig. 9, where the voltage source representation is used for the sensor, and equivalent input noise generators are also shown. Notice that, ideally, no noise is generated in the signal source, due to its reactive nature. In Fig. 9a, biasing resistor R_b has been included. This resistor must be large enough so that, in the frequency band of interest, the pole generated by the group $R_b C_c$ roughly cancels out the effects of the zero located in the origin, which arises due to C_c . Thus, the preamplifier gain is independent of frequency, as required in most wideband applications. This is a typical situation in preamplifiers for electret microphones, where, in the case of monolithic implementations, an active biasing resistor is generally used to avoid excessive silicon area occupation due to the large resistance value required [10,11]. Noise considerations for this topology are very

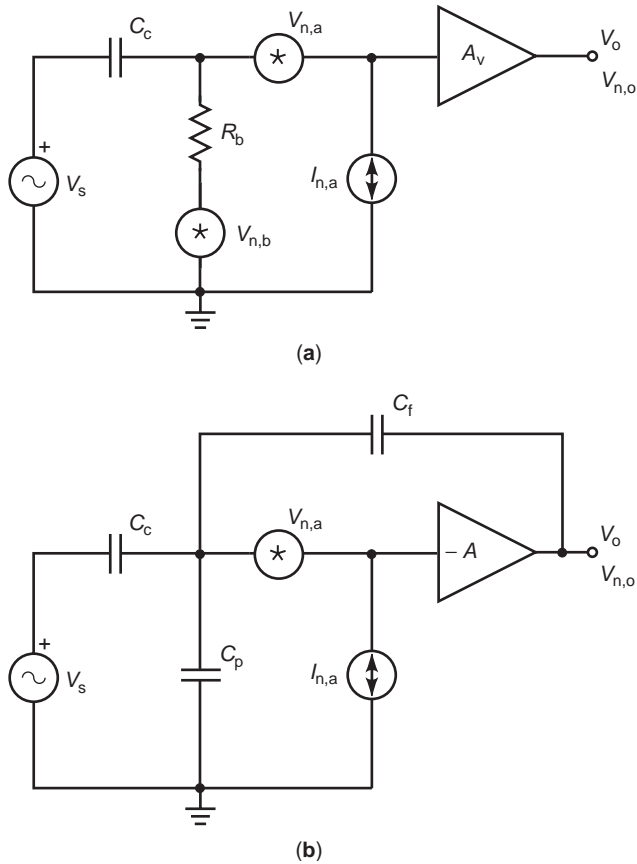

Figure 9. Preamplifier with capacitive sources: (a) voltage amplifier with biasing resistor; (b) voltage amplifier with capacitive feedback.

similar to those for voltage amplifiers with resistive sources, although in the present case the source resistance is assumed to be negligible, and obviously the dominant noise source is the amplifier.

In the capacitive feedback structure of Fig. 9b, no dc feedback or biasing elements has been drawn, although generally dc stabilization is required (this can be obtained, e.g., with a very large feedback resistor, and will be neglected in the following noise considerations). In this scheme, the feedback capacitor C_f sets the midfrequency voltage gain equal to $-C_s/C_f$. Also in this case, therefore, the gain is substantially independent of frequency. Moreover, it shows no dependence upon the parasitic capacitance C_p associated to the input line, which is very useful in applications requiring long cable connections between the sensor and the amplifier [12]. Choosing the best value of C_f derives from two contrasting requirements. On the one hand, a small capacitor C_f should be chosen, so that the minimum input signal must be amplified to a level adequate to drive the cascaded stages, while on the other hand, capacitor C_f should not be so small that the amplifier output saturates in the presence of the maximum allowed input signal.

Again, regardless of the application, the noise performance of the preamplifier is of paramount importance, as it generally determines the sensitivity of the overall sys-

tem. From Fig. 9b, the equivalent input noise voltage is

$$V_{n,eq}^2 = V_{n,a}^2 \left[\frac{C_f + C_s + C_p}{C_s} \right]^2 + I_{n,a}^2 \left| \frac{1}{j\omega C_s} \right|^2 + 2\gamma \left| V_{n,a} I_{n,a} \frac{1}{j\omega C_s} \right| \frac{C_f + C_s + C_p}{C_s} \quad (23)$$

For the best noise performance, the most straightforward choice is again the use of single-ended input stages, although fully differential amplifier solutions are also used for this kind of sensor [12,13]. As pointed out above, in this section we consider mainly bipolar and MOS input devices, as currently JFET circuits are used only in specific applications (e.g., in charge-sensitive amplifiers for nuclear physics experiments; see below). In the case of a bipolar input transistor, taking into account its equivalent input sources given in Eqs. (17) and neglecting the correlation factor γ , the total equivalent input noise turns out to be

$$V_{n,eq}^2 = 4KT \left(r_b + \frac{KT}{2qI_C} \right) \cdot \left(\frac{C_f + C_s + C_p}{C_s} \right)^2 + \left(\frac{2qI_C}{\beta} \right) \left| \frac{1}{j\omega C_s} \right|^2 \quad (24)$$

It is apparent that a small base resistance r_b and a high large current gain β are needed for low noise. Moreover, one can see that, for any given value of I_C , the base current shot noise contribution [second term in Eq. (24)] is dominant at low frequencies, while voltage noise [first term in Eq. (24)] dominates at high frequencies. To achieve noise minimization, noise matching must be achieved by a suitable choice of the collector bias current I_C . Indeed, increasing I_C has opposite effects on two noise contributions. The optimal value of I_C can be easily calculated by taking the derivative of Eq. (24) with respect to I_C , obtaining [3,7]

$$I_{C,opt} = \frac{KT}{q} \omega(C_s + C_p + C_f) \sqrt{\beta} \quad (25)$$

Notice that Eq. (25) is formally identical to Eq. (19): $\omega(C_s + C_p + C_f)$ represents the module of the admittance to the input network. As observed, $I_{C,opt}$ depends on the frequency. As a consequence, when required, wideband noise optimization with bipolar input stages is not possible. Obviously, when choosing the value of I_C , other features such as gain and operation speed must also be taken into account.

In the case of a MOS input transistor, using the noise sources in Eqs. (21), the equivalent input voltage noise source turns out to be

$$V_{n,eq}^2 = V_{n,a}^2 \left[\frac{C_f + C_s + C_p + C_i}{C_s} \right]^2 \quad (26)$$

where the term C_i results from the presence of the input noise current, taking also in account the 100% correlation existing between $V_{n,a}$ and $I_{n,a}$.

It should be emphasized that noise transfer gain does not depend on frequency. The term $V_{n,a}^2$ includes a flicker as well as a thermal component. Both these contributions should be reduced to a minimum to achieve low-noise performance. To reduce input-referred noise, capacitances C_p and C_f must be minimized, even though they are noiseless elements. As far as C_i is concerned, it is worth pointing out that its value is strictly related to the input transistor size. Changing its value has two opposite effects on noise performance. On one hand, increasing the aspect ratio W/L of the input device leads to a decrease in both flicker and thermal noise, as a result of the corresponding increase in its gate capacitance and transconductance, respectively. On the other, from Eq. (26), increasing C_i will also degrade noise performance. An optimized value of the input transistor capacitance and, hence, of its size, is therefore necessary, which is determined by taking the derivative of Eq. (26) with respect to C_i . The gate length should be set to the minimum to maximize amplifier performance in terms of thermal noise and gain–bandwidth product. Noise optimization results are different when flicker and thermal components are considered, as a consequence of the different dependence of their noise spectral density upon C_i . In the case of flicker noise, the best capacitance matching is obtained by setting $C_i = C_s + C_p + C_f$, while for thermal noise, the best value is $C_i = (C_s + C_p + C_f)/3$. When both flicker and thermal noise contributions are important, a tradeoff value of C_i is chosen, for example, the average of the two optimal values [3]. An analytical derivation of the optimum C_i value in the presence of both thermal and flicker series noise can be found in Ref. 14. A suitably large bias current is also required to maximize the transconductance of the input transistor and, hence, reduce its thermal noise. An n-channel input device also helps to this end. On the contrary, flicker noise is generally smaller for p-channel devices [15–17].

It has been shown [3] that, for a capacitive source, an MOS input device offers better noise performance than does a bipolar one. Obviously, a suitable design is needed to minimize noise contributions by the other components and following stages in the circuit (for the latter purpose, e.g., some gain should be introduced in the first stage of the amplifier). Depending on the application, high linearity, large load drive capability, and wide output dynamic range can also be required of the preamplifier, as these features are related mainly to an optimized design of its output stage. Moreover, due to the presence of the feedback loop, adequate frequency stability must be provided. Bipolar technology offers inherent advantages for such requirements; however, CMOS preamplifiers meeting all the specifications needed can be developed using adequate circuit design approaches. These include using a three-stage topology, a noninverting class A–B output stage, and suitable compensation techniques [3] and employing parasitic bipolar transistors [12]. When possible, CMOS technology is the preferred choice as it allows the designer to integrate the preamplifier together with the cascaded processing section at low cost.

BiCMOS technology has also been proposed to implement the preamplifier [3]. BiCMOS technology provides both CMOS and bipolar devices on the same chip. This

allows the designer to take advantage of the superior noise performance of a CMOS transistor used as the input device and, at the same time, to exploit the excellent features of bipolar transistors to achieve the other requirements with simpler circuits with respect to fully CMOS solutions. The main disadvantage of BiCMOS technology is its increased process complexity and, hence, its higher cost.

2.4. Charge-Sensitive Preamplifiers

In some very important applications using a capacitive source, the input signal is delivered as a charge packet Q_i . The signal source can be generally represented as a delta-like current source $Q_i\delta(t)$. Popular examples are detector systems for elementary particle physics experiments [18,19] and spectrophotometers and vision systems based on photodiodes operating in the storage mode [20]. The basic scheme (Fig. 10) is substantially the same as the previous one. The readout amplifier, generally referred to as a *charge-sensitive amplifier*, produces an output voltage step with an amplitude equal to $-Q_iC_f$ in response to an input charge packet Q_i ; DC stabilization is generally obtained either with a very large feedback resistor or with a feedback switch S_R , which is turned on during suitable reset time intervals.

These noise-matching considerations still apply (in particular, the relationships obtained for the optimal input capacitance of the amplifier). In these applications, noise performance is usually expressed in terms of equivalent noise charge (ENC). This is defined as the charge which the detector must deliver to the amplifier input in order to achieve unity signal-to-noise ratio at the output, and is usually expressed in electrons.

Detectors for nuclear physics experiments represent a very critical application of charge-sensitive amplifiers. Here, the amplifier is generally followed by a noise-shaping filter (or “pulseshaper”), which has the purpose of optimizing the overall signal-to-noise ratio of the detector system. This is required as, in general, electronic noise sets the limit to the accuracy of these systems. The best achievable value of ENC increases, with a substantially

Figure 10. Basic scheme of a charge-sensitive preamplifier.

linear relationship, with increasing detector capacitance C_s (in fact, a larger C_s leads to a larger equivalent noise charge for the same equivalent input noise). The obtained values of ENC ranges from few electrons for $C_s < 1$ pF (pixel detectors), to hundreds of electrons for microstrip detectors (C_s in the order of several hundred or even more than 1000 pF).

In some applications, junction field-effect transistors (JFETs) are preferred in front-end electronics for ionization detectors of capacitive nature, mainly because they show better radiation tolerance with respect to MOS devices and much smaller input current as compared to BJTs [21,22]. Nevertheless, under particular operating conditions, such as very short shaping time (< 50 ns) and low-power constraints, BJTs can offer superior performance [23,24]. CMOS solutions have also been developed for readout electronics to exploit the capability of CMOS technology for very high integration density and low power consumption [3,25]. In fact, as a huge number of readout channels are needed in modern detector systems, small size and low power dissipation are also important requirements, which make the monolithic approach the most appealing solution. CMOS technology is very attractive, especially for detectors that are placed not very close to the radiation environment and use a pulse shaper with a very fast response (i.e., short peaking time), so that flicker noise is negligible with respect to thermal noise. A BiCMOS solution implementing a low-power high-gain transresistance amplifier has also been presented [26].

2.5. Preamplifiers for Inductive Sources

An inductive sensor source can be generally modeled as a current source in parallel with an inductance. An internal resistance can also be present, to account for the real part of the sensor impedance. Examples of inductive sensors include magnetic heads (e.g., for tape and video cassette recorders), inductive pickups, dynamic microphones, ferrite antennas, and so forth. The operation principle of such sensors is to convert the information, received in the form of an electromagnetic field, into an electrical signal by means of an inductive coil. In most cases, very weak signals are generated and, therefore, very severe noise specifications have to be met by the preamplifier. Obviously, the reactive elements in the circuit do not contribute any noise directly, however, their presence affects the noise behavior of the circuit.

Very different situations occur when narrowband and wideband applications are considered. A typical preamplifier topology for narrowband inductive signal sources is illustrated in Fig. 11, where equivalent input noise generators are also shown. L_p is the source inductance, R_s is the sensor resistance, R_b can be a biasing or a load resistor, and C_p is a shunt capacitance (including both parasitic and, in this case, added capacitances). C_c is a DC decoupling capacitor ($C_c \gg C_p$), and will be regarded as a short circuit in the frequency band of interest. The voltage signal at the amplifier input turns out to be equal to

$$V_i = \frac{I_s \cdot j\omega L_p R_T}{j\omega L_p + (1 - \omega^2 L_p C_p) R_T} \quad (27)$$

where $R_T = R_b || R_s$. The presence of the resonance due to the group $L_p C_p$ is apparent.

For this configuration, one can choose a suitable size of the shunt capacitance C_p to obtain the best noise matching [6]. In fact, the expression of the equivalent input noise current for the circuit in Fig. 11 is easily calculated as

$$I_{n,eq}^2 = I_{n,s}^2 + I_{n,b}^2 + I_{n,a}^2 + V_{n,a}^2 \left| \frac{1}{R_T} + \frac{1 - \omega^2 L_p C_p}{j\omega L_p} \right|^2 + 2\text{Re} \left\{ I_{n,a}^* V_{n,a} \left(\frac{1}{R_T} + \frac{1 - \omega^2 L_p C_p}{j\omega L_p} \right) \right\} \quad (28)$$

Each noise current source reflects unchanged to the input at any frequency. By contrast, the coefficient of the noise voltage contribution is frequency dependent, and turns out to be minimum at the resonant frequency $\omega_0 = 1/(L_p C_p)^{1/2}$. This behavior obviously derives from the large impedance shown by the parallel group $L_p C_p$ at the resonance frequency. Neglecting the correlation effect between $V_{n,a}$ and $I_{n,a}$, the resulting equivalent input noise current is given by $I_{n,eq}^2 = I_{n,s}^2 + I_{n,b}^2 + I_{n,a}^2 + V_{n,a}^2/R_T^2$. It should be pointed out that no reactive element appears in the expression for minimum noise.

Let us now turn our attention to wideband applications, where a flat response is required for the signal. The amplifier configuration in Fig. 11 can no longer be used, as the resonant group inherently provides narrowband signal response. To overcome this limitation, a constant transimpedance topology can be used, as shown in Fig. 12. The voltage across the group $L_p C_p$ is ideally maintained constant, regardless of signal amplitude and frequency, thereby preventing any resonance effect. The current I_s delivered by the sensor is injected into R_f , thus achieving the desired frequency-independent transfer gain: $V_o/I_s = -R_f$. The equivalent input noise current in this topology turns out to be

$$I_{n,eq}^2 = I_{n,s}^2 + I_{n,f}^2 + I_{n,a}^2 + V_{n,a}^2 \left| \frac{1}{R_s} + \frac{1}{R_f} + \frac{1 - \omega^2 L_p C_p}{j\omega L_p} \right|^2 + 2\text{Re} \left\{ I_{n,a}^* V_{n,a} \left(\frac{1}{R_s} + \frac{1}{R_f} + \frac{1 - \omega^2 L_p C_p}{j\omega L_p} \right) \right\} \quad (29)$$

The noise contributed by the amplifier is represented by the terms including $I_{n,a}$ and $V_{n,a}$. The use of a large inductance L_p reduces the contribution of $V_{n,a}^2$. This is especially true at low frequencies, where $\omega^2 L_p C_p \ll 1$. By contrast, at high frequencies, a small value of C_p helps to achieve low noise.

For practical cases, when very low noise is required, the term $I_{n,f}^2 = 4KT/R_f$ due to the feedback resistor can result too high, thus setting too large a noise floor to the structure. To reduce this contribution, a combined capacitive and resistive feedback configuration has been proposed, as shown in Fig. 13 [27]. The transimpedance gain of this structure is equal to $-[1 + j\omega(C_1 + C_2)R_f]/j\omega C_1$, which for the frequency range $\omega \gg 1/[(C_1 + C_2)R_f]$ can be approximated by $-R_f(C_1 + C_2)/C_1$ and, hence, achieves the

Figure 11. Basic topology of a preamplifier for a narrowband inductive source (shunt capacitance C_p includes both parasitic and, in this case, added capacitances).

required frequency independence. Obviously, a careful stability analysis is required when designing the amplifier for this feedback configuration. The input-referred noise current due to the feedback network turns out to be $I_{n,f}^2 [C_1 / (C_1 + C_2)]^2$, and is, therefore, reduced by a factor of $(1 + C_2 / C_1)^2$, with respect to the noise generated by the feedback resistor. To obtain a substantial noise reduction, C_2 is set much larger than C_1 and, hence, the reduction factor becomes $\sim (C_2 / C_1)^2$. In practice, to achieve any given transimpedance gain, we now use a resistor which is C_2 / C_1 times smaller than in the case of a conventional transimpedance topology using a purely resistive feedback. Its current noise $I_{n,f}^2$ is, therefore, larger by the same factor, however, its input-referred contribution is divided by a factor of $(C_2 / C_1)^2$ and, therefore, a substantial improvement (by a factor of C_2 / C_1) is achieved. It should be noted that with this assumption ($C_2 \gg C_1$), the resonance frequency in the input network is approximately equal to $\omega_{LC} = 1 / [L_p (C_p + C_1)]^{1/2}$.

When a bipolar input transistor is used in the amplifier, the correlation term in Eq. (29) can be neglected, and noise minimization requires a small base resistance r_b and a large current gain β . Moreover, as in the case of a capacitive signal source, the collector current I_C must be set to an optimal value, as a consequence of its opposite effects on input voltage and current noise components. Again, this optimal current is frequency dependent, and therefore noise optimization cannot be obtained in a wide

frequency range [3,27] leading to the choice of a tradeoff current for any given application.

When using CMOS technology, no noise contribution due to the gate current is present, thus removing the basic limiting factor to the noise performance in bipolar preamplifiers (i.e., the base shot noise component). As for the case of capacitive signal sources, it can be shown that noise optimization is achieved by suitably sizing the input transistor of the preamplifier. Again, the optimal size is different when considering flicker and thermal noise. Furthermore, as a consequence of the frequency dependence of the coefficient of $V_{n,a}^2$ in the expression of the total equivalent input noise current [see Eq. (29)], the optimal transistor size also depends on frequency, in contrast with the case of preamplifiers for capacitive sources. For frequencies much lower than the resonance frequency ω_{LC} , optimization is achieved by choosing an amplifier input capacitance $C_i \cong 1 / (\omega^2 L_p)$ for both flicker and thermal noise [3]. For $\omega > \omega_{LC}$, wideband noise optimization can be obtained by setting $C_i = \sim (C_p + C_1) / 3$ and $C_i = \sim (C_p + C_1)$ in the thermal and flicker noise domains, respectively. Both noise components must be taken into account when determining the input transistor size for any given application, which can be done by using numerical simulation.

Also in the case of wideband preamplifiers for inductive sources, a detailed noise analysis [3] shows that, in spite of the presence of a large flicker noise component, CMOS technology leads to better noise performance than does the

Figure 12. A transimpedance configuration for an inductive source ensures frequency-independent gain.

Figure 13. The use of a combined resistive and capacitive feedback in a transimpedance amplifier minimizes the noise contribution of the feedback network.

bipolar one. Again, BiCMOS technology has been proposed to exploit the advantages coming from integrating both CMOS and bipolar devices in the same chip, even though at an increased cost of the fabrication process.

1. INTRODUCTION

The surging demand of modern wireless silicon-based radiofrequency integrated circuits (RFICs) has placed great importance and interest in on-chip passive components. The design criteria for wireless mobile communication equipment, which include low cost, low supply voltage, low power dissipation, low noise, high frequency of operation, and low distortion, cannot be satisfactorily met in many cases without the use of on-chip monolithic silicon spiral inductors. These monolithic inductors allow significantly improved levels of performance in monolithic power amplifiers, low-noise amplifiers, upconversion-downconversion mixers, and low-phase-noise local oscillators. The on-chip inductor is able to resonate with any parasitic capacitance, thus allowing potentially higher frequency operation. It provides bias current with no significant dc drop, which incidentally improves linearity of the system. An added advantage of the on-chip inductor is that inductive degeneration can lead to simultaneous noise and power matching.

In order to reap these advantages, it becomes crucial for the circuit designer to be able to predict, design, optimize, and model accurately the characteristics of the on-chip inductor. Although there are several good textbooks [1–4] that present overviews of the printed inductors, except for Niknejad [5], few have delved indepth into the subject of spiral inductor analysis and characterization. It

is thus the objective of this article to provide a summarized description of the various methods of designing, modeling, and characterizing the on-chip spiral inductor. The emphasis is to present useful techniques of on-chip spiral inductor designing and modeling that complement information given in other handbooks or textbooks. Interested readers who require a good overview of printed inductors can refer to Refs. 1–5 for further details.

2. SPIRAL INDUCTOR DESIGN

The spiral inductor is the most common structure for implementing the on-chip inductor in many foundry processes, and a typical on-chip spiral inductor structure is shown in Fig. 1. A spiral structure is typically laid out using two or more of the top metal layers in most of the standard foundry process. The top metal layers are used primarily because this will help in minimizing the resistive coupling to the substrate and in turn, in reducing the loss of the overall spiral inductor. More than two metal layers can be utilized to increase the Q factor.

The quality factor (Q) of an inductor, which is defined as

$$Q = 2\pi \frac{\text{energy stored}}{\text{energy loss in one oscillation cycle}} \quad (1)$$

is a gauge of the effective magnetic energy storage capability of the inductor. Thus, a high quality factor is critical for a spiral inductor. For silicon-based RFICs, the spiral inductor suffers from performance limitations related to issues such as substrate injection through oxide, substrate coupling by ohmic and displacement current, lateral currents to nearby substrate taps, and skin effects [6]. This causes the Q of the inductor to be low (i.e., <10) at high frequencies. As a result, many high-speed RF components such as voltage-controlled oscillators (VCO) or high power amplifiers using on-chip inductors have limited performance compared to designs using off-chip components. The use of off-chip components adds complexity and cost to the design of these circuits, which has directly led to intense research aimed at improving the performance of

Figure 1. Magnetic field intensity comparison of symmetric and the asymmetrical spiral inductors.

on-chip spiral inductors. Significant efforts [7,8] have been expended with the aim of providing high- Q inductors for critical RF applications. These methods include (1) growing a high-resistivity silicon substrate with thicker metallization so as to mimic the low-loss semiinsulating GaAs substrate; (2) creating a bulk cavity in the silicon substrate under the inductor; (3) introducing patterned ground shield to reflect the electric field between the inductor and the substrate; (4) varying the inductor's geometry such as the shape, trace width, metal spacing, number of turns, number of metal layers, and topology; and finally (5) exciting the inductor in a differential manner.

Techniques 1–3 involve extra processing cost, whereas techniques 4 and 5 are adversely affected by both the non-uniform metal thickness and the parasitic capacitance effects. Of particular interest and worthy of mention under technique 4 is the design of the symmetric spiral inductor, which can give higher Q than can the asymmetric spiral inductor. Wrapping of the metal lines of the squared spiral inductor, as shown in Fig. 1, allows the flux from each turn to be added, thus increasing the inductance per unit length of the structure. From the comparison of the magnetic field intensity plot presented in Fig. 1, one can intuitively deduce that the “golden rule” of designing high- Q inductor [9] would be to reduce the number of overlaps in the inductor, ensure that the geometric center coincides with the magnetoelectric center (MEC), and force the current to loop in the same direction. The magneto-electric center corresponds to the point where both the magnetic and electric fields are a local minimum. With fewer overlaps, the electric coupling, which is counterproductive to Q , can be minimized. With the same loop current flows, and coincident MEC and geometric center, less magnetic field cancellation would result, thus leading to higher magnetic energy storage in the inductor.

3. SPIRAL INDUCTOR MODELING AND CHARACTERIZATION

An accurate model for the on-chip spiral inductor, which can efficiently represent its electrical performance for circuit simulation and optimization with other design components, is of great importance for silicon-based radiofrequency integrated circuit designers. Although the generic electromagnetic field solver such as Ansoft HFSS, or other partial-element equivalent-circuit (PEEC)-based solvers, can provide reasonable performance evaluation of the spiral inductor; these simulators are computationally intensive and time-consuming. Other techniques for analysis include the Greenhouse method [10], the Wheeler formula [11] and a “data-fitted monomial expression” [12]. A crude estimate (within 30%) for the inductance value of a spiral inductor provided by Lee [13] is given as

$$L = \mu_0 n^2 r \approx 1.2 \times 10^{-6} n^2 r \quad (2)$$

where n and r represent respectively the number of turns and radius of the spiral inductor and μ_0 is the permeability

of the semiconductor substrate. These techniques are either relatively inaccurate or not scalable over a wide range of layout dimensions and process parameters. For inductor design insights and optimization, a compact, physical lumped-element circuit model would be preferred as it could be easily integrated in any commercial computer-aided design software program such as Microwave Office, Agilent Advanced Design System (ADS), or Serenade from Ansoft.

Figure 2 reviews a typically adopted equivalent circuit used for spiral inductor modeling. In the model, L_s represents the spiral inductance whereas R_s is the metal series resistance whose behavior at high frequency is governed by the eddy-current effect and the skin effect. The series feedforward capacitance C_s , which accounts for the capacitance due to overlaps between the spiral and the center-tap underpass, is usually expressed as

$$C_s = \frac{nW^2 \epsilon_{\text{SiO}_2}}{t_{\text{SiO}_2}} \quad (3)$$

The parasitic C_{ox} , C_{si} , and R_{si} , which are respectively the oxide capacitance, substrate capacitance, and resistance, are computed from

$$C_{\text{ox}} = \frac{\epsilon_0 \epsilon_{\text{eff}}(\epsilon_{\text{SiO}_2}, h_1)}{F(h_1, W)} \quad (4)$$

$$C_{\text{si}} = \frac{\epsilon_0 \epsilon_{\text{eff}}(\epsilon_{\text{Si}}, h_2)}{F(h_2, W)} \quad (5)$$

$$R_{\text{si}} = \frac{2F(h_2, W)}{\sigma_{\text{si}}(1 + \sqrt{1 + 10h_2/W})} \quad (6)$$

Figure 2. A typical equivalent circuit for spiral inductor.

where

$$F(h_2, W) = \begin{cases} \frac{1}{2\pi} \ln(8h/W + W/4h), & h/W \geq 1 \\ WW/h + 2.42 - 0.44h/W + (1 - h/W)^6, & h/W \leq 1 \end{cases} \quad (7)$$

$$\epsilon_{\text{eff}}(\epsilon, h) = \frac{(\epsilon + 1)}{2} + \frac{(\epsilon - 1)}{2\sqrt{1 + 10h/W}} \quad (8)$$

where n is the number of the overlaps, ϵ_{SiO_2} and t_{SiO_2} denote the dielectric constant and thickness of the oxide layer, ϵ_{Si} is the permittivity of the silicon substrate, and W is the spiral linewidth.

The equivalent circuit, as shown in Fig. 2, strongly lacks the frequency dependence of R_s and L_s as a result of current crowding in the conductor. The circuit also fails to describe the distributed characteristics of the inductor under high-frequency operation. Prominent effects such as eddy-current effect and skin effect are not incorporated in the model. An improved circuit model [14], which represents the eddy current as an electrical component, is shown in Fig. 3. The branch constituted by the series connection of L'_s , R'_s , and in parallel with R_s is taken as circuit elements contributing to the overall eddy-current loss. The voltage over R_s represents the total voltage effect of each induced eddy-current segment. Compared with the conventional spiral inductor model in Fig. 2, the new model has an added advantage. By circuit theory

$$\text{Re}(Z_{\text{in}}) = R_s - \frac{R_s^2(R_s + R'_s)}{(R_s + R'_s)^2 + \omega^2 L_s'^2} \quad (9)$$

$$\text{Im}(Z_{\text{in}})/\omega = L_s + \frac{R_s^2 L_s'}{(R_s + R'_s)^2 + \omega^2 L_s'^2} \quad (10)$$

where Z_{in} is the input impedance of the inductor, Eqs. (9) and (10) provide a frequency varying effect for both the resistance and inductance. This overcomes the limitation of the conventional circuit model in that it can only offer constant values for both resistance and inductance.

Figure 3. A modified circuit model for spiral inductor.

Figures 4a and 4b illustrate the accuracy of the improved circuit model (as in Fig. 3) over the conventional circuit model given in Fig. 2. The measured S parameters, which are indicated in blue, are taken from a sample inductor 1 of 1.75 turns, $10\ \mu\text{m}$ width (W), $15\ \mu\text{m}$ pitch (P), $100\ \mu\text{m}$ outer dimension (D), and $1.5\ \mu\text{m}$ metal thickness (h_2). As shown in the figure, the improved circuit model gives a better agreement than does the conventional circuit model.

Conventionally, the Q of a spiral inductor is experimentally evaluated by

$$Q = \frac{\text{Im}(1/Y_{11})}{\text{Re}(1/Y_{11})} \quad (11)$$

Figure 4. Comparison of two equivalent-circuit models for a typical spiral inductor: (a) measured S parameters (indicated in blue) versus new model (indicated in red); (b) measured S parameters (indicated in blue) versus old model (indicated in red). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

where Y_{11} is the Y parameter of the spiral inductor. With the presence of the equivalent-circuit model as in Fig. 2, a greater insight into the dependence of equivalent-circuit parameters on Q can be obtained. Yue and Wong [15] had expressed the Q of a typical spiral inductor as

$$Q = \left[\frac{\omega L_s}{R_s} \right] \left[\frac{R_p}{R_p + [(\omega L_s/R_s)^2 + 1]R_s} \right] \left[1 - \frac{R_s^2(C_s + C_p)}{L_s} - \omega^2 L_s(C_s + C_p) \right] \quad (12)$$

where

$$R_p = \frac{1}{\omega^2 C_{ox}^2 R_{si}} + \frac{R_{si}(C_{ox} + C_{si})^2}{C_{ox}^2} \quad (13)$$

and

$$C_p = C_{ox} \frac{1 + \omega^2(C_{ox} + C_{si})C_{si}R_{si}^2}{1 + \omega^2(C_{ox} + C_{si})R_{si}^2} \quad (14)$$

One can deduce from Eq. (12) that Q depends solely on three terms indicated by the enclosed square brackets. The term $\omega L_s/R_s$ represents the magnetic energy stored and the ohmic loss in the series resistance. The second term in Eq. (12) is the substrate loss factor, which accounts for the energy dissipated in the semiconducting silicon substrate. The last term is the self-resonance factor describing the reduction in Q due to a change in the peak electric energy with frequency and the vanishing of Q at the self-resonant frequency. This term is a strong function on the inherent capacitance of the spiral inductor. The self-resonant frequency is the upper bound for an inductor to be functional. The equivalent-circuit models as shown in Figs. 2 and 3 help facilitate a greater insight into the operation of the spiral inductor and provide meaningful hints in minimizing the induced loss, which is important for RFIC technology.

3.1. Resistance Calculation

Normally, one would expect multiple turns to be required for a spiral inductor to attain higher inductances. However, with more turns, the current on the trace will be non-uniformly distributed and the overall inductance will not be as high as one would expect. The concept of current redistribution in the metallic trace of the spiral inductor can be traced from two effects: the skin effect and the eddy-current effect. Conventionally, the series resistance R of the spiral inductor under skin effect often assumes the form

$$R = \frac{\rho l}{W\delta(1 - e^{-T/\delta})} \quad (15)$$

where ρ , W , and l represent respectively the resistivity, metal width, and total length of the spiral inductor. T and δ denote respectively the metal thickness and skin depth ($\delta = \sqrt{2/\omega\sigma\mu}$). For frequencies below 2 GHz, the skin effect

is relatively small in most process since the metallic trace thickness is typically less than or equal to the skin depth. For frequencies higher than 2 GHz, the series resistance increases as the skin effect becomes more prominent, and approaches an asymptote proportional to the square root of frequency. In contrast, current crowding, which is caused by the eddy currents in the metal traces of the spiral inductor, is a strong function of frequency. It causes the resistance to increase at a higher frequency. The eddy current, which has a significant effect on the inductance of the spiral inductor, manifests itself not only as a skin effect but also as a proximity effect. This major current crowding mechanism is generally missing in most of the inductor equivalent-circuit modeling and incorporation of these effects in spiral inductor modeling is thus the subject of this section.

The basic concept of current crowding lies in the current redistribution caused by the B -field variation on the adjacent turn. The B field can actually adopt a simplified expression given as

$$B(n) \approx \frac{B_0(n - M)}{(N - M)} = \frac{I_{ex}0.65\mu_0(n - M)}{P(N - M)} \quad (16)$$

where n is the index for the turn number, N is the total number of turns, B_0 is the field at the innermost turn (turn number N), M is the turn number where the field falls to zero and reverses direction, P is the turn pitch (refer to Fig. 5), and I_{ex} is the excitation current. Using

$$J = \begin{cases} J_0 e^{(z-T/2)/\delta}, & T/2 \geq z \geq 0 \\ J_0 e^{-(z+T/2)/\delta}, & 0 \geq z \geq -T/2 \end{cases} \quad (17)$$

where T is the metal trace thickness and applying the Faraday's law, the per unit length surface eddy current for the n th turn [16] becomes

$$\begin{aligned} |I_{eddy,n}| &= 2 \int_0^{T/2} \int_0^{W/2} \omega \sigma B(n) x e^{(z-T/2)/\delta} dx dz \\ &= 0.162 \omega \sigma W^2 I_{ex} \delta (1 - e^{-T/2\delta}) \frac{\mu_0 |n - M|}{P(N - M)} \end{aligned} \quad (18)$$

where δ refers to the skin depth. σ and μ are respectively the conductivity and permeability of the metallic trace. The power dissipated in the n th turn due to the eddy current is thus expressed as

$$\begin{aligned} P_{eddy,n} &= 4\sigma l_n \omega^2 B^2(n) \int_0^{T/2} \int_0^{W/2} x^2 e^{2(z-T/2)/\delta} dx dz \\ &= \frac{1}{12} \sigma l_n \omega^2 B^2(n) W^3 \delta (1 - e^{-T/\delta}) \end{aligned} \quad (19)$$

Figure 5. Simplified illustration of eddy-current effect.

where l_n is the length of the n th turn. Therefore, the total spiral resistance is given as

$$R_{\text{total}} = R_0 + \frac{0.05W^4T\sigma^{3/2}\mu_0^2}{\mu^{1/2}P^2(N-M)^2} \sum_{n=1}^N R_n(n-M)^2 \times \omega^{3/2}(1 - e^{-\sqrt{T^2\mu\sigma\omega/2}}) \quad (20)$$

where R_0 is the theoretical DC resistance of the inductor and is computed by $R_0 = \sum_n l_n / \sigma WT$. Here, $\sum_n l_n$ is total metal length of the spiral inductor. In order to obtain a rough review of the ω dependence on R_{total} at the various frequency ranges, through simplification of Eq. (20), we have

$$R_{\text{total}} = R_0 + 0.05W^4T\sigma^{3/2} \times \frac{\mu_0^2}{\mu^{1/2}P^2} \sum_{n=1}^N R_n \frac{(n-M)^2}{(N-M)^2} \omega^{3/2} \quad (21)$$

at high frequency,

$$R_{\text{total}} \approx R_0 + 0.035W^4T^2\sigma^2 \times \frac{\mu_0^2}{P^2} \sum_{n=1}^N R_n \frac{(n-M)^2}{(N-M)^2} \omega^2, \quad (22)$$

at low frequency

Figures 6a and 6b provide a comparison of the resistance values computed from Eqs. (20)–(22). The adopted

parameters for inductor 3 include 3.5 turns, 10 μm width, 11.5 μm pitch, 75 μm inner dimension (d), and 0.7 μm alumini-metal thickness whereas for inductor 4, the parameters include 2 turns, 6 μm width, 8 μm pitch, 75 μm inner dimension, and 1 μm copper metal thickness. In the figures, predicted curve 1 refers to Eq. (20), and predicted curve 2 refers to Eq. (21), whereas predicted curve 3 refers to Eq. (22). As illustrated in Fig. 6, Eq. (20) is relatively more accurate for the resistance simulation in the whole frequency domain. Equation (22) is valid when ω is very low and the skin depth δ is much larger than the metal thickness T . By comparing prediction curve 2 of inductor 4 with that of inductor 3, we conclude that Eq. (21) is valid only when ω is high enough that δ is much smaller than T .

