Attenuation in microstrip lines is caused by three loss components: conductor loss, dielectric loss, and radiation loss. They are discussed briefly next.

3.1.12.1. Ohmic Losses. Within the conductors, these result from the finite conductivity σ of the metal. The following approximate expression (9) is found sufficient in most situations

$$\alpha_c \approx 8.686 \frac{R_s}{wZ_0} \text{ dB/m} \tag{35}$$

where $R_s = \sqrt{\omega\mu/2\sigma}$ is the metal wall surface resistance.

3.1.12.2. Dielectric Losses. Produced by the energy dissipated within the substrate, these are proportional to its dielectric loss tangent $\tan \delta$ [9]

$$\alpha_d \approx 27.3 \cdot \frac{\epsilon_e - 1}{\epsilon_r - 1} \cdot \frac{\epsilon_r}{\sqrt{\epsilon_e}} \cdot \frac{f}{c} \cdot \tan \delta \text{ dB/m} \tag{36}$$

where c is the velocity of light in free space, and f is the frequency. The dielectric loss due to the substrate is normally very small compared with the conductor loss. However, the dielectric loss in silicon substrates (used for monolithic MICs) is usually of the same order as or even larger than the conductor loss because of the large loss tangent $\tan \delta$ of the silicon wafers.

3.1.12.3. Radiation Losses. An infinite straight microstrip line propagating the dominant quasi-TEM mode does not radiate. However, at every discontinuity, higher-order modes are excited, some of which will radiate part of the power.

3.2. Frequency Range of Operation

Like any other transmission line, microstrip lines cannot be utilized above a certain upper frequency limit. The maximum frequency of operation of a microstrip line is

limited because of several factors such as effects of dispersion, excitation of higher-order modes, and radiation losses.

The frequency at which significant coupling occurs between the quasi-TEM mode and the lowest-order TM surface wave is given by [20]

$$f_T = \frac{300 \tan^{-1}(\epsilon_r)}{\pi h \sqrt{2\epsilon_r - 2}} \quad (37)$$

where f_T is in gigahertz and h is in millimeters.

For a sufficiently wide microstrip line, a transverse resonant mode can exist that can also couple strongly to the quasi-TEM microstrip mode. By employing the transverse resonance equivalent circuit model, and taking into account the microstrip side-fringing effect, the cutoff frequency of the transverse resonant mode can be easily derived [20] as follows

$$f_c \approx \frac{300}{\sqrt{\epsilon_r}(2w + 0.8h)} \quad (38)$$

where f_c is in gigahertz and w and h are in millimeters.

For a microstrip line, radiation losses become significant at frequencies higher than [9]

$$f = 2.14 \cdot \frac{(\epsilon_r)^{0.25}}{h} \quad (39)$$

where f is in gigahertz and h is in millimeters.

3.3. Power-Handling Capability

Although microstrip lines are not as well suited for high-power application as are waveguides or coaxial lines of comparable cross section, they can be used for some medium-power applications. A 50- Ω microstrip on a 25-mil-thick alumina substrate can handle a few kilowatts of power [6].

The power-handling capacity of a microstrip line, like that of any other dielectric-filled transmission line, is limited by dielectric breakdown and by heating caused by ohmic and dielectric losses. An increase in the temperature due to conductor and dielectric losses limits the average power-handling capability of the microstrip line, while the breakdown between the strip conductor and ground plane limits the peak power-handling capability.

The average power-handling capability of microstrip lines is determined by the temperature rise of the conductor strip and the dielectric substrate. The transmission-line losses, the thermal conductivity of the substrate material, the surface area of the strip, and the temperature of the medium surrounding the microstrip line are the main factors determining the average power-handling capability of microstrip lines. Therefore, dielectric substrates with low-loss tangent and larger thermal conductivity will enhance the average power-handling capability of microstrip lines.

The peak voltage that can be applied without causing dielectric breakdown determines the peak power-handling capability of microstrip lines. Thick substrates can

support higher voltages. Therefore, low-impedance lines and lines on thick substrates have generally larger peak power-handling capability.

3.4. Other Types of Microstrip Lines

Several derivatives of microstrip lines are being used in MICs. These include inverted and suspended microstrip lines, a multilayered microstrip, a thin-film microstrip, and a valley microstrip line. These structures are briefly described in Refs. 6 and 7.

4. OTHER TOPICS

In actual microstrip circuits, various types of transmission line discontinuities, such as open ends, gaps, steps in width, bends, T junctions, and cross-junctions are frequently encountered. In the design of microstrip circuits, a complete understanding of the characteristics of microstrip discontinuities included in the circuits is necessary. At low frequencies, discontinuities can be represented by lumped-element equivalent circuits based on quasistatic models. However, at high frequencies, a more rigorous characterization of frequency-dependent parameters such as the scattering parameters is required. Various methods including quasistatic and full-wave analysis methods for characterizing microstrip discontinuities are described in Refs. 6–10 and 17.

Microstrip line is now the most widely used structure for microwave systems in radar and communication purposes. Examples of passive circuits include filters, impedance transformers, hybrids, couplers, power dividers/combiners, delay lines, baluns, and circulators. Amplifiers, oscillators, and mixers employing solid-state devices (diodes and transistors) constitute the other class. Microstrip-based antennas have also found wide applications [11,21,22]. Descriptions of the analysis and design of passive and active microstrip circuits and their applications in MICs and monolithic MICs (MMICs) are contained in numerous publications [6–10]. For further knowledge of the design and fabrication process of MICs and MMICs, see Refs. 23 and 24.

There have been a number of sophisticated microwave computer-aided design (CAD) packages available on the market. They can be used for analysis purpose (the user describes a structure and determines its electrical response) and synthesis purpose (the software determines a physical structure meeting a special electrical behavior). A survey of available CAD softwares for microwave circuits is given in Refs. 7 and 9.

In addition to the microstrip lines, two other types of planar transmission lines are also widely used today in various microwave systems. They are the *slotlines and coplanar lines* (coplanar waveguides and coplanar strips). Hybrid combination of these planer lines with microstrip lines allows flexibility of circuit design and improves the performance of some circuit functions. Coplanar lines have received particular attention because of their many appealing properties. These include low dispersion, high flexibility in the design of characteristic impedance, and ease of connecting shunt and series lumped elements, or

active devices without using via holes. Consequently, coplanar lines are used commonly in MMICs in conjunction with semiconductor devices, which are also coplanar in nature. Descriptions of the analysis and design of slotline and coplanar line circuits can be found in Ref. 6 for further study.

It is worth mentioning finally that the major portion of this article is devoted to the analysis and design aspects of the microstrip line with applications to the microwave integrated circuits. However, high-speed digital circuits include, as do microwave integrated circuits, active and passive circuit elements interconnected by sections of strip and other microstrip transmission lines having a wide range of characteristic impedances. The speed of digital circuits has steadily increased since the late 1980s; hence, the inductive effects on interconnect line performance due to line inductance that were previously assumed to be insignificant may be important. Moreover, the resulting junctions and discontinuities, and the electromagnetic coupling between the interconnects, contribute to reflections, signal delay and distortion, and crosstalk, which can degrade the circuit and system performance. The same problems are encountered in printed-circuit boards, single- and multichip modules, and other packages. Therefore, a high-speed circuit design and simulation must incorporate these interconnections. The analysis of the microstrip line in this article applies to the vast area of electrical interconnections for printed-circuit boards, single and multichip modules, and other packages. Examples of these additional applications can be found in Refs. 25–29, listed below.

MICROSTRIP TRANSITIONS

ERIC L. HOLZMAN
Northrop Grumman Corporation
Baltimore, Maryland

1. INTRODUCTION

Microstrip transmission lines are used widely in microwave and millimeter-wave printed electronic circuits for routing electromagnetic signals between components such

Figure 1. Microstrip transmission-line cross section.

as oscillators, amplifiers, and filters. As shown in Fig. 1, microstrip is a two-conductor transmission line. An insulating substrate separates the two conductors and supports a transverse field that is similar to the transverse electromagnetic (TEM) mode of a parallel-plate waveguide. A small portion of the transverse field permeates the air above the strip, thus making microstrip inhomogeneous. The dominant microstrip mode is a *quasi-TEM mode* that is slightly dispersive (the propagation constant is not a perfectly linear function of frequency). In general, this mode is broadband, with a cutoff frequency of 0 Hz. The first higher-order mode is a surface mode that propagates at a much higher frequency with a cutoff frequency that depends on the substrate's electrical thickness [1]. The TEM mode has two field components, both directed transversely. Figure 1 shows the electric field, oriented perpendicular to the conductors. The magnetic field is parallel to the conductors in the region between the strip and ground plane. Longitudinal current flows both in the strip and the ground plane. In the following discussion, we assume that only the quasi-TEM mode is propagating within the microstrip.

The *characteristic impedance* of a transmission-line mode is defined as the ratio of the mode's transverse electric and magnetic fields. Thus, two different transmission lines, such as microstrip and coaxial line, could have the same characteristic impedance but have very different field configurations. Typically, microstrip is dimensioned for a quasi-TEM mode characteristic impedance of 50 Ω . This impedance tends to decrease with frequency at a rate that depends on the substrate's electrical thickness. For substrates that are thin relative to a wavelength, the characteristic impedance is nearly constant over a wide frequency bandwidth.

One of microstrip's disadvantages is its lack of electrical isolation; the strip conductor is not completely surrounded by the ground plane. Consequently, microstrip circuits generally have to be housed in a conductive enclosure to prevent unwanted interference with other circuits in a microwave system. Coaxial or waveguide transmission lines provide the interconnections between different enclosed microstrip circuits. A *microstrip transition* is required to convert as efficiently as possible the microstrip electromagnetic properties to that of the interconnecting transmission line.

A well-designed microstrip transition converts the transverse field configuration and characteristic impedance of microstrip to that of the other transmission line over a desired frequency band of operation while maintaining low *insertion loss*, minimal radiation, and high

input *return loss*. Insertion loss, the amount of power exiting the transition, expressed as a fraction of the input level, should be less than 0.25 dB. Return loss, the amount of power reflected at the transition, expressed as a fraction of the input level, should exceed 15 dB. A good transition also is easy to fabricate, mechanically robust and insensitive to temperature variations.

Since the first microstrip circuits were constructed, a wide variety of transitions to other transmission lines have been developed. These transitions can be sorted into two main groups: (1) those that require a direct physical connection to the strip conductor and (2) those that use electromagnetic coupling to the strip conductor. Transitions to other TEM transmission lines such as coax most often use direct connections, which can provide very broadband performance. Transitions to waveguide tend to utilize electromagnetic coupling, which generally is more mechanically tolerant than a direct connection but is less broadband.

2. MICROSTRIP-TO-TEM TRANSMISSION LINES

Transitions between microstrip and other transmission lines propagating the TEM mode can have very wide *bandwidth* because the TEM-mode field configuration and characteristic impedance remain constant with frequency. In general, the upper frequency of these transitions is limited by the length of the electrical path connecting the ground conductors and by the tendency of the interconnections to radiate. In this section, we will study a number of microstrip transitions to other TEM structures.

2.1. Transitions to Coaxial Line

The coaxial transmission line provides an inexpensive and mechanically flexible means for making interconnections below 20 GHz. Figure 2 shows the cross section and electric field configuration of the dominant TEM mode in coax. At first glance, the field configuration of coax seems quite different than that of microstrip, but both have their primary field confined between two conductors. Unlike microstrip, the coaxial field is uniformly distributed around

Figure 2. Coaxial transmission-line cross section.

Figure 3. Microstrip-to-coax transition. (After Eisenhart [2].)

the center conductor. *Eisenhart's transition*, shown in Fig. 3, matches the two field configurations by offsetting the coaxial line center conductor in a controlled manner, forcing the coaxial-line field to concentrate below the center conductor much like that in the microstrip line [2]. The style of this transition is termed *inline or edge launch*, since the coaxial line and microstrip have their longitudinal or propagational axes in line. Eisenhart's transition attains very high performance: he has demonstrated greater than 25 dB return loss up to 18 GHz. Such a transition is ideal for testing prototype microstrip circuits. However, its significant length and relatively high cost make it undesirable as a transition for inexpensive microwave circuit boards.