3.2. Inductance Calculation by Partial Inductance Method

The total inductance of a spiral inductor can be separated into two aspects: self- and mutual inductance. Since an inductor is intended for storing magnetic energy only, an ideal expression of its inductance in terms of width, gap spacing, and length is essential in terms of equivalent-circuit modeling [16]. The eddy-current and skin effects will result in nonuniform current distributions in the metallic trace, thus forcing the inductance to be *current-dependent*. As a result, the self- and mutual inductances must be derived from a more fundamental electromotive definition

$$e = -\frac{d\phi}{dt} = -L \frac{di}{dt} \quad (23)$$

where e is the electromotive force induced by the change of magnetic flux ϕ in one closed loop. The concept of partial inductance, which involves the magnetic flux between a conductor and infinity, will be adopted in this section.

By ignoring the effect of the ground plane and the substrate, the width and thickness of the cross section are divided into infinitely thin, uniformly distributed segments as in Fig. 7. Using Eq. (23), the overall self-inductance caused by the magnetic flux in the N -filament system is approximated as

$$L_{\text{self}} \approx \frac{L_1 + \sum_{n=1}^N \left(\left[\frac{k_n}{\sum_{j=1}^N k_j} \right] \sum_{\substack{m=1 \\ m \neq n}}^N M_{mn} \right)}{N} \tag{24}$$

$$\approx \frac{\sum_{n=1}^N \left(k_n \sum_{\substack{m=1 \\ m \neq n}}^N M_{mn} \right)}{N \sum_{j=1}^N k_j}$$

where $N = M_1 N_1 = M_2 N_2 = \dots$ is the total number of filaments in each metallic trace, M_{mn} is the mutual inductance value between the m th and n th current filaments, L_1 is the self-inductance of a filament, and

$$i_n = \frac{k_n i_{\text{total}}}{\sum_{j=1}^N k_j} \tag{25}$$

Similarly, the mutual inductance between any two different traces with N filaments (see Fig. 7) is expressed as

$$L_{\text{mutual}} = \frac{1}{M_1 N_1} \sum_{n=1}^{M_2 N_2} \sum_{m=1}^{M_1 N_1} \left(\frac{k_n M'_{mn}}{\sum_{j=1}^N k_j} \right) \tag{26}$$

where M'_{mn} refers to the mutual inductance between the m th and n th current filaments in different conductors. The sum of each M' due to all the other parts in the metallic trace will provide an overall interparts mutual inductance of a spiral inductor. The mutual inductance is computed from

$$M_{mn} = 0.002\ell \left[\ln \left(\frac{\ell}{g} + \sqrt{1 + \frac{\ell^2}{g^2}} \right) - \sqrt{1 + \frac{g^2}{\ell^2}} + \frac{g}{\ell} \right] \tag{27}$$

$$\approx 0.002\ell \left(\ln \frac{2\ell}{g} - 1 + \frac{g}{\ell} - \frac{g^2}{4\ell^2} + \dots \right)$$

where ℓ is the length of the filaments, g is the geometric mean distance between the two filaments and is expressed

Figure 6. Resistance comparison for (a) inductor 3 and (b) inductor 4 after deembedding.

as

$$g = \lim_{N \rightarrow \infty} \left[\prod_{m=1}^N \left(\prod_{n=1}^N \sqrt{c^2 + \left[(m-n) \frac{b}{N} \right]^2} \right)^{1/n} \right]^{1/m}$$

where c and b are respectively the longitudinal length and separation distance of the cross section of two filaments.

Under the skin effect, the attenuation of the current density J_s as a function of distance z away from the surface can be represented by the function

$$J_s(z) = \begin{cases} J_0 e^{z/\delta}, & 0 \geq z \geq -T/2 \\ J_0 e^{-(z+T)/\delta}, & -T/2 \geq z \geq -T \end{cases} \tag{28}$$

where J_0 refers to the current density at the surface ($z = 0$) as indicated in Fig. 8. The current I can be obtained by

Figure 7. Cross section illustration of two conductors in parallel.

integrating J_s over the total cross-sectional area, yielding

$$\begin{aligned} I &= W \left(\int_{-T/2}^0 J_0 e^{z/\delta} dz + \int_{-T}^{-T/2} J_0 e^{-(z+T)/\delta} dz \right) \\ &= 2WJ_0\delta(1 - e^{-T/2\delta}) \end{aligned} \quad (29)$$

By dividing the cross section of the trace into smaller filaments as in Fig. 8, followed by setting $k_n = J_s$ ($z = -nT/N$) TW/N , and combining with Eqs. (24)–(26), the inductance calculation due to the current redistribution under the skin depth effect becomes

$$\begin{aligned} \frac{L_{\text{self}}^\beta}{L_{\text{self}}^\alpha} &= K_1 \\ &= \lim_{N \rightarrow \infty} \frac{T \sum_{n=1}^{N/2} e^{-Tn/(N\delta)} \sum_{\substack{m=1 \\ m \neq n}}^N \overline{M}_{mn}}{\delta(1 - e^{-T/2\delta}) \sum_{n=1}^N \sum_{\substack{m=1 \\ m \neq n}}^N \overline{M}_{mn}} \end{aligned} \quad (30)$$

and

$$\frac{L_{\text{mutual}}^\beta}{L_{\text{mutual}}^\alpha} = \lim_{N \rightarrow \infty} \frac{T \sum_{n=1}^{N/2} e^{-Tn/(N\delta)} \sum_{m=1}^N \overline{M}'_{mn}}{\delta(1 - e^{-T/2\delta}) \sum_{n=1}^N \sum_{m=1}^N \overline{M}_{mn}} \quad (31)$$

Figure 8. Segmentation method on the cross section of metallic trace under skin effect.

where the superscripts α and β represent respectively the conditions when the current is uniform and when it is under skin effect. \overline{M}_{mn} refers to the mutual inductance between the m th and n th filaments within the same trace, and \overline{M}'_{mn} denotes the mutual inductance between the m th and n th filaments of different traces. Since the distance between two filaments of different traces is much larger than a single filament thickness, we can approximate

$$\sum_n \overline{M}_{m1} = \sum_m \overline{M}'_{mn} = \dots = \sum_m \overline{M}'_{mn} \quad (32)$$

If the skin effect is considered alone, we have

$$L_{\text{mutual}}^\alpha \approx L_{\text{mutual}}^\beta \quad (33)$$

The eddy currents in the metallic trace of the spiral inductor are induced by the initial excitation current (see Fig. 5). Using Eqs. (16) and Faraday's and Ohm's law, an approximate expression to describe the eddy current is given as

$$J_{\text{eddy},n}(x) = \frac{0.65\omega\mu_0}{P} I_0 \sigma x \left(\frac{n-M}{N-M} \right) \quad (34)$$

From Fig. 9, one can observe that the eddy current effect on the overall self-inductance is neutralized as the currents on both sides of a metallic trace are in opposite directions. This, in turn, causes the overall magnetic field to be canceled. If we divide the cross section into infinite thin filaments along the x direction as in Fig. 9, we can achieve

$$\begin{aligned} L_{\text{self}}^\gamma &\propto \lim_{N, N' \rightarrow \infty} \sum_{n=1}^N \left(\sum_{\substack{m=1 \\ m \neq n}}^N \overline{M}_{mn} + \sum_{m'=1}^{N'} \overline{M}'_{m'n} \right) \\ &- \lim_{N, N' \rightarrow \infty} \sum_{n'=1}^{N'} \left(\sum_{m=1}^N \overline{M}_{mn'} + \sum_{\substack{m'=1 \\ m' \neq n'}}^{N'} \overline{M}'_{m'n'} \right) = 0 \end{aligned} \quad (35)$$

where the superscript γ represents the condition only under the eddy-current effect. This phenomenon also exists under the presence of skin effect, and Eq. (35) is valid under the incorporation of both skin depth and eddy-current effect.

While considering the mutual inductance between two different metallic traces caused by the eddy current, the total excitation current should be taken as I_0 . Using Eqs. (34) and (26) and setting $k_n = J_{\text{eddy}}[x = (nW/2N)]TW/2N$, we obtain

$$\frac{L_{\text{mutual}}^\gamma}{L_{\text{mutual}}^\alpha} = \frac{0.325\omega\mu_0 T \sigma W^2 K_2}{P} \left(\frac{n-M}{N-M} \right) \quad (36)$$

Figure 9. Segmentation method on the cross section of metallic trace with eddy current.

with

$$K_2 = \frac{\lim_{N, N' \rightarrow \infty} \sum_{n=1}^N \frac{n}{N} \left(\sum_{m=1}^N \overline{M'_{mn}} + \sum_{m'=1}^{N'} \overline{M'_{m'n'}} \right) - \lim_{N, N' \rightarrow \infty} \sum_{n'=1}^{N'} \frac{n'}{N'} \left(\sum_{m=1}^N \overline{M'_{mn'}} + \sum_{m'=1}^{N'} \overline{M'_{m'n'}} \right)}{\lim_{N, N' \rightarrow \infty} \sum_{n=1}^N \left(\sum_{m=1}^N \overline{M'_{mn}} + \sum_{m'=1}^{N'} \overline{M'_{m'n'}} \right) + \lim_{N, N' \rightarrow \infty} \sum_{n'=1}^{N'} \left(\sum_{m=1}^N \overline{M'_{mn'}} + \sum_{m'=1}^{N'} \overline{M'_{m'n'}} \right)} \quad (37)$$

But the eddy currents are in quadrature with the excitation current, and by first-order estimation [17–18], one may neglect the effect of eddy currents on the overall inductance calculation as the magnetic flux induced by the eddy currents within the metal trace provides no effective contribution to the initial magnetic field. In doing so, K_2 can be assumed as zero.

Figure 10 plots the weighting expression $e^{-kT/(N\delta)} \sum_{j=1}^N M_{kj} / \sum_{i=1}^{N/2} e^{-kT/(N\delta)} \sum_{j=1}^N M_{ij}$ versus k , where

$k = 1, 2, \dots, N$ is the filament number in Fig. 8 in a typical case with parameters $J_0 = 1 \text{ A/m}^2$, $T = 1 \mu\text{m}$, $W = 10 \mu\text{m}$, $N = 16$, and $l = 100 \mu\text{m}$. The weighting expression shows the self-inductance weightage of a filament over the total self-inductance of the single conductor. As shown in the diagram, under the skin effect, the self-inductance of each filament is nearly a constant and therefore, can be taken to be the same in subsequent computation in Section 3.3. Figure 11 shows a typical trend for K_1 found in Eq. (32)

Figure 10. The self-inductance weightage and the current density under skin effect.

Figure 11. The characteristic change of K_1 .

for copper and gold trace spiral inductors of the same geometric parameters, namely, $T=1\ \mu\text{m}$, $W=10\ \mu\text{m}$, $N=16$, and $l=100\ \mu\text{m}$. As noted from the figure, K_1 in Eq. (32) can be taken as a constant to facilitate a faster computation for Eq. (32).

3.3. Frequency-Dependent Formulation for Inductance under the Skin Effect

The formulation for the series inductance as given in Section 3.2 has neglected the coupling effect of the series resistance. From the partitioning shown in Fig. 8, one can deduce that the specific skin effect complex internal impedance can be computed from the following expression

$$Y(\omega) = \sum_{n=1}^N \frac{1}{R_n + j\omega L} \quad (38)$$

where L is the self-inductance of each filament and is as given in Eq. (30). The value of L in Eq. (38) can be empirically taken as [21]

$$L = 0.002\ell_{\text{total}} \left[\ln\left(\frac{2\ell_{\text{total}}}{W+t}\right) + 0.5 - 0.00239 \right] \quad (39)$$

Figure 12. The conformal mapping from rectangular domain to circular domain.

where t is the thickness of each filament. To find R_n , the cross-section of the spiral inductor as in Fig. 8 is first mapped into a circle in the w plane using Ref. 19, and this transformation is expressed as

$$t = \ln(w + e^{-T}) \quad (40)$$

where

$$t = z + ix \quad (41)$$

With this transformation, each filament in Fig. 8 is subsequently mapped into a concentric ring within the circle as shown in Fig. 12. As a result of this, by borrowing the concept introduced by Gatous [20], R_n can be deduced to be

$$R_n = \frac{(4n-1)^2\pi}{64\sigma(1-e^{-T})^2} \quad (42)$$

The series term on the right-hand side of Eq. (38), evidently, may be considered as an equivalent circuit of parallel RL circuits as shown in Fig. 13. The specific skin effect complex internal impedance can thus be obtained by rearranging Eq. (38) to yield

$$R(\omega) + j\omega L_{\text{int}}(\omega) = \frac{1}{Y(\omega)} \quad (43)$$

where the resistive and reactive components on the surface of the metal are related by

$$R(\omega) = \frac{\sum_{n=1}^N \frac{R_n}{R_n^2 + \omega^2 L^2}}{\left(\sum_{n=1}^N \frac{R_n}{R_n^2 + \omega^2 L^2} \right)^2 + \omega^2 \left(\sum_{n=1}^N \frac{L}{R_n^2 + \omega^2 L^2} \right)^2} \quad (44)$$

$$L_{\text{int}}(\omega) = \frac{\sum_{n=1}^N \frac{L}{R_n^2 + \omega^2 L^2}}{\left(\sum_{n=1}^N \frac{R_n}{R_n^2 + \omega^2 L^2} \right)^2 + \omega^2 \left(\sum_{n=1}^N \frac{L}{R_n^2 + \omega^2 L^2} \right)^2} \quad (45)$$

It is clear here that when R_n equals zero, $R(\omega)$ would be zero whereas $L_{\text{int}}(\omega)$ would be equal to the parallel of all

Figure 13. Equivalent circuit for the internal impedance in the metallic trace.

the self-inductance of the filament as given in Fig. 8. From Section 3.2, it is noted that this value of $L_{\text{int}}(\omega)$ will be a near constant under the effect when R_n equals zero. When the frequency is zero, Eqs. (44) and (45) are reduced to the well-known DC value. The DC inductance value is approximately given as [21]

$$L_{\text{DC}}^{\text{self}} = 0.002\ell_{\text{total}} \left[\ln \left(\frac{2\ell_{\text{total}}}{W+T} \right) + 0.5 - 0.00239 \right] \quad (46)$$

As the frequency increases, under the skin effect, the resistance $R(\omega)$ increases and the internal inductance $L_{\text{int}}(\omega)$ decreases to some limiting values depending on the geometry of the spiral inductor.

4. EXPERIMENTAL RESULTS AND DISCUSSION

From the discussion in Section 3.3, owing to the presence of the skin effect, the behavior of the theoretical inductance value of the spiral inductor is expected to be a decreasing function of frequency. However, in the measurement, the measured inductance is seriously affected by the presence of coupling capacitance C_s . For subsequent comparison in Fig. 14, we have subtracted from the measured data this capacitance's contribution through the following expression

$$L_s(f) = \frac{\text{imag}((-Y_{12} - j\omega C_s)^{-1})}{\omega} \quad (47)$$

where the value of C_s is attained by circuit optimizations and $\text{imag}(\cdot)$ denotes the imaginary part of the term enclosed in parentheses. In the circuit model shown in Fig. 3, $L_s(f)$ represents the theoretical frequency-dependent inductance of the spiral inductor. The simulated inductance $L_s(f)$ is computed by using the theoretical frequency-dependent inductance in Eqs. (30), (31), (45), and (46).

Figure 14. The measured and predicted inductances of spiral inductors.

To confirm that expression (47) can indeed predict the overall inductance behavior, we fabricated a series of circular copper-traced inductors. The layout parameters of the inductors include $6\ \mu\text{m}$ width, $2\ \mu\text{m}$ spacing, $1\ \mu\text{m}$ metal thickness, and $75\ \mu\text{m}$ inner dimension. The numbers of turns for inductors 5–7 are 3, 4, and 5, respectively. Figure 14 compares the measured inductance value and the simulated inductance from Eq. (47) for all the sample spiral inductors. The Cascade wafer probe and the HP8510 are used to measure the wafer containing the spiral inductors. Good agreement between the measured and predicted inductance values, especially for the domain below the resonance frequency of inductors, has been achieved in Fig. 14.

PULSE COMPRESSION

JENS BIEGERT
 JEAN-CLAUDE DIELS
 University of New Mexico
 Albuquerque, New Mexico

1. INTRODUCTION

The generation of ultrashort laser pulses is of tremendous interest because their attractive features—ultrabroadband spectra (nearing 1 octave) and ultrahigh intensity (terawatt range)—make them suitable for probing dynamic processes at never-before-accessed timescales and to study light-matter interaction at unprecedented intensity levels. Current techniques to generate the desired milli-

joule-level femtosecond pulses are, however, rather complex and expensive [1,2]. The most common technique [3] is to use a femtosecond Ti:sapphire laser oscillator followed by one or more amplification stages. To avoid laser-induced damage during the amplification process, the pulse to be amplified is stretched in time, thus decreasing its intensity, and then amplified and afterward recompressed. The overall source therefore consists of a pump laser, an oscillator, a stretcher, amplifiers with their pump lasers (generally, frequency-doubled and q -switched neodymium based systems like Nd:YAG), and finally a compressor. A major drawback is that the complexity of these systems increases rapidly the shorter the amplified pulses have to be. For many applications, systems capable of producing pulses several 100 fs long are needed; the most sophisticated large-scale systems, however, are capable of producing 10-fs pulses in the low millijoule range.

Hence, one major objective of pulse compression through second harmonic generation is to design a cheaper, compact alternative to these large systems, with a simple Nd:YAG laser as source of energy. The Nd:YAG laser has been the workhorse of industrial applications for a couple of decades and may become the most economical source of femtosecond pulses as well. Pulses of 40–100 ps duration are routinely generated by mode-locked commercial Nd:YAG lasers, and the implementation of negative feedback has made it possible to decrease the pulse duration to 10 ps, and the pulse-to-pulse energy fluctuations to less than 1% [4]. After amplification, pulses of 10 ps duration and hundreds of millijoules energy are routinely generated at 1.064 μm . These picosecond pulses have sufficiently high peak intensity to be an ideal source for harmonic conversion through nonlinear optics.

Another very exciting possibility is to further reduce the already ultrashort (10-fs) pulses. The ultimate limit for propagating electromagnetic radiation is hereby half a cycle of the carrier electric field, which—at 800 nm—is 1.35 fs. Both cases, compression of long and ultrashort pulses, will be discussed.

A prerequisite for pulse compression is clearly the fact that the processes involved have to respond instantaneously on the timescale of the shortest optical pulse. Nonlinear crystals lend themselves nearly ideally to frequency conversion with ultrashort pulses because their nonlinearity is electronic and nonresonant. There appears to be no limit in the palette of frequencies that can be generated through nonlinear optics, from DC (optical rectification) to infrared (difference frequency generation and optical parametric generation and amplification), to visible, and to UV (sum frequency generation). The shorter the pulse, the higher the peak intensity for a given pulse energy (and thus the more efficient the nonlinear process). There is, however, an insidious problem that plagues nonlinear optics with ultrashort pulses—the velocity of a wave packet is not the same as that of the individual waves. In second-harmonic generation, even though the fundamental and second-harmonic waves are “phase-matched” (i.e., these waves propagate at the same wave velocity), the fundamental pulse propagates at a different velocity (in general faster) than the second harmonic pulse.

This effect, generally labeled *group velocity dispersion*, appears to be the nemesis of most frequency-mixing schemes. In general, because of group velocity dispersion, the second harmonic will propagate more slowly than the fundamental that feeds it. Therefore, the nonlinear interaction between two pulses of duration τ at frequencies ω_1 and ω_2 is limited to the walkoff distance $L = \tau / (v_{g1}^{-1} - v_{g2}^{-1})$, where v_{g1} and v_{g2} are the group velocities at their respective wavelengths. For instance, in type I interaction, the second harmonic of 800 nm radiation in BBO ($\beta\text{-BaB}_2\text{O}_4$) is delayed with respect to the fundamental by 194 fs/mm. Therefore, very thin (<1-mm) crystals are generally selected for all nonlinear mixing processes involving femtosecond pulses. It has been shown, however, that group velocity dispersion, combined with amplitude modulation associated with the depletion of the fundamental waves, can lead to efficient pulse compression [5,6]. Small amounts of compression was first demonstrated with subpicosecond pulses [7,8]. Subsequently, pulse compression through second-harmonic generation in very long (5–6-cm) KDP (KH_2PO_4) and KD*P (KD_2PO_4) crystals was predicted [6] and demonstrated [9]. It should be noted that a similar compression mechanism has been investigated in synchronously pumped optical parametric oscillators [10–13].

2. A SIMPLE MODEL OF PULSE COMPRESSION IN SECOND-HARMONIC GENERATION

Let us assume second-harmonic generation of two interacting fundamental waves with orthogonal polarizations (type II). Furthermore, assume the second harmonic, the group velocity (an extraordinary wave), to be intermediate between that of the ordinary (o) and extraordinary (e) fundamental waves. The second harmonic e wave is being generated by the nonlinear polarization $P_{e,\text{NL}} = \varepsilon_0 \chi^{(2)} E_o E_e$, where $E_j = \mathcal{E}_j \exp i(\omega t - k_j z)$ ($j = o, e$) are the electric fields of the ordinary and extraordinary fundamental waves and $\chi^{(2)}$ is the second-order nonlinear susceptibility. The wavevectors of the ordinary and extraordinary fundamental waves are $k_o = \omega n_o(\omega)/c$ and $k_e = \omega n_e(\omega)/c$ and for the second-harmonic wave $k_2 = \omega n_2(\omega_2)/c$, respectively; $n_o(\omega)$, $n_e(\omega)$ and $n_2(\omega_2)$ are the refractive indices of the nonlinear crystal. This nonlinear polarization generates a second-harmonic field as an extraordinary wave $E_2 = \mathcal{E}_2 \exp i(\omega_2 t - k_2 z)$ at the frequency $\omega_2 = 2\omega$. The propagating second harmonic will remain in phase with the second harmonic generated at any point z in the crystal, if momentum conservation (“phase matching”) is satisfied:

$$k_2 = k_o + k_e \quad (1)$$

This phase-matching condition is satisfied if the crystal orientation is chosen such that

$$n_2 = \frac{n_o + n_e}{2} \quad (2)$$

The phase-matching condition implies that the *phase velocities* are matched. After a propagation length L through the crystal, the phase delay of the second harmonic $L/v_{p,2}$ is equal to the sum of the phase delay of the two fundamentals $L/v_{p,o} + L/v_{p,e}$. The phase velocities are defined as

$$v_{p,2} = \frac{c}{n_e(\omega_2)} \quad v_{p,o} = \frac{c}{n_o(\omega)} \quad v_{p,e} = \frac{c}{n_e(\omega)} \quad (3)$$

The fact that the waves remain in phase does not necessarily imply that *pulses* simultaneously reach the end of the crystal. The three wavepackets propagate at the *group velocities* given by

$$\begin{aligned} \frac{1}{v_{g,2}} &= \frac{1}{c} \left[n_e(\omega_2) - \lambda \left. \frac{dn_e}{d\lambda} \right|_{\omega_2} \right] \\ \frac{1}{v_{g,o}} &= \frac{1}{c} \left[n_o(\omega) - \lambda \left. \frac{dn_o}{d\lambda} \right|_{\omega} \right] \\ \frac{1}{v_{g,e}} &= \frac{1}{c} \left[n_e(\omega) - \lambda \left. \frac{dn_e}{d\lambda} \right|_{\omega} \right]. \end{aligned} \quad (4)$$

If a fundamental pulse with an e and an o component enters the crystal, it will generate a second-harmonic pulse that will propagate at a different group velocity than either component of the fundamental. We have required that the velocity of the second harmonic is intermediate between that of the two fundamentals. Let us now consider the case where the fundamental e wave enters the crystal *delayed* with respect to the fundamental o wave. A second harmonic will be generated at the temporal overlap

between the two pulses, as sketched in Fig. 1a. In a frame of reference moving at the group velocity of the second harmonic, the two fundamental pulses will travel toward each other (since the faster e wave has been delayed). After some propagation distance, the overlap of the fundamentals increases, and so does the second harmonic (Fig. 1b). However, if the fundamental pulses are sufficiently intense as sketched in Figs. 1c and 1d, the growth of the second harmonic may be so rapid as to deplete the fundamentals. As a result, the spatial overlap of the two fundamentals remains small, as they move into each other (Fig. 1d). Crude order of magnitude estimates of the power required can be made by considering square fundamental pulses (temporal profile). Let us assume first that the group velocity of the second harmonic is exactly the average of the group velocities of the extraordinary and ordinary fundamentals. If, as in Fig. 1a, the two fundamental pulses are given a pre-delay, they will move across each other, in a frame of reference moving with the second harmonic, as they propagate through the crystal. One expects also that the second-harmonic pulse will be even longer than the fundamental. At perfect phase matching, the second harmonic generated after a distance z is given by [14]

$$\mathcal{E}_2(z) = \mathcal{E}(0) \tanh \frac{z}{L_{\text{sh}}} \quad (5)$$

where, at $z=0$, $\mathcal{E}_o = \mathcal{E}_e = \mathcal{E}$, and the characteristic distance L_{sh} is given by

$$\frac{1}{L_{\text{sh}}} = \frac{\omega \chi^{(2)}}{n_2 c} \mathcal{E} \quad (6)$$

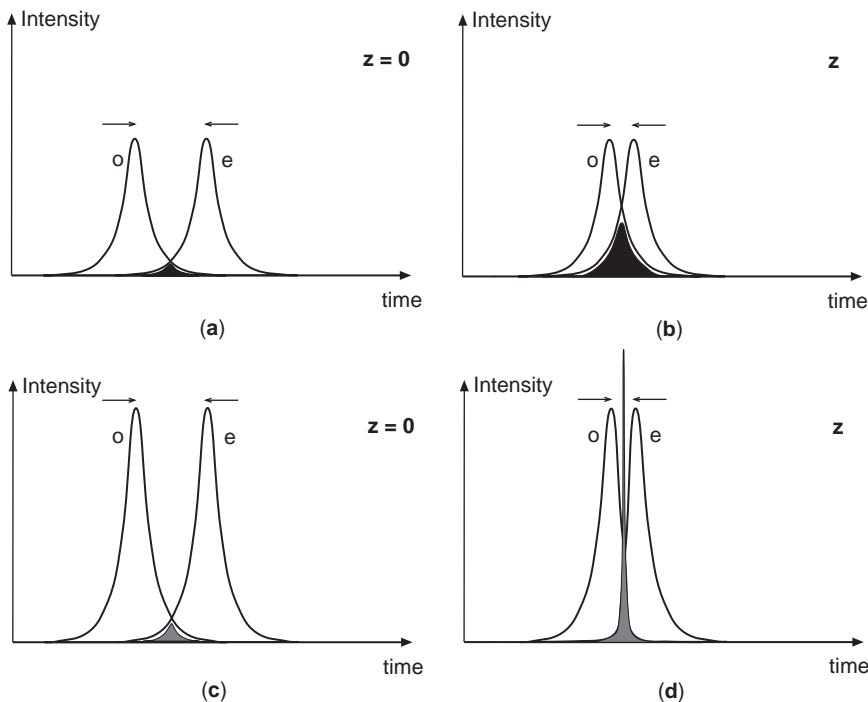

Figure 1. The three pulses are represented in a temporal frame of reference moving with the group velocity of the second harmonic. Initially, at $z=0$, the fundamental e is delayed with respect to the fundamental o wave [panels (a) and (c)]. For low input energies (a), the second harmonic will be broadened as the two fundamental pulses move into each other (b). For sufficiently high input energies (c), the overlap between the two fundamentals remains small because they are depleted by the upconversion process, and the second-harmonic pulse remains short (d).

For optimum production of a second-harmonic pulse of duration τ_{ov} , the fundamental pulses should move into each other by an overlap time τ_{ov} over the characteristic distance L_{sh} . The condition

$$\tau_{ov} = \frac{n_2 c}{\omega \chi^{(2)} \mathcal{E}} \left(\frac{1}{v_{g,e}} - \frac{1}{v_{g,o}} \right) \quad (7)$$

leads to an optimum intensity $I_0 = W_0/\tau_{ov}$ (where W_0 is the pulse energy density over the overlap time) for the fundamental pulses. The intensity I_0 of the fundamental square pulses is given by

$$I_{o,e} = \frac{\varepsilon_0 c n_{o,e} \mathcal{E}^2}{2} = \frac{0 c^3 n_{o,e} n_2^2}{2(\omega \chi^{(2)} \tau_{ov})^2} \left(\frac{1}{v_{g,e}} - \frac{1}{v_{g,o}} \right)^2 \quad (8)$$

3. APPLICABILITY TO VARIOUS WAVELENGTH RANGES

The basic requirement for pulse compression is that the group velocity of the second harmonic be intermediate in the group velocities of the o and e fundamentals. This allows, in a frame of reference that moves at the second-harmonic group velocity, the fundamental pulses to cross over each other. As mentioned above, this requirement is, unfortunately, satisfied only for conversion of near-infrared pulses [15] in KDP and KD*P crystals. It is, however, possible to control the relative group velocities while maintaining the phase matching condition, either by tilting an energy front with respect to the wavefront [16,17], or by using noncollinear interaction. It is particularly intriguing that large pulse compression can be achieved despite the following circumstances:

1. The crystal is longer than the minimum length over which all frequency components of the pulse spectrum remain in phase.
2. The shortest pulses that are generated are affected by group velocity dispersion (to all orders).

The first point can be explained by the fast depletion of the fundamental wave. It is this fast amplitude modulation that provides the frequency components that make the broad bandwidth for these short pulses. The exact conditions for compression are not easily met—in fact, pulse broadening rather than compression has also been predicted and observed [18]. The second point has never been completely addressed, because all models to date are based on Maxwell's equations in the time domain, where group velocity effects have to be treated by higher (higher than 1) order differential operators. We present here an approach in the frequency domain, where the dispersion is taken exactly into account to any order. It has been shown [15,19], as expected, that the influence of the higher-order terms is significant for femtosecond pulses and cannot be neglected.

4. GENERAL EQUATIONS AND NOTATIONS

Our model is based on a Fourier transformation of Maxwell's wave equations for a total electric field vector \mathbf{E} that is the sum of the second harmonic-field polarized as an e wave, and the fundamentals polarized as o and e waves [20]

$$\begin{aligned} & \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) \mathbf{E}(x, y, z, t) \\ & = \mu_0 \frac{\partial^2}{\partial t^2} \mathbf{P}(x, y, z, t) \end{aligned} \quad (9)$$

where μ_0 is the magnetic permeability of free space. The source term of Eq. (9) contains the polarization \mathbf{P} , which is decomposed into two parts:

$$\mathbf{P} = \mathbf{P}^L + \mathbf{P}^{NL} \quad (10)$$

For the linearly polarized plane wave propagating along z , the wave equation reduces to

$$\left(\frac{\partial^2}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) \mathbf{E}(z, t) = \mu_0 \frac{\partial^2}{\partial t^2} [\mathbf{P}^L + \mathbf{P}^{NL}] \quad (11)$$

Substituting for the Fourier transformed linear polarization $\tilde{\mathbf{P}}^L(\Omega, z) = \varepsilon_0 \chi(\Omega) \tilde{\mathbf{E}}(\Omega, z)$ in the Fourier transform of the propagation equation [Eq. (11)], we get

$$\begin{aligned} & \left[\frac{\partial}{\partial z} + i \frac{\Omega}{c} \sqrt{\varepsilon(\Omega)} \right] \left[\frac{\partial}{\partial z} - i \frac{\Omega}{c} \sqrt{\varepsilon(\Omega)} \right] \tilde{\mathbf{E}}(z, \Omega) \\ & = \mu_0 \Omega^2 \tilde{\mathbf{P}}^{NL}(\Omega, z) \end{aligned} \quad (12)$$

where we have introduced the dielectric constant

$$\varepsilon(\Omega) = [1 + \chi(\Omega)] \quad (13)$$

and the Fourier transform of the nonlinear polarization $\tilde{\mathbf{P}}^{NL}(\Omega, z)$. Let us substitute for the total field \mathbf{E} in the Fourier transform of Eq. (11)

$$\begin{aligned} \tilde{\mathbf{E}}(\Omega, z) & = \tilde{\mathbf{E}}_2(\Omega, z) + \tilde{\mathbf{E}}_o(\Omega, z) + \tilde{\mathbf{E}}_e(\Omega, z) \\ & = \frac{1}{2} \tilde{\mathcal{E}}_2[(\Omega - \omega_2), z] e^{-ik_2(\Omega - \omega_2)z} \hat{\mathbf{i}}_e \\ & \quad + \frac{1}{2} \tilde{\mathcal{E}}_o[(\Omega - \omega), z] e^{-ik_o(\Omega - \omega)z} \hat{\mathbf{i}}_o \\ & \quad + \frac{1}{2} \tilde{\mathcal{E}}_e[(\Omega - \omega), z] e^{-ik_e(\Omega - \omega)z} \hat{\mathbf{i}}_e + \text{c.c.} \end{aligned} \quad (14)$$

where $\hat{\mathbf{i}}_o$ and $\hat{\mathbf{i}}_e$ represent unit vectors along the ordinary and extraordinary directions of polarization, Ω is the frequency variable in the Fourier transform, and c.c. denotes complex conjugate.

In Eq. (14), the propagation constants $k_i(\Omega)$ are defined by

$$\begin{aligned} k_2(\Omega) &= \frac{\Omega}{c} \sqrt{\varepsilon_2(\Omega)} = \frac{\Omega}{c} n_2(\Omega) \\ k_o(\Omega) &= \frac{\Omega}{c} \sqrt{\varepsilon_o(\Omega)} = \frac{\Omega}{c} n_o(\Omega) \\ k_e(\Omega) &= \frac{\Omega}{c} \sqrt{\varepsilon_e(\Omega)} = \frac{\Omega}{c} n_e(\Omega) \end{aligned} \quad (15)$$

The Fourier transforms of the fundamental fields $\tilde{\mathbf{E}}_o$ and $\tilde{\mathbf{E}}_e$ are centered at $\Omega = \omega$, and the Fourier transform of the second-harmonic field $\tilde{\mathbf{E}}_2$ is centered at $\Omega = \omega_2 = 2\omega$.