Most microwave circuit interfaces require neither the bandwidth nor the return loss of the Eisenhart transition. Figure 4 shows a common *edge launch transition* between a microstrip on a multilayer circuit board and a sub-miniature-A (SMA) coax. The board-mount connector includes much of the transition. The center conductor of the coax line is extended out for solder attachment to the microstrip. The coax ground contact is made with coax ground pins attached to the connector. Commonly, two pins are placed below the circuit board also. Because the circuit board in Fig. 4 has multiple layers, and the

microstrip ground plane is not the bottom layer, this transition connects the ground pins to metalized pads on the plane of the microstrip. The pads have drilled and plated holes or *vias* that carry the ground currents through the circuit board to the microstrip ground plane. The length of the ground path, and in particular, the separation of the ground pins determines the upper frequency of operation for this transition. A tuning stub (see Fig. 4), printed on the circuit board, can provide additional bandwidth. Without the stub, the return loss of this transition is better than 15 dB past 5 GHz. With the stub, the bandwidth can be extended to 7 GHz. How much additional bandwidth a stub provides depends on whether the transition can be constructed in a consistent and repeatable manner. If the stub length has to be adjusted on each circuit board, the manufacturing process is not sufficiently consistent. Liang et al. have performed extensive analytical investigations of edge-launched SMA coax-to-microstrip transitions [3]. They compensated capacitively for the parasitic inductance of the soldered coax center pin by increasing the microstrip linewidth. The measured return loss of their transition exceeded 15 dB up to 13 GHz.

Occasionally, a connector like that in Fig. 4 may be inadequate. The connector ground pathlength limits the upper frequency of operation. A *connectorless transition* like that shown in Fig. 5 has a much shorter path between the coax and microstrip grounds. This transition has a return loss of 15 dB up to 12 GHz for a 0.047-in. coax cable attached to microstrip on a 0.008-in.-thick Rogers 4003 substrate. The insertion loss at 12 GHz is less than 0.25 dB, which indicates that the transition is not suffering significant radiation. However, assembling the transition can be more difficult when miniature coax cable is used.

Edge-launch transitions, as their name belies, are limited to placement at the edge of a circuit board. *Vertical mount or orthogonal launch transitions* can be placed almost anywhere on a circuit board. Figure 6 shows a vertical mounted SMA coax transition. As with the edge launch connector, the vertical mount connector comes with an extended center conductor probe and four ground

Figure 4. Multilayer circuit board mountable edge launch microstrip-to-coax transition.

Figure 5. Inline, connectorless, microstrip-to-coax transition.

pins. The center conductor and ground pins pass through vias in the circuit board and are soldered to pads on the top layer. Within the circuit board, they propagate the electromagnetic wave as a five-wire transmission line. On all intervening conductor layers, it is important to clear metalization away so as not to short(-circuit) out the field. The transition shown in Fig. 6, with a 0.2-in. ground pin spacing, has a return loss greater than 25 dB to nearly 6 GHz. As with edge launch connectors, the pin-to-pin spacing establishes the maximum frequency of operation. An SMP connector, with 0.1-in. ground pin spacing, can be made to work up to 18 GHz. An indication that the spacing is too great or the circuit board too thick is excess insertion loss caused by radiation within the board. One can fix this problem and better confine the field by inserting circuit board vias close to the center conductor probe. The vias effectively replace the connector ground pins as carriers of the ground current within the circuit board.

2.2. Transitions to Other Planar Transmission Lines

Transitions from microstrip to other planar transmission lines are often required on multilayer circuit boards,

Figure 7. Microstrip-to-microstrip transition through a multi-layer circuit board: (a) top/bottom-layer metallization; (b) ground-layer metallization clearance; (c) circuit board cross section.

where it may be desirable to propagate the microwave energy within the circuit board. Figure 7 shows a *microstrip-to-microstrip transition* that passes vertically through a multilayer circuit board. Essentially, the transition comprises a pair of transitions from microstrip to three-via transmission line. The via separation and a microstrip open-circuited stub serve to tune the transition. The return loss of the transition on a circuit board made from three layers of FR4, 0.062 in. thick, exceeds 25 dB to nearly 5 GHz.

Transitions from *microstrip to coplanar waveguide* (CPW) are relatively common and straightforward to design. Via holes often are used to connect the microstrip ground to the coplanar waveguide ground as shown in Fig. 8. Such transitions are found on monolithic microwave integrated circuits (MMICs), which require wafer-probe-compatible CPW for their RF input and output [4]. Ellis et al. developed a CPW transition without vias for MMICs using a slotline to form a CPW as shown in Fig. 9

Figure 6. Vertical mount, microstrip-to-coax transition.

Figure 8. Microstrip-to-coplanar waveguide transition.

[5]. Their transition is unusual because it relies on coupling. The CPW is formed in the ground plane of the microstrip, and the microstrip conductor is coupled orthogonally to a single slotline that forms the pair of gaps in the CPW transmission line.

Transitions from microstrip to less commonly used planar transmission lines exist also. Drach and Koscica developed a transition between *microstrip and inverted microstrip* line for millimeter-wave applications [6].

3. MICROSTRIP TO WAVEGUIDE

Microstrip-to-waveguide transitions are used for the same reasons that transitions to coax are used—as interconnects between sealed modules or modules and antennas. However, unlike coaxial line, waveguides are used mostly above 20 GHz, often in the millimeter-wave bands, where their lower loss becomes a significant advantage.

Waveguide is formed from a single conductor, so its properties are markedly different than those of coax line.

Figure 9. Microstrip-to-coplanar waveguide transition that operates at 75–110 GHz. (Source: T. J. Ellis, J. P. Raskin L. P. B. Katehi, and G. M. Rebeiz, A wideband CPW-to-microstrip transition for millimeter-wave packaging, 1999 *MTT-S International Microwave Symposium Digest*, Vol. 2, pp. 629–632. © 1999 IEEE. Reprinted with permission.)

The dominant propagating mode, typically of the transverse electric (TE) configuration, has a cutoff frequency below which the waveguide is highly attenuative to EM signals. Figure 10 shows rectangular and circular waveguides and their dominant-mode field configurations. Most transitions are designed to operate within the frequency band of dominant-mode propagation only, which is at most 2 : 1 for rectangular waveguide and 1.3 : 1 for circular waveguide.

The impedance characteristics of waveguide modes tend to make transitions more challenging to design. First, the *dispersive* behavior of waveguide means that the characteristic impedance of its modes change with frequency; moreover, the characteristic impedances of standard guides are much higher than 50Ω, typically a few hundred ohms for TE modes. Consequently, the bandwidth for most microstrip-to-waveguide transitions rarely equals the dominant mode bandwidth.

3.1. Orthogonal Transitions to Waveguide

A transition to rectangular waveguide is often used as the RF interface between a millimeter-wave transmitter or receiver and the antenna. Figure 11 shows an *orthogonal or right-angle transition*. The microstrip extends through a narrow channel into the waveguide. The channel dimensions are made sufficiently small so that only the microstrip mode can propagate over the band of operation. Within the waveguide, the microstrip ground is removed, so the microstrip or probe behaves like an antenna. Because the probe will radiate equally well both up and down

Figure 10. Commonly used waveguides with dominant-mode electric fields: (a) rectangular and TE₁₀ mode; (b) circular and TE₁₁ mode.

Figure 11. Transition from microstrip to full-radius rectangular waveguide.

the waveguide, a backshort (waveguide short circuit) is placed in the undesired direction approximately a quarter-wavelength away from the probe. An impedance tuning section on the probe circuit board, just at the input to the waveguide, and a fan-shaped probe increase the transition's bandwidth. This transition can be tuned to operate over a 40% bandwidth with better than 25 dB return loss.

In fabricating this type of transition, one must be sure that the microstrip ground plane makes electrical contact with the channel surface to avoid undesired radiative effects. The probe shown in Fig. 11 is fabricated on a multilayer substrate, and the microstrip ground plane is not the bottom layer. To guarantee contact between the microstrip ground and the channel floor, one can drill via holes on both sides of the microstrip. Also, to reduce the machining cost, the waveguide can be fully radiused as it is in the figure.

The orthogonal transition works well for *circular waveguide* also as shown in Fig. 12. Circular waveguide is easier to machine than rectangular waveguide, and one can use a commercially available, adjustable tuner, or simple dowel as the backshort. The primary disadvantage of circular waveguide is bandwidth related. Since the circular waveguide dominant (TE_{11})-mode and first higher-order (TM_{01})-mode cutoff frequencies are more closely spaced than those in the rectangular waveguide, the transition

bandwidth will be less. The transition illustrated in Fig. 12 can provide a return loss of more than 25 dB over a 20% bandwidth. Also, unlike rectangular waveguide, circular waveguide's polarization is arbitrary, so discontinuities will excite cross-polarized fields. A short section of straight waveguide to the antenna is best.

The transitions in Figs. 11 and 12 require *waveguide backshorts* spaced about one quarter-wavelength away from the probe. The position of the backshort must be controlled precisely to get the lowest insertion loss through the transition. Further, the backshort can be the tallest feature in an otherwise very thin module. Consequently, transitions that do not require backshorts or are insensitive to backshort position have been developed. Park and Holzman developed two transitions shown in Fig. 13 that use a slot printed in the microstrip ground plane to excite the rectangular waveguide [7,8]. Neither transition requires a precisely placed backshort, although both enclose the transition in a rectangular cavity to contain any unwanted radiation. The cavity dimensions are chosen so that no modes are resonant in the frequency band of operation. For standard rectangular waveguide sizes, the characteristic impedance of the TE_{10} mode is several hundred ohms, so one cannot expect a good match if a 50-Ω microstrip line is centered over the waveguide. Since the slot field amplitude varies sinusoidally across

Figure 12. Microstrip-to-circular waveguide transition.

Figure 16. Inline, microstrip-to-waveguide transition. (After Ho and Shih [12].)

the length of the slot, while the magnetic field is essentially constant, one can offset the microstrip line as in Fig. 13a, and thereby lower the impedance presented to the strip. In Fig. 13b, a dipole-like structure terminates the microstrip line. Adjustment of the dipole position and arm-length matches the transition. In both transitions, all critical dimensions are photolithographically controlled with high accuracy. The transitions are extremely compact, but they also are narrowband, providing high return loss over less than a 10% bandwidth. Villegas et al. designed an end-launched transition that is much like Park and Holzman's and achieved a bandwidth of 10% centered around 45 GHz [9].

Davidovitz overcame the bandwidth limitation in the Park-Holzman transitions by adding a waveguide taper as shown in Fig. 14 [10]. Davidovitz reduced the waveguide height and mode impedance adjacent to the slot so that a centered microstrip could be matched. He flared the reduced height waveguide to the desired height using a tapered structure. His transition has a measured return loss exceeding 15 dB over a 50% bandwidth. Although Davidovitz' transition does not require a waveguide backshort, the length of his taper is about four TE_{10} mode wavelengths at the center of the band. To

Figure 17. Inset, microstrip-to-waveguide transition using a ridged waveguide transition.

save space, one could use a waveguide quarter-wave transformer instead of a taper at the cost of reduced bandwidth.

Davidovitz has used a similar approach to create a microstrip-to-microstrip transition through a thick metal plate as shown in Fig. 15 [11]. A reduced-height waveguide provides strong coupling between two microstrip lines but the bandwidth is very narrow, only a couple of percent.

3.2. Inline Transitions to Waveguide

Another type of microstrip-to-waveguide transition is the *inline* topology shown in Fig. 16 [12]. This particular structure is constructed by inserting the microstrip substrate in line with the waveguide, and a printed circuit version of a current loop couples to the TE₁₀ waveguide mode. The end of the loop must make electrical contact with the floor of the waveguide. This transition has about a 30% bandwidth.

The transition illustrated in Fig. 17 uses a section of ridged waveguide to transition to standard rectangular waveguide [13]. The principle of operation is similar to that used by Eisenhart in his transition to coaxial line [2]. The electric field concentrates under the ridge, and as the ridge depth increases, the field begins to resemble that of the microstrip mode. Electrical contact is necessary between the microstrip line and the ridge.

Figure 18 shows another inline transition developed by Holzman, in this case, to a parallel-plate waveguide feeding a TEM horn radiator [14,15]. A microstrip and its substrate protrude through a hole in a metalized faceplate. The microstrip and its ground plane are shaped and flared such that the electric field is rotated 90°, from the microstrip mode into a parallel-plate TEM mode, which

Figure 18. Inset, microstrip-to-parallel-plate waveguide transition feeding a TEM horn antenna. (Source: E. L. Holzman, A wide band TEM horn array radiator with a novel microstrip feed, *IEEE International Conference on Phased Array Systems and Technology Digest*, May 2000, pp. 441–444. © 2000 IEEE. Reprinted with permission.)

Figure 19. Inline, microstrip-to-waveguide transition using aperture coupling. (After Lynch [17].)

excites the flared horn. Because both the microstrip and parallel plate transmission lines propagate the TEM mode, this transition is very broadband, achieving a predicted bandwidth of 5 : 1. The transition's length must be at least a half-wavelength at the lowest frequency of operation. Because the field distribution is uniform in the parallel-plate waveguide, the transition works just as well whether the substrate is placed on the waveguide edge or centerline (see Fig. 18). Further, two or more substrates can be placed within a single parallel-plate waveguide, and the energy will be combined over the bandwidth of the transition. The inspiration for Holzman's transition was a similar transition to rectangular waveguide developed by van Heuven [16].

Figure 19 shows an inline transition that uses a printed slot in the microstrip ground plane to couple to a waveguide [17]. The substrate ground plane forms the upper surface of part of the rectangular waveguide.

4. CONCLUSION

Historically, transition design was an empirical effort, requiring time-consuming building, testing, tuning, and iteration of prototype circuits. Today, most transitions are designed with the aid of commercially available, highly accurate and fast three-dimensional, generalized electromagnetic software [18]. The first hardware prototype is built only after the transition design has been optimized on a computer. Further, the software affords those with new ideas the opportunity to evaluate them quickly. Thus, although many different microstrip transitions have been described in this article, one can expect to see new designs in the future.

Frequency multipliers are harmonic generators that produce various frequency multiples of an input (fundamental) frequency. These devices are employed in such diverse applications as electronic instruments, designing radar, communications, and electronic warfare systems. High-frequency signals are generated from lower-frequency signals by harmonic multiplication, as demonstrated in the simple representation depicted in Fig. 1. In the development of such a device, the circuit designer typically seeks to maximize the power delivered to the output load at the N th harmonic.

The capability of optimization of multiplier performance, in and of itself, can improve the overall performance of a system. Such potential for enhanced performance leads to the optimization process becoming a crucial consideration in the development of the system. Multiplier performance is dependent on the nonlinear device producing the required frequency harmonics and the design technique employed. The most important design considerations in frequency multipliers are conversion gain, harmonic suppression, output power, efficiency, DC bias requirements, and bandwidth. Frequency multipliers exhibiting high conversion gain, good harmonic suppression, wide bandwidth when required, and high efficiency are achieved from optimum designs. As will be discussed in this article, many authors give various, contradictory means of optimizing the performance of frequency multipliers.

One of the dominant operating parameters of a frequency multiplier is its conversion gain or conversion loss.

Figure 1. Simple harmonic multiplier.

The conversion gain is the ratio of the output power at the desired harmonic frequency to the input power at the fundamental frequency. It has been demonstrated that various parameters affecting the conversion gain include the bias level, the input power, the harmonic terminations, and the nonlinear device producing the frequency harmonics [1–7]. Techniques that maximize the conversion gain are necessary for the development of frequency multipliers.

With the advent of new active devices, such as the high-electron-mobility transistor (HEMT), the pseudomorphic high-electron-mobility transistor (PHEMT), and the heterojunction bipolar transistor (HBT), new multiplier designs incorporating these devices are desired. This has led to the emergence of new research areas where relatively little information has been reported in the literature. This presentation will address some of these areas. Some areas considered are the development of accurate nonlinear circuit models, identifying pertinent properties of the transistor, optimizing multiplier designs, and improving some of the existing design techniques.

1. APPLICATIONS OF FREQUENCY MULTIPLIERS

The extension of system operating frequencies into higher frequency bands has led to considerable interest in generating RF power at lower frequencies and using a nonlinear device to achieve RF power at a higher harmonic frequency. Harmonic generators provide a convenient source of signals at higher frequencies, where direct generation from an oscillator is difficult or inconvenient. The frequency multiplier produces an output signal at a harmonic frequency multiple of the fundamental input frequency and eliminates the requirement for a high-frequency oscillator. The ability to design frequency multipliers generating the higher harmonic frequencies has made frequency multipliers important circuits in RF and microwave components, and thus they find a wide range of use in the electronics arena. Applications include instrument design, radar systems, communication systems, subscriber radio systems, and low-phase-noise electronic warfare (EW) applications.

1.1. Communication Systems

As an illustration demonstrating the convenience of a frequency multiplier, consider a communication system requiring a 15 GHz local-oscillator (LO) source as shown in Fig. 2. The configuration shows a 15-GHz source driving the LO chain of the mixer. Alternatively, the 15 GHz source can be replaced by a 5-GHz local oscillator and frequency tripler to obtain the required 15 GHz signal. Advantages in using the 5-GHz source over the 15-GHz source lie in the cost associated with the two sources, because high-frequency components usually are more expensive than lower-frequency ones. Additionally, the 5-GHz source could possibly pose less of a design challenge than the 15-GHz source. With this change in the configuration, the final circuit is represented by Fig. 3.

Frequency multiplier applications have been extended to monolithic microwave integrated circuit (MMIC)

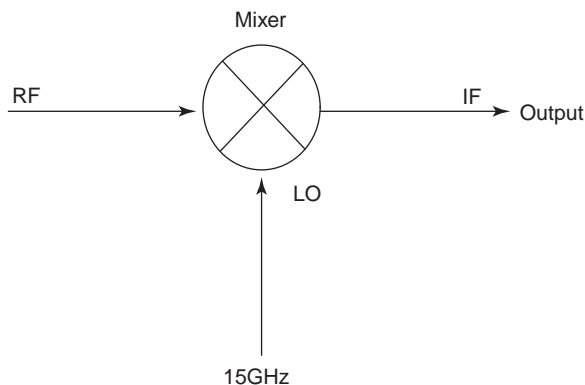

Figure 2. Configuration without frequency multiplier.

receivers in communication systems [8–11]. One such application is shown in Fig. 4 [9]. In this configuration, two doublers are used in series to supply the LO chain of the mixer. Using these doublers in the topology allows a 6.5 GHz voltage-controlled oscillation (VCO) to be implemented. The 6.5 GHz signal is led into the two frequency doubler circuits, which produce an output signal at 26 GHz. Without the use of the two doubler circuits in the block diagram, a 26-GHz VCO would have been required.

1.2. Cellular Applications

Wireless applications operating in the 900–2500 MHz range frequently use frequency multipliers in their design topologies. The systems include synthesizers, transmitters, receivers, and transceivers [12]. A transmitter topology demonstrating the use of frequency multipliers is shown in Fig. 5. The modulated signal at 450 MHz is multiplied by the doubler to produce a signal at 900 MHz for transmission.

The receiver topology using a frequency doubler is shown in Fig. 6. The doubler is placed in the LO chain of the downconverter. The downconverter produces an inter-

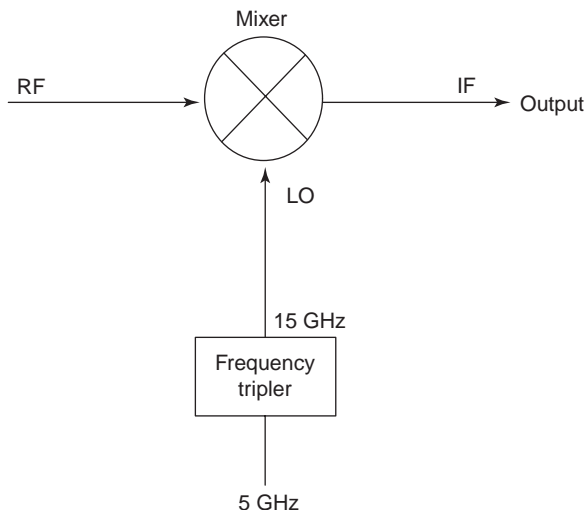

Figure 3. Configuration with frequency multiplier.

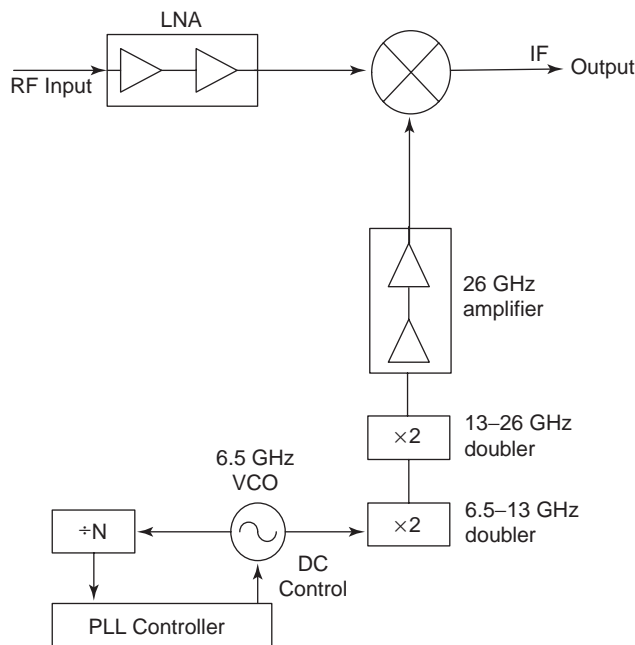

Figure 4. Block diagram of 26 GHz MMIC receiver Model.

mediate frequency (IF), which is signal-processed to obtain the desired information from the signal.

As a final example, a block diagram of a transceiver employing the use of a frequency doubler is shown in Fig. 7 [12]. This topology uses a single LO source. The doubler is used in the LO chain of the receiver and to produce the transmitting frequency in the transmitter.

2. PASSIVE FREQUENCY MULTIPLIERS

As mentioned previously, frequency multipliers are harmonic generators that produce frequency multiples of an input (fundamental) frequency. At radio- and microwave frequencies, frequency multipliers typically employ a nonlinear device to generate the desired harmonic spectrum. The choice of this nonlinear device divides multipliers into two categories: passive multipliers and active multipliers. In the case of the active multipliers, the nonlinear device includes any of the devices in the transistor classes (BJT, FET, MESFET, etc.), as will be discussed in the following section. This section will discuss the development of passive multipliers. The discussion will include the basic theory and operation of passive multipliers, various devices

Figure 5. Block diagram of 26 GHz MMIC receiver model.

Figure 6. Receiver employing frequency multiplier.

that are typically used in the development of passive multipliers with their various advantages and disadvantages, the nonlinear mechanism responsible for harmonic production, power considerations, optimization of efficiency, realizations, and design topologies.

2.1. Background and Theory

As mentioned, frequency multipliers at radiofrequencies typically require a nonlinear element to produce the desired harmonic spectrum. For passive multipliers, this requirement is fulfilled by the exploitation of the nonlinear characteristics of nonlinear resistors, nonlinear inductors, or nonlinear capacitors. The excitation of these devices by an input fundamental frequency produces an output spectrum possessing the desired harmonic output of interest. Typical nonlinear devices providing the aforementioned properties in the development of passive frequency multipliers include rectifying metal–semiconductor junctions with their nonlinear current–voltage characteristics, reverse-biased metal–semiconductor or p-n junctions with their nonlinear capacitance, and nonlinear transmission lines having distributed nonlinear capacitance [13].

As mentioned, harmonic generation is produced in a passive frequency multiplier whenever a sinusoidal input signal drives a nonlinear impedance. A variable resistance, inductance, or capacitance whose magnitude varies instantaneously with the applied voltage or current characterizes this nonlinear impedance. Semiconductor diodes have been reported throughout the literature as

an efficient means of providing the necessary nonlinear characteristics for passive multiplier design [9,11,13–41]. The diodes have various characteristics, which produce, as expected, different performance.

Varactor diodes are commonly used by microwave designers in the development of passive multipliers with great success [14–17]. The varactor diode is a variable-reactance element where the diode junction capacitance changes nonlinearly as a function of the applied voltage, as will be discussed in the following section. Varactors are classified into two major categories: (1) p-n junction varactors, which are widely used at microwave frequencies, and (2) Schottky junction devices, typically used for millimeter-wavelength applications. It has been shown by Manley and Rowe [42], as will be discussed later, and it has been mentioned by other authors [19,43,44] that a nonlinear capacitance (reactance) harmonic generator, such as that developed with a junction varactor, can theoretically generate harmonics with efficiencies ($= P_{out}/P_{in}$) approaching 100%. On the other hand, passive frequency multipliers utilizing passive nonlinear resistors for harmonic generation have at most an efficiency of $1/N^2$, where N is the order of the harmonic, as shown by Page [45] and referenced by other authors [15,16,19]. Therefore, in the case of a frequency doubler, theoretically, the highest efficiency achievable is 25% ($N = 2$).