To simplify the notation, we have introduced $\Delta\Omega$ as argument of the Fourier transforms of the envelopes:

$$\begin{aligned} \tilde{\mathcal{E}}_2(\Delta\Omega, z) &= \tilde{\mathcal{E}}_2(\Omega - 2\omega, z) \\ \tilde{\mathcal{E}}_o(\Delta\Omega, z) &= \tilde{\mathcal{E}}_o(\Omega - \omega, z) \\ \tilde{\mathcal{E}}_e(\Delta\Omega, z) &= \tilde{\mathcal{E}}_e(\Omega - \omega, z) \end{aligned} \quad (16)$$

After substitution of the fields [Eq. (14)], Eq. (12) thus leads to a system of three coupled differential equations for the evolution of each field $\tilde{\mathbf{E}}_o$, $\tilde{\mathbf{E}}_e$, and $\tilde{\mathbf{E}}_2$. For instance, the evolution of the second-harmonic field $\tilde{\mathbf{E}}_2(\Omega, z) = 1/2 \tilde{\mathcal{E}}_2(\Delta\Omega, z) \exp(-ik_2(\Delta\Omega)z) \hat{\mathbf{1}}_e$, is given by

$$\begin{aligned} \frac{\partial}{\partial z} \tilde{\mathcal{E}}_2(\Delta\Omega, z) &= i \frac{\mu_0}{k_2} (\omega + \Delta\Omega)^2 \tilde{\mathbf{P}}^{\text{NL}}(\Delta\Omega, z) e^{ik_2(\Delta\Omega)z} \\ &\quad - \frac{i}{2k_2} \frac{\partial^2}{\partial z^2} \tilde{\mathcal{E}}_2(\Delta\Omega, z) \end{aligned} \quad (17)$$

Note that there has been no slowly varying envelope approximation made in Eq. (17). The total nonlinear polarization, in the time domain, has contributions at the second harmonic and fundamental wavelength along the extraordinary direction, and one contribution at the fundamental wavelength along the ordinary wave:

$$\begin{aligned} \tilde{\mathbf{P}}^{\text{NL}}(t, z) &= \varepsilon_0 \chi^{(2)} \left[E_o(t, z) E_e(t, z) \hat{\mathbf{1}}_e \right. \\ &\quad \left. + E_2(t, z) E_o^*(t, z) \hat{\mathbf{1}}_e + E_2(t, z) E_e^*(t, z) \hat{\mathbf{1}}_o \right] \end{aligned} \quad (18)$$

It is straightforward to insert the total field [Eq. (14)] and the Fourier transform of the nonlinear polarization [Eq. (18)] — in which the products of time-dependent fields are replaced by convolutions and correlations — into the propagation equation [Eq. (12)]. The resulting system of three coupled equations, with one corresponding to the spectral

components around the second-harmonic frequency, and the other two corresponding to the ordinary and extraordinary components of the fundamental field is

$$\begin{aligned} \frac{\partial \tilde{\mathcal{E}}_2(\Delta\Omega, z)}{\partial z} &= -i \left(\frac{\omega_2 + \Delta\Omega}{4n_2 c \Delta\Omega} \right)^{(2)} \int_{-\infty}^{\infty} \tilde{\mathcal{E}}_o(\Delta\Omega', z) \tilde{\mathcal{E}}_e(\Delta\Omega - \Delta\Omega', z) \\ &\quad e^{-i[k_o(\Delta\Omega) + k_e(\Delta\Omega - \Delta\Omega) - k_2(\Delta\Omega)]z} d\Delta\Omega' \\ &\quad + \frac{i}{2k_2} \frac{\partial^2 \tilde{\mathcal{E}}_2(\Delta\Omega, z)}{\partial z^2} \end{aligned} \quad (19)$$

$$\begin{aligned} \frac{\partial \tilde{\mathcal{E}}_o(\Delta\Omega, z)}{\partial z} &= -i \frac{(\omega + \Delta\Omega)\chi^{(2)}}{4n_o c \Delta\Omega} \int_{-\infty}^{\infty} \tilde{\mathcal{E}}_2(\Delta\Omega', z) \tilde{\mathcal{E}}_e^*(\Delta\Omega' - \Delta\Omega, z) \\ &\quad e^{i[k_o(\Delta\Omega) + k_e(\Delta\Omega' - \Delta\Omega) - k_2(\Delta\Omega)]z} d\Delta\Omega' \\ &\quad + \frac{i}{2k_o} \frac{\partial^2 \tilde{\mathcal{E}}_o(\Delta\Omega, z)}{\partial z^2} \end{aligned} \quad (20)$$

$$\begin{aligned} \frac{\partial \tilde{\mathcal{E}}_e(\Delta\Omega, z)}{\partial z} &= -i \frac{(\omega + \Delta\Omega)\chi^{(2)}}{4n_e c \Delta\Omega} \int_{-\infty}^{\infty} \tilde{\mathcal{E}}_2(\Delta\Omega', z) \tilde{\mathcal{E}}_o^*(\Delta\Omega' - \Delta\Omega, z) \\ &\quad e^{i[k_e(\Delta\Omega) + k_o(\Delta\Omega' - \Delta\Omega) - k_2(\Delta\Omega)]z} d\Delta\Omega' \\ &\quad + \frac{i}{2k_e} \frac{\partial^2 \tilde{\mathcal{E}}_e(\Delta\Omega, z)}{\partial z^2} \end{aligned} \quad (21)$$

Note that $\Delta\Omega$ in Eq. (19) covers a 2 times broader bandwidth than $\Delta\Omega'$. Similarly, $\Delta\Omega'$ in Eqs. (20) and (21) cover 2 times the bandwidth of $\Delta\Omega$ in these equations. It is convenient to present the solutions in the time domain, in a frame of reference propagating with a group velocity v_{g_2} . The fields to be represented are given by

$$\begin{aligned} \tilde{\mathcal{E}}_2(t, z) &= \int_{-\infty}^{\infty} \tilde{\mathcal{E}}_2(\Delta\Omega, z) \exp \left\{ -i \left[k_2(\Delta\Omega) - k_2 - \frac{\Delta\Omega}{v_{g_2}} \right] z \right\} \\ &\quad e^{-i\Delta\Omega t} d\Delta\Omega \end{aligned} \quad (22)$$

$$\begin{aligned} \tilde{\mathcal{E}}_o(t, z) &= \int_{-\infty}^{\infty} \tilde{\mathcal{E}}_o(\Delta\Omega, z) \exp \left\{ -i \left[k_o(\Delta\Omega) - k_2 - \frac{\Delta\Omega}{v_{g_2}} \right] z \right\} \\ &\quad e^{-i\Delta\Omega t} d\Delta\Omega \end{aligned} \quad (23)$$

$$\begin{aligned} \tilde{\mathcal{E}}_e(t, z) &= \int_{-\infty}^{\infty} \tilde{\mathcal{E}}_e(\Delta\Omega, z) \exp \left\{ -i \left[k_e(\Delta\Omega) - k_2 - \frac{\Delta\Omega}{v_{g_2}} \right] z \right\} \\ &\quad e^{-i\Delta\Omega t} d\Delta\Omega \end{aligned} \quad (24)$$

The constant terms k_2 , k_o , and k_e are the leading terms of the Taylor expansions for the wavevectors $k_2(\Delta\Omega)$, $k_o(\Delta\Omega)$, and $k_e(\Delta\Omega)$, respectively. If we choose the frame of reference moving with the second-harmonic pulse, then

$$\frac{1}{v_{g_2}} = k_2'_{2\omega} \quad (25)$$

which can be calculated from Sellmeier's equations.

Equations (19)–(21) describe the nonlinear interaction accurately to all orders without any approximations. It would be desirable, however, to neglect the second derivatives of the electric fields in order to simplify the equations and to speed up the already involved numerics. In one of the worst case scenarios, namely, generation of a 3-fs second harmonic pulse, we have found that the maximum value for $\partial^2 \mathcal{E} / \partial z^2$ is 200 times smaller than $2k \partial \mathcal{E} / \partial z$, and can therefore be neglected. Hence, we conclude that for the pulse durations under investigation, the reduction to a system of first-order differential equations suffices. We would like to note that one possible improvement, however, would be to include the nonlinear refractive index \bar{n}_2 into the equations to correct for small variations due to the ultraintense fields that are involved. The phase shift $\ell \cdot \Delta k$ resulting from the nonlinear refractive index \bar{n}_2 in the worst-case scenario in Fig. 8a for compression of the e component fundamental to 2.5 fs can be estimated from the $\chi_{\text{int}}^{(3)}$ value given in Ref. 21, to be $\ell \cdot \Delta k = \ell \cdot 2\pi \cdot \bar{n}_2 \cdot I / \lambda = 0.09 < 1$. This value is, therefore, small enough not to contribute significantly to the equations.

5. COMPRESSION OF “LONG” PULSES

The following simulations are based on second-harmonic generation in KDP, where the full Sellmeier formulas have been used in the definition of the various k vectors that appear in the wave equations. As a result, our model takes into account *all* group velocity dispersion effects as they

affect the pulse propagation and the pulse conversion process. As an illustration of the simple analytical consideration in Section 2, we calculate the second harmonic generated by two step functions (temporal profile). Two step function fundamental pulses enter the crystal with no initial overlap (Fig. 2a).

The ordinary and the extraordinary fundamental intensities are chosen to be equal and the relative group velocities are also chosen to be equal but opposite in sign. A short pulse is generated after a distance of 1 cm, as shown in Fig. 2b. In agreement with the simple considerations of Section 2, the width of the generated second harmonic is determined by the depletion of the two fundamentals moving into each other. The situation is much more complex when the full frequency dependence of the k vectors is taken into account. Perfect phase matching exists only for a single-frequency component. Because of the frequency dependence of the wavevectors, there will be some transfer of energy back from the second harmonic to the fundamental. Figures 3 and 4 illustrate the propagation and harmonic generation of two fundamental pulses with a Gaussian temporal profile. The fundamental ordinary and extraordinary waves have respectively intensities of 1.4 and 1 GW/cm², with the extraordinary wave pre-delayed by 14 ps with respect to the ordinary wave. A three-dimensional representation of the propagation of the intensities of the three waves inside a 6-cm-long KDP crystal is shown in Fig. 3. The depleted fundamental and second harmonic waves are shown after a propagation distance of 6 cm in Figs. 4a and 4b. To assess the influence of group velocity dispersion and higher-order terms in the

Figure 2. Square pulse second-harmonic generation. The dotted and dashed lines represent the ordinary and extraordinary fundamental intensities, respectively. The solid lines represent the extraordinary second-harmonic intensity. The successive plots are for $z = 0$ cm (a), $z = 1$ cm (b), $z = 2$ cm (c), and $z = 3$ cm (d). Note the different scales in intensity.

Figure 3. Three-dimensional representation of the propagation of the fundamental and the second-harmonic pulses.

expansion of the k vectors, the same calculation was performed in the approximation of constant group velocity at the various wavelengths. The results are shown in Figs. 4c and 4d. The parameters of the calculation were chosen for optimum pulse compression in the complete model. The very large difference in conversion efficiency in both cases clearly indicates that the higher-order terms in the expansion of the wavevector cannot be neglected. We have also carried out the experimental investigation of pulse compression. Our experimental arrangement is similar to the arrangement described in Ref. 10. The pump source is an active-passive mode-locked Nd:YAG laser controlled by

passive negative feedback with successive amplifier stages. In the described experiment, the system was adjusted to yield 14 ps pulses with pulse energies up to 150 mJ. The linearly polarized output beam passes through a half-wave plate that rotates its plane of polarization by 45° . The beam is then separated into two components by a polarizing beamsplitter, and each component is given a relative delay before being recombined at a second polarizing beamsplitter. The rotation of the waveplate enables one to control the ratio between the energies of both beams. The recombined pulses are sent as extraordinary and ordinary waves into the second-harmonic-generating crystal (6-cm-

Figure 4. Results of the numerical simulation for pulse shapes of fundamental and second-harmonic pulses after propagation in 6-cm-long KDP crystal: (a) and (b) correspond to the exact calculation and (c) and (d), to the case of a linear approximation, neglecting group velocity dispersion.

long KDP). A portion of uniform intensity at the beam center is selected by a 9 mm apodized aperture positioned just before the crystal, giving a better than 95% top-hat transverse beam profile.

The duration of the compressed pulses at the second harmonic frequency was measured with a single-shot autocorrelator based on noncollinear second-harmonic generation in a 2 mm KDP type I crystal. An example of an autocorrelation trace of the second harmonic pulse, measured by a single-shot intensity autocorrelation, is shown in Fig. 5. The total power density of the 1.06- μm beam incident on the 6-cm-long KDP crystal was 2.6 GW/cm². The fundamental e beam was given a pre-delay of 10.5 ps with respect to the o wave. The intensity of the o pulse was 1.3 times that of the e pulse. The conversion efficiency was 14%. The width of the autocorrelation curve of the (green) compressed pulse is 480 fs, which corresponds to a sech^2 pulse of 309 fs duration. The compression factor is thus 45. The single-shot autocorrelator is a convenient diagnostic tool to optimize the laser. A trace such as in Fig. 5 is very sensitive to the quality of the optics used. For instance, the noise appearing on the right lobe of Fig. 5 is due to scratches on the filter (the autocorrelation should be exactly symmetric). In addition, the background is enhanced because of a contribution to the second harmonic from a non-uniform spatial beam structure.

The theoretical simulation led to a minimum compressed pulse duration of approximately 200 fs. The exact phase-matching condition for the central pulse wavelength was maintained for all numerical simulations. In the actual experiment, the shortest pulses are obtained after a slight retuning of the long frequency-doubling crystal. The two possible interpretations are that (1) the phase-matching condition is slightly different at high power than at low power, or (2) some dispersive effect of cascaded nonlinearities contribute to the pulse compression. Further simulations will be made in order to determine

Figure 5. Single-shot autocorrelation trace of a compressed 532-nm pulse. The time delay on the horizontal axis is 1 ps/div. The autocorrelation intensity is plotted in arbitrary units.

whether, within our theoretical model, optimum compression indeed occurs at some detuning from the low-power phase-matching condition.

6. COMPRESSION OF ULTRASHORT PULSES

Pulse compression of a factor of ≥ 60 has been demonstrated for Nd:YAG laser picosecond pulses and second harmonic type II in KDP and KD*P [9,15]. The condition of second-harmonic group velocity intermediate between the ordinary and extraordinary fundamentals cannot in general be met at any wavelength, for any crystal. It is, however, possible to adjust the group velocity through a tilt of the energy front with respect to the phase front. Figure 6 illustrates the basic principle for a degenerate type I process. As shown in the lower part of the figure, the temporal overlap of the interacting waves decreases because of the higher velocity of the SH wave relative to the fundamental waves. Furthermore, the spatial overlap decreases as a result of spatial walkoff (ρ) of the fundamental wave. These two negative effects can, however, be used in conjunction with pulse front tilt to match the relative velocities of the two waves, as illustrated in the upper part of Fig. 6. Loosely speaking, as seen in the frame of reference of the SH wave, the lateral walkoff of the fundamental wave slows this wave down just to match the velocity of the SH wave.

For femtosecond pulses, it is not practical to generate a large energy tilt. For instance, an energy tilt of the order of 40° would be required for second-harmonic type II generation and compression in BBO of a 800-nm pulse of a Ti:Sapphire laser in collinear interaction [22]. A dispersive element such as a prism with a beam diameter: base length ratio of 20 (in the case of SF10 glass) would be needed to achieve the required energy front tilt of 40° .

Figure 6. Shown is collinear degenerate type I interaction. For equal time intervals, the fundamental wave is illustrated as dark bars and the second-harmonic (SH) wave as gray bars. The gray bars are drawn with larger separation because of the typically higher velocity of the SH wave inside a crystal. The lower part shows temporal and lateral walkoff, whereas the upper part indicates how—for a given pulse front tilt—lateral walkoff can be used to adjust the relative velocities of the fundamental and SH waves to ensure overlap.

Table 1. Group Velocities for the *o*, *e*, and Second-Harmonic *e* Waves^a

Interaction	Fundamental (<i>o</i>) $v_{g,o}$ (10^8 m/s)	Second-Harmonic (<i>e</i>) $v_{g,2}$ (10^8 m/s)	Fundamental (<i>e</i>) $v_{g,e}$ (10^8 m/s)
Collinear	1.780	1.755	1.843
Noncollinear	1.798	1.905	1.934

^aValues are calculated for type II second-harmonic generation of 800-nm radiation for collinear and noncollinear (internal angle is 2°) interaction.

Dispersion in the glass would lead to large pulse broadening and phase modulation.

A better approach [22] is to use a noncollinear geometry; Table 1 shows how the group velocities of the participating waves can be changed from the collinear to the noncollinear case (here for an internal angle of 2°), leading to conditions for compression. The sketch of the interaction geometry in Fig. 7 shows that it is possible to obtain the respective group velocities through manipulation of the angles of incidence in the crystal and the energy tilt produced by a prism. Figure 7 pertains to the case of noncollinear interacting plane waves inside a 250- μm -long BBO crystal, cut for type II second-harmonic generation of laser pulses at 800 nm. Consistent with the one-dimensional approach used in the model [Eqs. (19)–(21)], the “energy-fronts” of all pulses should be aligned in the crystal. Since the interaction is noncollinear, the effect of energy front tilting from propagation under an angle through the air–crystal interface has to be precompensated to have zero energy front tilt inside the crystal. With the angle between the noncollinearly interacting fundamental beams set to $\theta = 2^\circ$ (internal angle; the external angle is $2\beta = 3.22^\circ$), the required pretilt angle can be achieved with a very thin prism (SF10) with a ratio of $a/b = 0.2$ for prism base length to beam diameter. The spatial chirp introduced by this thin prism is negligible compared to the value of $a/b = 20$ mentioned above.

The intensity profiles as function of interaction length in the case of the 10 fs fundamental with a 20-fs predelay

Figure 7. Experimental setup precompensating for the pulse front tilt that occurs from propagation through an interface under an angle $2\beta = 3.22^\circ$ (the pulse fronts are depicted as dotted lines). For the chosen type II SHG of 800-nm pulses $\theta = 2^\circ$, which is the angle between the incoming fundamental beams for noncollinear interaction. This requires a pulse front tilt of $\gamma = 0.62^\circ$ to precompensate for the propagation effect at the air–crystal interface. We also show that a very thin prism (SF10) can achieve γ with a ratio $a/b = 0.2$ for prism base length : beam diameter.

are shown in Figs. 8. It can be seen that the plots are not made exactly in the frame of reference of the second-harmonic wave that is indicated by the shift of the pulse in Fig. 8b with respect to the origin of the time axis. The group velocity difference between the fundamental waves relative to the second harmonic are also not exactly equal, which leads to several effects: The ordinary pulse is moving rapidly into the extraordinary pulse, causing strong modulation of the ordinary pulse, leading to the satellite in the extraordinary pulse. Furthermore, the strong energy exchange between the interacting waves and their imbalance in group velocities causes a rather pronounced satellite to appear only on the right side of the second-harmonic pulse profile instead of the expected smaller satellites on either side. Since the input parameters can be adjusted continuously in the experiment, it is conceivable that pulses without satellite could be generated by better symmetrization of the group velocities. Figure 8b shows a peak intensity of 9 GW/cm^2 for the 2.5-fs second harmonic for initial peak intensities for the fundamental pulses of roughly 13 GW/cm^2 . This indicates 70% conversion in intensity.

Furthermore, in order to more clearly understand the mechanisms involved, the simulations were performed for a broader range of input parameters: The fundamental input pulse duration was varied from 10 to 50 fs at the FWHM (full width at half-maximum) of the intensity profile. The more rapidly traveling *e* pulse was delayed with respect to the slower-traveling *o* pulse from 15 to 60 fs. Fundamental pulse energies were $400 \mu\text{J}$ each for the *o* and *e* pulses. The results are summarized through the contour plot of Fig. 9, showing the second-harmonic pulsewidth (FWHM) after an interaction length of $250 \mu\text{m}$ as a function of the input parameters mentioned above. The contour lines are separated on a logarithmic scale to base 10 in order to have a clearer picture of the range of pulsewidths. The emerging second-harmonic pulse shows widths ranging from about 2.5 to 34 fs. The shortest fundamental input pulses yield the shortest second-harmonic pulses as well. A 10-fs fundamental pulse, for instance, gives a second-harmonic pulse of about 2.5 fs for a pre-delay of 20 fs. The same result can be achieved for a pre-delay of 30 fs. This is a compression by a factor of 4. The longest calculated pulsewidth of 50 fs can yield a compressed second-harmonic of 10 fs, which has a compression factor of 5. If we were to draw a line in the contour plot, for which maximum compression can be achieved across the parameter range, it would roughly follow the gray dashed line in Fig. 9. Longer pulses therefore require a larger pre-delay to achieve maximum compression. It is clear that the overlap region of the *o* and *e* input pulses defines the initial second-harmonic pulsewidth. The strong energy exchange

Figure 8. Fundamental (a) and second-harmonic waves (b) as they propagate and interact inside a 250- μm -long BBO crystal [note the different scales for (a) and (b)]. Group velocity mismatch leads to a compressed second-harmonic pulse with a FWHM of 2.5 fs (b). Furthermore, considerable pulse reshaping can be seen for the extraordinary fundamental in (a), leading to a shortened FWHM from 10 to 2.5 fs with a shoulder. Pulse energies were 400 μJ for each fundamental pulse, at a FWHM of 10 fs with a predelay of 20 fs.

between the interacting waves will finally determine the width of all participating pulses at the end of the interaction region.

7. CONCLUSION

The main conclusion of this work is that dispersion and phase-matching bandwidth do not set a fundamental limit to type II pulse compression in sum frequency generation as long as they are used in a controlled fashion. Amplitude modulation through fast depletion of the fundamental pulses provides the extra bandwidth required to generate ultrashort pulses. We have presented a theoretical model sufficient to describe the desired effects, pointed out its limitations, and compared it to existing models that do not use the full dispersion dependence. The model has been applied to compression of 14 ps to 310 fs pulses and has also been experimentally verified. Furthermore, compression of 10-fs ultrashort pulses down to 2.5 fs in the second harmonic and the fundamental wavelength has been predicted. In the ultrashort pulse case, the experimental requirements are rather modest, since a relatively long crystal can be used, and the energy tilt requires only a small-angle prism. We have chosen to illustrate the method by specific calculations applied to second-harmonic generation of 800 nm pulses in BBO. However, it can be applied to frequency mixing in various crystals. The same approach can also be applied to parametric generation, extending the compression method demonstrated by Umbrasas et al. [10]. In this work we exploit the properties of group velocity dispersion at the various wavelengths to achieve the desired compression, rather than select a particular orientation of a particular crystal (BBO) that has near-zero dispersion [23]. The latter technique leads to impressive results, but is limited to amplification and gen-

eration of wavelengths longer than 560 nm. Another method to generate ultrashort UV pulses would be conventional frequency doubling of an 800-nm pulse, followed by dispersion and phase modulation (chirping) through a gas-filled hollow fiber or capillary. The method described here

Figure 9. This contour map shows the pulse duration of the emerging second-harmonic signal as function of the o, e input pulse duration and the predelay between the o and e fundamental pulses. The results are calculated for type II second-harmonic generation of 800-nm pulses with single-pulse energies of 400 μJ and for an interaction length of 250 μm inside a BBO crystal. The angle between the noncollinearly interacting fundamental waves inside the crystal is 2°.

provides the same result in a single step, and allows for the compression of bandwidth-limited pulses.

Digital communications systems such as wireless, optical, and wireline telecommunication networks have numerous well-known advantages over analog systems. These systems format binary data into discrete-time symbols, modulate the carrier using some form of digital modulation scheme (modulation in this simplified context includes symbol modulation and upconversion to a carrier frequency) to convert them to transmittable continuous-time signals, and transmit them over a channel. At the receiver the received signal is demodulated (demodulation includes both downconversion and symbol demodulation), symbol timing is recovered, and the received symbols are reformatted into a usable form. This process is shown in simplified form in Fig. 1.

The discrete-time symbols of a digital communication system are of duration T and are sequential; that is, they are orthogonal in time. To preserve the fixed time duration of symbols generated in the transmitter would require infinite bandwidth in the signal processing of the communication system and the communication channel. Finite bandwidth processing causes the symbols to spread in time. This causes the symbols to overlap in time and induces intersymbol interference (ISI).

Figure 1. Simplified block diagram of a digital communication system.

As will be described in the next section, even when finite bandwidth signal processing is used in the communication system, the effects of ISI could be eliminated if ideal signal processing components (brickwall filters as an example) could be implemented. This is, of course, not possible. Pulse shaping is used in the implementation of digital communication systems to minimize ISI caused by nonideal channel characteristics and nonideal component implementations.

Pulseshaping is performed in the transmit and receive filters of a communication system. The most common class of filters used for pulseshaping are Nyquist filters [1–3]. This article gives an overview of the theoretical foundations of pulseshaping and describes some practical implementations of pulseshaping filters. The material in this article assumes that the communication channel can be modeled as a linear time-invariant filter with additive white Gaussian noise (AWGN). For more detailed and in-depth coverage of pulse shaping the reader is referred to Refs. 1–3.

1. THEORETICAL BACKGROUND

Ideal data symbols are of fixed duration T . The spectrum for such a symbol is of the form

$$H_s(j\omega) = \frac{\sin[T(\omega/2)]}{T(\omega/2)} \tag{1}$$

Thus such a symbol would require infinite bandwidth, which is, of course, impractical. Real communication channels are of fixed bandwidth W . The ideal bandlimited channel response [1] is

$$H_C(j\omega) = \begin{cases} 1, & |\omega| < W \\ 0, & |\omega| \geq W \end{cases} \tag{2}$$

The transmit filter, which is designed to shape the transmit symbols to meet the power spectrum constraints of the

channel, has an ideal frequency-domain response [1] of

$$H_T(j\omega) = \begin{cases} \pi/W, & |\omega| < W \\ 0, & |\omega| \geq W \end{cases} \tag{3}$$

The time-domain transmit filter response is therefore

$$h_T(t) = \frac{\sin(Wt)}{Wt} \tag{4}$$

This response is referred to as the pulseshape. $h_T(t)$ is the familiar sinc function, which has zero crossings at integer multiples of Wt except at $Wt = 0$, where it has a value of 1. If we assume a symbol sequence S_n and set $T = \pi/W$, then the pulse for each symbol is of the form shown in Fig. 2 for a single pulse and in Fig 3 for multiple pulses.

From Fig. 3 it is obvious that if symbols are sampled at times $t = nT$, where n is an integer, the effects of ISI are mitigated. This is because the contribution to the composite waveform is zero for all pulses except for the pulse corresponding to S_0 because they are all at a zero crossing point.

The problem is that to produce $h_T(t) = \sin(Wt)/Wt$ requires an ideal brickwall filter, which is impossible to implement. One could attempt to approximate the ideal filter, but this would not be cost-effective and would have other undesirable effects on the system such as making timing recovery difficult [1]. To address these problems, more practical pulseshapes have been developed.

The pulseshape at the input to the demodulator, $h_P(t)$, is the convolution of the transmit filter, the channel response, and the receive filter:

$$h_P(t) = h_T(t) * h_C(t) * h_R(t) \tag{5}$$

From our preceding discussions it is clear that to eliminate ISI, $h_P(t)$ should be forced to cross zero at nonzero integer multiples of T . This can be written as

$$h_P(kT) = \delta_k \tag{6}$$

Figure 2. General form of a pulseshape for an ideally bandlimited symbol.

Figure 3. Multiple pulseshapes for an ideally bandlimited symbol.

The composite input to the demodulator is

$$R(t) = \sum_{n=-\infty}^{\infty} S_n h_P(t - nT) + N_R(t) \tag{7}$$

where $N_R(t)$ is the noise input at the demodulator:

$$N_R(t) = N(t) * h_R(t) \tag{8}$$

From Eq. (7) it can be seen that forcing the composite pulse to cross zero does not necessarily produce an optimal solution because it ignores the noise contribution. Joint optimizations are possible, but they are beyond the scope of this discussion. The reader is referred to Ref. 1 for in-depth coverage of this subject matter.

Taking the Fourier transform of Eq. (6) and applying the Nyquist sampling theorem, we get

$$\frac{1}{T} \sum_{n=-\infty}^{\infty} H_P \left(j\omega - n \frac{2\pi}{T} \right) = 1 \tag{9}$$

Equation (9) is referred to as the Nyquist criterion, and filter responses (pulses) that meet this criterion are referred to as Nyquist filters (pulses).

These filters require more than the ideal bandwidth defined in Eq. (3). While simplifying the system implementation, this additional bandwidth requirement costs additional spectrum and noise bandwidth at the receiver. The additional bandwidth is referred to as excess bandwidth and is usually expressed as a percentage of the ideal bandwidth:

$$B_{\text{excess}} = \left(\frac{B_{\text{actual}}}{B_{\text{ideal}}} - 1 \right) \times 100 \tag{10}$$

The actual pulseshape used in a particular application is highly dependent on the targeted channel characteristics. The most commonly used filters satisfying the Nyquist criterion for pulseshaping are raised-cosine filters. For this reason raised-cosine pulseshaping will be used in this article to describe implementations. Raised-cosine

filters are of the form

$$h_P(t) = \frac{\sin\left(\frac{\pi t}{T}\right)}{\pi t} \frac{\cos\left(\frac{\alpha \pi t}{T}\right)}{1 - \left(\frac{2\alpha t}{T}\right)^2} \tag{11}$$

$H_P(j\omega) =$

$$\begin{cases} T, & 0 \leq |\omega| \leq (1 - \alpha) \frac{\pi}{T} \\ \frac{T}{2} \left\{ 1 - \sin \left[\frac{T}{2\alpha} \left(|\omega| - \frac{\pi}{T} \right) \right] \right\}, & (1 - \alpha) \frac{\pi}{T} \leq |\omega| \leq (1 + \alpha) \frac{\pi}{T} \\ 0, & |\omega| > (1 + \alpha) \frac{\pi}{T} \end{cases} \tag{12}$$

where α controls the rate at which the energy rolls off. The smaller α is, the faster the rolloff. Note that for $\alpha = 0$,

$$h_P(t) = \frac{\sin\left(\frac{\pi t}{T}\right)}{\pi t} \tag{13}$$

which is the ideal pulseshape for a bandlimited channel.

In most actual implementations the raised-cosine filter is partitioned with part of the response implemented in the transmit filter and part implemented in the receive filter. The most common partitioning is to implement each as the square root of the raised-cosine filter. This is commonly referred to as a root-raised-cosine filter [1] and is given as

$$h_T(t) = h_R(t) = \frac{4\alpha \left(\cos\left((1 + \alpha) \frac{\pi t}{T} \right) + \frac{T \sin\left((1 + \alpha) \frac{\pi t}{T} \right)}{4\alpha t} \right)}{\pi \sqrt{T} \left[1 - \left(\frac{4\alpha t}{T} \right)^2 \right]} \tag{14}$$

and

$$H_T(j\omega) = H_R(j\omega) = \begin{cases} \sqrt{T}, & 0 \leq |\omega| \leq (1 - \alpha) \frac{\pi}{T} \\ \sqrt{\frac{T}{2} \left\{ 1 - \sin \left[\frac{T}{2\alpha} \left(|\omega| - \frac{\pi}{T} \right) \right] \right\}}, & (1 - \alpha) \frac{\pi}{T} \leq |\omega| \leq (1 + \alpha) \frac{\pi}{T} \\ 0, & |\omega| > (1 + \alpha) \frac{\pi}{T} \end{cases} \quad (15)$$

2. IMPLEMENTATION

In contemporary digital communication systems it is often not possible to achieve economically the required performance from analog pulse-shaping filters. Shaping filters are therefore implemented using a hybrid approach. The bulk of the shaping is done at baseband using finite impulse response (FIR) digital filters, which implement a truncated version of the pulse shape.

On the transmit side of a communication system data symbols are passed to an interpolating digital filter [4]. The impulse response of the digital filter typically spans multiple symbol times and is the convolution of the desired pulse-shaping response and precompensation for the rolloff frequency response of the subsequent digital-to-analog converter (DAC) if the rolloff is great enough to affect system performance. The output of the digital filter is passed to a DAC and a subsequent image-reject filter for conversion to continuous-time analog format. The output of the DAC in the spectral domain is the baseband spectrum and images of the baseband spectrum occurring within bands, which are bounded by integer multiples of one-half of the sampling rate f_s , all multiplied by a sinc function with nulls occurring at integer multiples of the sampling rate. In the case of lowpass signals the images are present near integer multiples of the sampling rate. In the time domain the output waveform is “stair-stepped.” The image-reject filter removes all of the spectral images and passes the baseband spectrum, thus “smoothing” or interpolating the time-domain waveform.

At the output of the image-reject filter, the shaped symbol pulses are in continuous-time analog format. They can then be up-converted to the desired radiofrequency (RF) for transmission. This process is shown in Fig. 4.

The operation at the receiver is the transpose of the transmit operation. The analog front end (AFE) of the

receiver translates the RF signal into a convertible pulse-train. The pulsetrain is then converted to a digital form via an analog-to-digital converter (ADC). The pulsetrain is filtered by a decimating FIR filter [4] with a root-raised-cosine response to complete the raised-cosine pulse-shaping operation. The receive process is shown in Fig. 5.

2.1. Digital Pulse-shaping Network

The actual design procedure for a pulse-shaping network is now presented. A transmit-side root-raised-cosine pulse-shaping network is described. The receive-side network will not be addressed since it is the network transpose of the transmit network.

Assume a digital data transmission system has a symbol period of T seconds, that is, every T seconds a new b_Q bit symbol is transmitted. In this description we assume $b_Q = 1$ for simplicity of illustration, although this is not necessary. Before transmission, it is necessary to shape each transmitted pulse. In this case a positive pulse-shape is transmitted for a bit value of zero. In addition to considering the desired pulse type, it is necessary to determine the length of the pulse relative to the symbol length and the resolution of the pulse or the number of bits used to compute the pulse values.

The interpolating FIR filter shown in Fig. 4 must be economically implementable and can therefore only approximate a desired pulse-shape, the root-raised cosine given by Eq. (14) in this case. The response is approximated by first determining the desired filter length. The filter length N is the product of the symbol interpolation factor L and the desired span M . The span is the number of symbol periods over which the shaping filter will operate.

The interpolation factor is selected to minimize the $\text{sinc}(x)$ distortion at the upper edge of the band of interest caused by the DAC and to simplify the implementation of the image-reject filter; the greatest consideration is the latter. As was mentioned previously, $\text{sinc}(x)$ distortion in the band of interest can be compensated for by putting a precompensation function $[1/\text{sinc}(x)]$ in the interpolating filter’s response. The higher the interpolation rate, the more distance there is between the band of interest and the first image in the spectral domain. The more distance there is, the simpler the image reject filter. Thus the interpolation factor becomes a tradeoff between the complexity of the digital interpolating filter and DAC speed, and the complexity of the image-reject filter. Typically, an interpolation factor of between 8 and 16 is a reasonable trade.

The span over which the impulse response is approximated depends on the amount of out-of-band energy that

Figure 4. Pulse-shaping process in a digital transmitter.

Figure 5. Pulseshaping process in a digital receiver.

can be tolerated. An ideal impulse response begins to approach zero after a number of time-domain sidelobes. However, the synthesized impulse is of finite duration. How closely the tails of the response approach zero is dependent on the length of time the impulse is approximated. Out-of-band energy is reduced as the span increases, so the tradeoff becomes filter order versus out-of-band energy due to time-domain sidelobe truncation. Typical values of the span factor are 4–16. A typical root-raised-cosine pulsedshaper would have an interpolation factor of 8 coupled with a span of 8 to yield a total filter length of 64.

2.2. Filter Coefficient Calculation

There are a number of possible methods for calculating the coefficients of the pulsedshaping filter. Two will be discussed here: the direct and optimal methods.

2.2.1. The Direct Method. An FIR digital filter is of the form

$$H(z) = \frac{Y(z)}{X(z)} = \sum_{n=0}^{N-1} a_n z^{-n} \tag{16}$$

The direct method samples the continuous-time impulse response at appropriate points in time to generate the filter coefficients a_n . Under the assumption of proper sampling

$$a_n = h(n) \stackrel{Z}{\Leftrightarrow} H(z) = \sum_{n=0}^{N-1} h(n) z^{-n} \cong H_D(z) \tag{17}$$

where $H_D(z)$ is the desired frequency-domain pulsedshape and $N-1$ is the filter order.

As stated previously, the total number of coefficients N is related to the span and interpolation factors by $N = LM$. Thus, continuing with the root-raised-cosine example, one would simply calculate N evenly spaced values using Eq. (14) to calculate the coefficients a_n . Since $h_T(t)$ is an even function about $t = 0$, it is necessary to shift $h_T(t)$ in time such that the sampled version of $h_T(t)$ [denoted by $h(n)$] is evenly symmetric around samples $(N-2)/2$ and $N/2$ to ensure a fully linear phase response [5]. Since there are L samples per symbol period T , $h_T(t)$ should be evaluated at integer multiples of T/L . This, along with the timeshift requirement, dictates that the discrete-time values neces-

sary to define $h_T(t)$ are given by

$$t(n) = \left(n + \frac{1}{2} - \frac{N}{2} \right) \frac{T}{L} \tag{18}$$

Substituting this into Eq. (14) gives the sampled version of $h_T(t)$,

$$h(n) = \frac{4\alpha \left(\cos \left((1 + \alpha) \frac{\pi t(n)}{T} \right) + \frac{T \sin \left((1 - \alpha) \frac{\pi t(n)}{T} \right)}{4\alpha t} \right)}{\pi \sqrt{T} \left[1 - \left(\frac{4\alpha t(n)}{T} \right)^2 \right]} \tag{19}$$

$n = 0, 1, \dots, N - 1$

This process is illustrated in Fig. 6 for a filter of length N equal to 64 and including $4\frac{1}{2}$ sidelobes on either side of the mainlobe of the root-raised-cosine function. Figure 7 shows the corresponding frequency-domain response of the pulsedshaping filter.

As is the case with any digital filter coefficient design method, once the floating-point coefficients are calculated, they must be converted to fixed-point format if the target digital filter is to be implemented in fixed-point arithmetic. Conversion of coefficients to fixed-point format can be as simple as truncation or rounding or can require sophisticated optimization processes. Let

$$a_n' = h'(n) = Q[h(n)] \tag{20}$$

Figure 6. A discrete-time sampled root raised cosine.

Figure 7. Frequency-domain response of the sampled root-raised cosine shown in Fig. 6.

be the quantized coefficients. The next step in the coefficient design process is to calculate the frequency response of the quantized filter coefficients and compare it with the desired frequency response to see if the filter is within acceptable error bounds. The frequency response of an FIR filter is found by evaluating the filter's z transform on the unit circle. That is, the magnitude frequency response of the quantized coefficients is given as

$$|H'(z)| = \left| \sum_{n=0}^{N-1} h'(n)z^{-n} \right|_{z=e^{j\omega}} \quad (21)$$

$H'(z)$ can be evaluated directly or by using a form of the DFT. If the filter's frequency response does not meet the required error bounds, then either the filter order N or the number of bits in the coefficient quantization must be increased and the appropriate steps in the coefficient design process must be repeated.

Coefficient quantization is not as straightforward as data quantization. The quantization of data words yields 6.02 dB of signal-to-noise ratio per bit. The number of bits required for coefficient quantization is a function of filter order and the frequency-response shape. A good rule of thumb for a worst-case metric [6] for the number of coefficient bits required is

$$b_C = \frac{(\text{required attenuation in dB})}{6.02} + \log_2 N \quad (22)$$

so that

$$\begin{aligned} \frac{(\text{required attenuation in dB})}{6.02} &\leq b_C \\ &\leq \frac{(\text{required attenuation in dB})}{6.02} + \log_2 N \end{aligned} \quad (23)$$

assuming no limiting roundoff error in the actual filter implementation. In most practical pulseshaping filter

implementations, the coefficient wordlength should be closer to the lower bound.

The floating-point coefficients (a_n) for the case $M=L=8$ are shown in matrix form. Each column represents samples in adjacent symbol periods. Since the impulse response spans eight symbol periods, there are eight corresponding columns.

$$a_n = \begin{bmatrix} -0.010 & -0.002 & 0.042 & -0.061 \\ -0.007 & -0.013 & 0.029 & 0.071 \\ 0 & -0.019 & -0.003 & 0.253 \\ 0.007 & -0.018 & -0.049 & 0.467 \\ 0.014 & -0.010 & -0.101 & 0.689 \\ 0.017 & 0.006 & -0.144 & 0.890 \\ 0.015 & 0.025 & -0.161 & 1.043 \\ 0.008 & 0.039 & -0.137 & 1.126 \\ 1.126 & -0.137 & 0.039 & 0.008 \\ 1.043 & -0.161 & 0.025 & 0.015 \\ 0.890 & -0.144 & 0.006 & 0.017 \\ 0.689 & -0.101 & -0.010 & 0.014 \\ 0.467 & -0.049 & -0.018 & 0.007 \\ 0.253 & -0.003 & -0.019 & 0 \\ 0.071 & 0.029 & -0.013 & -0.007 \\ -0.061 & 0.042 & -0.002 & -0.010 \end{bmatrix} \quad (24)$$

In converting the floating-point coefficients to fixed-point coefficients, maximum arithmetic efficiency can be obtained by scaling the fixed-point coefficients so that the maximum possible filter output is at the overflow threshold. Worst-case peak signals would occur for data patterns in which the maxima and minima of the impulse response overlap, or add (in the case of a negative pulse, the absolute value of the minima adds to the composite pulse). It turns out for the example here that an efficient peak value for the impulse response to take is 194 for a 9-bit integer two's-complement representation (maximum possible positive value of 255).

Scaling the matrix of the floating-point values to a peak value of 194 and rounding each coefficient to the nearest integer results in the coefficient set shown here, which

completes the synthesis of the pulse coefficients:

$$a_n' = \begin{bmatrix} -2 & 0 & 7 & -10 & 194 & -24 & 7 & 1 \\ -1 & -2 & 5 & 12 & 180 & -28 & 4 & 3 \\ 0 & -3 & 0 & 44 & 153 & -25 & 1 & 3 \\ 1 & -3 & -8 & 80 & 119 & -17 & -2 & 2 \\ 2 & -2 & -17 & 119 & 80 & -8 & -3 & 1 \\ 3 & 1 & -25 & 153 & 44 & 0 & -3 & 0 \\ 3 & 4 & -28 & 180 & 12 & 5 & -2 & -1 \\ 1 & 7 & -24 & 194 & -10 & 7 & 0 & -2 \end{bmatrix} \quad (25)$$

2.2.2. The Optimal Method. The optimal method requires an optimizing filter design program such as the Parks–McClellan program [5,7] but guarantees an optimum solution. To design the pulse-shaping filter coefficients using the optimal method, the EFF subroutine (EFF is the actual name of the subroutine in the published program) in the Parks–McClellan computer design program must be modified by inserting a floating-point, discrete-frequency version of the desired frequency-domain pulse-shape. The program is then executed with a desired filter order and the same iterative process of evaluating the frequency response of the quantized coefficient set as described previously for the direct method is followed until a set of coefficients is generated that is within the desired error bound. This method yields much more reliable results than the does direct method.

Even more sophisticated filter programs exist that optimize quantized coefficients. These programs allow designers to optimize the efficiency of a filter implementation.

2.3. Filter Hardware Implementation

The actual hardware realization of a pulse-shaping filter is highly dependent on symbol rates, filter order, process, and so on. Assuming symbol rates that allow implementations in state-of-the-art semiconductor processes, the filter would be implemented as some variation of a polyphase architecture [4].

Interpolation is the process of increasing the sampling rate while preserving the signal’s spectral content. The conceptual first step in interpolation is to insert $L - 1$ zero-valued samples between each valid input sample, expanding the sampling rate by L . This causes the original signal

spectrum to be repeated $L - 1$ times. This process is referred to as sample rate expansion. To complete the interpolation, the zero-valued input samples are converted to spectrally accurate approximations of the signal. This is equivalent to preserving the original signal spectrum. Thus, and again conceptually, the zero-stuffed input stream is filtered by a lowpass filter with a passband at the original spectral location and a passband gain of L . This filters out all the repeated spectra. This conceptual process is shown in Fig. 8.

In real implementations it would be a waste of storage and computational resources to store and multiply zero-valued data samples. For this reason, polyphase structures are used. A polyphase interpolator configures the standard N -tap filter structure into k phases of an $(N - 1)$ -element delay line. For example, an eighth-order ($N = 9$) FIR filter with $k = 3$ phases has three sets of three coefficients. The coefficients for the eighth-order filter are a_0, a_1, \dots, a_8 . The first polyphase taps the eight-element delay line at the input to the filter (a_0), after the third delay (a_3), and after the sixth delay (a_6). The second phase taps a_1, a_4 , and a_7 . The third phase taps a_2, a_5 , and a_8 . However, since all but every third element in the delay line would contain a zero-valued data sample, the delay line can be collapsed to a two-element delay line ($N/k - 1$ elements) with all phases using the same samples. The output of the interpolator is the commutated output of the three phases. Figure 9 illustrates the polyphase implementation of the nine-tap interpolator. Reference 4 details the efficient implementation of interpolation and decimation filters.

An interpolation filter can be implemented using standard multiply and accumulate elements, or in some cases it is most efficient to use table-lookup-based bit-slice filter methods [8]. The tradeoff is dependent on the number of bits required for the representation of a symbol. For low bit count, the bit-slice implementation is usually more efficient. As bit count increases, table sizes become unmanageable.

2.4. DAC

The DAC has the task of generating an analog output based on the digital input supplied by the FIR filter. The DAC must be linear to ensure that no unwanted spurious energy is generated. Several implementations are possible depending on the DAC resolution required. For relatively modest resolutions of 4–8 bits, simple binary-weighted current or charge-based approaches are possible. For higher resolutions, it may be desirable to use segmented approaches where each least significant bit (LSB) step has

Figure 8. Illustration of the conceptual interpolation process.

Figure 9. Polyphase implementation of an FIR interpolation filter.

a separate current- or charge-based generator. For example, a 5-bit segmented current-steered DAC would have 32 separate current sources feeding a common resistor to generate the desired output voltage. Sources are turned on or off depending on the value of the control word. This is opposed to a binary approach in which only five current sources are used scaled in binary fashion. For higher-bit resolutions, the binary approach can suffer from linearity errors due to mismatches at major carries. The advantage of a binary approach is smaller implementation area. For DACs of 9-bit resolution or higher, a combination of binary [for the most significant bits (MSBs)] and segmented (for the LSBs) is frequently used.

Standard DACs offer no image suppression, even if the DAC runs at a rate greater than the digital world update rate. Image suppression could be improved if the DAC could interpolate between successive word updates. Such a converter can be demonstrated, following up on the example begun for the pulse-shaping network. Suppose that specifications require that all spurious energy be at least 40 dB down with respect to the baseband level. This requires that all spectral images of the FIR filter be attenuated sufficiently to achieve this. Further suppose that the symbol rate is 128 kband. The update rate f_s of the digital filter is 1.024 MHz (because of the 1–8 interpolation factor from the preceding example), and hence the first

image replica will appear there. If the DAC were updated at the 1.024 MHz rate, then the amount of attenuation of the image due to rolloff would be only 17 dB. Consider an interpolating DAC operating at 5 times the digital update rate ($f_{s1} = 5.12$ MHz). The block diagram of an architecture suitable for monolithic integration accompanied by illustrative spectral plots is shown in Fig. 10. In this architecture, it is shown that interpolation can provide 20 dB of additional attenuation.

A simplified single-ended schematic of an interpolating DAC is shown in Fig. 11 [9]. ϕ_1 and ϕ_2 are nonoverlapping clocks operating at the interpolation frequency (5.12 MHz in the preceding example). The operational amplifiers are conventional fully differential folded cascade topologies. The input voltage reference is selected based on specific channel requirements and typically ranges from 250 mV to 1 V. It is usually supplied by an on-chip bandgap generator. The configuration is a cascaded charge redistribution DAC with the first stage an offset insensitive programmable amplifier to realize the four least significant bits [10]. Gain is determined by the sum of the binary-weighted capacitors at the input, dependent on the LSB word. The second stage is a modified second-order switched-capacitor biquad [11]. This stage has programmable gain to realize the four most significant bits of the DAC and acts as the summing point for the LSB portion. A straightforward charge transfer analysis yields the low-frequency output level as a function of the reference voltage V_{ref} and critical circuit capacitor values

$$V_{out} = \frac{C_3}{16C_3} \frac{V_{ref}}{C_1} (b_7C_12^{-4} + b_6C_12^{-3} + \dots + b_4C_12^{-1}) + \frac{V_{ref}}{C_7} (b_3C_72^{-4} \dots + b_0C_72^{-1}) \quad (26)$$

Here, b_0, b_1, \dots, b_7 represent the digital data (possible values of 0 or 1) with b_7 as the least significant bit. Since the DAC is fully differential, the sign bit is easily incorporated by cross-coupling the input connection to V_{ref} . Interpolation is accomplished by the fact that the final stage is really a switched-capacitor filter. DC–AC analysis is simplified by replacing the DAC capacitor array structure with an equivalent single-ended switched-capacitor network as shown in Fig. 12. Including the input offset voltages V_{off2}, V_{off3} for the operational amplifiers, the defining charge equations for this network are given by

$$[V_{o3}(n) - v_{off3}](1 + \alpha_2) + [V_{o2}(n) - v_{off3}]\alpha_6 = V_{o3}(n - 1) - v_{off3} \quad (27)$$

$$V_{o2}(n) - v_{off2} - \alpha_5v_{off2} - \alpha_3v_{off2} = [V_{in}(n - 1) - v_{off2}]\alpha_5 + [V_{o3}(n - 1) - v_{off2}]\alpha_3 + V_{o2}(n - 1) - v_{off2} \quad (28)$$

where V_{o2} and V_{o3} are outputs of amplifiers 2 and 3, respectively.

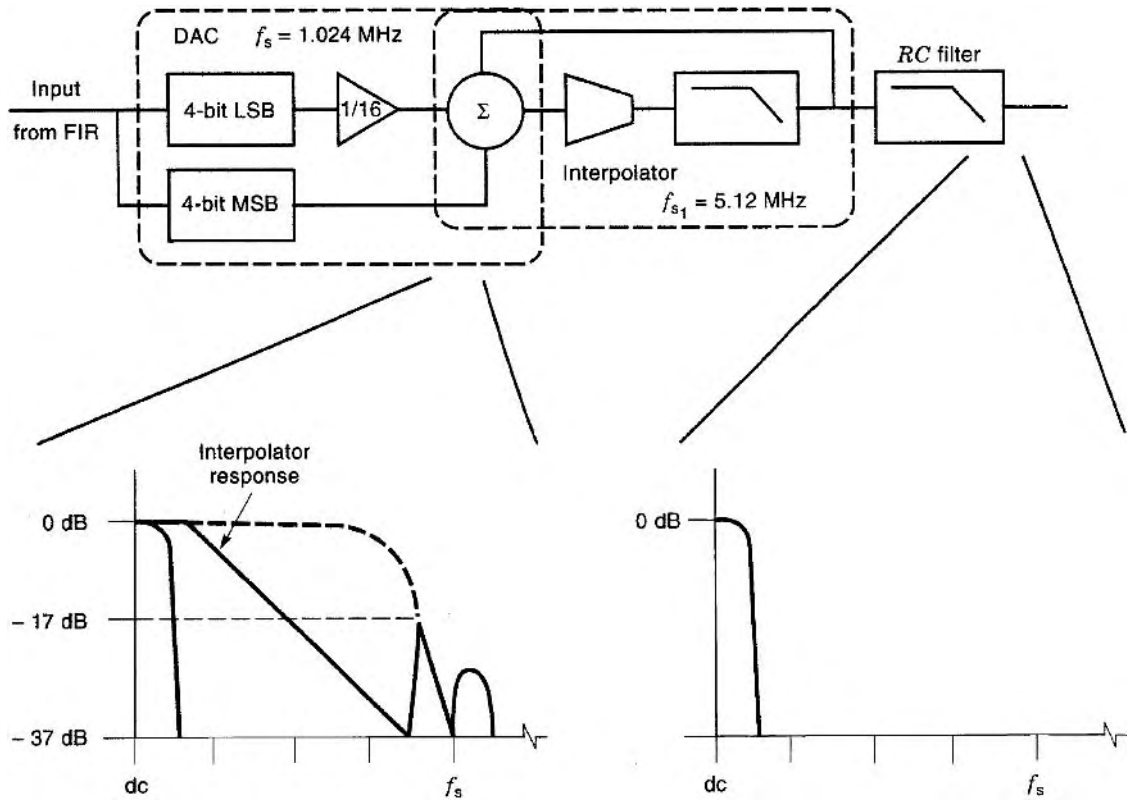

Figure 10. Digital-to-analog converter top-level block diagram.

Under steady-state conditions $n \rightarrow \infty$. With $V_{in}(n) = V_{in}(n - 1) = 0$, then

$$\begin{aligned} V_{o2}(n) &\rightarrow V_{o2}(n - 1) \rightarrow V_{o2}, \\ V_{o3}(n) &\rightarrow V_{o3}(n - 1) \rightarrow V_{o3} \end{aligned} \quad (29)$$

for the DAC

$$V_{o3} = 0 \quad (30)$$

$$V_{o2} = v_{off3} \left(1 + \frac{\alpha_2}{\alpha_6} \right) \quad (31)$$

where V_{o2} and V_{o3} are the DC offset voltage at the outputs of amplifiers 2 and 3, respectively. Under these conditions, solving Eqs. (27) and (28) yield the output offset voltages

where Eq. (31) is valid during high ϕ_1 . It is interesting to note that although the DAC output is a fully held signal over the 5.12 MHz clock period, it has no operational-amplifier-induced DC offset. This is simply due to the fact

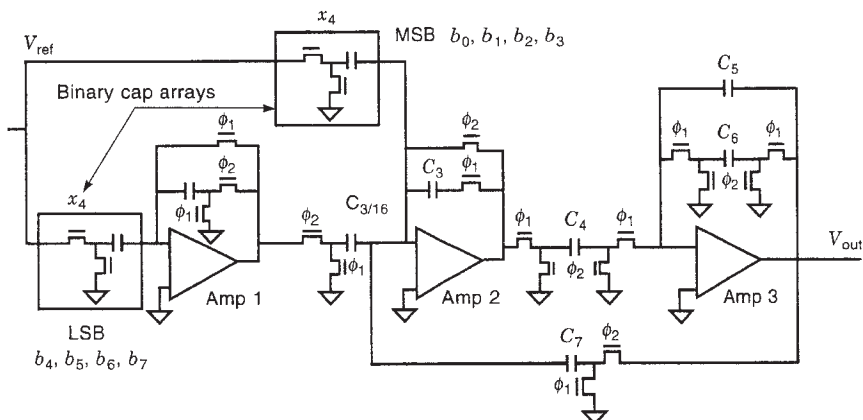

Figure 11. Simplified single-ended DAC schematic.

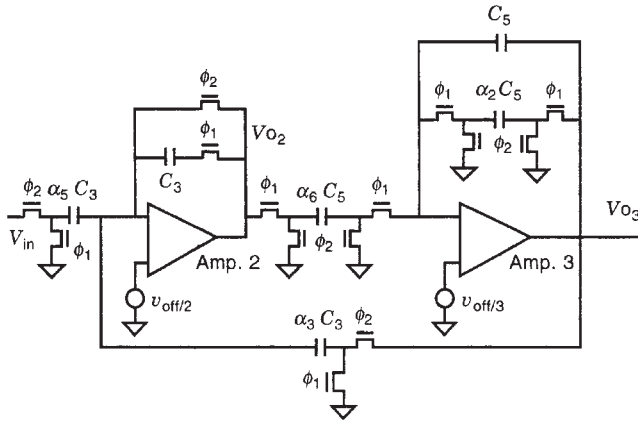

Figure 12. Interpolating filter.

that output offset at this point is due solely to amplifier 2, which has been nulled out.

Ignoring offset, Eqs. (27) and (28) may be transformed to the z domain, where the following transfer function may be derived:

$$\frac{V_{o3}(z)}{V_{in}(z)} = \frac{-\alpha_5\alpha_6}{1 + \alpha_2} \frac{z^{-1}}{1 - \frac{2 + \alpha_2 - \alpha_3\alpha_6}{1 + \alpha_2} z^{-1} + \frac{1}{1 + \alpha_2} z^{-2}} \quad (32)$$

This is the form of a second-order lowpass filter. Interpolation is accomplished by designing the filter such that little passband loss occurs at the digital filter's 3 dB point of 64 kHz. Setting specifications for the interpolating filter at no more than 0.3 dB loss at 100 kHz; then with a sampling frequency of 5.12 MHz, this leads to a desired transfer function of

$$H(z) = \frac{0.0910218z^{-1}}{1 - 1.4921346z^{-2} + 0.5831564z^{-2}} \quad (33)$$

Coefficient matching with Eq. (32) yields the necessary capacitor values. With 17 dB of loss due to the S/H effect and the loss at 1.024 MHz due to Eq. (33), the image at the DAC output is 37 dB lower. Hence, an additional 20 dB of image rejection is achieved with the use of interpolation techniques.

2.5. Image Filter

There are several techniques that are used to realize continuous-time monolithic filters. Standard active-filter techniques utilizing resistors and capacitors are the simplest approach but pole frequencies cannot be accurately placed due to typical process variations. If the image response is located very far away from the baseband spectrum, then accurate pole placement may not be necessary. In that case, the filter is simply designed such that the worst-case RC product leading to a high cutoff frequency is still sufficient to meet stopband energy requirements. Frequently, only first-order filters are required, but if the passive variation is significant enough, higher-order filters may be necessary to provide sufficient

attenuation. If a process has very linear components, such as thin-film resistors and double polysilicon or metal capacitors, it is possible to realize wide-dynamic-range filters with excellent linearity. Dynamic ranges over 93 dB are possible if linearity is a concern. If only diffuse resistors or depletion capacitors are available, then the corresponding voltage dependence of the passive devices reduces linearity considerably. In that case, interpolating DAC techniques may be desirable such that only a simple external RC filter is necessary for image filtering. Of course, linearity requirements must be considered to make a final decision.

Another technique that may be used includes MOSFET-C (metal oxide semiconductor field-effect transistor capacitance) filters [12], where MOSFET transistors operated in the linear region are used to replace resistors in active filters. Using special linearization techniques, MOSFET-C filters can achieve reasonable linearity (50–60 dB), and no special resistor material is required. However, MOSFET-C filters are limited in the frequency range that they can operate because of operational amplifier limitations and distributed parasitics [13]. They also require the use of tuning networks to ensure that the MOSFET devices stay in the linear region and close to the resistor values necessary to achieve the necessary time constants.

Finally, transconductance- C ($g_m - C$) networks can be used as image filters [14]. $g_m - C$ filters have the advantage of being able to achieve very high cutoff frequencies, typically in the 10–100 MHz area. These may be useful in cases where the data rate is very high and image frequencies may be close to baseband. Linearization techniques can achieve dynamic ranges in the area of 50–65 dB. $g_m - C$ filters have pole frequencies proportional to g_m/C , so stable transconductance networks are required to achieve stable pole locations. Usually, this implies some sort of tuning network to accurately set g_m for the desired cutoff.

3. SUMMARY

In this article an overview of the motivation, theory, and implementation of pulseshaping in digital communication systems has been presented. Digital communication systems transmit digital data as discrete-time symbols modulating a continuous-time waveform. Because actual communication channels are bandlimited, symbol times can overlap, inducing intersymbol interference. Pulse-shaping can reduce or eliminate intersymbol interference if it is closely matched to the characteristics of the channel.

A theoretical background for pulseshaping was established based on a channel that can be modeled as a linear time-invariant filter with additive white Gaussian noise. It was shown that for this type of channel a class of filters known as Nyquist filters are the most commonly used for pulseshaping, and the most popular filter in this class is the raised-cosine filter. Since the implementation of pulseshapers is commonly distributed between the transmit and receive sides of a communication system, an example

of the implementation of a transmit-side square root raised-cosine filter was presented.

The square-root-raised-cosine filter implementation presented was a hybrid analog–digital implementation, taking advantage of the strengths of both technologies.

Q-FACTOR

DARKO KAJFEZ
University of Mississippi
University, Mississippi

1. INTRODUCTION

Figure 1 shows several one-port resonators. The lumped-element resonator in Fig. 1a is a simple parallel-resonant circuit, the resonant frequency of which is

$$\omega_0 = \frac{1}{\sqrt{LC}} \quad (1)$$

At this frequency, the absolute value of the input impedance reaches a maximum (admittance reaches a minimum). At other frequencies, the absolute value of impedance monotonically decays according to a well known bell-shaped curve in Fig. 2. In the elementary circuit theory, the Q factor of the parallel resonant circuit is defined as

$$Q_0 = \frac{\omega_0 C}{G_0} \quad (2)$$

which is a ratio of the susceptance (at the resonant frequency) to the conductance $G_0 = 1/R_0$ of the circuit. The larger the Q factor is, the narrower the bell-shaped curve, so the resonator can better discriminate between signals of different frequencies. Hence, the letter Q is used to denote a “quality” of the resonant circuit. The example in Fig. 2 is plotted in a normalized manner, for a resonator that has $Q = 1000$. In this example, the absolute value of impedance drops down to 16% when the operating frequency is only 0.3% away from the resonant frequency.

Figure 1. Resonators: (a) lumped element, (b) microstrip, (c) dielectric resonator, (d) cavity resonator.

At rf and microwave frequencies, the resonators are seldom built in the form of lumped inductances and capacitances. Instead, they consist of distributed circuits, such as a half-wavelength-long microstrip transmission line as shown in Fig. 1b. Much higher Q factors can be achieved by using dielectric resonators, which are integrated with microstrip circuits, as shown in Fig. 1c. For high power handling, it may be necessary to employ a hollow cylindrical or rectangular cavity, such as shown in Fig. 1d, in which the input is connected through a coaxial transmission line. In the vicinity of the resonant frequency of interest, each of these resonators has similar properties as the basic parallel resonant circuit, namely, their input impedance exhibits a bell-shaped resonant curve, and the width of the curve (or bandwidth) is inversely proportional to the Q factor. However, a lumped-circuit theory definition of Q factor given by (2) is not applicable for microwave resonators.

A more general definition of Q factor, valid for both lumped element resonators and for rf and microwave resonators, is formulated in terms of energy and power [1, p. 116]:

$$Q = \left[\frac{\omega W_{\max}}{P_d} \right]_{\omega = \omega_0} \quad (3)$$

where W_{\max} is the maximum (peak) energy stored in the resonator and P_d is the average power dissipated in the resonator. There are two types of energy stored in any resonator: electric energy W_e and magnetic energy W_m . For time-harmonic (sine and cosine) behavior of electromagnetic fields, the energy in the resonator fluctuates between the electric and magnetic types—when W_e is at maximum, W_m is zero and a quarter-period later W_e is zero and W_m is maximum, and so on. When the resonator is operating at its resonant frequency, the peak value of W_e is the same as the peak value of W_m .

Figure 2. Normalized impedance of a parallel resonant circuit.

The lumped resonator from Fig. 1a has only one resonant frequency. This is in contrast to microwave resonators from Figs. 1b–1d, because each of them has an infinite number of resonant frequencies. To understand this, consider the half-wavelength microstrip resonator from Fig. 1b; when the frequency is twice as high as the first resonance, the length of the resonator becomes equal to one full wavelength. At that frequency, the input impedance again has a maximum, the peak of electric energy is equal to the peak of the magnetic energy, and one observes a second resonant frequency. For a still higher operating frequency, the point is reached where the length becomes equal to 1.5 wavelengths, thus becoming another resonance of the device. Each of these resonant frequencies is said to correspond to another resonant mode of operation. Likewise, the dielectric resonator from Fig. 1c as well as the hollow resonant cavity from Fig. 1d exhibit an infinite number of resonant modes, as the operating frequency grows higher and higher. At room temperature, the Q factors of the last two types of resonators may reach values higher than 10,000.

Resonators are the basic building blocks of RF filters and oscillators. The fundamental characteristics [2–4] that have to be specified for a resonator are (1) resonant frequency, (2) coupling coefficient, and (3) unloaded Q factor. Like any other circuit component, a resonator must be experimentally tested to determine its properties. Although some specialized instruments, called Q meters and *grid-dip meters*, were used in the past, the universal instrument for measuring the Q factor today is the automatic network analyzer.

By measuring a number of points on each side of the resonant frequency and by careful data processing, it is possible to determine the unloaded Q factors with an uncertainty smaller than 1%. Such accuracy is especially important in measuring the material properties of the samples that are inserted into a resonant cavity. By determining the difference in the cavity Q factor and its resonant frequency with and without the sample, one can accurately predict the complex permittivity and permeability of the sample and/or the surface resistivity of a conductor sample. For instance, by such a method one measures the surface resistance of high-temperature-superconductor samples [5].

2. LOADED, UNLOADED, AND EXTERNAL Q

To fully understand the operation of RF and microwave resonators of the types shown in Figs. 1c and 1d, a three-dimensional distribution of the electric and magnetic fields in the resonator should be determined by an analytical or a numerical procedure. It is then possible to integrate the stored energy over the volume of the resonator, and to determine the power dissipation in the resonator due to conductor losses and/or dielectric losses. These values substituted in (3) will provide the theoretical value of the Q factor of the resonator itself, the so-called unloaded Q factor.

For an experimental investigation of a resonator, it is convenient to study the resonant behavior with the use of

the equivalent circuit shown in Fig. 3a. It is assumed that the Q factor is larger than (at least) 100, and that the effect of other resonant modes is not noticeable within, say, 1% on each side of the resonant frequency under consideration. In other words, the treatment that follows is suitable for high- Q resonators.

Figure 3a shows the equivalent circuit, which is appropriate for all the distributed-element resonators from Fig. 1. The figure also contains an external Thevenin voltage source consisting of V_s and internal impedance R_c , which is equal to the characteristic impedance of the input transmission line. This source would represent the network analyzer, which is connected to input port 1 of the resonator. The transmission line of length l , located between input (port 1) and the location of the coupling (port 2), could be physically very short (e.g., just a length of one coaxial connector), but this length is seldom known very precisely.

Port 3 is the location of the resonator itself. The impedance $R_s + jX_s$ represents the transformation properties of the coupling mechanism. For a loop coupling, X_s is a positive reactance, and for a probe coupling, X_s is a negative reactance. The value of X_s can be considered to be constant in the frequency range of interest (say, 1% on each side of the resonant frequency). The susceptance B_0 of the

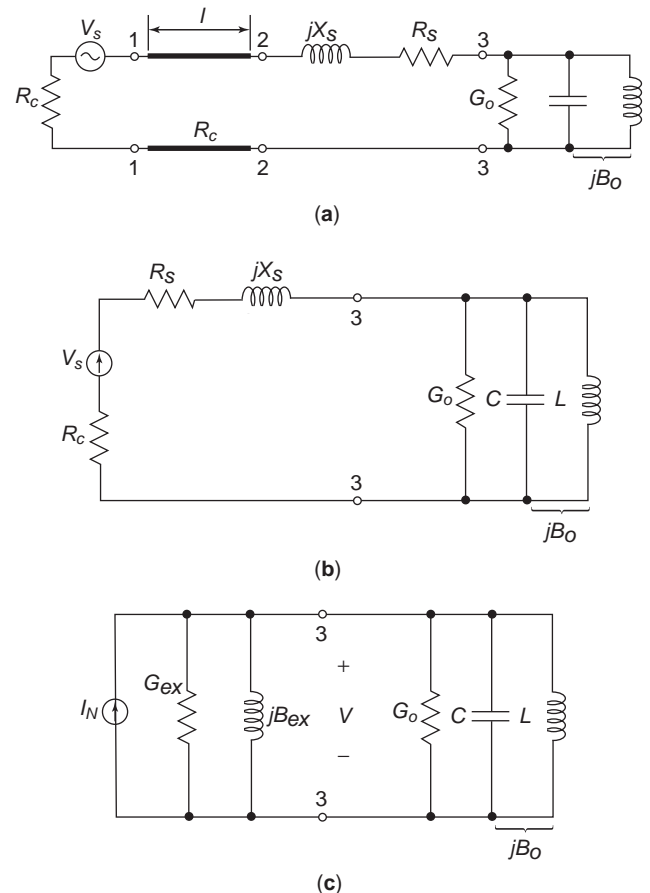

Figure 3. (a) The equivalent circuit of a one-port resonator; (b) Thevenin equivalent to the left of port 3; (c) Norton equivalent to the left of port 3.

resonator, represented by a parallel LC combination, is a function of frequency that varies hundreds or even thousands of times faster than X_s . The conductance G_0 represents the dissipation inside the resonator proper. The corresponding resistance is the inverse value, $R_0 = 1/G_0$.

Suppose that an observer can enter the resonator and look left and right from port 3 (see Fig. 3b). If the observer at port 3 now turns to the left (toward port 1), he/she sees the series combination of resistance R_s and the reactance X_s , and behind them a transmission line terminated in a Thevenin source. As the source impedance is equal to the characteristic impedance of the transmission line, the length of the transmission line does not change the impedance seen by the observer; any length of a transmission line, which is terminated in a matched load, has the same input impedance, equal to R_c .

Using elementary circuit theory rules, the external circuit that the observer saw, can now be replaced by a Norton's equivalent, consisting of a current source in parallel with an admittance, as shown in Fig. 3c. As a further simplification, impedance $R_c + R_s + jX_s$ was transformed into admittance $G_{ex} + jB_{ex}$, the external admittance felt by the resonator.

Now, the observer at port 3 can clearly see that the external circuit influences the resonator in two ways:

1. Susceptance B_{ex} is in parallel with B_0 and thus detunes the resonant frequency. However, this frequency shift is so small that it is of little consequence. The observer simply has to deal with a new, loaded resonator that has a slightly different resonant frequency, called *loaded resonant* frequency ω_L .
2. Conductance G_{ex} comes in parallel to G_0 , thus lowering the overall Q to a new value, called loaded Q , denoted Q_L . To find this value, consider the inverse of (3):

$$\left[\frac{P_d}{\omega W_{max}} \right]_{\omega=\omega_L} = \frac{P_0}{\omega_L W_{max}} + \frac{P_{ex}}{\omega_L W_{max}} \quad (4)$$

The dissipated power P_d consists of two parts: P_0 , the power dissipated in the unloaded resonator; and P_{ex} , the power dissipated in the external circuit. Each of the three terms in (4) is identified as a particular Q factor:

$$\frac{1}{Q_L} = \frac{1}{Q_0} + \frac{1}{Q_{ex}} \quad (5)$$

Q_L is the overall Q factor of the resonator and its external circuit. Q_0 is the unloaded Q factor of the unperturbed resonator, and Q_{ex} is the external Q factor.

The ratio of power dissipated in the external circuit to the power dissipated in the resonator is called coupling coefficient κ . In Fig. 3c, both G_0 and G_{ex} have common voltage V , so the ratio of powers is proportional to the ratio of conductances:

$$\kappa = \frac{V^2 G_{ex}}{V^2 G_0} = \frac{G_{ex}}{G_0} = \frac{Q_0}{Q_{ex}} \quad (6)$$

When an equal amount of power is dissipated in the external circuit as in the resonator itself, the coupling is said to be critical, and the coupling coefficient in this case is $\kappa = 1$. An undercritical coupling means that more power is dissipated in the resonator than in the external circuit, while an overcritical coupling means that more power is lost in the external circuit than in the resonator.

By eliminating Q_{ex} from (5) with the use of (6), one obtains the relationship between the unloaded and the loaded Q as follows:

$$Q_0 = Q_L(1 + \kappa) \quad (7)$$

As soon as one starts a measurement, the resonator is loaded by the external circuit (here the network analyzer), and the measurement will produce the loaded Q , namely, Q_L . The stronger the coupling one creates between the network analyzer and the resonator, the lower the value of the measured loaded Q . To find the unloaded Q , the measurement should be designed in such a way that it also provides the value of the coupling coefficient κ . Then, using Q_L and κ , one computes Q_0 from (7).

3. FREQUENTLY USED FORMULAS

The parallel resonant circuit in Fig. 4 is drawn in such a way that the lossless part of the circuit is to the right and the dissipative part is to the left of the observation port. The reactive part is described by the susceptance

$$B(\omega) = \omega_0 C \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right) \quad (8)$$

where ω_0 is specified by L and C according to (1). This behavior is plotted in Fig. 5. At very low frequency B tends to negative infinity, and at very high frequency B tends to positive infinity. At resonant frequency ω_0 , the susceptance passes through zero. Taking the derivative of (8), one obtains the slope of the susceptance to be

$$\left. \frac{dB}{d\omega} \right|_{\omega=\omega_0} = 2C \quad (9)$$

In a narrow frequency range around $\omega = \omega_0$, the susceptance can be approximated by a straight line:

$$B(\omega) = \left. \frac{dB}{d\omega} \right|_{\omega=\omega_0} (\omega - \omega_0) \quad (10)$$

Figure 4. Conductance and susceptance of a parallel resonant circuit.

Figure 5. Susceptance of the circuit from Fig. 4.