The step recovery diode is also used in passive frequency multiplier design for lower frequencies (30 GHz) [17]. The step recovery diode is another variable-reactance element, which is a variation of the varactor diode. Archer [26] states that the step recovery diode is a p-n junction diode explicitly designed to enhance the charge storage capacitance associated with minority carrier injection during forward conduction and that the charge storage capacitance supplies the nonlinearity necessary for harmonic generation. According to the available literature, step recovery diodes are not as popular as varactor diodes in the design of passive frequency multipliers because of the complexity in reproducible control of the forward injection of minority carriers. Therefore, the ensuing discussions will not focus on step recovery diodes.

2.2. Diode Model

As will be mentioned in the following section, one of the most important tools of microwave circuit designers is the

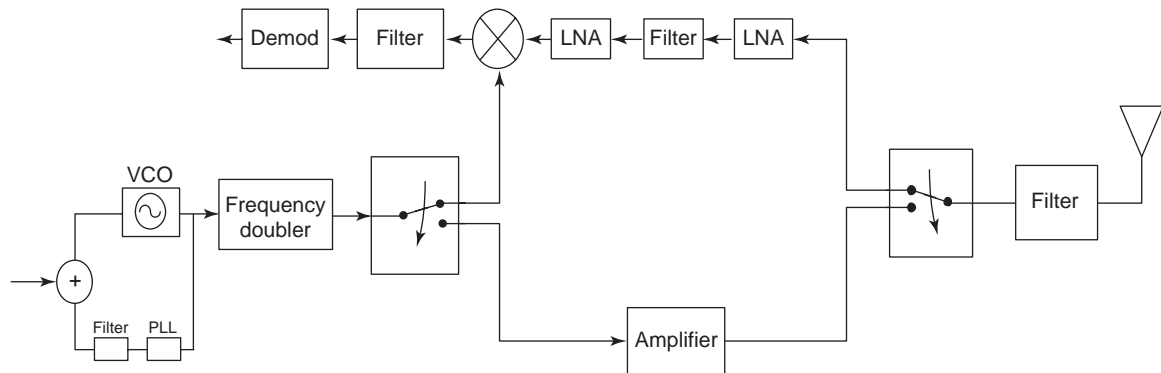

Figure 7. Transceiver employing frequency multiplier.

Figure 8. Varactor diode circuit model.

availability of device circuit models, which allows the performance of the device to be predicted before and after embedding with external networks. Since a diode model is essential in the understanding and development of passive frequency multipliers utilizing these devices as the source of nonlinearity, the following discussion will be devoted to the circuit model of the diode.

An equivalent-circuit model for the varactor model is shown in Fig. 8. This simple circuit model contains a frequency-dependent series resistance R_s and a voltage-dependent nonlinear conductance $g(v)$ in parallel with the voltage-dependent junction nonlinear capacitance $C_j(v)$, where v is the voltage over the junction [17,36]. The nonlinear conductance, which can produce resistive multiplication, is defined as [36]

$$g(v) = \frac{\partial i_g}{\partial v} \quad (1)$$

$$i_g = I_{\text{sat}} \left[\exp\left(\frac{qv}{\eta kT}\right) - 1 \right] \quad (2)$$

where I_{sat} is the diode saturation current, q is the magnitude of the electron charge, η is the ideality factor of the diode, k is the Boltzmann constant, and T is the diode temperature. The nonlinear capacitance $C_j(v)$, which is responsible for supplying the nonlinear reactance, is defined as [36]

$$C_j(v) = \frac{C_{j0}}{(1 - v/\phi_{\text{bi}})^2} \quad (3)$$

where C_{j0} is the zero-bias junction capacitance, “bi” is the built-in voltage potential, and is related to the doping profile in the epitaxial layer. Raisanen [36] indicates that typical values of these parameters for a varactor diode with radius of 1–5 m are as follows: the zero-bias junction capacitance $C_{j0} = 3\text{--}20$ fF, series resistance $R_s = 5\text{--}20$, built-in potential $\text{bi} = 0.6\text{--}1.0$ V, ranging from 0.4 to 0.5. The series resistance R_s arises from the undepleted materials in the diode and the contact resistance [14].

As shown in this model, suitable nonlinear elements exist for harmonic generation, namely, the nonlinear resistor $1/g(v)$ and the nonlinear capacitance $C_j(v)$. As was mentioned earlier and will be discussed later, harmonic generation due to the nonlinear reactance produced by $C_j(v)$ is theoretically more effective because it is possible to convert all the available power applied to a lossless nonlinear reactive element to output power at any higher harmonic frequency. An ideal resistive multiplier utilizing the nonlinear resistor $1/g(v)$ theoretically has a maximum efficiency of only $1/N_2$, where N is the harmonic frequency.

2.3. Nonlinear Mechanism

As mentioned previously, high-frequency signals can be generated from lower-frequency signals by harmonic multiplication. Frequency multipliers provide an efficient means of exploiting the nonlinear characteristics of various devices to provide the desired harmonic multiplication. The circuit designer of frequency multipliers seeks to accentuate the device nonlinearity in a particular way such that exciting the nonlinear device by a sinusoidal input signal at a fundamental frequency produces an output spectrum at harmonic frequencies of the input fundamental, which obviously includes the desired harmonic of interest. This section will identify and discuss the general nonlinear mechanisms responsible for harmonic production in passive frequency multipliers.

It was noted in the previous section that nonlinear resistors, nonlinear capacitors, and nonlinear inductors could be exploited for their nonlinear characteristics. Typical nonlinear devices providing these nonlinear characteristics essential for harmonic production include rectifying metal–semiconductor junctions with the nonlinear current–voltage characteristics, reverse-biased metal–semiconductor or p–n junctions with their nonlinear capacitance, and nonlinear transmission lines having distributed nonlinear capacitance [13]. As a simple example demonstrating harmonic generation, consider a nonlinear device whose nonlinear transfer function can be represented as a polynomial of the form

$$V_{\text{out}} = a_1 V_{\text{in}} + a_2 V_{\text{in}}^3 \quad (4)$$

where a_1 and a_2 are constants. Inserting a sinusoidal input ($V_{\text{in}} = \cos \omega t$) into Eq. (4) gives

$$\begin{aligned} V_{\text{out}} &= a_1 \cos \omega t + a_2 (\cos \omega t)^3 \\ &= a_1 \cos \omega t + a_2 \left(\frac{1}{4} \cos 3\omega t + \frac{3}{4} \cos \omega t \right) \\ &= \left(a_1 + \frac{3a_2}{4} \right) \cos \omega t + \frac{a_2}{4} \cos 3\omega t \end{aligned} \quad (5)$$

Equation (5) shows that an output harmonic is generated at the fundamental frequency (ω) and the third-harmonic frequency [3]. Therefore, for the specific application of a frequency tripler, this nonlinear device, as represented by the transfer function given in Eq. (4), theoretically provides the nonlinear characteristics for the design of a frequency tripler.

Throughout the literature, researchers and designers have developed passive multipliers, typically with nonlinear diodes. For this reason, the ensuing discussion focuses on the nonlinear mechanism associated with semiconductor diodes, which are used throughout the microwave industry.

As mentioned, semiconductor diodes have been reported throughout the literature as an efficient means of harmonic production. To demonstrate the nonlinear mechanism of the diode, consider an abrupt p–n junction diode, shown in Fig. 9, excited by an applied voltage V_a

Figure 9. p-n junction diode structure.

[46]. Muller and Kamins [46] show that

$$X_d = X_p + X_n = \left[\frac{2\epsilon}{q} (\phi - V_a) \left(\frac{1}{N_a} + \frac{1}{N_d} \right) \right]^{1/2} \quad (6)$$

$$X_p = \left(\frac{2\epsilon(\phi - V_a)}{qN_a(1 + N_a/N_d)} \right)^{1/2} \quad (7)$$

$$X_n = \left(\frac{2\epsilon(\phi - V_a)}{qN_d(1 + N_d/N_a)} \right)^{1/2} \quad (8)$$

where

- X_p = reactance of depletion region extension into p-type semiconductor
- X_n = reactance of depletion region extending into the n-type semiconductor
- X_d = reactance of total depletion region
- ϕ = built-in potential
- V_a = applied voltage
- N_a, N_d = semiconductor dopant concentrations
- ϵ = permittivity

By charge neutrality, we obtain

$$N_a X_p = N_d X_n \quad (9)$$

$$Q = qN_d X_n = qN_a X_p \quad (10)$$

$$dQ = qN_d dX_n = qN_a dX_p \quad (11)$$

$$C_j(V_a) = \frac{dQ}{dV_a} = \frac{dQ}{dX_p} \frac{dX_p}{dV_a} \quad (12)$$

$$= qN_a \left(\frac{\epsilon}{2qN_a(1 + N_a/N_d)(\phi - V_a)} \right)^{1/2} \quad (13)$$

$$= \left(\frac{q\epsilon N_a N_d}{2(N_a + N_d)} \right)^{1/2} \frac{1}{\sqrt{\phi - V_a}} \quad (14)$$

$$= \frac{C_{j0}}{\sqrt{1 - V_a/\phi}} \quad (15)$$

where

$$C_{j0} = \left(\frac{q\epsilon N_a N_d}{2(N_a + N_d)} \right)^{1/2} \quad (16)$$

Equation (15) shows that the magnitude of the junction capacitance varies nonlinearly as a function of applied voltage V_a , which is essential for generating frequency harmonics when a sinusoidal voltage is added to V_a . Using a binomial series expansion on Eq. (15) yields

$$C_j(V_a) = C_{j0} \left(\frac{1 - V_a}{\phi} \right)^{-1/2} = C_{j0} \left[1 + \frac{1}{2} \left(\frac{V_a}{\phi} \right) + \frac{3}{8} \left(\frac{V_a}{\phi} \right)^2 - \frac{5}{16} \left(\frac{V_a}{\phi} \right)^3 + \dots \right] \quad (17)$$

$$= \alpha_0 + \alpha_1 V_a + \alpha_2 V_a^2 + \alpha_3 V_a^3 + \dots \quad (18)$$

$$= \sum_{i=0}^{\infty} \alpha_i V_a^i \quad (19)$$

where

$$\alpha_0 = C_{j0}$$

$$\alpha_1 = \frac{C_{j0}}{2\phi}$$

$$\alpha_3 = -\frac{5C_{j0}}{16\phi^3}$$

\vdots

From Eqs. (12) and (18), we obtain

$$dQ(V_a) = C_j(V_a) dV_a \quad (20)$$

$$Q(V_a) = \int C_j(V_a) dV_a \quad (21)$$

$$= \int (\alpha_0 + \alpha_1 V_a + \alpha_2 V_a^2 + \dots) dV_a \quad (22)$$

$$= \alpha_0 V_a + \frac{1}{2} \alpha_1 V_a^2 + \frac{1}{3} \alpha_2 V_a^3 + \frac{1}{4} \alpha_3 V_a^4 + \dots \quad (23)$$

$$= \sum_{i=0}^{\infty} \alpha'_i V_a^{i+1} \quad (24)$$

where

$$\alpha'_0 = \alpha_0$$

$$\alpha'_1 = \frac{1}{2} \alpha_1$$

$$\alpha'_2 = \frac{1}{3} \alpha_2$$

\vdots

Demonstrating the effect of applying a sinusoidal signal across the p-n junction, the current across the diode can be calculated from

$$I(t) = \frac{dQ}{dt} \quad (25)$$

Inserting Eq. (23) into Eq. (25) with the p-n junction excited by the sinusoidal signal $V_a = \cos \omega t$ gives

$$Q = \alpha_0 V_a + \frac{1}{2} \alpha_1 V_a^2 + \frac{1}{3} \alpha_2 V_a^3 + \dots \tag{26}$$

$$= C_{j0}(\cos \omega t) + \frac{C_{j0}}{4\phi} \cos^2 \omega t + \frac{C_{j0}}{8\phi^2} \cos^3 \omega t + \dots$$

$$= \frac{C_{j0}}{8\phi^2} + \left(C_{j0} + \frac{3C_{j0}}{32\phi^2} \right) \cos \omega t + \frac{C_{j0}}{8\phi} \cos 2\omega t$$

$$+ \frac{C_{j0}}{32\phi^2} \cos 3\omega t + \tag{27}$$

and inserting Eq. (27) and differentiating gives

$$I(t) = \frac{dQ}{dt}$$

$$= -\omega + \left(C_{j0} + \frac{C_{j0}}{32\phi^2} \right) \sin \omega t$$

$$- \frac{2\omega C_{j0}}{8\phi} \sin 2\omega t - \frac{3\omega C_{j0}}{32\phi^2} \sin 3\omega t + \tag{28}$$

This result illustrates the various frequency harmonics produced by the p-n junction when excited by a sinusoidal source and demonstrates the nonlinear mechanism by which the semiconductor diode produces harmonic generation. This variable capacitance has led semiconductor diodes, varactors, and the like to be vital components aiding microwave engineers in nonlinear circuit development.