The situation is shown in Fig. 6, which can be thought of as a zoomed region of Fig. 5. When the susceptance becomes equal to the conductance, the absolute value of the admittance is increased by a factor of $\sqrt{2}$, which corresponds to 3 dB. The two points on each side of ω_0 corresponding to a 3 dB increase are denoted ω_1 and ω_2 :

$$\left. \frac{dB}{d\omega} \right|_{\omega=\omega_0} (\omega_1 - \omega_0) = -G \tag{11}$$

$$\left. \frac{dB}{d\omega} \right|_{\omega=\omega_0} (\omega_2 - \omega_0) = G$$

By subtracting the two equations from each other, and by using (9) and (2), one obtains the 3 dB bandwidth:

$$BW = \omega_2 - \omega_1 = \frac{\omega_0}{Q_0} \tag{12}$$

Thus, the 3 dB bandwidth of an unloaded resonator is Q_0 times smaller than its resonant frequency! For example, an unloaded resonator with $Q_0 = 1000$, having its

Figure 6. Linear approximation of susceptance in the vicinity of the resonant frequency.

Figure 7. Resistance and reactance of a series-resonant circuit.

resonant frequency equal to 1 GHz, will display a bandwidth of 1 MHz. An additional external loading would lower the overall Q to a new value Q_L , so that the bandwidth of the loaded resonator is then given by modified (12) with Q_0 replaced by Q_L .

By eliminating C in (9) with the use of (2), one obtains the Q factor in terms of the susceptance slope as follows:

$$Q_0 = \left. \frac{\omega_0}{2G_0} \frac{dB}{d\omega} \right|_{\omega=\omega_0} \tag{13}$$

This expression is associated with the parallel resonant circuit in Fig. 4. For a series resonant circuit in Fig. 7, the Q factor is expressed in terms of the reactance slope:

$$Q_0 = \left. \frac{\omega_0}{2R_0} \frac{dX}{d\omega} \right|_{\omega=\omega_0} \tag{14}$$

The 3 dB bandwidth of the series resonant circuit is related to Q_0 by the same equation (12) as for the parallel resonant circuit.

As mentioned before, a distributed circuit has an infinite number of resonant frequencies, while a circuit consisting of lumped elements can have only a finite number of resonant frequencies. However, for a narrow vicinity of a particular resonant frequency ω_0 , either the susceptance or the reactance of a distributed circuit could be approximated by a straight line of the type shown in Fig. 6. For instance, when a resonator exhibits a parallel-type resonance, its susceptance may be approximated by (10). For the sake of simplicity, suppose that the resonator is lossless, and its external load will be a known conductance G_0 as shown in Fig. 8. Furthermore, suppose that the susceptance $B(\omega)$ can be determined by solving circuit equations and/or transmission-line equations for this particular resonator. Then, the loaded Q factor can be found by applying (13). Needless to say, each resonant mode will have a different value of Q factor.

Figure 8. Microwave resonator and an external conductance.

Frequently, the resonator is created by using a half-wavelength section of microstrip transmission line open-circuited at both ends, or a quarter-wavelength coaxial line open-circuited at one end and short-circuited at the other. The propagation constant of a lossy transmission line is a complex number $\gamma = \alpha + j\beta$, where α is the attenuation constant [in nepers per meter (Np/m)] and β is the phase constant [in radians per meter (rad/m)]. When the attenuation is relatively small, the transmission line Q factor is defined as the ratio [1, p. 231]:

$$Q = \frac{\beta}{2\alpha} \tag{15}$$

Since Q is a dimensionless quantity, it is more convenient to specify the losses of a transmission line by its Q , rather than in terms of decibels (or nepers) per meter (or per 100 ft, as many manufacturers prefer to do). Typically, microstrip transmission lines have a Q factor of the order of 10^2 or more, and the solid-metal coaxial lines and waveguides of the order of 10^3 – 10^4 , depending on frequency, size of the cross section, and surface finishing.

4. TRANSMISSION-TYPE MEASUREMENT

Suppose that a manufacturer of the microstrip substrate wants to measure the Q factor of a transmission line fabricated from her material. She would probably create a half-wavelength resonator two-port, something like the one shown in Fig. 9a. Port A is the input, and port B is the output. The network analyzer is connected at both sides, and the transmission coefficient S_{21} is measured. The equivalent circuit of such a measurement is shown in Fig. 9b. For the sake of simplicity, the coupling loss resistors on the input and output sides have been ignored, and both reactances X_{s1} and X_{s2} are shown to be of capacitive nature.

As before, one can change a Thevenin equivalent into a Norton equivalent, and obtain Fig. 9c. Suppose that the observer at port 3 (the resonator port) wears very special tinted glasses, tuned to the resonant frequency of the loaded resonator. He will not see any susceptances, because they cancel each other at that frequency. All that he will see is the three conductances shown in Fig. 9d. Since they are connected in parallel, the corresponding powers are proportional to the conductance values, and one can therefore define the input and output coupling coefficients as follows:

$$\kappa_1 = \frac{G_{ex1}}{G_0} = \frac{Q_0}{Q_{ex1}}; \quad \kappa_2 = \frac{G_{ex2}}{G_0} = \frac{Q_0}{Q_{ex2}} \tag{16}$$

The overall coupling coefficient for this two-port resonator is the sum of the two:

$$\kappa = \kappa_1 + \kappa_2 \tag{17}$$

The magnitude of the forward transmission gain S_{21} displays the bell-shaped curve as a function of frequency, indicated in Fig. 10. The loaded Q of the system is

(a)

(b)

(c)

(d)

Figure 9. (a) Microstrip two-port resonator; (b) equivalent circuit of the resonator from Fig. 9a; (c) Norton's equivalent of the equivalent circuit from Fig. 9b; (d) equivalent circuit at the loaded resonant frequency.

inversely proportional to the difference between the 3 dB frequencies f_1 and f_2 at each side of the resonance:

$$Q_L = \frac{f_0}{f_2 - f_1} \tag{18}$$

Now that Q_L has been determined, one needs to find κ . That can be computed from magnitude S_{21} at the center frequency. It follows from Fig. 9d that the magnitude of S_{21} at the resonant frequency is

$$S_{21}(f_0) = \frac{2\sqrt{\kappa_1\kappa_2}}{1 + \kappa_1 + \kappa_2} \tag{19}$$

Figure 10. Forward transmission gain of the circuit from Fig. 9c.

Through a careful fabrication procedure, one can make the input and output airgaps equal to each other, so that

$$\kappa_1 = \kappa_2 \quad (20)$$

For such a symmetrical coupling, one obtains

$$\kappa = 2\kappa_1 = \frac{S_{21}(f_0)}{1 - S_{21}(f_0)} \quad (21)$$

and when this is substituted into (7), the unloaded Q can be computed as follows:

$$Q_0 = \frac{Q_L}{1 - S_{21}(f_0)} \quad (22)$$

This is the unloaded Q of the microstrip resonator, the number that the manufacturer of the substrate wanted to know.

Usually, the magnitude of $S_{21}(f_0)$ is expressed in decibels and called insertion loss α . Since S_{21} of a passive circuit is always smaller than unity, α is a negative number. Then, to compute $S_{21}(f_0)$, one uses the following expression:

$$S_{21}(f_0) = 10^{\alpha/20} \quad (23)$$

For the transmission-type measurement to be accurate, condition (20) must be satisfied, requiring that the input and output couplings equal each other. In this measurement, there is no possibility of verifying this equality; one must trust that the mechanical tolerances are tight enough to ensure equality. Another important factor to keep in mind is that the accuracy is seriously reduced when coupling is larger than critical. This happens because $S_{21}(f_0)$ approaches unity as the coupling strengthens. Therefore, the denominator of (22) becomes a difference of two almost equal numbers, so that even a small error in $S_{21}(f_0)$ will cause a large error in Q_0 (even though Q_L has been measured accurately). A detailed analysis of uncertainty in the transmission-type measurement can be found in Ref. 6.

5. REFLECTION-TYPE MEASUREMENT

For this measurement, the resonator needs only one accessible port. When the network analyzer is attached to this port, the equivalent circuit looks the same as shown in Fig. 3a. The measurement procedure is well documented in microwave measurement handbooks such as those by Ginzton [2], Sucher and Fox [3], or Matthaei et al. [4]. Although these books were written before the first network analyzer was produced, the principles involved remain unchanged. With few modifications, the reflection-type measurement can be performed with a network analyzer [7]. The beauty of this measurement is a perfect circle (so-called Q circle) that the measured reflection coefficient, plotted on a Smith chart, describes as a function of frequency.

Figure 11 shows a measured reflection coefficient S_{11} (a complex number) as function of frequency. The center of the Q circle is rotated by an angle θ with respect to the real axis of the Smith chart. Two particular circuit elements from Fig. 3a may cause this rotation: (1) the length of the transmission line l between the coupling loop and the reference position (input coaxial connector) rotates S_{11} by an angle $-2\beta l$, where β denotes the propagation constant of the line; then (2) the reactance X_s rotates (and also shrinks) the circle, as will be discussed in Section 7. Anyway, the rotation is of no importance for the determination of Q_L and κ . To determine the value of Q_L , it is necessary to identify three points on the Q circle. As shown in Fig. 11, the first of those points is center frequency f_L ($\cong f_0$). The other two frequencies, f_1 and f_2 , belong to the two points inclined by $\phi = 45^\circ$ on each side of the centerline. Then, the loaded Q is computed by (18).

To find the coupling coefficient, one has to measure the diameter d of the Q circle. Weakly coupled resonators will produce small Q circles and strongly coupled resonators, large ones. The equation for computing the coupling coefficient κ from the measured value of d is [7]

$$\kappa = \frac{1}{(2/d) - 1} \quad (24)$$

The unit of length for measuring d is the radius of the Smith chart. Thus, when $d = 1$, point f_L is located at the center of the Smith chart and the coupling coefficient is $\kappa = 1$ (critical coupling).

Thus, Ginzton's reflection-type measurement of Q is also a three-point method. In its original version, the Q circle was drawn by hand on the Smith chart point by point. The points were identified by their corresponding frequencies. To find the frequencies of $\phi = \pm 45^\circ$, it was necessary to graphically construct a linear scale for frequencies perpendicular to the $\phi = 0$ line, and then interpolate between the nearest measured points [2]. These constructions are nowadays performed numerically by the data processing procedures that are described in Section 8.

The reflection-type measurement can also be applied to transmission-type cavities [8]. In Fig. 12a, port 2 is terminated in a matched load R_c , and the reflection-type measurement is performed on reflection coefficient S_{11} . The measured results are denoted Q_{L1} and κ_{m1} . In

Figure 11. Network analyzer display of the Q-factor measurement by Ginzton's method.

Fig. 12b, port 1 is terminated in a matched load, and the reflection-type measurement is performed on reflection coefficient S_{22} . The results are Q_{L2} and κ_{m2} . In both measurements, the cavity is loaded by characteristic impedance at both ports, so values Q_{L1} and Q_{L2} should come out to be the same. Their difference provides information on how accurate the measurement is. The input and output coupling coefficients are then obtained as follows:

$$\kappa_1 = \kappa_{m1} \frac{1 + \kappa_{m2}}{1 - \kappa_{m1}\kappa_{m2}} \quad (25)$$

$$\kappa_2 = \kappa_{m2} \frac{1 + \kappa_{m1}}{1 - \kappa_{m1}\kappa_{m2}} \quad (26)$$

Figure 12. Reflection-type measurement of a transmission-type resonator: (a) measuring S_{11} , (b) measuring S_{22} .

Unlike the insertion loss procedure from Section 4, this procedure does not require the two coupling coefficients to be equal to each other. In fact, the procedure yields both values κ_1 and κ_2 , which can then be substituted in (17), and then the unloaded Q follows from (7).

6. REACTION-TYPE MEASUREMENT

When a dielectric resonator is mounted close to a microstrip transmission line so that it forms a two-port, it is possible to measure the Q factor by connecting the network analyzer to both ends of the microstrip (points A and B in Fig. 13). This configuration is called the *reaction-type measurement of Q factor*, and it was proposed by Podcameni et al. [9], and analyzed in more detail by Khanna and Garault [10].

The measured value of S_{11} , shown on the polar display of the network analyzer, also displays Q circles, and the stronger the coupling, the larger the diameter of the Q circle. Figure 14a shows several circles for couplings κ between 0.5 and 2. Also, the figure shows $\phi = \pm 45^\circ$ lines to read frequencies f_1 and f_2 for the determination of Q_L . Likewise, if the transmission coefficient S_{21} is observed on the polar display shown in Fig. 14b, the Q circles are clearly visible, but bunched toward the right-hand side. In both figures, all the circles are about half the size of those

Figure 13. Two-port resonator suitable for the reaction-type measurement of Q .

Figure 14. (a) Typical S_{11} circles in a reaction-type measurement; (b) typical S_{21} circles in a reaction-type measurement.

in the reflection-type measurement. For instance, the largest theoretically possible diameter of the Q circle for the reaction-type measurement is $d=1$ (for an infinitely strong coupling), and for the critical coupling, the diameter is $d=0.5$. Although the resolution of the measurement may be reduced because of the smaller circles, this is nevertheless a convenient procedure, because the resonator is mounted in exactly the same environment as will be used in a typical oscillator or filter design.

Reference 10 also describes a procedure for scalar reaction-type measurements, using only the amplitudes of S_{11} and S_{21} for determining the loaded and unloaded Q .

7. THE ROLE OF X_s

According to elementary circuit theory, the value of external susceptance G_{ex} , loading the resonator in Fig. 3c, is

given by

$$G_{ex} = \frac{R_c + R_s}{(R_c + R_s)^2 + X_s^2} \tag{27}$$

Therefore, the coupling coefficient, as defined by (6), becomes

$$\kappa = \frac{G_{ex}}{G_0} = \frac{R_0}{R_c} \cdot \frac{1 + \frac{R_s}{R_c}}{\left(1 + \frac{R_s}{R_c}\right)^2 + \left(\frac{X_s}{R_c}\right)^2} \tag{28}$$

If (X_s/R_c) and (R_s/R_c) are negligibly small quantities, then the coupling coefficient is simply

$$\kappa = \beta = \frac{R_0}{R_c} \tag{29}$$

The symbol β has traditionally been used to denote the coupling coefficient when the equivalent circuit does not contain the series reactance X_s [2-4,9,10]. For the full equivalent circuit, which also takes into account that reactance, it is safer to use a new symbol, κ , based on the definition of the coupling coefficient derived from a ratio of powers, as in (6). Furthermore, symbol β could be confused with the phase constant of the transmission line.

To demonstrate the influence of X_s on the Q -circle size and position, the reflection coefficient as "seen" by the network analyzer at port 1 in Fig. 3a has been computed for several values of X_s . For the sake of simplicity, the coupling losses were ignored ($R_s = 0$) and the length of the transmission line was set to zero. The characteristic impedance of the line was set to $R_c = 1$, and the resonator losses were represented by $R_0 = 1.5$. Four different values of X_s were shown: $X_s = 0, 0.5, 1, 2$. The resulting Q circles are shown in Fig. 15.

For the vanishing reactance, $\kappa = \beta = 1.5$, so that both definitions of the coupling coefficient give the same result. The Q circle is centered on the real axis, and its diameter is $d = 1.2$. The difference between the two definitions

Figure 15. Input reflection coefficient for several different values of X_s in Fig. 3.

becomes noticeable for $X_s = 0.5$, because the Q circle is rotated, and its diameter is now only $d = 1.09$. For a large reactance, such as $X_s = 2$, the diameter shrinks further to $d = 0.461$, and the corresponding coupling coefficient is only $\kappa = 0.3$. If definition (29) were used, the coupling coefficient for all four cases would be equal to $\beta = 1.2$.

One has to keep in mind that port 1 is the only terminal that can be either measured or incorporated into an external circuit, such as an oscillator or a filter. Port 3 is simply not amenable to any measurement. There is no such thing as an observer who can sneak into the resonator, sit on port 3, and tell us how big X_s is. A practical answer to this dilemma is to accept the coupling coefficient such as predicted by size d of the measured Q circle. To avoid the apparently impossible task of finding the accurate value of X_s , one should allow the length of the transmission line to be increased by the amount needed to rotate the observed Q circle back to the real axis. At this new reference position (which were previously called “the detuned short position”), one may use the equivalent circuit without X_s . At the same time, one should be aware that the loaded resonant frequency f_L is theoretically different from the unloaded resonant frequency f_0 . This difference can be ignored for all practical purposes, at least within the first three digits of f_0 . For the high- Q resonators, the loaded resonant frequency f_L is practically identical with the unloaded resonant frequency f_0 . The relationship is expressed as follows [16]:

$$f_0 = f_L \left(1 - \frac{\kappa X_s}{2Q_0 R_c} \right) \quad (30)$$

As an example, for a critically coupled resonator with $Q_0 = 1000$, having a normalized value of coupling reactance $(X_s/R_c) = 1$, the two frequencies differ by 0.05%.

The role of coupling resistance R_s has a different effect. Specifically, R_s detaches the Q circle from the outer rim of the Smith chart. This fact is used in the curve-fitting procedure to estimate the severity of coupling losses.

8. CURVE-FITTING PROCEDURES

Common to all the measurement procedures described until now is the fact that one has to measure manually some S parameters at frequencies f_0 , f_1 , and f_2 and then compute the values of Q_L and κ . These procedures may commonly be called “three-point procedures.” They were all developed during the era of analog instrumentation.

Today’s network analyzers are all computer-controlled and therefore digital instruments. They can measure almost instantly up to 1601 frequency points and either store them, or deliver them to a file to be read by another computer. Data processing can then be used to determine the center and the diameter of the circle on the Smith chart; interpolate the exact position of frequency points f_0 , f_1 , and f_2 ; and utilize any appropriate equation for an accurate computation of Q_L and κ . The data processing is usually based on a curve-fitting procedure that attempts to fit the data to a circle on a complex plane [11–15].

Typically, 50 or more points of the measured scattering parameter S_{11} (or S_{21}) are used.

The circle on a complex plane can be described by a fractional linear function of real variable t as follows:

$$S_{11}(t) = \frac{a_1 t + a_2}{a_3 t + 1} \quad (31)$$

Variable t is the relative frequency detuning with respect to the loaded resonant frequency f_L defined as follows:

$$t = 2 \frac{f - f_L}{f_0} \quad (32)$$

Although (32) requires f_0 in the denominator, very little error is committed by using f_L instead. The loaded resonant frequency f_L is determined as the point closest to the center of the Smith chart. The weighted least-square curve fitting is then used to find the three complex coefficients a_1 – a_3 [14]. From the three coefficients, one can determine the needed parameters Q_L , κ , and Q_0 . For instance, if the coupling losses R_s are negligible, the loaded Q factor is

$$Q_L = \text{Im}(a_3) \quad (33)$$

and the diameter of the Q circle is

$$d = \left| a_2 - \frac{a_1}{a_3} \right| \quad (34)$$

With the use of (24) one can now compute the coupling κ , and then the unloaded Q follows from (7).

A side benefit of a curve-fitting procedure is the fact that there are many more measured data than needed for determining the three unknown coefficients. The problem is thus overdetermined, which allows the possibility of statistically estimating the standard deviations for all the quantities of interest [17]. Figure 16 shows a display of the software QZERO for Windows¹ with the best-fit circle and the estimated values for the loaded and unloaded Q factors, coupling, and the loaded resonant frequency. The estimated values are also accompanied by their uncertainties (standard deviations). It should be emphasized that these uncertainties describe only the random errors and not the systematic errors. The systematic errors of various models of network analyzers differ from each other, and they also depend on the frequency of operation. An analysis of systematic errors for the reflection-type curve fitting-method can be found in Ref. 18.

As mentioned in the previous section, the coupling losses (modeled by the presence of resistor R_s) can cause the Q circle to be detached from the perimeter of the Smith chart. Figure 17 shows the effect of coupling losses when

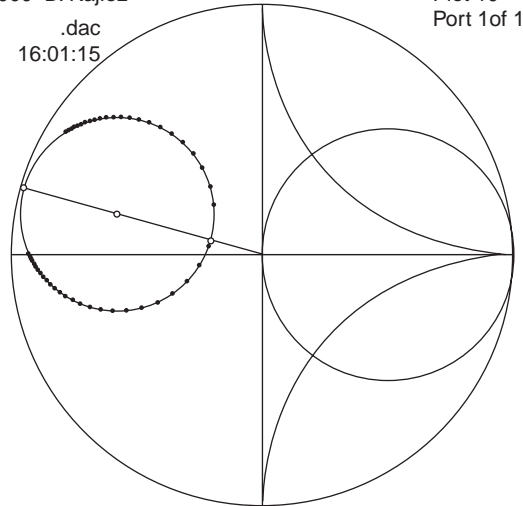

Figure 16. Measured data analyzed by the curve-fitting procedure.

$R_s = 0.04$, $X_s = 0.8$, $R_0 = 0.75$, and $R_c = 1$. Once the center and diameter d of the Q circle are known, it is possible to evaluate diameter d_2 of an auxiliary circle that is tangential to both the Q circle and the Smith chart perimeter. Diameter d_2 is now used to find the overall coupling coefficient κ , which includes also the coupling losses [17]:

$$\kappa = \frac{1}{\frac{d_2}{d} - 1} \quad (35)$$

For the special case when coupling losses are negligible, the auxiliary circle coincides with the perimeter of the Smith chart, so that $d_2 = 2$, and (35) becomes identical with (24).

Figure 17. Q -circle in the presence of coupling losses.

For carefully manufactured resonators, the coupling losses should be small, of the order of $R_s/R_0 < 0.01$. The overall coupling coefficient of a reflection type resonator now consists of two parts:

$$\kappa = \kappa_c + \kappa_s \quad (36)$$

where κ_c is the coupling that describes the power loss in external resistance R_c , and κ_s describes the power loss in the resistance R_s of the coupling mechanism. The ratio of κ_s to κ_c is proportional to normalized coupling loss resistance

$$\frac{\kappa_s}{\kappa_c} = \frac{R_s}{R_c} \quad (37)$$

The value of $\kappa_s = 0.00493$ is also shown on the display of QZERO in Fig. 16. This number is clearly an approximation, and the program does not attempt to find its standard deviation. Nevertheless, the value may be of use to a design engineer who wants to compare several different versions of coupling to the same resonator. In the example shown, approximately 0.5% of the total power is dissipated in the resistance of the coupling loop.

When a vector network analyzer is not available, it is possible to use the measured data taken with a scalar network analyzer and perform the data fitting to a theoretical resonance curve. Program SCALARQ² is intended for processing the amplitude (but not the phase) of reflection coefficient S_{11} . The theory of operation can be found in Ref. 19. An example of the display obtained by SCALARQ can be seen in Fig. 18. This example utilizes the same input data as in Fig. 16, except that the phase information is ignored. The measured data points are shown by black dots, and a solid line shows the best-fit resonant curve $|S_{11}(f)|$. Since the phase of the reflection coefficient is not known, one cannot plot the results on a Smith chart. Thus, one cannot tell whether this reflection coefficient represents an overcoupled or an undercoupled case. There are

²The DOS program SCALARQ is incorporated with the book *Q Factor* [17].

two possible interpretations of the measured data, and the display of SCALARQ shows both of them. Another, independent, experiment must be performed in order to decide which of the two answers is correct. Except for this limitation, the accuracy of the results obtained by SCALARQ is of the same order as the one obtained by QZERO. The resulting $Q_0 = 7500.9$ for the undercoupled case agrees very well with the value $Q_0 = 7500.7$ obtained in Fig. 16.

Q-FACTOR MEASUREMENTS

ANDRE LUITEN
University of Western Australia
Nedlands, Australia

1. INTRODUCTION

This article presents a review of both traditional and modern methods of “ Q factor” measurement. Many of the techniques to be described were first developed in order to determine the Q factors of resonances falling in the microwave frequency domain. One thus finds that the language of the microwave engineer has become all pervasive in the field, although the reader should note that the basic principles are just as applicable to measuring the Q factors of radiofrequency, millimeter, infrared, and optical resonators. The article commences with a definition of the Q factor and a description of the experimental parameters that need to be measured so as to determine the Q factor of a resonance. The various methods for measuring these parameters will then be outlined, including the particular advantages and disadvantages of a technique, the equipment required for the measurement, and its potential for accuracy. Finally, some of the latest developments in the field of Q measurement will be presented.

Measurement of the Q factor involves measurement of the defining characteristics of a resonance. Electromagnetic resonance will be found in any device that is able to store oscillatory energy for a length of time that is long compared to the period of oscillation of the electromagnetic energy. The Q factor is a measure of the “quality” of the resonance in the sense that a high- Q -factor resonance is one in which the energy dissipation rate is low, or equivalently that the energy storage time is long.

Clearly the concept of energy storage requires that the device both prevent the escape of energy into the environment, as well as to minimize conversion of this electromagnetic energy into other forms of energy. Microwave resonators make use of two main methods to trap energy: (1) storage of the fields in a volume that is surrounded by conductive material and (2) storage inside a high-dielectric material by total internal reflection at the dielectric surface. Resonators using method 1 are termed *microwave cavities*; those using method 2 are termed *dielectric resonators*. It is also possible, of course, to build hybrid resonators that use both mechanisms to trap energy. Any electromagnetic field pattern that satisfies Maxwell’s equations in the resonator volume and satisfies the boundary conditions imposed by the resonator surfaces, is called a *normal mode* or *resonance* of the resonator [1].

For energy to enter and leave a resonator, there must be some electrical or magnetic pathway between the resonator and an external transmission line. This pathway is most commonly provided by either a magnetic loop probe or electric stub probe on the end of a coaxial transmission line that protrudes into a cavity resonator or a direct opening in the metallic wall between a cavity and a waveguide transmission line (iris coupling), or by placing a dielectric resonator in close proximity to a microstrip

conductor (evanescent field or reactive coupling). The number of coupling ports, as well as the type of coupling used on those ports, is used to further characterize microwave resonators. Resonators with a single port using probe or iris coupling are termed *reflection resonators*. Resonators with two or more ports using probe or iris coupling are termed *transmission resonators*. Two-port resonators making use of reactive coupling are termed *reactive* or *absorption resonators*.

Microwave resonators, and accurate Q measurements to characterize those resonators, are vitally important in microwave engineering and physics:

1. Filters can be constructed from resonators because of their selective behavior in the frequency domain. A filter is a device that can transmit or reflect a desired signal while rejecting other nearby unwanted signals.
2. Resonators are widely used as oscillator tank circuits as well as for the study of materials in high electromagnetic fields. Both of these applications arise because of the energy enhancement qualities of resonators.
3. Measurements of electrical conductivity can be performed by an accurate measurement of the Q factor of a microwave resonator that has been constructed of the material of interest [2,3]. This measurement technique has undergone a renaissance with great interest in measurements on high-temperature superconductors [4].
4. Microwave properties of materials can be measured by their impact on the Q factor and resonant frequency of a microwave resonance when they are loaded into a microwave resonator [1,5,6]. Highly sensitive measurements of the Q and resonant frequency are required to gain accurate material characterization. The dielectric loss and dielectric constants of fluids and gases have been reported by a number of workers using this method [7,8]. Magnetic and electrical properties of solids have also been reported [9–12].
5. Oscillators that have a high frequency stability in the short term require high- Q resonators: the best frequency stabilities ever reported are by a superconducting cavity microwave oscillator operating near 2 K with a Q factor around 10^{11} [13], and by a sapphire dielectric resonator oscillator at 6 K with a Q above 4×10^9 [14].

Microwave Q factors of interest range from a low value of 2 [15] up to 10^{11} for an electropolished superconducting cavity at cryogenic temperatures [13]. Coupling factors (see below) to these resonances can vary from 10^{-3} for extremely lightly coupled wavemeter resonators up to 10^3 for superconducting cavities at cryogenic temperatures. No single technique can be expected to operate over this full range and always give high-resolution and high-accuracy measurements. The desire to generate accurate measurements over this full range of interest has led to the large number of Q measurement methods reported here.

Many traditional methods for obtaining the Q factor have fallen from favor either because of improvements in technology or because the original cumbersome technique can now be circumvented. For example, one of the major reasons for devising time-domain Q -measuring techniques was to avoid difficulties arising from the typically poor frequency stability of microwave signal generators of the time. However, modern quartz-based synthesizer technology provides a frequency stability that is adequate to measure the Q factors of all except the very highest- Q resonators. A second example is found with the very rare use of traditional voltage standing-wave ratio (VSWR) measurement techniques in modern laboratories. These techniques are slow [16] and cumbersome as they require a device to be moved mechanically to perform measurements. Modern network analyzers can make equivalent measurements essentially instantaneously without the need for mechanical changes to the circuit. Nevertheless, traditional Q measurement techniques still have importance because of their simplicity, low-cost instrumentation, and instructional value. For these reasons they will be discussed below. For highly detailed instructions on performing these methods, the reader should refer to excellent descriptions in the classical texts [17,18].

2. DEFINITIONS

The letter Q was first used to describe the ratio of reactance to resistance of low-frequency inductors and capacitors [18]. The widespread technique of describing microwave resonators in terms of low-frequency circuit elements led to an association of the letter Q with the ratio of reactance to resistance in resonant circuits. A simple calculation [see Eq. (3)] shows that there is also a close relationship between Q and the time for energy to dissipate in such an equivalent circuit. This led to the incorrect but widespread belief that Q is the initial letter of the expression “quality factor” (abbreviated as Q factor), a term related to the length of time that a resonant circuit stores energy. The agreed modern definition of the Q factor of any general resonant circuit (including electronic, optical, and mechanical resonators) is [18] 2π multiplied by the ratio of stored energy to the energy dissipated per cycle or expressed symbolically

$$Q = \frac{2\pi U}{\Delta U} \tag{1}$$

where U is the total energy of the system and ΔU is the energy dissipated in a cycle. This equation can be solved to determine how the stored energy decays as a function of time. The energy dissipated in one cycle can be written as

$$\Delta U = \frac{\partial U}{\partial t} \frac{1}{f_0} \tag{2}$$

where f_0 is the resonant frequency. Substituting (2) into (1) the time dependence of U is found as

$$U(t) = U_0 e^{-(\omega_0/Q)t} \tag{3}$$

where U_0 is the initial energy of the resonant system and $\omega_0 \equiv 2\pi f_0$ is the angular resonant frequency. From a simple inspection of Eq. (3) another more practical definition of Q can be stated as: 2π times the number of cycles required for the energy in the system to decay to $1/e$ of some initial amount, or

$$Q = \frac{2\pi\tau}{T_0} \tag{4}$$

where τ is the time taken for the energy to decrease to $1/e$ of its value (conventionally called the *ringdown time*) and $T_0 \equiv 1/f_0$ is the resonant period. As will be seen below, direct use is made of expression (4) in determining Q factors with one of the time-domain measurement techniques. All other measurement techniques make use of the response of the resonator to forced oscillation. To understand these techniques, we will need to derive expressions that will describe the behavior of the resonator under the influence of an external field.

2.1. Microwave Resonators

A diagram of a transmission microwave resonator is given in Fig. 1a. The figure shows an empty metallic cavity where a coupling between the resonator and some external transmission lines is provided by small openings in the walls of the cavity. A general low-frequency analog to this microwave resonator, its coupling arrangement, and the external transmission lines is given by Fig. 1b. In general, such a resonant cavity has an infinite number of normal modes, each represented by a parallel LCR circuit [19]. The k th resonant frequency is given by the expression

$$(f_0)_k = \frac{1}{2\pi\sqrt{L_k C_k}} \tag{5}$$

and the unloaded Q of the k th resonance can be determined by substituting the energy dissipation provided by R_k and the energy storage provided by C_k and L_k into Eq. (1):

$$(Q_u)_k = R_k \sqrt{\frac{L_k}{C_k}} \tag{6}$$

The iris coupling has been modeled as a transformer of an arbitrary turns ratio [17,20]. X_{e1} and R_{e1} are the equivalent reactance and shunt resistance of the input coupling network and transmission line, respectively, while X_{e2} and R_{e2} are the equivalent parameters for the resonator output coupling network. R_s is the series impedance of the signal generator, and R_L is the equivalent load resistance of the equipment that is monitoring the resonator. Any measurement of the resonant system represented by Fig. 1b will yield a result that is a combination of the properties of the transmission line and the coupling mechanism as well as the resonator. However, under certain conditions it is possible to determine the Q of a particular mode while ignoring the influences of the load, the coupling mechanism, the transmission line, and other modes. In this case the external impedances can be transformed into the resonant circuit giving the circuit shown in Fig. 1c. This circuit is far more amenable to analysis and is the resonance model

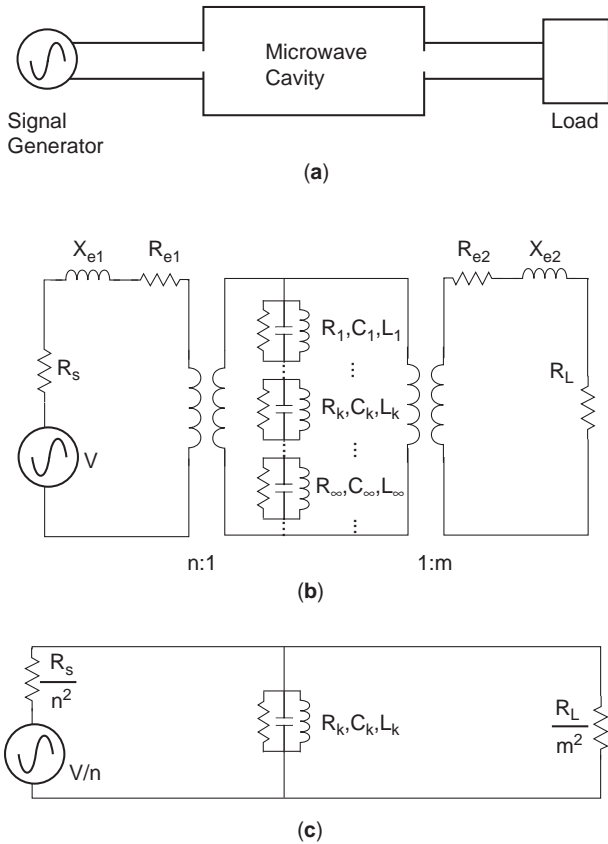

Figure 1. (a) A block diagram of a microwave cavity resonator with iris coupling on the input and output ports. The source and load are coupled to the cavity with waveguide transmission lines. (b) An equivalent LCR circuit for the microwave system in Fig. 1a. The infinite number of possible resonant modes of the cavity resonator is represented by an infinite series of LCR circuits: $(R_1, C_1, L_1), \dots, (R_k, C_k, L_k), \dots, (R_\infty, C_\infty, L_\infty)$. The input and output coupling networks have been modeled with a series loss (R_{e1}, R_{e2}) and series inductance (X_{e1}, X_{e2}) to factor in any losses or reactance of the coupling network. The source and load series impedance are denoted by R_s and R_L , respectively. The iris coupling has been modeled as a transformer of unknown turns ratio. (c) A simplified version of part (b) in which the traditional assumptions of Q-factor measurement have been made. The coupling reactance and loss are assumed to be zero. The source and load are assumed to be perfectly impedance-matched to the line impedance. All other resonances of the cavity are assumed to be sufficiently far from the resonance of interest that they can be safely ignored. The transformers have been eliminated by transforming the external components into an effective impedance that would be seen by the resonant circuit.

assumed by traditional measurement techniques as it greatly simplifies postmeasurement analysis (attempts were sometimes made to allow for coupling losses, i.e., $R_{e1} \neq 0$ [18]). These simplifications will lead to important errors if the resonator is strongly overcoupled, the Q of the resonance is relatively low, the generator or source is poorly matched to the transmission line or there is an excessive level of reactance in the coupling mechanism or transmission line. For the sake of a simple introduction, we will use the circuit shown in Fig. 1c and reserve discussion of the more complex situation until Section 4.2.

Figure 2. A diagram representing the scattering of microwave voltage waves by a general microwave two-port.