2.3.1. Voltage–Capacitance and Charge–Capacitance Characteristics. As previously stated, harmonic generators utilizing the nonlinear capacitance characteristics of varactors are often employed throughout the microwave industry by researchers and designers. The voltage– and charge–capacitance characteristics of the varactor diode are important in analyzing and studying the behavior of diodes. This section will discuss the relationships between the voltage and the capacitance and between the charge and the capacitance, since they are often utilized in studying the performance and the design of passive frequency multipliers.

We refer to the diode example above along with Eqs. (12) and (15), which are restated below [18]:

$$C_j(v) = \frac{dQ}{dv} = \frac{C_{j0}}{1 - v/\phi^m} \tag{29}$$

where

- v = voltage across the junction in the absence of any applied bias
- ϕ = built-in potential
- C_{j0} = zero-bias junction capacitance
- m = index number ($\frac{1}{2}$ for abrupt junctions, and for linearly graded junctions)

Scanlan (18) indicates that the minimum capacitance (C_{\min}) occurs at the reverse breakdown voltage ($v = -V_R$)

and the junction capacitance at this bias is

$$C_{\min} = C_j(-V_R) = \frac{C_{j0}}{(1 + V_R/\phi)^m} \tag{30}$$

Letting $V_0 = V_R + \phi$ and rewriting Eq. (30) gives

$$C_{j0} = C_{\min} \left(1 + \frac{V_R}{\phi} \right)^m$$

$$= C_{\min} \left(1 + \frac{V_0 - \phi}{\phi} \right)^m \tag{31}$$

and inserting Eq. (31) in Eq. (29) gives

$$C_j(v) = \frac{C_{\min} \left(1 + \frac{V_0 - \phi}{\phi} \right)^m}{\left(1 - \frac{v}{\phi} \right)^m}$$

$$= C_{\min} \left(\frac{V_0}{\phi - v} \right)^m \tag{32}$$

From Eq. (29)

$$dQ = C_j(v)dv \tag{33}$$

and inserting Eq. (32), we obtain

$$Q(v) = \int C_j(v)dv$$

$$= -\frac{C_{\min} V_0^m}{1 - m} (\phi - v)^{1-m} + k \tag{34}$$

where k is the constant of integration. When $v = \phi$, the voltage across the junction is zero and the charge is zero, which indicates that $k = 0$ as well. This allows Eq. (34) to be rewritten as follows, where the charge is represented as a function of the voltage:

$$Q(v) = -\frac{C_{\min} V_0^m}{1 - m} (\phi - v)^{1-m} \tag{35}$$

The depletion region reactances X_p , X_n and the electric field across p-n junctions increase as the reverse bias increases [46]. Intuitively, there are physical limitations to these increases, as governed by the structure of the junction and the dopant concentrations. As the reverse bias increases, eventually a voltage is encountered where the barrier to current flow is broken, and current flow increases substantially. The voltage at which this occurs is defined as the breakdown voltage ($v = -V_R$). At the breakdown voltage, Eq. (35) gives

$$Q(-V_R) = Q_R = -\frac{C_{\min} V_0^m}{1 - m} (\phi + V_R)^{1-m} \tag{36}$$

and recalling that $V_0 = V_R + \phi$ gives

$$Q(-V_R) = Q_R = -\frac{C_{\min} V_0}{1 - m} \tag{37}$$

Now, dividing Eq. (35) by Eq. (37) gives

$$\begin{aligned} \frac{Q(v)}{Q_R} &= \frac{\frac{C_{\min} V_0^m}{1-m} (\phi - V_R)^{1-m}}{\frac{C_{\min} V_0^m}{1-m}} \\ &= \left(\frac{\phi - v}{V_0} \right)^{1-m} \end{aligned} \quad (38)$$

This expression relates the charge across the junction in terms of breakdown characteristics (V_R , Q_R) and the minimum capacitance (C_{\min}).

Historically, in the literature, the capacitance is used in defining the elastance [18,19]:

$$S(v) = \frac{1}{C(v)} \quad \text{and} \quad S_{\max} = \frac{1}{C_{\min}} \quad (39)$$

This allows Eq. (32) to be rewritten in terms of the elastance as shown below, where the elastance is written as a function of voltage:

$$\frac{C(v)}{C_{\min}} = \left(\frac{V_0}{\phi - v} \right)^m = \frac{S_{\max}}{S(v)} \quad (40)$$

or

$$\frac{S(v)}{S_{\max}} = \left(\frac{\phi - v}{V_0} \right)^m \quad (41)$$

Referring back to Eq. (38), the charge $Q(v)$ is expressed as a function of v . Alternatively, Eq. (38) can be rearranged to give the voltage as a function of the charge:

$$\begin{aligned} v(Q) &= \phi - V_0 \left(\frac{Q}{Q_R} \right)^{1/(1-m)} \\ &= V_0 - \phi - V_0 \left(\frac{Q}{Q_R} \right)^{1/(1-m)} \end{aligned} \quad (42)$$

and therefore

$$\begin{aligned} v + V_R &= V_0 \left[1 - \left(\frac{Q}{Q_R} \right)^{1/(1-m)} \right] \\ &= V_0 \left[1 - \left(\frac{Q}{Q_R} \right)^\gamma \right] \end{aligned} \quad (43)$$

where

$$\gamma = \frac{1}{1-m}$$

Equations (29)–(43) are mathematical expressions for the characteristics between the voltage, charge, capacitance, and elastance of p-n junction semiconductor diodes. Researchers and designers often use these expressions, among others, in analyzing diodes and incorporating diodes into multiplier designs.

2.4. Power Considerations

A discussion on power flow into and out of the nonlinear device is very useful in understanding the behavior of passive nonlinear devices and their usefulness in designing passive frequency multipliers, as it can be used to predict optimum power and conversion efficiency. Here we will discuss the power flow at the various harmonics and their relation to the performance of frequency multiplier designs, which leads to a fundamental understanding of the limitations imposed by diodes.

Manley and Rowe [42] have provided a general relation, which is commonly used throughout the microwave industry, for discussing the power flow of a particular class of nonlinear elements. They derive general power relations that govern single-valued nonlinear elements such as nonlinear inductors and capacitors. Their final derivations, independent of input power, give two independent equations characterizing the power content at various harmonics.

Manley and Rowe perform their derivation on an ideal nonlinear capacitor, but state that a similar analysis can be performed on a nonlinear inductor. Their analysis begins by evaluating the voltage across the nonlinear capacitor, which is defined as some arbitrary function of the charge. Then, they write an equation for the charge across the capacitor represented in a Fourier series. From the charge, they are able to calculate the current in Fourier series form. Next, the voltage across the nonlinear capacitor is given in a Fourier series, from which the Fourier coefficients for the voltage are calculated using orthogonality. After further substitutions and integrations, they conclude with the following equations

$$\sum_n \sum_m \frac{mP_{mn}}{mf_1 + nf_2} = 0 \quad (44)$$

$$\sum_n \sum_m \frac{nP_{mn}}{mf_1 + nf_2} = 0 \quad (45)$$

where m and n are integers representing various harmonics and P_{mn} is the average power flowing into the nonlinear reactances at the frequencies mf_1 and nf_2 . These equations are significant in that they indicate that for an ideal, lossless capacitance (with $R_s = 0$ in Fig. 8), the sum of all inward power flows at the different frequencies must be zero. This indicates, theoretically, that on exciting the nonlinear capacitor at a fundamental frequency, the output power at the desired harmonic has the same magnitude as the input power of the fundamental. This is achieved *provided* all power at the undesirable harmonics has been reactively terminated, which ensures that no power is dissipated at these undesirable harmonics.

As an example demonstrating this procedure, consider exciting a nonlinear capacitor at the fundamental frequency f_1 ($m = 1$, $n = 0$). Then Eq. (44) gives

$$\frac{P_{10}}{f_1} + \frac{mP_{m0}}{mf_1} = 0 \quad (46)$$

or

$$P_{10} = - \sum_{m=2}^{\infty} P_{m0} \quad (47)$$

or in general, the sum of all powers flowing at the various harmonic frequencies must be zero. Equation (47) indicates that the input power P_{10} at the fundamental is the sum of the output powers at all harmonics combined. Therefore, if external embedding circuitry to which the nonlinear capacitor is connected is developed such that the power at all undesirable harmonics is reactively terminated, then the power delivered to the load at the desired harmonic can, theoretically, represent conversion efficiencies of 100% (17). Practical diodes, however, exhibit nonzero series resistance ($R_s \neq 0$), so that practical conversion efficiencies are less than 100%.

2.5. Optimization of Efficiency

Achieving optimum efficiency is an essential goal in the design of any component. In the case of passive multipliers, proper techniques should be employed in efforts to maximize the conversion efficiency of the multiplier and maximize the power delivered to the load at the desired harmonic.

The Manly–Rowe equations given above indicate that, theoretically, an ideal nonlinear capacitor can achieve 100% conversion efficiency. In practical applications, nonlinear capacitors (varactors) are not ideal components but have some loss. Therefore, as a general example, the varactor utilized in passive multiplier design should exhibit low series resistance (R_s) at the frequency and power level of operation [18,36]. Impedance matching at the input of the nonlinear device is also required, to ensure that the input power is efficiently coupled to the diode. Similarly, output impedance matching at the desired harmonic of interest should be implemented so that power generated in the nonlinear device at the output harmonic is efficiently transferred to the load. Significant real power should exist in the diode at the fundamental and the output harmonic of interest and low-loss resonators should be utilized as idler circuits [13,42–44,47], which will be discussed later in the article.

Archer and Batchelor [17] note that an equivalent-circuit model of a varactor diode embedded in external circuitry can be utilized to predict and optimize the performance of a passive multiplier. They give an equivalent circuit for a varactor multiplier, showing the connection between the varactor and the embedding network, as in Fig. 10. There, the embedding network models the impedance presented to the diode at the fundamental frequency and other harmonics. The two networks (embedding and equivalent diode circuit model) are optimized to obtain maximum power transfer between the embedding network and the reactance of the diode at the input fundamental frequency and the output harmonics. This optimization can be performed manually using the mathematical equations governing the response of the networks or through an optimization routine provided by a commercial circuit simulator.

The conversion efficiency is dependent on the large-signal diode currents and voltages, which are determined by the impedances presented to the diode at the fundamental and higher harmonic frequencies [17,18]. Simulations can be performed to optimize the conversion efficiency,

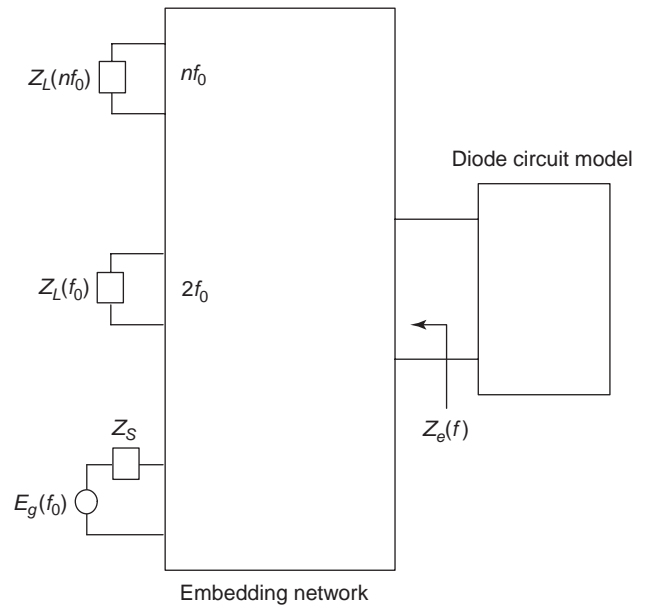

Figure 10. Equivalent network model of passive frequency multiplier.

utilizing the impedances presented to the diode in conjunction with the diode circuit model.

The steady-state large-signal voltage and current coefficients are V_k and I_k [17].

$$v_j(t) = \sum_k V_k e^{jk2\pi ft} \tag{48}$$

$$i_c(t) = \sum_k I_k e^{jk2\pi ft} \tag{49}$$

where f is the fundamental frequency. The predicted performance and thus the optimization of efficiency are determined after solving Eqs. (48) and (49) subject to the boundary conditions imposed by the diode and the embedding network [the embedding impedance $Z_c(f)$]. Such solutions have been calculated and presented by various authors [9,11,14–18,20–41], using idealized models, to obtain the nonlinear large-signal behavior of specific multipliers (doubblers, triplers, etc.). They present data on the efficiency, power handling, input and load resistances, and P_{max}/P_{in} , for example, versus frequency for various multipliers. Using such plots and data, theoretical optimization can be achieved for specific multiplier types.

In summary, it is important to optimize the performance of frequency multipliers. Chang et al. [29] state general guidelines for achieving this:

1. Good impedance matching should be provided at the input and output of the nonlinear device over the frequency range of interest, and all idler circuits terminated reactively with low loss.
2. At frequencies other than the fundamental, desired harmonic of interest, and idler harmonics, the nonlinear device should be mismatched to the embedding circuitry to minimize power loss.

3. The input and output networks should be isolated physically and electrically.

2.6. Idlers

An important concept in the fundamental development of passive frequency multipliers, as briefly mentioned in prior sections, is that of idler currents and idler circuits. Idler currents are currents flowing at frequencies other than the input fundamental frequency and output harmonic frequency, which are required for a particular class of passive multipliers [47]. This section will discuss the property of idlers and demonstrate the requirement of them for particular multiplier designs.

In Section 2.3.1, the voltage and charge relations of nonlinear varactors were discussed. Referring to Eq. (42), it is observed that a square-law characteristic is exhibited by an abrupt junction diode ($m = \frac{1}{2}$); the voltage is proportional to the square of the charge [43]. Consider the condition in which the charge across the junction of an abrupt junction diode is sinusoidal at the fundamental frequency ($\omega = 2\pi f$)

$$Q(t) = Q_0 + Q_1 \cos \omega t \quad (50)$$

where Q_0 is the DC biasing component. Inserting Eq. (50) into Eq. (42) and using the trigonometric identities gives

$$v(Q) = \phi - V_0 \left(\frac{Q}{Q_R} \right)^2 \quad (51)$$

$$\begin{aligned} v(t) &= \phi - V_0 \left(\frac{Q_0 + Q_1 \cos \omega t}{Q_R} \right)^2 \quad (52) \\ &= \phi - \frac{V_0}{Q_R^2} \left(Q_0^2 + \frac{Q_1^2}{2} \right) - \frac{2V_0 Q_0 Q_1}{Q_R^2} \cos \omega t \\ &\quad - \frac{V_0 Q_1^2}{2Q_R^2} \cos 2\omega t \quad (53) \end{aligned}$$

From Eq. (53) it is observed that the voltage produced by the charge across the abrupt junction diode has a DC component, a component at the fundamental frequency, and a component at the second-harmonic frequency, but no component at any harmonic higher than the second, such as required for frequency triplers, quadruplers, and so on. The component at the second-harmonic frequency indicates that this diode is suitable for a frequency doubler, however. This example indicates that except for the case of the doubler, if currents flow only at the input and output frequencies, it is impossible to generate harmonics higher than the second with an *abrupt* junction varactor. This is an expected result due to the square law behavior of the varactor. Thus, in order to achieve output harmonics for $n > 2$, it is necessary for intermediate currents (idler currents) to flow in the varactor at specific harmonic frequencies.

The abrupt junction varactor can be regarded as providing a mechanism for frequency doubling (due to the square-law relationship mentioned previously) and for frequency mixing when idler currents are utilized [19].

In the case of mixing, currents flowing at specific harmonic frequencies are mixed with the fundamental frequency and with each other (if more than one is introduced) to produce additional currents at various harmonics. Therefore, introducing an idler current into an abrupt junction varactor at the second-harmonic causes the second-harmonic to mix with the fundamental frequency to produce an output at the third harmonic. This additional idler produces the component necessary for frequency tripler design.

Introducing additional currents into an abrupt junction varactor provides a means for the device to generate higher harmonics. This extends the use of abrupt junction varactors from frequency doublers to higher-order multipliers.

2.7. Analysis Techniques

Passive frequency multipliers are nonlinear circuits requiring solutions from large-signal circuit analysis. As stated in preceding subsections, the efficiency of passive multipliers utilizing diodes is affected by the diode parameters: the embedding impedance $Z_e(nf_0)$ at the fundamental and harmonic frequencies, the input power level P_{in} , and the bias voltage. Various techniques are utilized by researchers and designers for analyzing and optimizing nonlinear circuits and, specifically, passive multipliers. In some simple cases, analytic closed-form solutions may be obtained for optimizing the efficiency; however, for most cases the most convenient method is through numerical analysis. Some of these techniques include power series analysis, Volterra series analysis, and harmonic balance techniques where time-domain current and voltage solutions are sought that satisfy the diode boundary conditions and frequency-domain solutions are sought that satisfy the external circuit equations. Using these analysis techniques along with an accurate equivalent circuit model of the passive nonlinear device, the predicted performance of the device embedded in external circuitry can be obtained.

Since the analysis techniques for passive and active frequency multipliers are similar, the author refers further discussion on this topic to a later section, where a detailed discussion is presented on the analysis techniques mentioned above. The final section of this article deals with active frequency multipliers, but the analysis techniques are applicable for passive nonlinear devices as well.

2.8. Pertinent Properties of Passive Devices

The RF performance of passive multipliers is governed by, among other things, the pertinent properties of the nonlinear device. These properties can be divided into two categories [41]: (1) those affecting the efficiency of the multiplier and (2) those affecting its power-handling capability. Tolmunen [41] notes that the efficiency of the nonlinear diode is affected mostly by the cutoff frequency, which will be defined below, the strength of the nonlinearity, and the type of multiplication (resistive or reactive, as discussed in Section 2.1). The power-handling capability is affected by the device area, the extent of the nonlin-

earity, and the breakdown voltage, which was discussed in Section 2.3.1).

Focusing on varactor frequency multipliers, for efficient varactor operation, it is necessary, as expected, for the reactance of the junction capacitance of the varactor to be much larger than the device series resistance (R_s in Fig. 8) [17]. Therefore, this necessitates an upper frequency limit (cutoff frequency) on the usefulness of a given varactor [18]. The dynamic cutoff frequency is defined as [41]

$$f_{cd} = \frac{1/C_{min} - 1/C_{max}}{2\pi R_s} \tag{54}$$

where C_{min} and C_{max} are the minimum and the maximum capacitance of the varactor and R_s is the diode series resistance. Therefore, for optimum performance, the cutoff frequency should be greater than the frequency of application.

A sharp nonlinearity in the C - V response of the varactor results in efficient harmonic generation, since the nonlinearity of the device is responsible for harmonic generation. The advantages of a sharp or steep nonlinearity depend on the extent of the voltage swing across the diode generated by the input power. Varactors have high input impedance, thus enabling large voltage swings to be generated across the device. A diode with high nonlinearity, even at low input power levels, produces significant voltage swings, and therefore is capable of achieving optimum performance. Typically, the optimum conditions occur in applications where the nonlinearity extends over voltages comparable to the voltage swing of the input power signal.

Tolmune [41] states that the power-handling capability is proportional to the average capacitance of the device area. As in the case of other high-power devices, diodes with large surface areas are able to handle larger input power levels and consequently produce larger RF current. In practical diode applications, however, this may result in matching problems, because matching the diode over a broad voltage range is quite challenging, and thus trade-offs have to be made. As will be shown in the discussion of design techniques in the last section, another approach commonly used to improve the power-handling capability is to stack devices in series or parallel. This configuration increases the total area of the diode, thus allowing it to sustain larger voltage swings. Large device arrays are useful in high-power applications.

2.9. Classical Realizations

The previous sections highlighted some of the basic properties of passive multipliers and the fundamental

Figure 11. Series-mounted passive diode frequency multiplier.

Figure 12. Shunt-mounted passive diode frequency multiplier.

characteristics of nonlinear components, which are utilized extensively in passive multiplier development. As mentioned, the nonlinear component is embedded in external circuitry to accentuate the desired harmonic. As seen throughout the literature, various topologies exist for realizing passive multipliers, revealing the interaction between the embedding circuitry and the nonlinear device. This section will highlight some of the classical realizations utilized extensively by microwave designers and researchers.

Scanlan [18] and Leeson and Weinreb [20] have presented some simple, classical realizations for passive multipliers, as shown in Figs. 11 and 12. Scanlan identifies the passive multiplier topology shown in Fig. 11 as a series model where the varactor diode is series-mounted with the embedding network. The input and output networks F_1 and F_N , respectively, represent ideal filters at the fundamental frequency and the N th harmonic, which permit voltages to exist at the fundamental frequency and the N th harmonic, respectively.

In other words, F_1 acts to short-circuit all frequencies other than the fundamental frequency, and F_N acts to short-circuit all frequencies other than the harmonic frequency of interest. Although more sophisticated filters may be required, parallel LC networks can be synthesized for F_1 and F_N at their respective frequencies, as shown by

$$\omega_0 = \frac{1}{\sqrt{LC}} \tag{55}$$

Figure 12, on the other hand, shows the shunt diode topology for passive frequency multiplier design using a nonlinear diode. Again, the input and output networks, F_1 and F_N , respectively, represent ideal filters at the

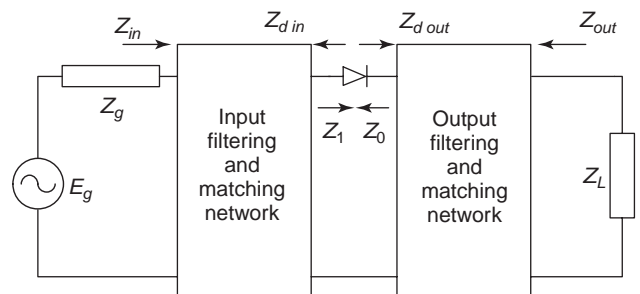

Figure 13. Block diagram of series-mounted diode frequency multiplier.

Figure 14. Block diagram of shunt-mounted diode frequency multiplier.

fundamental frequency and the N th harmonic, which permit currents to flow at the fundamental frequency and the N th harmonic, respectively. This indicates that F_1 acts to open-circuit all frequencies other than the fundamental frequency and F_N acts to open-circuit all frequencies other than the harmonic frequency of interest. Similarly, F_1 and F_N can be synthesized as series LC networks resonant at the fundamental frequency and the output harmonic frequency of interest.

Faber (13) has discussed the realizations presented by Scanlan, with emphasis on achieving optimum efficiency of the multiplier. Block diagrams of the realizations (series-mounted and shunt-mounted) shown by Faber are given in Figs. 13 and 14. Recall from the Section 2.4 that the Manly-Rowe power equations imply that it is theoretically possible to deliver all input power at the fundamental frequency to the output load at the desired harmonic of interest, thereby achieving 100% efficiency. Achieving optimum efficiency requires that should not be dissipated at any of the undesired harmonics in either the input network or the output network.

This indicates, with regard to Fig. 13, that

$$\text{Re } Z_{d, \text{out}}(f) \approx 0 \tag{56}$$

$$\text{Re } Z_{d, \text{in}}(nf) \approx 0 \tag{57}$$

when the input and output networks contribute to the device reactance compensation. If the conditions represented by Eqs. (56) and (57) are met, power is not dissipated at the fundamental frequency in the output network and power is not dissipated at any of the harmonic frequencies in the input network, respectively.

Similarly, for Fig. 14 the following conditions are sought:

$$\text{Re } Y_{d, \text{out}}(f) \approx 0 \tag{58}$$

$$\text{Re } Y_{d, \text{in}}(nf) \approx 0 \tag{59}$$

Figure 15. Series-connected diode multiplier topology.

Figure 16. Parallel-connected diode multiplier topology.

Apart from the realizations mentioned previously, several variations of these topologies have been utilized as well. At RF and microwave frequencies several diodes connected in series or parallel have been utilized to handle cases where there was insufficient power, voltage, or current-handling capability of a single device or where the single-device impedance levels were inconvenient. Connecting m diodes in series (stacking) produces a breakdown voltage m times as high, and m diodes in parallel provide m times higher current [13]. Therefore, topologies such as those shown in Figs. 15 and 16 are commonly encountered.

The circuit complexity of passive multipliers can be increased even further. Some more complicated topologies are shown in Figs. 17–20 [13,17,18,30]. The antiparallel topology of Fig. 17 produces currents containing components at the fundamental frequency and higher odd-order harmonics. This can substantially simplify the design of input and output filters in the development of odd-order multipliers.

Figure 18 shows the antiseriess topology utilizing a transformer between the input signal and the diode circuit. The transformer provides a 180° phase shift between the input signal voltages feeding the two diodes. Therefore, the current components cancel in the load, producing no voltage across the load at the fundamental frequency. In contrast to the antiparallel topology, the antiseriess topology provides even-order harmonics and therefore leads to less stringent requirements on the input and output filters.