To describe how microwave radiation interacts with a resonator, we will use a scattering matrix formalism. Figure 2 shows a voltage wave \tilde{a}_1 incident on an arbitrary microwave two-port device. The wave is scattered by the two-port, some of its energy going into a reflected wave \tilde{a}_2 and part into a transmitted wave \tilde{b}_2 . We express all three waves as

$$A \exp(j\omega t + \beta z) \tag{7}$$

where ω is the applied angular microwave frequency, A is the voltage amplitude of the wave, β is the propagation constant, and z is the measurement position. We define the resonator scattering terms s_{11} and s_{21} as

$$s_{11} \equiv \frac{\tilde{a}_2}{\tilde{a}_1} \text{ and } s_{21} \equiv \frac{\tilde{b}_2}{\tilde{a}_1} \tag{8}$$

We can, of course, define equivalent parameters for port 2. By substituting Eq. (7) into Eq. (8) we note that s_{11} and s_{21} will depend on the measurement position. This leads to the difficulty that we need to specify the measurement plane each time we quote the resonator scattering parameters. Theoretically we could avoid this difficulty by always referring the measurement to some special preestablished measurement plane, such as the plane that is coincident with the coupling device. However, in practice, always taking measurements at some particular position could pose a great deal of difficulty. Instead we choose to define some special planes that have a well-defined measurable characteristic. If a measurement is made of s_{11} at a frequency that is far from the resonant frequency, we can always find a position on the line that responds as if there were a short circuit or an open circuit on the transmission line. These planes are termed the *detuned short* or *detuned open* positions [17,18,20]. From the *detuned short* position the equivalent low-frequency circuit shown in Fig. 1c is an accurate representation of the real microwave circuit (given that all the assumptions stated above still hold). Modern measurements can avoid this difficulty of determining the reference plane, as will be shown below. The scattering parameters at the *detuned short* position for the circuit shown in Fig. 1c have been calculated as [21,22]

$$s_{11}(\varepsilon) = \frac{\beta_1 - \beta_2 - 1 - jQ_u \varepsilon}{1 + \beta_1 + \beta_2 + jQ_u \varepsilon} \tag{9}$$

$$s_{21}(\varepsilon) \equiv s_{12}(\varepsilon) = \frac{2\sqrt{\beta_1 \beta_2}}{1 + \beta_1 + \beta_2 + jQ_u \varepsilon} \tag{10}$$

where $\varepsilon \equiv (f/f_0) - (f_0/f)$, f is the incident frequency, f_0 is the resonant frequency as defined in Eq. (5), Q_u is the unloaded Q of the resonator as defined in Eq. (6), and β_1 and β_2 are the coupling factors that are defined as the ratio of the internal resonant resistance to the external resistances when transformed into the resonant circuit

$$\beta_1 = \frac{n^2 R_k}{R_s} \quad \text{and} \quad \beta_2 = \frac{m^2 R_k}{R_L} \quad (11)$$

where n is the effective turns ratio of the input coupling mechanism and m is the effective turns ratio of the output coupling mechanism. If $\beta < 1$, a resonator is termed *undercoupled*; if $\beta > 1$, a resonator is termed *overcoupled*; and if $\beta = 1$, the resonator is critically coupled. Equation (9) also applies to single-port reflection resonators if β_2 is set to zero. We note also that the coupling factor represents the ratio of the power dissipated in the relevant external circuit to the power dissipated in the resonator.

It is useful to split expressions (9) and (10) into their real and imaginary parts as this will give us the in-phase response and quadrature phase response of the resonator, respectively. In other words, the real part of Eq. (9) gives us the portion of the reflected wave that is in phase with the incident signal, and the imaginary part will give the fraction of the reflected signal that is $\pi/2$ out of phase with the incident signal:

$$\text{Real}[s_{11}] = \frac{(1 + \beta_1 + \beta_2)(\beta_1 - \beta_2 - 1) - \varepsilon^2 Q_u^2}{(1 + \beta_1 + \beta_2)^2 + \varepsilon^2 Q_u^2} \quad (12)$$

$$\text{Imag}[s_{11}] = \frac{-2\beta_1 \varepsilon Q_u}{(1 + \beta_1 + \beta_2)^2 + \varepsilon^2 Q_u^2} \quad (13)$$

$$\text{Real}[s_{21}] = \frac{2\sqrt{\beta_1 \beta_2}(1 + \beta_1 + \beta_2)}{(1 + \beta_1 + \beta_2)^2 + \varepsilon^2 Q_u^2} \quad (14)$$

$$\text{Imag}[s_{21}] = \frac{-2\sqrt{\beta_1 \beta_2} \varepsilon Q_u}{(1 + \beta_1 + \beta_2)^2 + \varepsilon^2 Q_u^2} \quad (15)$$

An interesting and novel way of summarizing this information is by using a three-dimensional parametric plot of the resonator response as a function of frequency (see Fig. 3). If we make two-dimensional projections of this plot along the principal axes, we will see response curves that are more familiar to the microwave engineer. To display this, we have projected the three-dimensional plot onto the faces of the box in Fig. 3 and then rotated these faces into view. Viewing the curve that has been projected onto the plane perpendicular to the real axis, we see the imaginary response of the resonator (Fig. 3b); looking along the imaginary axis, we observe the real response of the resonator (Fig. 3c); and finally, looking parallel to the frequency axis, we observe a circle—which is termed the “ Q circle” of the resonator (Fig. 3d). This horizontal projection plane is more readily recognized as the Smith chart [23]. The Smith chart gives the magnitude of s_{11} by the distance that a plotted point is from the origin, while the phase of s_{11} (ϕ) is given by the angle that the line joining the point to the origin makes with the real axis. The most important

Figure 3. (a) A three-dimensional display of the scattering parameter s_{11} from a reflection resonator. The curve has been projected onto the faces of the box, and these faces have been rotated into view. (b) The imaginary (or quadrature phase) reflection response of the resonator. (c) The real (or in-phase) reflection response of the resonator. (d) The Q circle of the resonator on a Smith chart. The phase and magnitude of the reflection coefficient at a particular frequency are respectively given by the distance of a plotted point is from the origin and the angle it forms with the real axis.

advantage of this three-dimensional description of the resonator response is the clear demonstration of the intimate relationship that exists between the many descriptions of microwave resonators given in the literature: the real and imaginary components of the scattering matrix, the Smith chart, and the magnitude and phase of the response.

Q -factor measurements of two-port microwave resonators frequently employ measurements of the transmitted and reflected power as a function of frequency. In cases of moderate to high Q , the derived frequency variable ε defined above can be simplified with negligible error to

$$\varepsilon \approx \frac{2\Delta f}{f_0} \quad (16)$$

where we define a frequency detuning Δf as $\Delta f \equiv f - f_0$. The squared magnitude of s_{11} and s_{21} (which gives the reflected and transmitted power coefficients, respectively) can be derived from Eqs. (9) and (10) as follows:

$$|s_{11}(\Delta f)|^2 = \frac{(1 - \beta_1 + \beta_2)^2 + 4\left(\frac{Q_u \Delta f}{f_0}\right)^2}{(1 + \beta_1 + \beta_2)^2 + 4\left(\frac{Q_u \Delta f}{f_0}\right)^2} \quad (17)$$

$$|s_{21}(\Delta f)|^2 = \frac{4\beta_1 \beta_2}{(1 + \beta_1 + \beta_2)^2 + 4\left(\frac{Q_u \Delta f}{f_0}\right)^2} \quad (18)$$

Plots of these functions have been given in Fig. 4 together with some important limiting values. Throughout

Figure 4. The power reflection and transmission coefficients of a two-port resonator with $\beta_1=1$ and $\beta_2=2$. The loaded Q of the resonator is given by $Q_L=f_0/(f_2-f_1)$, where f_1 and f_2 are the points at which the power transmission coefficient is half the maximum power transmission, or the points where the power reflection coefficient is the average of the on- and off-resonance power reflection coefficients.

the rest of this article, we will assume that the approximation shown in Eq. (16) can always be made. For simplicity, the argument of the scattering parameter functions will henceforth be just the frequency detuning as shown above.

2.2. Loaded Q (Q_L), Unloaded Q (Q_U), and External Q (Q_E)

There are three distinct Q factors associated with the losses in a microwave circuit. The unloaded Q (Q_U) is the Q factor that would be measured as the electromagnetic coupling to the resonator tended to zero. Thus, it is associated with dissipation that occurs inside the resonator [R_k in Fig. 1c; see also Eq. (6)]. The external Q (Q_e) is the dissipation that occurs external to the resonator but is coupled into the resonance by the coupling to the external circuit (R_s and R_L in Fig. 1c). We can derive an expression for the external Q factors in the same way as we found the unloaded Q factor [Eq. (6)]:

$$Q_{e1} = \frac{R_s}{n^2} \sqrt{\frac{C}{L}} \quad \text{and} \quad Q_{e2} = \frac{R_L}{m^2} \sqrt{\frac{C}{L}} \quad (19)$$

The loaded Q (Q_L) is the Q factor actually measured by the experimenter. It includes the contributions of all losses in the circuit that provide a dissipation mechanism for the resonant energy (both internal and external to the resonant circuit). We can write the relationship between the loaded Q , the unloaded Q , and the external Q factors as follows:

$$\frac{1}{Q_L} = \frac{1}{Q_U} + \frac{1}{Q_{e1}} + \frac{1}{Q_{e2}} \quad (20)$$

Using the definitions of the coupling factors [Eq. (11)] and the definitions of the unloaded and external Q factors [Eqs. (6) and (19)], we can simplify Eq. (20) to

$$Q_u = (1 + \beta_1 + \beta_2)Q_L \quad (21)$$

2.3. Overview of Q-Factor Measurement Techniques

A simplification of some of the preceding expressions can be used to generate a few practical methods to measure the Q factor. From an examination of Eq. (17) we see that

the maximum power transmitted through the resonator occurs when the incident frequency is exactly equal to the resonant frequency. As we move away from the resonant frequency, the transmitted power falls as the square of the frequency detuning. Clearly an important measure of such a resonant feature would be its sharpness. We choose to measure the sharpness of the feature by the frequency difference between the two frequency points that transmit half the maximum power; that is, we need to find the two values of the frequency detuning Δf that satisfy the following equation:

$$|s_{21}(\Delta f)|^2 = \frac{1}{2} |s_{21}(0)|^2 \quad (22)$$

The solutions to this equation are

$$(\Delta f) = \pm \frac{1}{2} \frac{(1 + \beta_1 + \beta_2)f_0}{Q_U} = \pm \frac{1}{2} \frac{f_0}{Q_L} \quad (23)$$

Let us define a new parameter, Δf_L : the loaded half-bandwidth of the resonance that is equal to the positive solution of Eq. (23):

$$\Delta f_L = \frac{1}{2} \frac{f_0}{Q_L} \quad (24)$$

The analysis above suggests a method for measuring Q_L in transmission resonators. By measuring the resonant frequency, the maximum transmission power, and the two frequency points at which the transmitted power is down by half, we can directly calculate the loaded Q .

To derive the unloaded Q (Q_u) from this measurement, we will need to determine the coupling factors and use Eq. (21). A measurement of the scalar reflection coefficient on resonance and the scalar transmission coefficient on resonance yields the left-hand sides of Eqs. (17) and (18). Rearranging these equations, we can solve for the coupling coefficients in terms of the measured quantities

$$\beta_1 = \frac{(\Gamma_0 \pm 1)^2}{1 - \Gamma_0^2 - T_0^2} \quad \text{and} \quad \beta_2 = \frac{T_0^2}{1 - \Gamma_0^2 - T_0^2} \quad (25)$$

where we have defined the on-resonance values to be $\Gamma_0 = |s_{11}(0)|$ and $T_0 = |s_{21}(0)|$. Equation (17) can also be

applied to find the coupling coefficient of a one-port resonator by letting β_2 be equal to zero. Rearranging as with Eq. (25), we find

$$\beta_1 = \frac{1 \pm \Gamma_0}{1 \mp \Gamma_0} \quad (26)$$

It is not possible to determine which of the two possible solutions for β_1 shown in Eqs. (25) and (26) is, in fact, the actual one if we are limited to scalar measurements. To remove this ambiguity, it is necessary to either measure the phase shift on resonance [16], or to vary the physical coupling in a known way and then remeasure the scalar reflection coefficient [18,24]. If it is unnecessary to know the coupling factors individually but only for the purpose of determining the unloaded Q factor from the measured loaded Q factor, then one can use [22]

$$1 + \beta_1 + \beta_2 = \frac{2}{s_{11}(0) + s_{22}(0)} \quad (27)$$

If it is possible to measure the full complex character (a vector measurement) of the scattering parameters, then there are a large number of alternative methods to estimating the Q factor of a resonator. For simplicity, we will perform the following calculations for a one-port reflection resonator ($\beta_2 = 0$). Nonetheless, it should be noted that the equations that govern reflection, transmission, and reaction resonators are all essentially equivalent [25], and so most Q measurement techniques can be equally applied to all three types of resonator [25,26].

To commence, let us determine the relationship that exists between the real and imaginary components of s_{11} at an arbitrary frequency detuning that will allow us to directly determine the unloaded Q factor. Let us define an unloaded half-resonance bandwidth in the same way as we did for a loaded half-resonance bandwidth [Eq. (24)]:

$$\Delta f_U \equiv \frac{1}{2} \frac{f_0}{Q_U} \quad (28)$$

Substituting Δf_L and Δf_U into the real and imaginary parts of s_{11} [Eqs. (12) and (13)], we find the following relationships:

$$\text{Im}[s_{11}(\pm \Delta f_L)] = \mp \{1 + \text{Re}[s_{11}(\pm \Delta f_L)]\} \quad (29)$$

$$\text{Im}[s_{11}(\pm \Delta f_U)] = \mp \left\{ 1 - \sqrt{2 - (\text{Re}[s_{11}(\pm \Delta f_U)])^2} \right\} \quad (30)$$

If the frequency detuning is varied until one of these equations are satisfied, the value of the detuning will directly give the loaded or unloaded half-bandwidth. By backsubstitution into Eqs. (28) and (24), the unloaded and loaded Q may be found.

3. SOURCES OF Q MEASUREMENT ERRORS

We can divide measurement error into two categories: systematic and random. A systematic error yields a consistent result on a repeated measurement of a constant

quantity but with a value that differs from the true value. Such a measurement could have a high resolution but simultaneously a relatively poor accuracy. Random measurement errors (noise) result in a scattering of measurement values when making a repeated measurement of a constant quantity. If a measurement system is dominated by random noise, it is relatively easy to estimate its accuracy by making multiple measurements of a constant quantity and quoting some statistical measure of the measurement sequence. An improvement in the resolution of the measurement can also usually be made by averaging multiple measurements. An estimation of the accuracy of a system that is dominated by systematic errors is far more difficult. If one has another system with a known accuracy, it is possible to compare the measurement system with this second accurate system. If this is not possible because this new technique has accuracy superior to that of all other devices, or because such a reference system is not available, then the usual technique is to measure the same quantity with two or more completely independent techniques under varying conditions and quote the differences between the results.

3.1. Systematic Q Measurement Errors

Any Q estimation technique that samples the scattering parameters at a number of separate instants requires that we place conditions on the amplitude and frequency stability of the probing microwave source. Any drift in the source frequency during the measurement will result in distortions to the resonance curve shape and thus a consequent distortion of the loaded Q value. Of course, this becomes more serious as the Q factor becomes higher. Drifts in the amplitude of the source will give rise to distortions in the measured coupling factors, which will result in errors in the estimation of the unloaded Q . This effect will have higher significance as the relevant coupling factor becomes smaller. The relative error in the Q factor under these conditions depends on the order in which the measurements are taken as well as the particular values of the coupling and Q factors. However, for a worst-case estimate using a frequency drifting source, we can assume that the measurements are taken in ascending or descending frequency order and equally spaced; then the fractional error in estimation of Q_L will be

$$\frac{\Delta Q_L}{Q_L} = \pm \frac{tkQ_L}{f_0} \quad (31)$$

where t is the time required to sample the response between $+\Delta f_L$ and $-\Delta f_L$ and k is the frequency drift rate of the source in Hertz per second (Hz/s).

Drifts in the resonant frequency of the resonance during the measurement will also cause distortions to the measured Q values in much the same way as will drifts in the source frequency. This is especially important when the temperature coefficient of the resonator is large and the resonator Q factor is high. For example, in the case of a sapphire dielectric resonator at 77 K the fractional frequency temperature coefficient is around $10^{-5}/\text{K}$, while Q_L is around 5×10^7 [27]. Temperature drifts of the order

of 200 μK during the period of measurement will limit the accuracy of the Q -factor measurement to 10%.

Almost all non-time-domain Q measurements have traditionally relied on the ability to treat the resonance as a single resonance that is well described by an equivalent LCR network. In a situation where there are losses or reactance in the coupling network, a mismatch of the source or measurement equipment with the transmission lines, or interfering resonances in the resonator or in the external transmission lines, there will be distortions to the classic resonance shape with consequent errors in the measured Q factors. It is difficult to summarize all the errors induced by ignoring these effects since there are so many possibilities. The reader is best referred to a number of articles for examples of treatment of these issues [28–30]. However, as an example, if we consider the modern Q circle method (see below), it will give a Q_U that is 15% in error for each 1 dB of return loss that is ignored in the lines leading to a critically coupled resonator.

In resonators that are remote from the experimental apparatus, or in systems with poorly matched loads and sources, resonances can appear in the connecting transmission lines that cause distortions to the resonance shape. The best solution to this problem is to suppress these spurious resonances by using microwave isolators. To overcome high levels of coupling reactance or interfering resonances in the resonator itself, one must refer to some of the methods covered in the Section 4.2 [30].

If the resonator contains materials that have properties (either reactive or resistive) that are altered by the amplitude of the incident microwave fields, then one must consider the effects of nonlinear behavior in altering the measured Q factor [31,32]. For example, microwave resonators that have been loaded with ruby have even demonstrated negative Q factors [31]. Probing the resonance can also introduce other problems such as inducing temperature changes in the resonator that will displace the resonance feature, cause electrical breakdown, or otherwise modify the properties of the dielectric or conductive material in the cavity. For example, most superconducting cavities demonstrate a very strong Q dependence on power [3,33]. Under all these circumstances great care must be taken to ensure that correct results are obtained. One obvious method to test for nonlinear effects is to measure the Q factor over a range of incident powers and ensure that no change has occurred in its measured value. Alternatively, by making a Q measurement based on the points just near the center of resonance, one can attempt to reduce the effect of the nonlinearity [33].

Finally, any inaccuracies in the calibrations of the measuring instruments will lead to inaccuracies in the Q -factor measurement. For example, Sucher [18] has calculated the error in measurement of the Q of a transmission resonator from an error in the attenuation measurement (ΔA) of the half-power transmission points as follows:

$$\frac{\Delta Q_L}{Q_L} = -0.23\Delta A \quad (32)$$

Thus a 0.1-dB error in measurement leads to an inaccuracy of 2.3%.

3.2. Random Q Measurement Errors

Random noise in the Q -factor measurement apparatus will lead to random variations in a series of measurements of a constant resonance. Many of the mechanisms mentioned above as sources of systematic errors can also be sources of random errors if the property or mechanism exhibits fluctuations rather than just causing a fixed offset in the measurement result. For instance, frequency fluctuations (phase noise) of the microwave source will create an amplitude noise in the reflected or transmitted power. This will limit the experimenter's ability to identify a particular point on a resonance curve. For example, to measure the Q factor of an X-band dielectric resonator that is of order 10^5 to an accuracy of 1% requires that the position of the measured frequency points be known to better than 1 kHz. Such frequency stability is achieved only by quartz-based microwave frequency synthesizers.

All Q measurements are ultimately limited by the intrinsic noise of the amplitude or phase sensor in the analyzing instruments. The resulting fractional noise in the Q measurement is very dependent on the prevailing conditions of the measurement. For example, with weakly coupled resonators the effects of noise in the amplitude measurement will have a greatly magnified effect in producing inaccuracy in the Q measurement. For further details of the effects of noise, the reader is referred to the more recent literature on the subject [28,30].

4. SURVEY OF Q-FACTOR MEASUREMENT TECHNIQUES

To assist the reader, the multitude of Q measurement techniques have been classified into the categories shown in Fig. 5. A major distinction has been drawn between spatial and temporal techniques because of the very different technologies required for the two types of measurement. *Spatial* techniques rely on using a slotted-line device to measure the voltage standing-wave ratio (VSWR) in the incident microwave line. The VSWR gives a measure of the magnitude of the reflection coefficient of the resonator while the position of the voltage minima in the VSWR pattern gives a measure of the reflection phase.

The *temporal* classification includes Q measurements made using frequency- and time-domain techniques. *Frequency-domain* techniques rely on measuring the scalar or vector components of the scattering parameters as a function of frequency. Frequency domain measurements are the most commonly encountered of all Q -factor estimation techniques in modern times as they are both precise and easily implemented using modern equipment. *Time-domain* measurements rely on measuring the time response of a resonance excited by an impulse of energy. These techniques have the advantage of avoiding the need for high-quality signal sources, and can also be of use when high-speed Q -factor estimation is required. *Static frequency-domain* techniques include techniques that either rely on a stepwise measurement of the scattering parameters at a number of particular frequency points or could be performed with a continuously swept source as long as the swept frequency during a single measurement is much less than the bandwidth of the resonance. Within

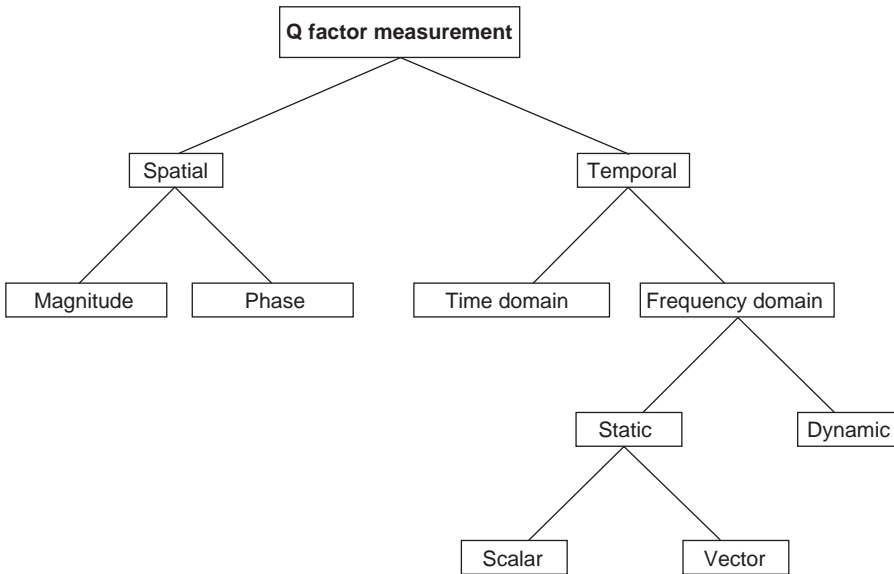

Figure 5. The very large number of different methods of Q measurement have been classified within this scheme to clarify the broad differences between the techniques. The headings of the following sections follow the classifications shown on this diagram.

these frequency-domain techniques the experimenter has the choice of measuring the scalar or full vector components of the scattering parameters depending on the available equipment. *Dynamic frequency-domain* measurements rely on measuring the response of a resonance to a frequency-modulated incident signal. These types of measurement are still quasistatic in the sense that the modulation frequency is much less than the resonance width.

4.1. Traditional Methods of Q Measurement

Below we present a number of measurement techniques that were traditionally used to estimate the Q factor. These techniques have fallen out of favor in more recent times because of the wide availability of network analyzers and quartz-based microwave synthesizers together with the inherently time-consuming nature of these approaches. Nonetheless, their instructional value and previous importance requires a quick review of the techniques. Indeed, as we will see later, some modern Q -factor measurements are simply modern implementations of these fundamental techniques.

4.1.1. Spatial Methods: Magnitude and Phase. If a measurement is made of the voltage along the incident line of the microwave resonator in Fig. 2, we would find a standing wave formed by the interference of the incoming and outgoing waves. The ratio of the minimum to maximum voltage as measured along this transmission line is termed the voltage standing-wave ratio (VSWR) and can be directly measured with a slotted-line device. The locations of the voltage minima (or maxima) in this pattern are determined by the phase of the reflected signal [17,18]. The amplitude of the VSWR is given by

$$\text{VSWR} = \frac{1 + |s_{11}|}{1 - |s_{11}|} \tag{33}$$

To compare s_{11} for under and overcoupled resonators, a plot of each is given on a Smith chart in Fig. 6 (as viewed from the *detuned short* position). One notes that $|s_{11}|$ (and hence the VSWR also) of an overcoupled resonator is large and relatively constant, although the reflection phase changes by 2π across the resonance. The undercoupled resonance demonstrates a relatively small phase variation, although the relative VSWR change is large. This knowledge arms the engineer with a technique for an accurate measurement of the Q using a slotted-line device whatever the coupling value. If a resonator is overcoupled, a measurement of the position of the voltage minima should be made; if the resonator is undercoupled, a measurement of the magnitude of the VSWR will yield the more accurate result.

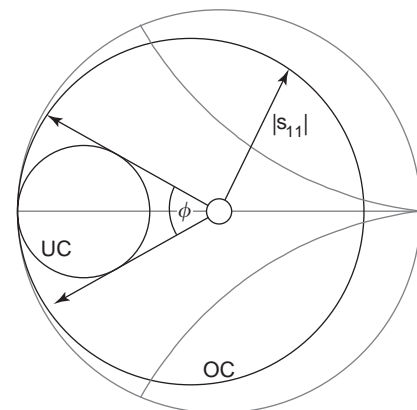

Figure 6. Smith chart plots of the s_{11} responses of an overcoupled (OC) and an undercoupled (UC) resonance. The reflection phase of the OC resonance changes by 2π across the resonance, while the reflection phase of the UC resonance reaches a maximum value of $\phi/2$ before returning to zero and then reaching a minimum value of $-\phi/2$ before once again returning to zero. However, the relative changes in magnitude of the reflection coefficient across resonance are much larger in the case of the undercoupled resonator.

Substitution of Eq. (9) into Eq. (33) yields the result that the VSWR on resonance is equal to $\beta_1^{\pm 1}$ for a one-port resonator. A measurement of the VSWR alone is unable to resolve the sign of the exponent, although an additional measurement can determine this (see below).

The VSWR at $\pm\Delta f_L$ and $\pm\Delta f_U$ for the undercoupled case can be calculated as a function of the VSWR on resonance (V_0) to be

$$V(\pm\Delta f_L) = \frac{\left| \frac{j+V_0}{1+V_0} + 1 \right|}{\left| \frac{j+V_0}{1+V_0} - 1 \right|} \quad \text{and} \quad V(\pm\Delta f_U) = \frac{\left| \frac{1-(1+j)V_0}{1+(1+j)V_0} + 1 \right|}{\left| \frac{1-(1+j)V_0}{1+(1+j)V_0} - 1 \right|} \quad (34)$$

Thus, if we measure V_0 , substitute it into equation above, and then measure the frequency detuning at which the VSWR is equal to the calculated value, we can immediately determine Q_U and Q_L .

For overcoupled resonators, the Q is accurately determined by measuring the position of the voltage minima (or maxima) as the resonant frequency is changed (for a tunable resonator), or as the incident signal frequency is changed. A plot of the position of the voltage minima for two single-port resonators ($\beta_1 = 0.6$ and 1.6) is given in Fig. 7 as a function of resonant frequency. The relatively large change in the position of the minima for overcoupled resonators is clearly visible. The points on the overcoupled resonator curve that are most easily identified experimentally occur where the minima shift is $\pm \pi/2$ (this is half the maximum shift). As the phase shift on reflection from the resonator is given by

$$\phi = \text{Arctan} \left[\frac{\text{Im}[s_{11}]}{\text{Re}[s_{11}]} \right] \quad (35)$$

it is clear that a phase shift of $\pm \pi/2$ occurs when the real part of s_{11} [Eq. (12)] is equal to zero. Solving this to find the $\pi/2$ frequency detuning points gives

$$\Delta f_{\pi/2} = \pm \frac{1}{2} \frac{f_0}{Q_U} \sqrt{\beta_1^2 - 1} \quad (36)$$

Figure 7. Calculated position shift (in radians) of the minima in the VSWR pattern as a function of resonant frequency for two resonances with $\beta_1 = 0.6$ (upper curve) and 1.6 (lower curve). The position shift is much larger for the overcoupled resonator, which is in accordance with our prediction from the Smith chart plot in Fig. 6.

Thus a measurement of the particular frequency detuning that gives a $\pi/2$ shift combined with a measurement of the on-resonance VSWR will yield the unloaded Q of the resonator.

Figure 7 also suggests a simple method to determine whether a resonator is under- or overcoupled. For undercoupled resonators the position of the minima is the same when the input signal is on resonance as well as when it is tuned far from resonance. This is not the case for overcoupled resonators. Thus, if the slotted-line probe is adjusted onto a voltage minimum at resonance, and then the resonant frequency is shifted so that it is far from resonance, only in the case of an undercoupled resonator will the probe still be at a voltage minimum.

4.1.2. Time-Domain Techniques

4.1.2.1. Decrement Method. The decrement method [17,18] is one of the older methods of measuring the Q factors of high- Q resonators. Before the advent of quartz-based microwave synthesizers, the frequency stability of the best Gunn oscillators and klystrons meant that measurements of Q factors higher than 10^4 – 10^5 would be inaccurate. To overcome this difficulty, a new method was developed that would excite the resonance with an impulse of energy and then directly monitor the dissipation of energy with time.

The technique requires a microwave oscillator whose output power can be switched on or off by an external signal driven by a pulse generator with a repetition rate much slower than the resonator ringdown time [see Eq. (4)]. This pulsed generator also triggers an oscilloscope that is monitoring the energy leaking from resonator from either the input or output port using a crystal detector. The power leaking from the resonator is proportional to the stored energy in the resonator. If the crystal detector has an accurate square law response (i.e., if its output voltage is proportional to the incident power), then the oscilloscope screen display is an accurate representation of Eq. (3) and the Q can be directly determined by measuring the time taken for the signal to drop by a factor of e . This time interval can then be substituted into Eq. (4) and the loaded Q determined.

Care must be taken to ensure that the microwave source frequency is resonant with the resonance under study and that the source output power is constant. To avoid this difficulty a method making use of a continuously swept source has been suggested [34]. In this case, the source is swept across the resonance, and when it becomes resonant, the increase in transmitted power is used to automatically trigger the oscilloscope and switch off the source.

Decrement techniques can be used to measure loaded Q factors near 10 GHz in the range upward from 10^3 (ring-down times longer than a fraction of a microsecond). However, inaccuracies enter the decrement techniques if the bandwidth of the power detector and/or the oscilloscope is inadequate to correctly capture the transient response of the resonator, and thus the technique is more often used for Q factors higher than 10^5 . The measured Q factor will also be in error if the response of the crystal detector is not accurately proportional to power.

Unfortunately, time-domain methods provide no information on the coupling and thus can only generate the loaded Q of a resonance. This difficulty may be overcome if it is possible to vary the coupling to the resonator. In this case the coupling can be made progressively smaller until the measured Q does not change with any further reduction in coupling. At this point the loaded Q will be equal to the unloaded Q to within the experimental resolution. The accuracy of the decrement techniques is directly proportional to the fractional error in the estimation of the ring-down time.

4.1.2.2. Fast-Sweep Decrement Method. The fast sweep decrement method [35] is a modification of the above-described method with three advantages: (1) the researcher can make use of more widely available continuous-wave (CW) sweep microwave generators rather than the pulsed generator required above, (2) the required frequency stability of the microwave source is much less stringent, and (3) no sophisticated electronics are required.

This measurement is suitable for a reflection resonator and requires a microwave detector to monitor the signal reflected from the resonator. The source is swept over a frequency range that is much wider than the bandwidth of the resonance with a sweep time that is much longer than the ringdown time of the resonator. The frequency sweep rate, however, is set such that the source sweeps across the resonance in a time that is much shorter than the ringdown time. An instant after the sweep has passed through the resonance, the detector mounted on the reflected port receives two signals: (1) the reflected off-resonance signal, which has a frequency corresponding to the instantaneous frequency of the source and (2) the signal leaking out from the resonator at the resonant frequency. The detector mixes these two signals, giving rise to a characteristic frequency chirp arising because the frequency difference between the instantaneous source frequency and the resonant frequency is time-dependent. The chirp has an exponential envelope that follows the decreasing strength of the leaking signal. From Ref. 35 we see that the envelope of the chirp has an exponential time constant that is twice as long as that seen in the normal decrement method

$$Q_L = \pi \tau_e f_0 \tag{37}$$

where τ_e is the time required for the signal envelope to decrease to $1/e$ of its amplitude. Clearly, a measurement of τ_e can yield Q_L via Eq. (37).

A colleague of the author [36] has developed a high-speed and reasonably precise Q measurement system based around the sweep decrement technique. A crystal detector is used to monitor the reflected power from the resonator under test. Two multimeters follow the AC and DC voltage outputs of this detector. The DC voltage is proportional to the microwave power incident on the resonator, while the AC voltage is proportional to the amplitude of the transient frequency chirp. The amplitude of the chirp is, in turn, proportional to both the incident power and the Q of the resonance. The ratio of the AC and DC voltages is thus proportional to the loaded Q factor of

the resonance, while the constant of proportionality can be determined by an initial calibration using one of the other techniques for measuring Q factors. This technique can then generate a measurement of the loaded Q after every sweep cycle, which is limited only by the requirement that the sweep time be long compared to the ringdown time of the resonance. The technique has been shown to give measurements with a resolution of around 5%, and more importantly can be used to monitor the Q factor when it is changing quickly.

4.1.3. Scalar Static Frequency-Domain Techniques

4.1.3.1. Half-Power Points Technique. Earlier in this article we outlined a method to determine the loaded Q based on a transmission measurement. To state this again, if we determine the particular frequency detuning at which the transmitted power has dropped to half of the on-resonance value, then substitution of this value into Eq. (23) will allow calculation of Q_L . This technique requires the accurate determination of the resonant frequency in order to calculate the correct value of Δf . However, determination of the exact resonant frequency by a measurement of the frequency dependence of the transmitted power is an inaccurate method since the transmitted power has only a weak frequency dependence near the center of resonance. Furthermore, the fractional error induced in the Q is highly sensitive to an error in the calculation of Δf arising from a misidentification of the resonant frequency (Δf_0):

$$\frac{\Delta Q_L}{Q_L} = \frac{\Delta f_0}{f_0} Q_L \tag{38}$$

Since we can measure source frequency differences very accurately using an electronic frequency counter, a much better method of measuring Q relies on measuring the two frequencies f_1 and f_2 at which the transmission power is down by half from the on-resonance value [17,18]:

$$f_1 - f_0 = \frac{1}{2} \frac{f_0}{Q_L} \quad \text{and} \quad f_2 - f_0 = -\frac{1}{2} \frac{f_0}{Q_L} \tag{39}$$

If we calculate the difference between these two equations, we obtain

$$f_1 - f_2 = \frac{f_0}{Q_L} \tag{40}$$

where we can determine Q_L without the need for an accurate determination of f_0 (see Fig. 4). An additional measurement of the on-resonance reflection and transmission coefficients [Eq. (25)] gives us the additional coupling information required to calculate Q_U .

Nonetheless it is important to note that an accurate measurement of the Q factor using this method relies on extremely accurate attenuation measurements [Eq. (32)]. An alternative microwave bridge method has also been proposed that can find the half transmission points very accurately [37].

4.1.3.2. Calibrated Attenuator Method. One of the difficulties of the half-power points technique is the necessity

for an accurately calibrated power detector. To avoid this difficulty, we can make use of a calibrated attenuator. This method relies on finding the maximum transmission point while there is 50% attenuator placed in the signal path between the microwave source and the detector. This attenuation is then removed and the source detuned to the two frequency points at which the original output voltage is regained on the detector. Once again the loaded Q is calculated using Eq. (40).

4.1.3.3. Reflected Power Technique. An alternative way to determine both Q_L and Q_U is through the use of reflected power measurements as a function of frequency. An initial measurement is made of the reflection coefficient on resonance so as to determine the coupling using Eq. (26). We can then modify Eq. (17) so as to determine the power reflected from a single-port resonator at the loaded half-bandwidth points $\pm\Delta f_L$ to obtain

$$|s_{11}(\pm\Delta f_L)|^2 = \frac{1 + \beta_1^2}{(1 + \beta_1)^2} \tag{41}$$

Substitution of the coupling into the right-hand side of Eq. (41) decides the expected reflection coefficient at the half-bandwidth points. Finally, adjustment of the source frequency to the two detunings that yield the expected reflection coefficient will determine the loaded bandwidth. From these values, together with the coupling coefficient determined earlier, we can clearly calculate Q_L and Q_U .

4.1.3.4. Straight-Line Methods. Several methods have been suggested for measuring the Q factor from a scalar reflection or transmission coefficient where transformed frequency coordinates are used so that the resonance shape appears to be linear [18,38,39]. This method lends itself to a manual graphical solution or to a simple least-squares fit on a computer. We can rearrange Eq. (17) for a one-port resonator [we can also do the same thing for the transmission coefficients (38)] to define a new variable:

$$\delta_U(\Delta f) \equiv \left(\frac{Q_U \Delta f}{f_0} \right) = \pm \sqrt{\frac{(1 + \beta_1)^2 |s_{11}(\Delta f)|^2 - (1 - \beta_1)^2}{1 - |s_{11}(\Delta f)|^2}} \tag{42}$$

If we have calculated β_1 from a measurement of the on-resonance reflection coefficient [see Eq. (25)], then for each measurement of s_{11} we can calculate a value for the variable δ_U [all values are known on the right-hand side of Eq. (42)]. If we plot these values of δ_U as a function of frequency detuning (Δf), we will find a straight line that has a slope equal to Q_U/f_0 . From the slope we can clearly generate the unloaded Q [39].

When implemented in a computer-based system, this technique has the potential for excellent high-accuracy measurements of the order of 0.01% for Q factors of the order of 10^4 [38]. This accuracy arises because the measurement scheme makes use only of reflection data that are in close proximity to the center of resonance, as well as

because it is possible to take many more measurements than there are free parameters to be determined. By limiting the measurement to small frequency detunings, there is a reduction in the effect of interference from other resonator and transmission-line modes. To achieve the accuracy reported, the researchers used nearly 1000 data points to characterize the resonance. This technique also has another advantage in that the degree of linearity of the plot is a measure of the level of interference from other modes. This provides an immediate indication as to the quality of the measurement.

A method similar to the one mentioned above has been suggested in connection with transmission measurements at 93 GHz [40,41]. One of the potential problems with the abovementioned method is finding the exact center of resonance. Any errors in this identification introduce a large error because Δf in Eq. (42) will be in error [see Eq. (38)]. If we define a new variable, m

$$m^2 \equiv \frac{|s_{21}(0)|^2}{|s_{21}(\Delta f)|^2} \tag{43}$$

then we can rewrite Eq. (18) as follows:

$$m^2 = 1 + 4 \left(\frac{Q_L \Delta f}{f_0} \right)^2 \tag{44}$$

If we measure the left-hand side of Eq. (43) at a known frequency detuning, we can immediately calculate Q_L from Eq. (44). However, any error in the measurement of the resonant frequency will introduce large errors. We would like to perform the calculation in a way that is insensitive to the exact value of the resonant frequency. If we measure m^2 at two frequency points on either side of the resonance, we can rewrite Eq. (44) as follows:

$$\begin{aligned} \Delta f_1 = f_1 - f_0 &= \frac{f_0}{2Q_L} \sqrt{m_1^2 - 1} \quad \text{and} \\ \Delta f_2 = f_2 - f_0 &= \frac{f_0}{2Q_L} \sqrt{m_2^2 - 1} \end{aligned} \tag{45}$$

If we take the difference of these two equations, we can derive a further equation to define Q which is dependent only on a frequency difference that can be measured very accurately:

$$Q_L(f_1, f_2) = \frac{f_0}{2(f_1 - f_2)} \left(\sqrt{m_1^2 - 1} + \sqrt{m_2^2 - 1} \right) \tag{46}$$

If we make N measurements of m^2 on either side of the resonant frequency, then we have N^2 pairs of m values. From each pair we can calculate a value for Q_L using Eq. (46). The variance of the ensemble of Q_L values is a measure of the closeness with which the data follow the theoretical resonance curve. If there is any systematic variation of Q_L as a function of frequency, this suggests the effects of interfering resonances. This method is therefore a very useful indicator of the “isolation” of the resonance [42].

4.1.3.5. Single-Frequency Techniques. As mentioned above, resonators and the resonator Q factor are commonly used to measure the electrical, optical, or magnetic properties of materials [43,44]. These measurements are usually undertaken by measuring the properties of a resonator before and after making some change to that resonator such as, for example, inserting a small sample into the resonator, changing the illumination level on a sample already in the resonator, or changing the resonator temperature. In these cases, we are more interested in a measurement of the change in Q rather than absolute measurement of the Q factor. A single-frequency measurement technique determines changes in the Q factor essentially instantaneously and doesn't require measurements in the time or frequency domain.

If the change we have made to the resonator is sufficiently small such that the electromagnetic field distribution near the coupling ports is unchanged, then we can expect that the effective coupling ratios m and n in Fig. 1 will also remain unchanged. Thus, if a change causes a modification to the losses in the resonator [R_k in Eqs. (6) and (11)], then the measured Q_u and coupling will change but the ratio of these two parameters will remain constant:

$$\frac{Q_u}{\beta_1} = \frac{R_s}{n^2} \sqrt{\frac{L_k}{C_k}} = C \quad (47)$$

where C is some constant. Thus a simple continuous measurement of the reflected power on resonance will determine any changes in the coupling and hence also from Eq. (47) any changes in Q_u . In more recent times these single-measurement techniques have been used to measure the properties of high-temperature superconducting films with high speed and precision [45].

4.1.3.6. Dual-Resonator Techniques. A novel method for determining all resonator parameters from a simultaneous measurement of two resonators has been described by a number of authors [46–48]. In these techniques the power transmission and/or reflection coefficient of a resonator are (is) plotted as a function of the transmission coefficient of a tunable reference resonator. The output plots are a function of the difference in resonant frequency of the two resonators and the ratio of their Q factors. Analytic expressions for the shapes of these curves have been derived in terms of the difference frequency and Q factor ratio, and these can be adjusted to fit experimentally derived measurements [46,48]. The accuracy of this method is similar to those of the other techniques reported here ($\sim 2\%$), although it is necessary to know the Q factor of the reference resonator in advance of these measurements using one of the other methods. The major advantage of the technique is that it is unnecessary to use calibrated power detectors, although the detectors must have a matched response. The second major advantage arises because any source frequency instability is suppressed as this is common to both resonator measurements. The quality of the measurement is determined by the stability of the reference resonator.

4.1.3.7. Integration Technique. If neither a frequency-stable source nor a calibrated power measuring device is available (meaning that accurate measurements of the half-power transmission points are impossible), then it is possible to use a so-called integration method [49]. Let us integrate the transmitted power coefficient [Eq. (18)] as a function of frequency to obtain the following expression

$$\int_{-\infty}^{\infty} P_{\text{inc}} |s_{21}|^2 d\Delta f = \frac{P_0 \pi f_0}{2Q_L} \quad (48)$$

where P_{inc} is the incident microwave power and P_0 is the power transmitted at the resonant frequency. This equation can be implemented experimentally if we use a microwave sweep oscillator to sweep the frequency over many loaded bandwidths and then use an analog integrator to integrate the output of a crystal detector monitoring the transmission port of the resonator. An additional measurement of the output voltage of the detector when the generator is on-resonance determines the only other unknown parameter so that Q_L can be determined. The integration method has also been proposed as an accurate method to determine the small changes in Q associated with determining losses in materials via resonator perturbation methods [50].

4.1.3.8. Numerical Methods. One of the earliest computer-based methods of measuring the Q factor was reported by Pandrangi et al. [51]. A computer directed a voltage-controlled oscillator (VCO) to step through the resonance curve of a transmission resonator at around 1 GHz. The incident and transmitted power were monitored by detectors that were in turn monitored by the computer. The power transmission coefficient was obtained by a division of these signals and a polynomial fitted to a smoothed version of these data. By differentiation of this polynomial, the inflection points of the resonance curve were found (see Fig. 8). To determine how the inflection points are related to the Q , we need to find when

Figure 8. A plot of the frequency dependence of the power transmission coefficient (region A) as well as its first (region B) and second derivative (region C) with respect to frequency (arbitrary vertical scale). Note that the curve possesses two inflection points (points where the second derivative is equal to zero).

the second frequency derivative of Eq. (18) is equal to zero, specifically

$$\frac{\partial^2}{\partial \Delta f^2} \{|s_{21}(\Delta f_{\text{inf}})|^2\} = 0 \quad (49)$$

which has the following equation as its solution:

$$\Delta f_{\text{inf}} = \pm \frac{f_0}{2\sqrt{3}Q_L} \quad (50)$$

The experimental results were limited by frequency instability in the VCO to around 5%.

4.1.3.9. Oscillator Frequency Lock Technique. An interesting method for accurately measuring the phase as a function of frequency is presented by Linzer and Stokesberry [52]. In this case a klystron is frequency-locked to the center of a resonance by detection of the imaginary part of the reflection or transmission coefficient and then by controlling the frequency of the klystron to hold the imaginary response at zero. Adjustment of the feedback mechanism is then made so that the locking system is now partially sensitive to the real part of the reflection coefficient, and thus it will then lock at some distance from the center of resonance. The particular dependence of the oscillator frequency on this adjustment is determined by the loaded Q of the resonator, and hence a measurement of the frequency dependence of the oscillator on this adjustment allows determination of the loaded Q with a relatively high accuracy.

4.1.4. Vector Static Frequency-Domain Methods

4.1.4.1. Q Circles Method. If one measures both the phase and magnitude (or real and imaginary components) of s_{11} using either the VSWR method, a reflection bridge [53], or a network analyzer, then it is possible to plot s_{11} directly on a Smith chart. If plots of the loci of Eqs. (29) and (30) for all Δf_L and Δf_U are also placed on the chart, then the intersections of the s_{11} curve and these two solution sets give the loaded and unloaded half-bandwidths. This manual graphical solution method has been outlined in great detail by Ginzton [17].

4.1.4.2. Straight-Line Methods. If one can measure the real and imaginary components of s_{11} or s_{21} of a resonator separately, then one can plot the following ratios as a function of Δf for each of the different resonator types:

$$\frac{\text{Im}[s_{11}(\Delta f)]}{\text{Re}[s_{11}(\Delta f)]} \quad \text{[reaction (54)],}$$

$$\frac{\text{Im}[s_{21}(\Delta f)]}{\text{Re}[s_{21}(\Delta f)]} \quad \text{(transmission),}$$

$$\frac{\text{Im}[s_{11}(\Delta f)]}{\text{Re}[s_{11}(\Delta f)]} \quad \text{(reflection)}$$

All of these ratios yield a straight line with a slope of $2Q_L/f_0$. Clearly a simple measurement of the slope yields a value for Q_L .

4.1.5. Dynamic Frequency-Domain Techniques. There are two main dynamic frequency-domain techniques: the harmonic or inflection point technique and the intermodulation method. Both of these techniques rely on the fact that at two frequency points on either side of the resonant frequency there are points where the second derivative of the resonance curve is equal to zero [see Fig. 8 and Eqs. (48) and (49)]. It is important to note that the sweep rates (in Hz/s^1) for both of these techniques need to be much slower than $(f_0/Q_L)^2$ for the measurement to be accurate. In this sense the measurements are still quasistatic, although we have chosen to term them “dynamic” as the measurement is made at a frequency that differs from the sweep frequency.

4.1.5.1. Harmonic (Inflection Points) Technique. When a frequency-modulated (FM) signal is incident on a typical transmission or reflection resonance response (as shown in Fig. 4), it will result in an amplitude modulation of the transmitted or reflected signal because of the intrinsically dispersive nature of a resonance. If the frequency deviation is small, the magnitude of the resulting amplitude modulation (AM) will be proportional to the slope of the response curve at the average frequency of the incident signal. If the resonance response has a nonzero curvature, that is, if the second derivative is not zero, then the transmitted or reflected signal will also contain an AM component at the second harmonic of the modulating frequency. For example, a measurement of the second-harmonic AM amplitude when transmitted through a resonance will yield a curve that is proportional to curve C in Fig. 8 (the second frequency derivative of the resonance). Since extremely sensitive synchronous detection techniques exist (such as lockin amplifiers) this method can very accurately find the points for which there is no second-harmonic AM [17,18]. Using Eq. (50), this value can be easily converted to the loaded Q of the resonator.

4.1.5.2. Intermodulation Method. A potential problem arises in the previous method if the original FM signal is not completely free from higher-harmonic content, as is often the case. If the incident signal already contains some level of second-harmonic AM, then the measurement of the inflection points will be in error. To avoid this, it is possible to use a development of the method mentioned in Section 4.1.5.1 termed the *intermodulation method* [17,18]. If we simultaneously frequency-modulate an incident signal at two different frequencies, it is clear that we will generate AM components in the transmitted signal at the two fundamental FM frequencies. However, if there is any nonlinearity of the frequency dependence of the resonance response, then we will also generate AM components at the difference and sum frequency of the two modulating frequencies. We can set the detection system to be sensitive to one of these intermodulation components. Once again, when identification of the inflection points is completed, we can calculate Q_L using Eq. (50).

4.2. Modern Measurement Techniques

Because of advent of powerful personal computers for data analysis, combined with the wide availability of

microwave equipment with computer interfaces, many new techniques have been devised that allow the lifting of the restrictions that were previously placed on Q measurement. For example, accurate measurements can now be made in the presence of transmission-line or coupling reactance. An additional advantage of computer-aided measurement is that a large number of measurements that would be tedious to take manually, are easily made. The data averaging that occurs from using such large numbers of data samples gives improved immunity to random noise in the Q measurement. This section describes some of the latest methods and is divided into sections that highlight the major advantage of the technique.

4.2.1. Scalar High-Resolution Measurements. Kajfez [24] has developed a technique that uses a scalar network analyzer to measure the values of the reflection coefficient as a function of frequency. This technique takes into account moderate coupling losses and therefore allows the off-resonance reflection coefficient to differ from 1. When compared to vector curve-fitting methods, this technique, like all scalar techniques, suffers from the disadvantage that it is impossible to tell whether a resonator is over- or under-coupled. Nonetheless, its accuracy is comparable with vector methods ($\sim 0.2\%$).

Luiten et al. [55] have developed a new data averaging technique that eliminates the need for expensive network analyzers and relies only a measurement of the square of the magnitude of the reflection or transmission coefficient as a function of frequency. The acquired data are then fitted using a nonlinear algorithm to the expected shape of a completely general resonance [Eq. (17) or (18)]. The fitting mechanism is adaptive, which gives the program a robustness and an ability to “follow” the parameters of a resonance if these evolve during the measurement. This feature has been used to measure the temperature dependence of the thermal, electrical, and magnetic properties of TiO_2 and Al_2O_3 crystals [10]. The extreme frequency stability of the source in this case (fractional frequency stability $\sim 10^{-15}$) meant that the Q measurements had a resolution of 0.03% despite the loaded bandwidth being only 10 Hz.

4.2.2. Vector High-Resolution Measurements. Al Zoubi et al. [56] have developed a modern method that is essentially an update of the traditional VSWR-based techniques mentioned earlier in this article. This method is intended for accurate, automatic, and rapid measurements of resonators intended for integrated microwave circuit devices. It yields Q -factor measurements with 2–3% accuracy in just a few seconds of measurement time.

A simple modification to the Q -circle method has been suggested by Hearn et al. [57] to take into account losses in the coupling network. It can be shown that Eq. (30) is equivalent to the condition that the magnitude of the real and imaginary parts of the impedance of the resonator are equal. In cases where there is loss in the coupling mechanism or the transmission lines, a correction needs to be made; otherwise the estimated Q will be less than the true value. Hearn et al. have suggested a correction that reduces the errors of the traditional measurement by

around 80 times in the case of high coupling loss and small coupling. Unfortunately this correction cannot be implemented with a simple Smith chart overlay, although it is easily implemented in an automated measurement system.

Sanchez et al. [54] report an absorption resonator Q measurement system based on a computer-driven network analyzer. This system empirically removes the effects of any loss in the coupling network, or transmission lines, by rescaling the data by a factor obtained from the transmission coefficient far from resonance. A fit is performed to the Q circle from which the coupling and Q is found. The Q_U measurement error is around 1%.

Kajfez [58] has developed a method that uses a network analyzer combined with computer analysis to generate and fit Q circles [Figs. 3d and 6]. Instead of graphically finding the solutions, he uses a least-squares fitting routine to an expression that includes the effects of a frequency-independent line and coupling reactance as well as any losses in the coupling network. This technique avoids the ambiguity that exists between over- and under-coupled resonators in scalar techniques. The technique’s accuracy is estimated at around 0.1% when utilizing approximately 1000 data points. This technique is now available as a commercial software product.

In the presence of significant line inductance we find that instead of the ideal circle that should be seen in a plot of the real and imaginary components of the resonator impedance, we find a curve that is nearly circular but with a smaller diameter and that crosses over itself [59]. By finding the two frequencies corresponding to the cross over point as well as those corresponding to the maximum and minimum of the imaginary impedance component (the “critical points”), we can determine Q_U very accurately. These measurements are relatively easy using a modern network analyzer and will generate Q factors that have an accuracy of about 0.5%

4.2.3. Harmonic Power Ratiometry. A very interesting technique has been developed that is closely related to the dynamic frequency-domain techniques mentioned above and offers high speed and extreme precision as well as a very inexpensive measurement system in order to determine the loaded Q factor [60]. The basis of the technique is to lock the average frequency of a frequency-modulated (FM) microwave signal to the resonant frequency. The dispersion of the resonance generates amplitude modulation (AM) in the reflected or transmitted signals, but since the resonance is an even function about the resonant frequency, there will be power only in the even harmonics of the modulation frequency. The power ratio in two adjacent even harmonic orders is related to both the bandwidth of the resonance and the frequency deviation of the incident signal. The remarkable performance of synchronous detection methods allows a measurement precision of better than parts in 10^4 .

4.2.4. Measuring Resonance Parameters in the Presence of Other Resonances. Kajfez and Hwan [61] have developed an overlay for a network analyzer that takes into account the effects of inductance and loss in the coupling

and transmission network as well as the effects of any distant resonant modes. These effects are modeled as a frequency-dependent reactance in series with the mode of interest. The effect of this frequency-dependent series inductance is to cause the Q circle to develop distortions that make its apparent diameter smaller than it would otherwise be. If an accurate determination of the reference plane of the measurement is made, this technique can also generate the inductance of the coupling network.

Sauer et al. [62] have modeled the effects of reflections that exist in the lines between the measuring apparatus and the resonator under test. These reflections create subsidiary line resonances that distort the resonance shape and create errors in measurement of the Q factor. The model can accurately fit experimental data taken in the presence of interfering line resonances and thus yield a Q factor with an accuracy of $\sim 1\%$.

An extensive analysis and experimental procedure has been developed that allows for the accurate measurement of Q factors and coupling coefficients of two or more modes that are in extremely close proximity [19,63]. The process relies on developing an expression that fully represents the circuit shown in Fig. 1b with enough free parameters to represent all visible resonance curves in the data as well as an additional frequency-dependent term to represent any coupling reactance. The free parameters are then adjusted by a least-squares fitting procedure to the experimental data. Even in the situation where a double loop is visible on the Smith chart because two resonances are within a few bandwidths of each other, the accuracy of the Q measurement is maintained at around 2%.

4.2.5. Measuring the Q of Low- Q Resonators. Resonator measurements are generally made through transmission lines or coupling networks that have poorly understood characteristics. The interaction between these external networks causes distortions to the resonance and therefore to the apparent Q factor. This is an especially difficult problem when the Q factor of the resonator is low since the frequency dependence of the resonator impedance becomes comparable to that of the external circuit parameters. Kajfez and Wheless [64] have developed an expression for determining Q_U when it is measured through an arbitrary two-port. Using a similar approach, Drozd and Joines [15] have developed a general Q -factor measuring method based on the full s_{11} parameters as determined by a computer-driven network analyzer. The loaded Q is shown to be given by

$$Q_L = \frac{\omega_0}{2R_k} \left| \frac{dX_k}{d\omega} \right| \quad (51)$$

where X_k is the total reactance of the k th resonance and R_k is the total resistance of the k th resonance. The frequency derivative of the reactance is estimated from a number of measurements of s_{11} in the immediate neighborhood of center frequency of the resonance. Measuring near the center of resonance gives immunity from the influences of stray inductance in the transmission line and coupling mechanism. This method proves to be far more accurate than a measurement of the half-power points or of the

critical points, both of which are relatively distant from the resonant frequency. In addition, this method does not make the common assumption of Eq. (16), which can cause errors for the lowest Q values. As a result, this method yields accurate results even for Q factors of the order of 2.

4.2.6. Oscillator Phase Noise Determination. Fuchs [65] has made use of Leeson's [66] relation that in a microwave resonator-oscillator the loaded Q factor of the resonator translates the phase fluctuations of the oscillator components into frequency fluctuations for noise frequencies within the bandwidth of the resonance. By artificially introducing high levels of component phase noise, the oscillator frequency noise can easily prevail over the noise of the measurement system. A measurement of the spectrum of the oscillator phase noise will yield the loaded Q to an accuracy of around 10%.

4.2.7. Theoretical Q Estimates. Theoretical estimation of Q factors has always been extremely difficult for all except the simplest metallic cavities with a well-known surface resistance. A number of attempts have been made to model more complex hybrid dielectric resonators and estimate the Q factors on purely theoretical grounds [42,67,68]. These estimates have value in that they could allow an independent verification of the veracity of Q measurement techniques. Unfortunately, as the accuracy of these calculations is still only around 10%, their predictive power is not yet useful in selecting between the results of various measurement techniques.

Acknowledgment

The author would like to sincerely thank Tony Mann for a critical reading of the original manuscript. In addition, I would also like to thank all the personnel of the Frequency Standards and Metrology research group at the Physics School of UWA for providing an innovative and challenging workplace that has created the environment for this work. The interest of others has always been the strongest motivation for my work.

QUADRATURE PHASE SHIFT KEYING (QPSK)

SERIOJA O. TATU
RENATO G. BOSISIO
École Polytechnique
Montreal, Quebec, Canada

1. INTRODUCTION

The various modulation techniques offered different solutions in terms of cost and received signal quality. Frequency modulation and phase modulation present certain immunity to noise, whereas amplitude modulation was simple to demodulate. More recently, however, digital modulation has gained in popularity.

Quadrature phase shift keying (QPSK) is a digital frequency modulation technique used for sending data over radio or cable networks. In QPSK modulation, a cosine carrier is varied in phase while keeping amplitude and frequency constant. The term “quadrature” implies that there are four possible phase values of the carrier in time. In QPSK modulation, information is conveyed through phase variations. In each time period, the phase can change only once. Since there are four possible phases, there are two bits of information conveyed within each timeslot.

Figure 1 shows a typical QPSK constellation in the complex plane and the bit pair associated with each possible signal phase value. The bits are mapped onto corresponding QPSK symbols using the Gray code. An important property of this code is that the adjacent symbols (phase states) differ by only one bit. In transmission systems corrupted by noise and interference, the most frequent errors are introduced by decision errors between adjacent states. In such cases, the Gray code is advantageous, particularly when QPSK systems are followed by single-error-correcting decoders.

Each QPSK symbol is represented by a complex number $I + jQ$, corresponding to the real-valued I and Q channels, respectively.

Figure 1. The QPSK constellation.

2. QPSK MODULATORS

2.1. QPSK Modulating Principle

Figure 2 shows a block diagram of the QPSK modulator [1]. The datastream is converted by a serial-to-parallel converter into two separate streams. One stream, $I(t)$, is in phase signal, and the other, $Q(t)$, is in quadrature signal, and each stream has a symbol rate equal to half the incoming bit rate. Both I and Q signals are separately applied to multipliers. The second input to the I multiplier is the carrier signal, $\cos(\omega t)$, and the second input to the Q multiplier is the quadrature carrier, the signal shifted by exactly 90° . The outputs of both multipliers are BPSK signals. The I and Q multiplier outputs are then added to give the QPSK signal, $S(t)$.

For an unfiltered QPSK signal, phase transitions occur instantaneously and the signal has a constant-amplitude envelope. According to this principle, the QPSK modulated signal $S(t)$ can be expressed as follows:

$$S(t) = I(t) \cdot \cos(\omega t) + Q(t) \cdot \cos\left(\omega t + \frac{\pi}{2}\right) \quad (1)$$

Each real signal, $I(t)$ or $Q(t)$, has two possible values. These values are $A/\sqrt{2}$ and $-(A/\sqrt{2})$, respectively, considering that the radius value in Fig. 1 is equal to A .

Therefore, for a QPSK-modulated signal, four possible phase values of $S(t)$ signal can be obtained: $\pi/4$, $3\pi/4$, $5\pi/4$, and $7\pi/4$. These values are expressed in the following four equations:

$$\begin{aligned} & \frac{A}{\sqrt{2}} \cdot \cos(\omega t) + \frac{A}{\sqrt{2}} \cdot \cos\left(\omega t + \frac{\pi}{2}\right) \\ &= A \cdot \left[\cos(\omega t) \cdot \cos\left(\frac{\pi}{4}\right) - \sin(\omega t) \cdot \sin\left(\frac{\pi}{4}\right) \right] \quad (2) \\ &= A \cdot \cos\left(\omega t + \frac{\pi}{4}\right) \end{aligned}$$

Figure 2. The QPSK modulating principle.

$$\begin{aligned} & -\frac{A}{\sqrt{2}} \cdot \cos(\omega t) + \frac{A}{\sqrt{2}} \cdot \cos\left(\omega t + \frac{\pi}{2}\right) \\ &= A \cdot \left[-\cos(\omega t) \cdot \cos\left(\frac{\pi}{4}\right) - \sin(\omega t) \cdot \sin\left(\frac{\pi}{4}\right) \right] \quad (3) \end{aligned}$$

$$= A \cdot \cos\left(\omega t + \frac{3\pi}{4}\right)$$

$$\begin{aligned} & -\frac{A}{\sqrt{2}} \cdot \cos(\omega t) - \frac{A}{\sqrt{2}} \cdot \cos\left(\omega t + \frac{\pi}{2}\right) \\ &= A \cdot \left[-\cos(\omega t) \cdot \cos\left(\frac{\pi}{4}\right) + \sin(\omega t) \cdot \sin\left(\frac{\pi}{4}\right) \right] \quad (4) \end{aligned}$$

$$= A \cdot \cos\left(\omega t + \frac{5\pi}{4}\right)$$

$$\begin{aligned} & \frac{A}{\sqrt{2}} \cdot \cos(\omega t) - \frac{A}{\sqrt{2}} \cdot \cos\left(\omega t + \frac{\pi}{2}\right) \\ &= A \cdot \left[\cos(\omega t) \cdot \cos\left(\frac{\pi}{4}\right) + \sin(\omega t) \cdot \sin\left(\frac{\pi}{4}\right) \right] \quad (5) \end{aligned}$$

$$= A \cdot \cos\left(\omega t + \frac{7\pi}{4}\right)$$

Figure 3 represents a typical phase variation of a QPSK modulated signal versus time. The simulation was performed using the proprietary Advanced Design System (ADS) simulator of Agilent Technologies. Typically, during simulations, a random bit generator is employed as a bit source, and such is the case here. Four possible phases can be clearly identified, as seen in this figure. In the case of the simulation presented in Fig. 3, the bit rate was set at 2 Mbps (1 Mbps on each channel I or Q).

Figure 4 shows the spectrum of an unfiltered QPSK signal, obtained using an ADS simulation having the same bit rate of 2 Mbps. The spectrum is centered on the carrier frequency. The baseband signals, $I(t)$ and $Q(t)$, and the QPSK signal at the modulator output were not filtered. Therefore, the resulting spectrum is a wideband signal.

Phase changes for filtered QPSK signals result in a varying envelope amplitude. The effects of the envelope fluctuation on the transmitter RF spectrum and the bit error rate (BER) performances are presented by Feher [1].

At the modulator the QPSK signal output is usually filtered to limit the radiated spectrum, then amplified, and finally transmitted to the receiver over the transmission channel.

The offset-keyed quadrature-phase shift-keyed (OQPSK) modulation is quite similar to the conventional or coincident QPSK modulation [1]. The difference lies in the data transitions between the I and Q streams as they enter in the multipliers. One of the serial-to-parallel converter output streams is then *offset* from the other by delaying with a half of the incoming bit duration. The I and Q datastreams can never be in transition simultaneously. The result is that only the 90° phase transition occurs in the modulator output signals. Similarly to the QPSK, the unfiltered OQPSK signal has a constant-amplitude envelope. However, for filtered OQPSK signals, the transmitted signal has an amplitude envelope variation of 3 dB

Figure 3. The phase of a QPSK-modulated signal using a random bit sequence.

(30%), as compared to the 100% amplitude envelope variation for conventional QPSK systems [1].

The design of coherent QPSK and OQPSK demodulators is a difficult task, particularly if very fast modem synchronization is required. To avoid the need of a complex carrier recovery circuit and to improve the synchronization speed of the demodulator, differential QPSK (DQPSK) demodulation may be employed instead of coherent demodulation [1].

2.2. Six-Port QPSK Modulator

In practice, especially at millimeter-wave frequencies, the mixers are costly components and difficult to fabricate. To avoid this problem, a different type of QPSK modulator, the six-port modulator, can be designed using power dividers and couplers [2].

The basic components of this QPSK modulator are the Wilkinson power divider and the 90° hybrid coupler. Figure 5 shows the Wilkinson power divider and the 90° hybrid coupler symbols.

The related *S* parameters of the Wilkinson power divider and of the 90° hybrid coupler, respectively, are as follows:

$$S = -\frac{1}{\sqrt{2}} \begin{bmatrix} 0 & j & j \\ j & 0 & 0 \\ j & 0 & 0 \end{bmatrix} \quad (6)$$

$$S = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & j & 1 & 0 \\ j & 0 & 0 & 1 \\ 1 & 0 & 0 & j \\ 0 & 1 & j & 0 \end{bmatrix} \quad (7)$$

Figure 4. Simulated spectrum of an unfiltered QPSK signal.

In order to understand the six-port QPSK modulator principle, a basic circuit—the controlled phase shifter must be first presented. This circuit consists of a 90° hybrid coupler and two monoports having the reflection coefficient equal to Γ . Figure 6 shows the phase shifter block diagram.

The scattering parameters are used to express the circuit equations. For each monoport, the input and output reflected signals, *a* and *b*, are related by the equation $a_i = \Gamma \cdot b_i$, where $i = 2, 3$. Therefore, we obtain

$$\begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{bmatrix} = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & j & 1 & 0 \\ j & 0 & 0 & 1 \\ 1 & 0 & 0 & j \\ 0 & 1 & j & 0 \end{bmatrix} \cdot \begin{bmatrix} a_1 \\ \Gamma b_2 \\ \Gamma b_3 \\ a_4 \end{bmatrix} \quad (8)$$

and

$$b_1 = \frac{1}{\sqrt{2}} (j\Gamma b_2 + \Gamma b_3) \quad (9)$$

$$b_2 = \frac{1}{\sqrt{2}} (ja_1 + a_4) \quad (10)$$

$$b_3 = \frac{1}{\sqrt{2}} (a_1 + ja_4) \quad (11)$$

$$b_4 = \frac{1}{\sqrt{2}} (\Gamma b_2 + j\Gamma b_3) \quad (12)$$

The relationship between the output and the input signal can be obtained using the previous equations. The phase of the output signal *b*₄ depends of the phase of the reflection coefficient Γ :

$$b_4 = j\Gamma a_1 \quad (13)$$

Supposing that $\Gamma = \exp(j\phi)$, the output signal will be equal to

$$b_4 = ja_1 \exp(j\phi) \quad (14)$$

If a 50-Ω load is connected at the output port of this circuit, the reflected signal to the input port ($b_1 = j\Gamma a_4$) will be equal to zero because $a_4 = 0$. Therefore, the circuit will

Figure 5. Wilkinson power divider (a) and the 90° hybrid coupler (b) symbols.

Figure 6. Phase shifter block diagram.

be a phase shifter having an excellent return loss to the input port.

Figure 7 shows the six-port modulator diagram according to relations (6) and (7). A 90° hybrid coupler, two controlled phase shifters, and a Wilkinson power combiner, compose the six-port QPSK modulator. This modulator circuit has six ports: an RF input port connected to the carrier generator, an RF output port that generates the modulated signal, and four control ports connected to monoports.

The signal values are specified on the diagram in Fig. 7. The output signal is a function of the input signal a , and of the monoports reflection coefficients Γ_1 and Γ_2 :

$$S(t) = \frac{a}{2} [j\Gamma_1(t) + \Gamma_2(t)] \quad (15)$$

During the modulation process, each reflection coefficient, $\Gamma_1(t)$ or $\Gamma_2(t)$, has two possible values. In this study, these values are -1 (equivalent to a short circuit) and $+1$ (equivalent to an open circuit). Table 1 shows the four states of the output QPSK modulated signal and related Γ values. In this table, four possible phase values of the RF signal can be clearly identified.

3. QPSK DEMODULATORS

3.1. QPSK Demodulating Principle

Figure 8 shows a block diagram of the QPSK demodulator. The demodulated signals $I(t)$ and $Q(t)$ are obtained using a

Figure 7. Block diagram of the six-port QPSK modulator.

Table 1. The Four States of Output QPSK-Modulated Signal and Related Γ Values

Γ_1	Γ_2	QPSK Signal
1	1	$\frac{a}{2}(1+j) = \frac{a}{\sqrt{2}} \exp(j\frac{\pi}{4})$
1	-1	$\frac{a}{2}(-1+j) = \frac{a}{\sqrt{2}} \exp(j\frac{3\pi}{4})$
-1	-1	$\frac{a}{2}(-1-j) = \frac{a}{\sqrt{2}} \exp(j\frac{5\pi}{4})$
-1	1	$\frac{a}{2}(1-j) = \frac{a}{\sqrt{2}} \exp(j\frac{7\pi}{4})$

reference signal, a 90° phase shifter, mixers, and lowpass filters.

The QPSK-modulated signal can be expressed as

$$S(t) = \text{Re}\{A \exp[j(\omega t + \varphi_i)]\} = A \cos(\omega t + \varphi_i) \quad (16)$$

where the phase variation during the time φ_i has four possible states, according to the QPSK constellation of Fig. 1:

$$\varphi_i = (2i - 1)\frac{\pi}{4}, \quad i = 1, 2, 3, 4 \quad (17)$$

The demodulation of QPSK signals requires coherent detection. Because the I and Q signals are in quadrature (orthogonal), the receiver is able to demodulate them independently of each other, operating effectively as two independent BPSK receivers.

The signal value to the I multiplier output can be expressed as

$$\begin{aligned} & A \cos(\omega t + \varphi_i) \cdot A \cos(\omega t) \\ &= \frac{A^2}{2} \cos(2\omega t + \varphi_i) + \frac{A^2}{2} \cos \varphi_i \end{aligned} \quad (18)$$

The signal value to the Q multiplier output is given by the equation

$$\begin{aligned} & A \cos(\omega t + \varphi_i) \cdot A \cos\left(\omega t + \frac{\pi}{2}\right) \\ &= -A^2 \cos(\omega t + \varphi_i) \cdot \sin(\omega t) \\ &= -\frac{A^2}{2} \cdot \sin(2\omega t + \varphi_i) + \frac{A^2}{2} \sin \varphi_i \end{aligned} \quad (19)$$

Figure 8. Block diagram of the QPSK demodulator.

Table 2. Specific Binary Outputs for Four Possible Input Symbols

φ_i	I	Q	Binary Output
$\frac{\pi}{4}$	C	C	11
$\frac{3\pi}{4}$	-C	C	01
$\frac{5\pi}{4}$	-C	-C	00
$\frac{7\pi}{4}$	C	-C	10

Finally, at the output of the lowpass filters we obtain the I/Q-demodulated signals:

$$I(T) = \int_0^T \left[\frac{A^2}{2} \cos(2\omega t + \varphi_i) + \frac{A^2}{2} \cos \varphi_i \right] dt \tag{20}$$

$$= \frac{A^2 T}{2} \cos \varphi_i$$

$$Q(T) = \int_0^T \left[-\frac{A^2}{2} \sin(2\omega t + \varphi_i) + \frac{A^2}{2} \sin \varphi_i \right] dt \tag{21}$$

$$= \frac{A^2 T}{2} \sin \varphi_i$$

where T is the symbol period and φ_i is the phase of the i th QPSK signal. The regenerated I and Q streams are then recombined in a parallel-to-serial converter to recover the original input datastream.