Figure 19 utilizes a transformer in the antiparallel series topology as well. Faber notes that the odd-order components are in phase, so that when the odd-order components flow through the transformer primary winding, they do not excite the load mesh. The even-order components, on the other hand, are of opposite phase, so they cancel in the input signal source branch but excite current in the load mesh. This action causes the antiparallel series topology to produce even-order harmonic multiplication.

Figure 17. Antiparallel diode pairs.

Figure 18. Antiseries diode pairs.

Figure 20. Bridge frequency multiplier.

Finally, Fig. 20 shows a bridge frequency multiplier. Similarly to full-wave rectifiers, bridge rectifiers can be used to produce even-order harmonic multiplication.

2.10. Passive Multiplier Design Techniques

2.10.1. Existing Design Techniques. Numerous techniques exist for the design of passive multipliers utilizing various topologies, many of which are presented in Section 2. This section presents, in perusal of the available literature, various existing design techniques, and in some cases details their performance.

A fundamental topological representation for realization of passive RF/microwave multiplier circuits is shown in Fig. 21, where networks N_1 and N_2 are on the input and output of the nonlinear device, respectively. As mentioned in a previous section, multiplier performance is governed by the embedding circuitry (networks N_1 and N_2) and the pertinent properties of the nonlinear device. Authors have used various networks in the synthesis of N_1 and N_2 . Traditional synthesis have included short-circuited and open-circuited stubs at the fundamental frequency and various harmonics [16,24,25], impedance matching and filter networks [15,26–29], and waveguides and filters [11,14,31–33,36–40].

As shown in Fig. 21, in the synthesis of N_1 and N_2 , several authors have utilized short-circuited and open-circuited stubs for low-frequency and high-frequency applications. Gavan and Peled [16], for example, use microstrip stubs in the development of a 1250–2500-MHz step recovery diode frequency doubler. They synthesize N_1 with a 0/8 stub (at $2f_0$) on the input network to provide a short circuit for the second-harmonic signal, and synthesize N_2 with a 0/4 microstrip stub (at f_0), which provides a short circuit to ground for the fundamental frequency. Using this design technique, they achieve conversion gain efficiency of 75%, but do not present any data on harmonic suppression. Chen et al. [24,25] perform a 47–94-GHz Schottky barrier

varactor diode frequency doubler design utilizing MMIC technology. They use a 0/2 short-circuited stub (at $2f_0$) on the input network to create an RF short circuit at 94 GHz, and a 0/4 short-circuited stub (at f_0) on the output to create an RF short circuit at the fundamental frequency. This high-frequency MMIC design provided a maximum conversion efficiency of 25% (6 dB conversion loss).

Several authors have developed passive frequency multipliers utilizing impedance-matching networks and filters in the input and output networks [15,26–29]. The impedance-matching networks are employed to match the input and output impedances of the nonlinear device, while the filters are used to attenuate specific harmonics. Gavan and Peled [15] designed a 1250–2500-MHz varactor frequency doubler utilizing the shunt varactor topology shown in Fig. 14 along with a lowpass filter in the input network and a two-section coupled bandpass filter at 2500 MHz in the output network. This design technique yields a maximum conversion gain efficiency of 71%. Chang et al. [29] developed a varactor 46–92-GHz frequency doubler utilizing a topology similar to that shown in Fig. 14. Input and output networks are synthesized with filters and additional matching networks to achieve optimum power transfer at the source and load. This design achieves a conversion loss of 8–9 dB over a 500 MHz bandwidth.

Furthermore, some authors have chosen to utilize a balanced topology for the design of frequency multipliers [30–33]. A block diagram of a balanced design topology is shown in Fig. 22. In typical balanced circuits, a 180° phase difference in the input signals feeding the nonlinear device produces fundamental signals and other odd-harmonic signals with opposite phase. By destructive interference, the fundamental and other odd harmonics cancel, giving good harmonic suppression, while the second-harmonic signals, on the other hand, interfere constructively, thereby enhancing the output signal at the second-harmonic. This design technique will be revisited in the discussion of active frequency multipliers.

Figure 19. Antiparallel series-connected diodes.

Figure 21. Passive frequency multiplier realization.

Figure 22. Block diagram of typical passive balanced frequency multiplier.

Bitzer [30] utilized a balanced topology similar to that shown in Fig. 19 and presented again in Fig. 23 to design a broadband Schottky barrier diode frequency doubler. In this structure, the input signal is fed antiphase to the diodes in order to switch on one diode patch every half-cycle. The rectified output signal is coupled to the load via a balun. As mentioned previously, the fundamental signals and other odd-harmonic signals from the diodes have opposite phase and therefore, by destructive interference, cancel, giving good harmonic suppression. The second-harmonic signals interfere constructively, thereby enhancing the output signal at the second-harmonic. Bitzer's data show that from 6–18 GHz, the conversion loss is 9.5 ± 1 dB and harmonic suppression > 15 dBc.

Archer [33] developed a balanced varactor diode 85–116-GHz frequency doubler similar to the typical topology shown in Fig. 22. Archer uses a waveguide T junction as a power divider on the input to feed two varactor diodes. On the output, a matched waveguide hybrid T junction combines the power at the output port. Using this design topology, a maximum conversion efficiency of 16.5% was achieved. Unfortunately, Archer does not present any data on harmonic suppression.

Waveguide circuitry provides an efficient means of realizing frequency multipliers [14]. Waveguides provide low loss, possess desirable highpass filter characteristics, and provide a good thermal path for dissipated power. Energy is typically coupled/decoupled from the input and output of the waveguide through a lowpass filter. Various authors have utilized waveguide circuitry in high-frequency multiplier designs [11,14,31–33,36–40]. Raisanen [36] notes that for frequencies from 100 ~ 500 GHz, for example, the highest efficiencies and highest output powers have been achieved with waveguide multipliers.

Figure 23. Antiparallel balanced diode configuration.

Archer [38] has developed a varactor frequency doubler at 260 GHz utilizing waveguides and filters. The input network consists of a lowpass filter and a waveguide. The lowpass filter is a seven-section design that passes the fundamental signal while attenuating higher-order harmonics. The output network consists of a $\lambda_0/4$ impedance transformer and a waveguide. Using this design technique, Archer achieves a conversion gain efficiency of 20% for narrowband applications (5% bandwidth) and conversion efficiencies of 10% for wider-band applications (8% bandwidth).

Mott [11] has developed a varactor frequency doubler design at a lower frequency (19–38 GHz), utilizing waveguides as well. Mott synthesized the input network with a waveguide, a $\lambda_0/4$ impedance transformer, and a lowpass filter and notes that the characteristic impedance of the filter is synthesized so that it equals the real part of the diode input impedance. The output network consists of an output waveguide impedance transformer synthesized to present the optimum load impedance to the output of the diode. Mott achieves a conversion efficiency of 60% (conversion loss of 2.2 dB) over a 1 dB output bandwidth of 640 MHz.

At higher frequencies, frequency multipliers are capable of achieving high conversion efficiency at low input powers, but the output power tends to saturate at rather low power levels [31]. The use of series arrays of diodes provides an attractive approach to overcoming this defect. Cascading multiple-diode junctions increases the breakdown voltage and provides greater power-handling capability [9]. A series array of n identical diodes can handle n^2 times as much power as a single diode [31]. For these reasons, various authors have utilized series- and parallel-stacked diodes in passive design, as shown in Figs. 15 and 16, to improve the power-handling capability of passive frequency multipliers [9,14,30,31,34,35]. Chu [34] developed an 18–36-GHz stacked-diode frequency doubler utilizing two series diodes. The input/output-matching circuits consist of $\lambda_0/4$ impedance transformer sections with open-circuited stubs resonant at the input and output frequencies. This design produced a maximum output power of 150 mW with a conversion efficiency of 24%, and a peak conversion efficiency of 35% at 95 mW of output power.

2.10.2. State of the Art. In the development of passive frequency multipliers as well as other technologies, researchers and designers are constantly pushing the leading edge in attempts to achieve better performance. In passive frequency multipliers, designers desire, among other things, greater power-handling capability and greater conversion gain efficiency. This section highlights state-of-the-art developments in passive frequency designs.

The available literature indicates that the leading edge of technology in passive designs is not focused so much on developing new design topologies as on new methods of fabricating new semiconductor diodes, particularly for millimeter and submillimeter-wavelength applications [25,36,39,41]. It has been demonstrated that the performance of passive frequency multipliers is highly dependent on the pertinent properties of the nonlinear device.

Therefore, it is reasonable to expect that efforts at improving the performance of passive frequency multipliers would begin with the nonlinear device.

Over the years, the GaAs Schottky varactor diode has served as one of the most important nonlinear elements for frequency multipliers [36,41]. Consequently, growing interest in novel diodes has brought to light new structures showing excellent theoretical performance comparable to or better than the conventional Schottky varactor. In comparison with the Schottky varactor, these new diodes have potential advantages, such as stronger nonlinearity or a special symmetry, which make them very attractive for millimeter and submillimeter-wave frequency multiplication. Stronger nonlinearities allow more efficient higher-order harmonic generation with smaller input signal levels [36]. These novel diodes include single-barrier varactors (SBVs), quantum barrier varactors (QBV), barrier-intrinsic- n^+ (BIN) diodes, and high-electron-mobility varactors (HEMVs).

The quantum well diode (QWD) has been studied since 1970 [41]. The QWD is a heterojunction diode in which a thin undoped layer between two thin barriers forms the quantum well. Its high speed and negative differential resistance make it attractive for millimeter-wave oscillators. Because of its symmetric structure, the highly nonlinear antisymmetric I - V curves and symmetric C - V characteristics result in odd-harmonic generation. Therefore, as expected, QWDs have been utilized in tripler designs, with some designs going up to 200 GHz. Raisanen [36] notes that the resulting output powers from these tripler designs are promising, but are lower than those achieved from the best Schottky multipliers. Replacing the quantum well with a single thicker barrier produces a QBV or a SBV, where the nonlinear current is suppressed but the nonlinear C - V characteristic remains. Because of its symmetric C - V characteristic, this diode is also attractive for tripler and quintupler design. SBV triplers have been developed up to 280 GHz, producing output powers of 2.5 mW [36].

The BIN diode has been proposed as an improved diode for harmonic generation [41]. Unlike QWDs or SBVs, which consist of a heterostructure and two ohmic contacts as terminals, the BIN diode is essentially a Schottky varactor with a unique doping profile that yields a sharper C - V characteristic than the Schottky varactor. The BIN diode consists of a Schottky contact, a barrier layer, and an intrinsic layer. Tolmunen [41] notes that connecting two BIN diodes back to back produces a symmetric C - V characteristic.

The HEMV is a modification of the planar Schottky varactor where a heterostructure is used. The electrons in this device have higher mobility, as in HEMTs (which are modeled and used in active multiplier designs in the final section), thus making it attractive for high-frequency applications. In a varactor, this structure produces a strongly nonlinear capacitance, but with an undesirable high parasitic capacitance associated with its structure.

Tolmunen [41] has designed several multipliers utilizing the abovementioned novel devices at 200 GHz. The conclusions from his study reveal that the sharp C - V characteristic of the BIN diodes improves the performance

at low input powers (10 mW) and makes them the most effective of all the devices. The SBV yields excellent theoretical performance, but is less efficient because of its high resistive losses. It does however, provide the best performance at high input power levels.

As researchers and designers continue to push the envelope of technology for higher-performance devices, these novel devices will be utilized extensively, particularly at submillimeter and millimeter frequencies.

3. ACTIVE FREQUENCY MULTIPLIERS

Another class of frequency multipliers encompasses those that are designed and constructed utilizing active nonlinear devices. As discussed earlier, multipliers require a nonlinear element for harmonic production [133–135]. Active frequency multipliers, as shown in the block diagram in Fig. 24, utilize the nonlinear characteristics of an active element properly biased to produce an output spectrum rich in harmonics when excited by a sinusoidal source. Typically, the active element consists of any of the transistor classes, which include the BJT, HBT, field-effect transistor (FET), MESFET, HEMT, and PHEMT.

Active multipliers offer various advantages over their passive counterparts. An example, which will be discussed in the following section, is in the conversion gain. Active multipliers are capable of producing conversion gains greater than 0 dB, whereas passive multipliers are not. This section will also discuss the development of active frequency multiplier technology, including the fundamental performance descriptions, and pertinent properties of the active device (which include modeling and quantification of the nonlinear properties). Design techniques of active frequency multipliers are discussed in Section 4.1.

In the systematic design of any *linear microwave amplifier*, an essential initial step in modern engineering practice, is the computer analysis of the proposed topology utilizing such tools as the HP/Agilent ADS simulator. An essential ingredient in this process is the use of realistic circuit models, some of which have required many worker-hours of development as exemplified by the microstripline models in that simulator. Simultaneously, realistic models of the transistor (FET, HEMT, HBT, etc.) are utilized. This model may be in the form of a physical model, measured S -parameter data, or an empirical model. In any case, some reasonable active device representation is used.

Such has *not* been the case for active microwave frequency multipliers until quite recently. These recent computer-based designs will be described in Section 4.2.

Figure 24. Block diagram of active frequency multiplier.

Numerous authors have presented discussions of active frequency multipliers that will be referenced throughout this presentation. A systematic design approach for development of active frequency multipliers, which is analogous to that for linear amplifiers, utilizes computer-based simulation. As a result, one of the primary concerns is the ability to accurately predict the linear and nonlinear performance of the active device before embedding it into other networks, which is typical in the development and design of frequency multipliers. Several authors [48–86,129,158–163] have presented details and techniques for modeling the active devices. Each author delineates the various advantages and disadvantage of their study. Techniques for modeling HEMTs are presented as an example in this discussion, since they are employed in the illustrative multiplier designs in later sections.

3.1. Fundamental Performance Descriptions

As discussed previously, frequency multipliers are nonlinear circuits that convert signals at an input fundamental frequency (f_0) into signals at a harmonic frequency multiple of the input frequency (nf_0). Several performance descriptions and parameters represent the effectiveness of frequency multipliers for frequency conversion. The objective of this section is to identify and discuss the prominent fundamental performance descriptions of active frequency multipliers.

Active frequency multipliers utilize the nonlinear characteristics possessed by any of the several properly biased transistor classes (BJT, FET, etc.). Exciting the nonlinear device with a fundamental frequency provides an output spectrum rich in frequency harmonics. One of the main advantages of active multipliers is their capability of producing positive conversion gains (conversion gains greater than 0 dB). The *conversion gain* of a frequency multiplier is defined as the ratio of the output power for a particular harmonic delivered to the load to the fundamental input power. Maximizing the conversion gain is crucial in the development and design of frequency multipliers. In the specific case of frequency doublers, an input signal at the fundamental frequency (f_0) is converted into a signal at the second-harmonic ($2f_0$). Mathematically, the conversion gain can be expressed as [87]

$$\text{Conversion gain} = \frac{P_{\text{out}}(2f_0)}{P_{\text{in}}(f_0)} \quad (60)$$

or

$$\text{Conversion gain (dB)} = P_{\text{out},2f_0}(\text{dBm}) - P_{\text{in},f_0}(\text{dBm}) \quad (61)$$

Frequency doublers, which will be presented in the next section, have been designed and developed exhibiting conversion gains approaching 12 dB. Alternatively, the conversion gain can be expressed as a percentage [88]. This percentage is defined as the ratio of the input power at the fundamental to the output power delivered to the load at the desired harmonic. Using the example of the frequency doubler, this can be represented as

$$\eta = \frac{P_{\text{in}}(f_0)}{P_{\text{out}}(2f_0)} \times 100\% \quad (62)$$

Similarly, as in the consideration of RF amplifiers, the effectiveness of the conversion of DC power into AC power is also a meaningful parameter in discussing frequency multipliers. In the case of frequency doublers, the consideration is focused on the effectiveness of converting DC power into AC power at the second-harmonic. A general expression for the DC-to-RF efficiency can be represented as [88]

$$\text{DC-to-RF} = \frac{P_{\text{out}}(\text{harmonic})}{P_{\text{DC}}} \times 100\% \quad (63)$$

From this equation, it is observed that optimum DC-to-RF efficiency performance is achieved when maximum RF power is produced from minimum DC power. For the class of frequency multipliers presented in the next subsection, DC-to-RF efficiencies of up to 24% have been obtained.

The transfer of power from the fundamental frequency at the generator to the desired harmonic at the load is dependent, amongst other things, on the return loss or voltage standing-wave ratio (VSWR) of the input port and the output port of the multiplier circuitry. The return loss is a measure of the impedance match of the input and output ports of the frequency multiplier to the source impedance and the load impedance. Computer simulations for HEMT frequency doublers are performed in Section 3.4.3. (see Tables 3 and 4) delineating the advantages of good impedance matching. In these simulations significant improvements in the conversion gain are achieved in the cases where the input and output ports are impedance-matched.

As discussed previously, frequency multipliers are harmonic generators that produce an output harmonic (nf_0) when excited by a fundamental frequency (f_0). In the generation of the desired harmonic, undesired harmonics are generated as well. As an example, in the case of a frequency doubler, the desired output harmonic is $2f_0$, but other harmonics at f_0 , $3f_0$, $4f_0$, are generated. The ability of the multiplier to suppress the undesired harmonics is another key performance factor. This property of the frequency multiplier is called *harmonic suppression*. It is defined mathematically as

$$\text{Suppression}_{(mf_0)}(\text{dBc}) = P_{0(nf_0)}(\text{dBm}) - P_{0(mf_0)}(\text{dBm}) \quad (64)$$

where nf_0 is the desired frequency harmonic and mf_0 is an undesired harmonic. In the case of the frequency doubler, $n = 2$ and $m = 1, 3, 4$, which indicates that the desired harmonic is $2f_0$ and harmonic suppression is calculated for the fundamental frequency (f_0), third-harmonic frequency ($3f_0$), and so on.

A previously discussed application of frequency multipliers is their use in communication systems in receivers and transmitters. A performance description of receivers in communication systems, and therefore of frequency multipliers used in receivers, is their *dynamic range*, defined as the range of input or output power levels where signals can be processed with high quality without signal distortion. At low power levels, the dynamic range is limited by the sensitivity to the noise floor or the minimum

detectable signal as governed by the noise floor. At higher powers, the dynamic range is limited by the acceptable level of signal distortion or, specifically, by the power level where the small-signal gain has been compressed by 1 dB [89,90].

Using these definitions for the dynamic range, the optimum dynamic range for frequency multipliers is achieved when the power range between the noise floor and signal distortion is maximized. It involves tradeoffs between the input signal drive level, the noise floor level, and the output signal distortion.

Another important multiplier performance parameter is the operational bandwidth. *Bandwidth* is defined as the frequency band where specific performance specifications are met; typically, one uses the conversion gain. Specifying a -3 dB bandwidth indicates the frequency band where the conversion gain decreases by 3 dB from its peak. Optimizing multiplier bandwidth is an important task to the designer. Typically, tradeoffs have to be made in the performance of the devices to achieve high bandwidths. As an example, higher conversion gains are achieved for narrow-bandwidth designs, and usually wide-bandwidth designs are accomplished at the expense of the conversion gain. One explanation for this is the difficulty of achieving impedance matching over broad ranges. Consequently, the conversion gain is reduced over the band to compensate for the extended bandwidth. Over narrow frequency bands impedance matching is less of a challenge and thus readily facilitates optimization of conversion gain.

3.2. Pertinent Properties of the Active Device

3.2.1. Nonlinear Modeling. As pointed out previously, accurate device models are an essential ingredient for the efficient design of active microwave multipliers. This section presents typical information on active devices necessary in active multiplier design. Since most of the effort on active multipliers employs FET-type devices, the remaining portions of this presentation will stress this class of active elements. Some multiplier realizations utilizing *Bipolar* devices are addressed in Ref. 95,155,156, and 164.

3.2.2. Classification of Device Models. Active-device circuit models are developed and categorized according to their specific applications. Depending on this classification, a specific model is typically employed, such as small-signal models and *S*-parameter data for small-signal amplifier applications.

Alternatively, for frequency multiplier applications, excellent nonlinear models are required to predict both the linear and nonlinear device performances.

The development of such models is a challenging undertaking that requires more depth in its exposition than space permits. The interested reader is referred to the literature [49–78] and [158–163] for in-depth treatment of this topic.

3.2.3. Development of Precision Models. Because of the necessity of precision nonlinear models for illustration of accurate multiplier designs, we will utilize a high-elec-

tron-mobility transistor manufactured by Fujitsu (FHX35LG) for that purpose.

Additionally, the frequency multiplier examples illustrated below are doublers, and thus, the highest frequency harmonic that will be modeled is the third harmonic. Furthermore, it has been pointed out in these applications, that the first three harmonics are of the greatest significance [99].

A number of authors [48–78] have developed nonlinear active-device models that are typically employable in active multiplier development. The interested reader is referred to Refs. 49 and 56 for in-depth discussion of most of these models.

For the purposes of our discussion, a general nonlinear FET/HEMT model is shown in Fig. 25. In this model, the nonlinear parameters include the following [49]:

D_{gs} = gate-to-source diode

D_{gd} = gate-to-drain diode

C_{gs} = gate-to-source capacitance

C_{gd} = gate-to-drain capacitance

C_{ds} = drain-to-source capacitance

I_{ds} = drain-to-source current

R_{ds} = output resistance = $\left(\frac{\partial I_{ds}}{\partial V_{gs}}\right)^{-1}$

g_m = transconductance (not shown in model but is represented by the equation: $g_m = \partial I_{ds} / \partial V_{gs}$)

In-depth discussions of these parameters and their device design implications are presented in Refs. 49 and 56.

3.3. Device Nonlinearities

It was discussed above that while the class of active devices available for multiplier applications includes BJT, MESFET, HEMT, and similar devices, this work will employ HEMT transistors as a vehicle for design illustrations.

The equivalent circuit for this device was shown in Fig. 25 with the nonlinear elements displayed that are exploited in the generation of frequency harmonics.

3.3.1. Analysis of Nonlinearities. In analyzing FET/HEMT performance, several authors have addressed the issue of identifying the elements that contribute to the nonlinear behavior of FET transistors [49,75,76,79,86,93,97,98,101]. Maas [86] has analyzed the nonlinear behavior of MESFET transistors. In his study, Maas provided the magnitude of all parasitic components (L_s , L_g , L_d , R_g , and R_d) and intrinsic components (R_i , R_{ds} , C_{gs} , C_{gd} , and g_m) in tabular form for various bias voltages. This provides insight into the nonlinear behavior of these components. R_i (not shown in Fig. 25) is the charging resistance in series with C_{gs} for a typical transistor. Maas' data for the parasitic inductors (L_s , L_g , and L_d) show that the magnitudes of these inductors are very small and are on the order of hundredths of nH. Their values vary from 0.03 to 0.08 nH for L_s , from 0.09 to 0.12 for L_g , and 0.06 to 0.07 nH for L_d or, in the worst case, their magnitudes vary by only 0.05 nH over the bias ranges. This

Figure 25. Nonlinear device equivalent circuit model.

indicates that at an arbitrary frequency of 1 GHz, the impedance of this inductance variation is approximately 0.25. This implies that the parasitic inductors can be approximated with fixed, constant values for all bias regions and, therefore, do not contribute as a source of nonlinearity to the MESFET. The magnitude of the parasitic resistors (R_g , R_s , and R_d) vary by only a few tenths of an ohm as functions of applied voltage. Therefore, similar to the parasitic inductors, their magnitudes can be fixed as constants in the device models.

Maas' data show that the output resistance of the MESFET varies nonlinearly over bias from approximately 10 to 283 [86].

This variation is significant and indicates that, as a result of this nonlinear characteristic, the output resistance of the transistor is one of the potential contributors to the nonlinear effects observed in the MESFET transistor. The gate-to-source and gate-to-drain capacitors (C_{gs} and C_{gd}) also vary nonlinearly as functions of applied voltage. C_{gs} is shown to vary from 0.415 to 0.636 pF, and C_{gd} varies from 0.049 to 0.266 pF. This nonlinear variation in C_{gs} and C_{gd} indicates that they are viable contributors to the harmonic production of the MESFET as well. The final element considered by Maas is the transconductance. The transconductance shows significant nonlinear variation over bias, particularly in the saturation region as it varies nonlinearly from 61.3 to 89.2 mS. This nonlinear variation indicates that it also contributes to the nonlinear behavior of the MESFET. In summary, Maas' study reveals that the elements significantly contributing to the nonlinear behavior of the MESFET are R_{ds} , C_{gs} , C_{gd} , and g_m . The remaining elements (L_s , L_g , L_d , R_i , R_g , R_s , and R_d) do not vary nonlinearly and can be considered to be constants in the models. Maas' study was performed on a MESFET; however, his results can be employed in identifying the nonlinear contributors to HEMT/PHEMT performance as well.

Gopinath and