Table 2 lists the specific binary outputs in the case of the four possible input symbols, where the constant C is defined as $A^2 T / 2\sqrt{2}$. Comparison with the diagram presented in Fig. 1 shows that the correct binary data are recovered by the QPSK demodulator.

The OQPSK demodulator is identical to that used for coincident QPSK, except that the regenerated I datastream is delayed with half the incoming bit duration (if the Q datastream is delayed in the modulation process), so that when combined with the regenerated Q stream, the original input data stream is recreated. Details of encoding and decoding subsystems QPSK, OQPSK, and DQPSK are presented in Ref. 1.

A typically standard demodulator, the MAX 2701 circuit from the Maxim Company, is shown in Fig. 9. The circuit diagram follows the demodulator principle. This circuit uses differential amplifiers, mixers, and external bandpass and lowpass filters. This circuit operates excellently up to 2.45 GHz [3].

In practice, especially at millimeter-wave frequencies, the mixers are costly components, and are difficult to fabricate. To avoid this problem, a different type of QPSK demodulator, the six-port demodulator, will be presented in the next section.

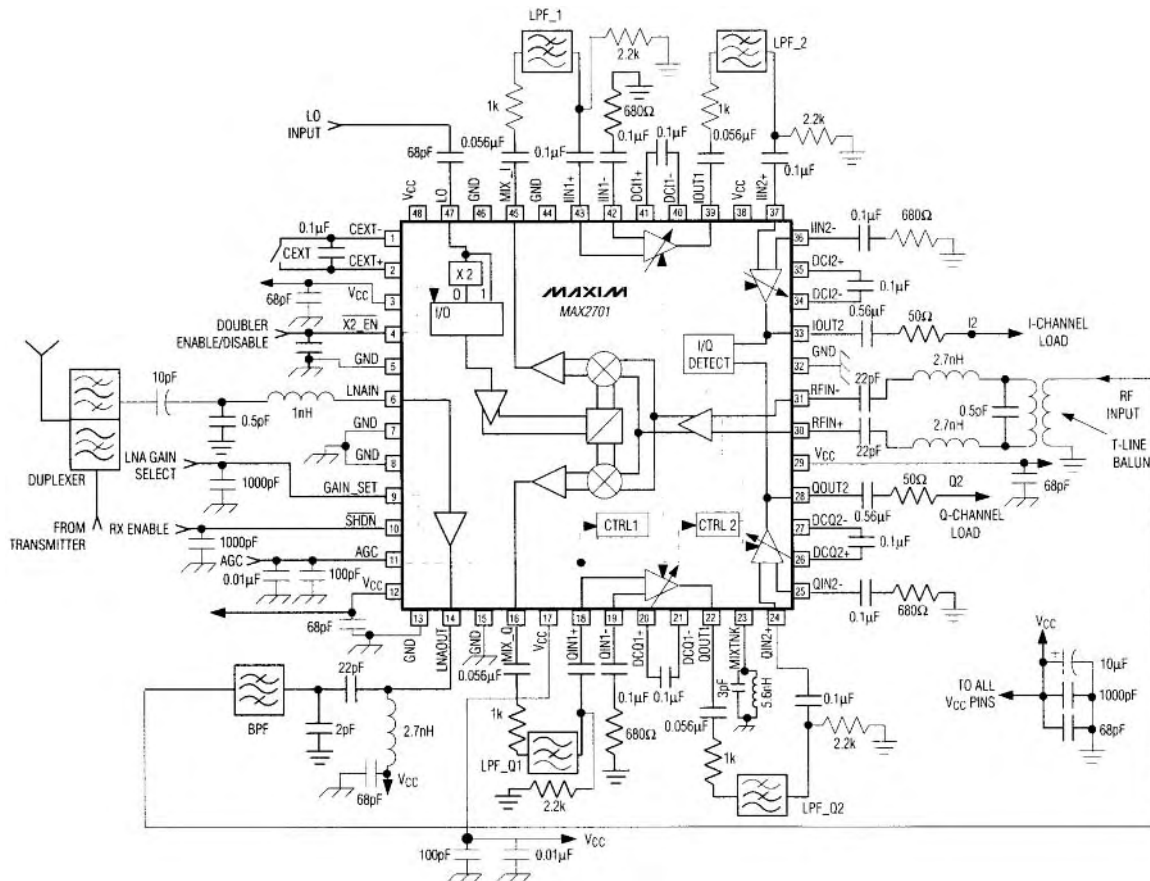

Figure 9. Diagram of a typically standard QPSK demodulator.

3.2. Six-Port QPSK Demodulator

3.2.1. Basic Theory. The six-port junction is a passive and linear microwave circuit composed of several couplers. The four six-port output signals are a function of two RF input signals. Complex impedance or phase measurements can be obtained by simple power or voltage magnitude measurements at the four output ports [4].

The six-port junction was first utilized as a low-cost alternative to a network analyzer. A number of six-ports were designed to perform measurements of reflection coefficients [5–7].

The six-port can also be designed to perform phase measurements between two input RF signals. If one of these signals is a reference signal, and the second one is an unknown RF signal, their phase difference can be measured. Therefore, a phase shift key (PSK) demodulator can be developed using direct-conversion architecture. Excellent demodulation results were obtained in direct-conversion receivers (DCRs) for QPSK modulation [8–12].

Figure 10 shows the complete diagram of the six-port phase discriminator, composed of a Wilkinson power divider and three 90° hybrid couplers. This junction is specially designed to perform phase measurements. The phase shift between the RF input signal and the RF reference signal can be obtained using power measurements to the six-port outputs.

The S matrix of the proposed six-port phase discriminator can be easily obtained using this figure and the S parameters of the Wilkinson power divider and the 90° hybrid coupler as presented in Eqs. (6) and (7). The S matrix of the six-port phase discriminator is

$$[S] = \frac{1}{2} \begin{bmatrix} 0 & 0 & 0 & 0 & -j & +j \\ 0 & 0 & 0 & 0 & +1 & +j \\ 0 & 0 & 0 & 0 & +1 & +1 \\ 0 & 0 & 0 & 0 & -j & -1 \\ -j & +1 & +1 & -j & 0 & 0 \\ +j & +j & +1 & -1 & 0 & 0 \end{bmatrix} \quad (22)$$

Figure 10. Block diagram of the six-port phase discriminator.

If the two input signals have the same amplitude a , the general equation of the six-port output signals is

$$b_i = a \cdot [S_{5i} \exp(j\theta_5) + S_{6i} \exp(j\theta_6)], \quad i = 1, 2, 3, 4 \quad (23)$$

$$b_i = \frac{a}{2} \exp(j\theta_5) \cdot \left\{ 1 - \exp \left[j \left(\theta_6 - \theta_5 - (i-1) \frac{\pi}{2} \right) \right] \right\}, \quad (24)$$

$$i = 1, 2, 3, 4$$

Each output power is proportional with $|b_i|^2$ and has a minimum value corresponding to a certain phase difference $\Delta\theta = \theta_6 - \theta_5$, according to Eq. (24).

Therefore, the six-port junction can be used directly to demodulate a QPSK signal, where each minimum corresponds to a different state of the input signal. The two RF signals have the same frequency, but a different phase: the reference phase θ_5 , for the local-oscillator (LO) signal and an unknown phase θ_6 , for the input PSK modulated signal.

If the phase of the reference signal is set at $\theta_5 = \pi/4$, the q_i points of the six-port junction are

$$q_i = \exp \left\{ j \left[\frac{\pi}{4} + (i-1) \frac{\pi}{2} \right] \right\}, \quad i = 1, 2, 3, 4 \quad (25)$$

where the q_i points represent the complex solution of the equations $b_i = 0$.

Four power detectors are connected to the six-port circuit outputs. The DC output voltage of an ideal power detector is proportional to the second power of the magnitude of the RF input signal:

$$V_i = K_i |b_i|^2, \quad i = 1, 2, 3, 4 \quad (26)$$

Assuming that four identical detectors $K_i = K$ are used, the theoretical DC output voltages are

$$V_i = K |a|^2 \left| \sin \left(\frac{\Delta\theta}{2} - (i-1) \frac{\pi}{4} \right) \right|^2, \quad i = 1, 2, 3, 4 \quad (27)$$

Each DC output voltage is periodical with 360° and shifted in phase with 90° multiples compared to the other DC output signals. The normalized output voltages can be obtained using Eq. (27):

$$v_i = \left| \sin \left(\frac{\Delta\theta}{2} - (i-1) \frac{\pi}{4} \right) \right|^2, \quad i = 1, 2, 3, 4 \quad (28)$$

Figure 11 shows the normalized output voltages as a function of phase difference between the two RF input

Figure 11. Normalized six-port DC output voltages versus the phase difference between the RF input signals.

signals. Each output voltage has a single maximum (or minimum) value corresponding to a 0° to 360° phase difference between the RF input signals.

In the I/Q complex plane a Γ vector can be defined using the four six-port DC output voltages:

$$\Gamma = [(V_3 - V_1) + j(V_4 - V_2)] \exp\left(j\frac{\pi}{4}\right) \quad (29)$$

The normalized Γ_n vector is obtained using the normalized six-port DC output voltages:

$$\Gamma_n = [(v_3 - v_1) + j(v_4 - v_2)] \exp\left(j\frac{\pi}{4}\right) \quad (30)$$

In the I/Q complex plane the Γ_n vector turns in a circle having the radius equal to one and the center in the origin. This Γ_n vector, always having the magnitude equal to one and the phase equal with the RF input signal phase θ_6 , represents the analog demodulated signal in the I/Q plane.

A QPSK modulated signal has four possible phase states: $\pi/4$, $3\pi/4$, $5\pi/4$ and $7\pi/4$, as presented in Fig. 1. The analog direct demodulated signal can be calculated using the six-port DC output voltage equations (28) and the Γ_n vector (30). The theoretical demodulation results are presented in Table 3.

This new approach allows for high-speed QPSK demodulation because the direct demodulated signal is obtained using only a linear combination of six-port DC output voltages. However, a reference signal must be obtained using a carrier recovery technique.

3.2.2. Examples of Six-Port Demodulators. Three six-port circuits operating in the Ka frequency band will be presented in this section: a hybrid circuit (MHMIC) and two MMIC (monolithic microwave integrated circuit) circuits.

As is known, the six-port junction is composed of three 90° hybrid couplers and a Wilkinson power divider. Four RF power detectors, connected to the six-port outputs, are also integrated on the same circuit.

Figure 12 shows a photograph of the distributed parameters MHMIC Ka-band six-port circuit, fabricated on a 250- μm ceramic substrate having a relative permittivity of 9.9. The RF power detectors are realized using Schottky diodes. The MHMIC six-port circuit size is 23 \times 23 mm [11].

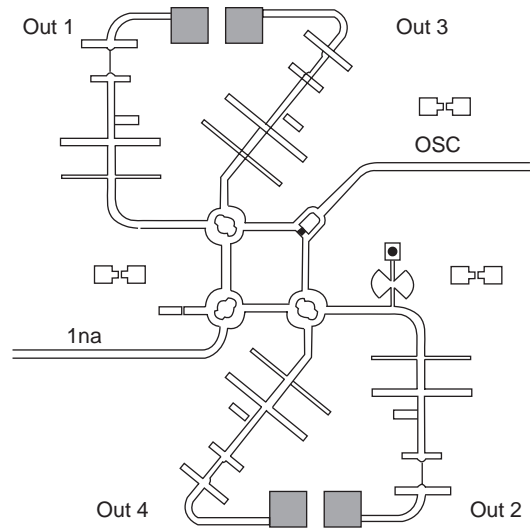

Figure 12. The MHMIC circuit (size 23 \times 23 mm).

Figure 13 shows a photograph of the distributed parameters MMIC six-port circuit fabricated on a 100- μm GaAs substrate, having a relative permittivity of 12.9. The RF power detectors are implemented using integrated Schottky diodes. Transitions to a coplanar line were used to the RF inputs. The size of the distributed parameters MMIC six-port circuit is 4 \times 4 mm [12].

A photograph of the second MMIC six-port circuit, fabricated on the same type of GaAs substrate, is presented in Fig. 14. Shunt capacitors connected to the ports were used in order to reduce the size of the 90° hybrid coupler. Therefore, the diameter of the 90° hybrid coupler becomes 600 μm , compared to 1300 μm in the first MMIC version. The matching networks are made using transmission lines and shunt capacitors. The size of the distributed and discrete parameters MMIC six-port circuit is 2 \times 3-mm [12].

Analog signal processing (ASP) was used to demodulate a QPSK signal according to Eqs (27)–(30). Comparative demodulation results for these six-port junctions, in the operating frequency band, are presented.

The six-port output signals are a function of six-port S parameters and input RF signals according to Eq. (23). Therefore, the QPSK-demodulated signal, represented by the Γ vector in the I/Q complex plane, is a function of the six-port S parameters in the operating frequency band, the input RF power to DC voltage conversion

Table 3. Theoretical Demodulation Results for QPSK Modulation Using a Six-Port Demodulator

Bits Tx	θ_6	v_1	v_2	v_3	v_4	$\Gamma_n(\text{Rx})$	Bits Rx
11	$\frac{\pi}{4}$	0	0.5	1	0.5	$\exp\left(j\frac{\pi}{4}\right)$	11
01	$\frac{3\pi}{4}$	0.5	0	0.5	1	$\exp\left(j\frac{3\pi}{4}\right)$	01
00	$\frac{5\pi}{4}$	1	0.5	0	0.5	$\exp\left(j\frac{5\pi}{4}\right)$	00
10	$\frac{7\pi}{4}$	0.5	1	0.5	0	$\exp\left(j\frac{7\pi}{4}\right)$	10

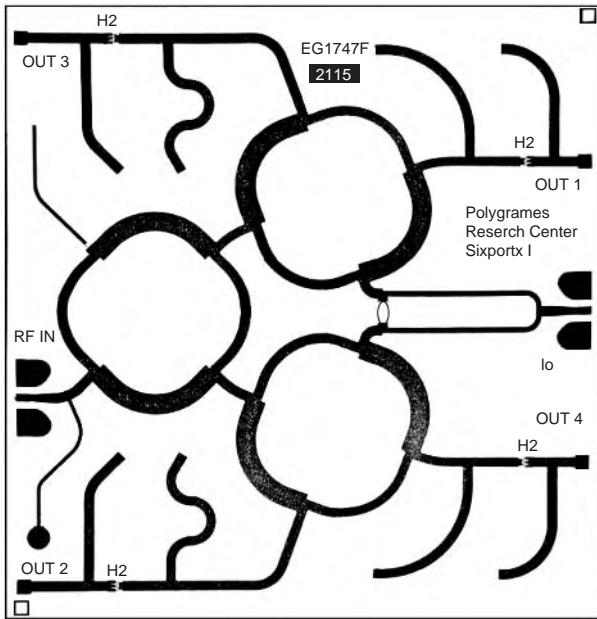

Figure 13. The first MMIC six-port (size 4 × 4 mm).

characteristic of the Schottky detector, and the input RF signal power.

Figure 15 shows the six-port DC output voltages versus the phase difference between the RF input signals for the MHMIC circuit. The LO power level and the RF input power level are -20 dBm.

The geometric representation of the Γ vector in the I/Q plane was obtained through Advanced Design System (ADS) simulations using a sweep of the phase difference between the RF input signals. The phase step was set at 5°.

Figure 16 shows the demodulation results for various input power levels, at the central frequency of 27 GHz (MHMIC circuit). The markers indicate the demodulation result corresponding to a QPSK modulation, having a phase error of the demodulated signal of less than 2°. Even if the RF levels are not equal, the Γ vector still turns on a circle. The reduced radii correspond to the decrease of the RF input power level. The DC offset is close to zero, as seen in this figure, because a differential approach was

Figure 15. Six-port DC output voltages versus the phase difference between the RF input signals for the MHMIC circuit.

used in the Γ equation and all the detectors are almost identical.

Figure 17 shows the Γ vector using a sweep of the phase difference between the RF input signals, in the frequency band. The four states corresponding to the QPSK modulation can be clearly identified. This shows that the MHMIC circuit is an excellent direct demodulator and can be used for other PSK modulations, because the Γ vector turns practically on a circle, as presented in the theoretical part. Two MMIC circuits, fabricated at the *TriQuint Semiconductor Foundry* using 0.25 μm GaAs PHEMT technology, were also investigated using the same method.

The conversion result of the DC output voltage versus the RF input power in the case of the distributed parameters MMIC detector is nonlinear. Therefore, the shape of the six-port DC output voltages versus the phase difference between the RF input signals corresponding to the first MMIC circuit, presented in Fig. 18, are different compared to the theoretical result of Fig. 11. However, each output voltage has a single maximum value corresponding to a 360° phase difference sweep, which allows the direct demodulation of a BPSK or a QPSK signal. The geometric representation of Γ vector in the I/Q complex plane was obtained using ADS simulations. The phase step was set at 5°.

Figure 19 shows the simulated demodulation results corresponding to various input power levels at the central

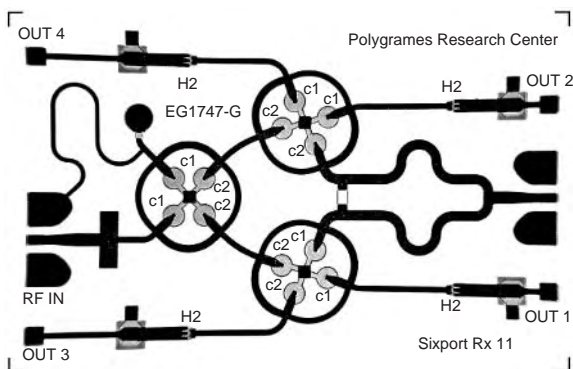

Figure 14. The second MMIC six-port (size 2 × 3 mm).

Figure 16. Demodulation results for various input power levels at the central frequency of 27 GHz (MHMIC circuit).

Figure 17. Demodulation results in the frequency band (MHMIC circuit).

frequency of 27 GHz. The dynamic range is reduced, compared to the MHMIC circuit, because the MMIC detector is not very sensitive for small RF input power levels. The markers indicate the demodulation result corresponding to a QPSK modulation, having a phase error of less than 2°. Even if the RF levels are not equal the Γ vector turns around the origin, and the DC offset is close to zero. The Γ shape is no longer a circle because of the nonlinearity of the RF power to DC voltage detector conversion. However, BPSK or QPSK signals can be demodulated with no need of the six-port calibration.

Figure 20 shows Γ vector as a function of the sweep of the phase difference between the RF input signals in the frequency band of 1 GHz. The four states corresponding to the QPSK modulation can be clearly identified in this figure.

The conversion result of the DC output voltage versus the RF input power corresponding to the second MMIC detector is not linear. Therefore, the shape of the six-port DC output voltages versus the phase difference between the RF input signals for the second MMIC circuit, presented in Fig. 21, are also different from the theoretical result of Fig. 11.

In the case of this MMIC implementation, the detector sensibility increases by using a higher load value, but the

Figure 18. Six-port DC output voltages versus the phase difference between the RF input signals for the first MMIC circuit.

Figure 19. Demodulation results for various input power levels at the central frequency of 27 GHz (the first MMIC circuit).

linearity of the conversion result deteriorates. For this reason, a 1000 Ω load value was used for a greater sensitivity of the Schottky detector, instead of a 50 Ω load value, as used for the first MMIC circuit.

Figure 21 shows that each six-port DC output voltage has a single maximum value corresponding to a 360° phase difference sweep, which allows the direct demodulation of a BPSK or QPSK signal.

Figure 22 shows the simulated demodulation results corresponding to various input power levels, at the central frequency of 27 GHz. The markers indicate the demodulation result corresponding to a QPSK modulation, having a phase error of less than 1°. Even if the RF levels are not equal, the Γ vector turns around the origin. Therefore, the DC offset is close to zero. The Γ shape is no longer a circle because of the nonlinearity of the RF power to DC voltage

Figure 20. Demodulation results in the frequency band (the first MMIC circuit).

Figure 21. Six-port DC output voltages versus the phase difference between the RF input signals for the second MMIC circuit.

detector conversion. However, BPSK or QPSK signals can be demodulated with no need of the six-port calibration.

Figure 23 shows the Γ vector in function of the sweep of the phase difference between the RF input signals in the frequency band of 0.75 GHz. The four states corresponding to the QPSK modulation can be clearly identified in this figure.

In order to perform bit error rate (BER) measurements, baseband circuits were designed. To build up the baseband circuits, operational amplifiers, high-speed comparators and NAND logic circuits are used [11,12]. These circuits make up an analog to digital converter and generate output bits [a TTL (transistor–transistor logic) signal] using the analog vector Γ represented in the I/Q complex plane, as seen in Figs. 16,17,19,20,22, and 23.

In conclusion, analog signal processing (ASP) and a six-port circuit were used to directly demodulate a QPSK signal. This new approach allows a high-speed PSK demodulation because the direct demodulated signal (the Γ vector) is obtained using only a linear combination of the six-port DC output voltages. The DC offset is close to zero, due to the differential approach used in Γ equation.

The six-port calibration and the use of a digital signal processing (DSP) are not needed in the case of this application. Therefore, the bit rate is limited only by the speed of the baseband circuit, composed of operational amplifiers and comparators, and not by the speed of the DSP module.

Figure 23. Demodulation results in the frequency band (the second MMIC circuit).

In the case of a general PSK modulation, RF power detectors having almost a linear conversion characteristic must be used. In particular, for BPSK or QPSK modulations, this condition can be avoided, due to the particular six-port architecture, as concluded in the case of the MMIC circuits.

The main advantages of the six-port direct-conversion receiver, compared to a standard one, are the low cost and high bit rate. This new QPSK demodulator avoids the use of mixers using a passive circuit, the six-port phase discriminator.

4. CARRIER RECOVERY

The design of the coherent carrier recovery circuit for the demodulation of QPSK signals is critical and involves several performance considerations and tradeoffs. Therefore, various carrier regeneration schemes have been developed and implemented.

Design of the coherent carrier recovery circuit has to be done considering various critical requirements. The effects of the input data rate and the signal to noise ratio variations on the overall performance of the system have to be considered, and system elements having broadband characteristics must be designed.

The following schemes are considered to implement the coherent carrier recovery in a QPSK demodulator: the Costas loop [13], the multiplication loop [14], and the reverse-modulation loop [15].

4.1. The Costas Loop

A block diagram of this carrier recovery method is presented in Fig. 24.

The input-modulated signal is split into two paths, which are mixed with the voltage-controlled oscillator (VCO) signal in the QPSK detector to produce the demodulated I and Q signals.

Figure 22. Demodulation results for various input power levels at the central frequency of 27 GHz (the second MMIC circuit).

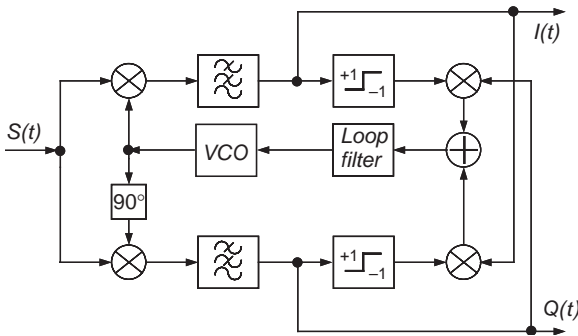

Figure 24. Block diagram of QPSK demodulator with the Costas loop.

The samples of the same I and Q datastreams are also amplified and filtered into the Costas arm filters. The arm filter outputs feed the Costas phase detectors, which generate an estimated phase error signal through a polarity loop. The corresponding output phase error signal feeds a loop filter or a phase-locked loop (PLL) circuit, which drives the VCO. The VCO replaces the local oscillator (LO) of the coherent detector.

4.2. The Multiplication Loop

A multiplication loop block diagram for QPSK carrier recovery is given in Fig. 25.

The input QPSK modulated signal is

$$S(t) = \text{Re}\{A \exp[j(\omega t + \varphi_i)]\} = A \cos(\omega t + \varphi_i) \tag{31}$$

where

$$\varphi_i = (2i - 1) \frac{\pi}{4}, \quad i = 1, 2, 3, 4 \tag{32}$$

during the time, for a QPSK modulated signal.

Considering the output of Fourth-order nonlinearity and assuming ideal quadrupling, by a trigonometric identity, we obtain

$$S^4(t) = [A \cos(\omega t + \varphi_i)]^4 = 3 \frac{A^4}{8} + \frac{A^4}{2} \cos[2(\omega t + \varphi_i)] + \frac{A^4}{8} \cos[4(\omega t + \varphi_i)] \tag{33}$$

Figure 25. Block diagram of QPSK demodulator with the multiplication loop.

The filtered output contains the desired harmonic:

$$\begin{aligned} \cos[4(\omega t + \varphi_i)] &= \cos[4\omega t + (2i - 1)\pi] \\ &= \cos(4\omega t - \pi) = -\cos(4\omega t) \end{aligned} \tag{34}$$

Frequency division by 4 yields the desired coherent carrier component:

$$R(t) = \cos(\omega t) \tag{35}$$

4.3. The Reverse Modulation Loop

A remodulation technique for QPSK carrier recovery is shown in Fig. 26.

The input-modulated signal is split into two paths. The first path feeds the QPSK demodulator. The second one is delayed with a percentage of the bit period (τ); this signal represents the local oscillator signal of the QPSK modulator. The I and Q streams are also amplified and filtered. The filter outputs feed the phase detectors. The reverse-modulated signal feeds the loop filter circuit, which replaces the VCO (voltage-controlled oscillator) of the coherent demodulator.

For a high signal-to-noise ratio (SNR), the phase detector error characteristic has four stable lock points situated at 90° multiples. Therefore, the QPSK remodulator should exhibit a faster acquisition time compared to a conventional Costas loop [15].

A reverse-modulation loop (RML) using the six-port demodulator was proposed for Ka-band direct-conversion receivers [16].

The RML provides a rapid carrier recovery using the input QPSK-modulated signal. The proposed RML generates the reference signal using a QPSK modulator, controlled by output-demodulated signals, and avoids the need of a PLL circuit with VCO. For a 4-Mbps QPSK signal, the time delay is set at $0.1 \mu\text{s}$, which corresponds to 20% of a bit length.

Figure 27 shows the simulated QPSK signal spectrum and the carrier recovery signal spectrum corresponding to the same bit rate. It is seen that the signal level of the recovered signal is at least 30 dB above other spectral lines. The power level of the carrier-recovered signal is related to the power level of the input QPSK signal.

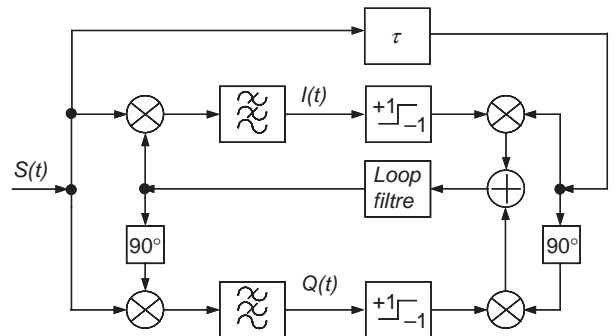

Figure 26. Block diagram of QPSK demodulator with the reverse modulation loop.

Figure 27. The QPSK and carrier recovery signal spectrum using a reverse modulation loop.

Therefore, the dynamic range of the QPSK six-port receiver increases [12].

Figure 28 shows demodulation results using a QPSK six-port demodulator with a carrier recovery circuit based on this reverse modulation loop. The phases of the input QPSK signal and carrier recovery signal, the pseudorandom bit sequence at the transmitter (labeled “In I” and “In Q” on the diagram) and the received bit sequence (“Out I” and “Out Q”) versus the time are presented.

The phase error of the recovered signal is about $\pm 20^\circ$, except for the glitches. These glitches produce spectral lines spaced at around 2 MHz, as seen in Fig. 27.

The I/Q bit sequence obtained at the six-port QPSK demodulator output shows excellent demodulation results. The time delay between output and input I/Q signals corresponds to the propagation time from transmitter to receiver.

5. PROBABILITY OF ERROR FOR QPSK

The probability of error for the QPSK signals can be derived using the equations of I and Q demodulated signals [Eqs. (20) and (21)] in the presence of noise. The presence of noise may cause an incorrect reception of symbols by the demodulator [17].

By symmetry, the error rates for all input symbols are equal, so it can be assumed that one of these symbols (e.g., $i = 2$) is received. According to Eqs. (16) and (17), this signal can be expressed by

$$\begin{aligned} S_2(t) &= \text{Re}\{A \exp[j \cdot (\omega t + \varphi_2)]\} \\ &= A \cos(\omega t + \varphi_2) \\ &= A \cos\left(\omega t + 3\frac{\pi}{4}\right) \end{aligned} \quad (36)$$

Then, considering the additive Gaussian noise having a power spectral density of $N_0/2$, the received signal is

$$\begin{aligned} S(t) + N(t) &= S_2(t) + N(t) \\ &= A \cos\left(\omega t + 3\frac{\pi}{4}\right) + N(t) \end{aligned} \quad (37)$$

Figure 28. RF signals phases and related IQ signals using a six-port QPSK demodulator.

According to Eqs. (20) and (21), the output filtered I and Q signals are

$$I(T) = -\frac{A^2T}{2\sqrt{2}} + N_0(T) = -\frac{E_S}{\sqrt{2}} + N_0(T) \tag{38}$$

$$Q(T) = \frac{A^2T}{2\sqrt{2}} + N_0(T) = \frac{E_S}{\sqrt{2}} + N_0(T) \tag{39}$$

where $E_S = (A^2T)/2$ is the symbol energy and $N_0(T)$ is the noise component of the output:

$$N_0(T) = \int_0^T N(t)A \cos \omega t dt \tag{40}$$

which represents a Gaussian random variable.

The variance of $N_0(T)$ can be calculated as follows:

$$\begin{aligned} \sigma^2 &= E\{N_0^2(T)\} \\ &= E\left\{ \int_{t=0}^T \int_{s=0}^T A^2 N(t)N(s) \cos \omega t \cos \omega s dt ds \right\} \tag{41} \\ &= \frac{A^2TN_0}{4} = \frac{E_S N_0}{2} \end{aligned}$$

The detection threshold for both detectors is zero, so the probability of a symbol error for I signal is

$$\begin{aligned} P_e^I &= P(I \geq 0) = P\left\{ N_0(T) \geq \frac{E_S}{\sqrt{2}} \right\} \\ &= \int_{E_S/\sqrt{2}}^{\infty} \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{u^2}{2\sigma^2}\right) du \end{aligned} \tag{42}$$

By changing the variable $x = u/(\sigma\sqrt{2})$, the error probability becomes

$$P_e^I = \frac{1}{\sqrt{\pi}} \int_{E_S/2\sigma}^{\infty} \exp(-x^2) \cdot dx = \frac{1}{2} \operatorname{erfc}\left(\frac{E_S}{2\sigma}\right) \tag{43}$$

Using equation (41) it can be obtained that:

$$\frac{E_S}{2\sigma} = \sqrt{\frac{E_S}{2N_0}} \tag{44}$$

Because the symbol period T is twice the bit period, it can be concluded that $E_S = 2E_b$, where E_b is the bit energy. Therefore, the error probability will be

$$\begin{aligned} P_e^I &= \frac{1}{2} \operatorname{erfc}\left(\frac{E_S}{2\sigma}\right) = \frac{1}{2} \operatorname{erfc}\left(\sqrt{\frac{E_S}{2N_0}}\right) \\ &= \frac{1}{2} \operatorname{erfc}\left(\sqrt{\frac{E_b}{N_0}}\right) \end{aligned} \tag{45}$$

By symmetry, the probability of a symbol error for Q is

$$\begin{aligned} P_e^Q &= \frac{1}{2} \operatorname{erfc}\left(\frac{E_S}{2\sigma}\right) = \frac{1}{2} \operatorname{erfc}\left(\sqrt{\frac{E_S}{2N_0}}\right) \\ &= \frac{1}{2} \operatorname{erfc}\left(\sqrt{\frac{E_b}{N_0}}\right) \end{aligned} \tag{46}$$

Since the overall probability that a symbol is received correctly is the product of the probabilities that each arm operates correctly, the overall probability of error for a symbol is

$$\begin{aligned} P_e^{(S)} &= 1 - (1 - P_e^I) \cdot (1 - P_e^Q) = 2P_e^I \\ &- (P_e^I)^2 \approx 2P_e^I = \operatorname{erfc}\left(\sqrt{\frac{E_b}{N_0}}\right) \end{aligned} \tag{47}$$

In practice, the QPSK signal with Gray coding is used. We can then assume that a symbol error is most likely to cause only a single bit error. Since each symbol contains 2 bits, the bit error rate for the QPSK will be one half the symbol error rate:

$$P_e^{\text{QPSK(gray)}} = \frac{1}{2} \operatorname{erfc}\left(\sqrt{\frac{E_b}{N_0}}\right) \tag{48}$$

This equation (48) shows that the probability of error of a QPSK signal (Gray coded) is equivalent to the probability of error for a BPSK signal. Thus, using QPSK modulation it is possible to achieve twice the data rate of the BPSK modulation, with the same bandwidth and error rate. This fact has led to the extensive use of QPSK modulation in a wide variety of applications.

Figure 29 shows the theoretical bit error rate (BER) versus the E_b/N_0 ratio for a QPSK modulation, according to Eq. (48).

Figure 29. The theoretical bit error rate (BER) versus the E_b/N_0 ratio for a QPSK modulation.

QUASI-OPTICAL CIRCUITS

WAYNE A. SHIROMA

MICHAEL P. DELISIO

University of Hawaii at Manoa

In contrast to conventional electronic circuits in which the input and output signals are voltages and currents, quasi-optical circuits have input and output signals that are electromagnetic beams. Quasioptical circuits use components typically associated with optics, such as lenses, mirrors, and polarizers, but are targeted toward the millimeter- and sub-millimeter-wave regimes of the electromagnetic spectrum between 30 GHz and a few terahertz. This article focuses on *active* quasioptical circuits used for generating, amplifying, and processing millimeter-wave beams.

Millimeter-wave systems offer a number of advantages over their microwave and optical counterparts. Compared with microwave systems, millimeter-wave systems have wider bandwidth and reduced size and weight. Compared with optical systems, millimeter waves have the advantage of penetrating smoke, fog, and dust. Millimeter-wave applications include high-resolution imaging systems, satellite crosslinks, automotive collision avoidance, indoor wireless communications, and identification tagging for tracking inventory.

These applications often exploit the atmospheric absorption characteristics of the millimeter-wave regime (Fig. 1). For example, the attenuation windows are used for long-range communications and radar systems, while the absorption peaks are used for short-range communication systems such as indoor wireless local-area networks and covert battlefield communications.

A major obstacle in developing millimeter-wave systems, however, is the limited power-handling capacity of semiconductor devices in this frequency range. Figure 2 [1] compares the average power of representative solid-state and vacuum electronic devices. While solid-state devices have the advantage of size, weight, reliability, manufacturability, and DC requirements, their power tends to fall off with a $1/f$ to $1/f^2$ frequency dependence.

To take advantage of the benefits of solid-state technology while at the same time meeting system specifications, the power from many individual devices must be added coherently. Although a variety of power combiners based on conventional circuit techniques have been developed [2] they have serious limitations at millimeter-wave frequencies where large numbers of devices must be combined and transmission losses are excessive.

Figure 1. Atmospheric absorption of millimeter waves (horizontal propagation). Attenuation windows occur at 35, 94, 140, and 260 GHz. Absorption peaks occur at 21, 60, 119, and 183 GHz [1].

1. QUASIOPTICAL POWER COMBINING

To address this problem, research has concentrated on developing power combiners using quasioptical methods. Although active quasioptical techniques have a history dating back several decades, it was Mink's classical paper on quasioptical power combining [3] that provided the catalyst for the increased research activity in recent years. A quasioptical power combiner can be likened to a gas laser system, shown in Fig. 3. Even though each gas molecule contributes just a small portion of the total power in the

optical beam, the total power can be quite large. This combining scheme is efficient for two reasons: because of the dense packing of molecules in the system and because the combined power is guided in free space rather than by lossy metal walls.
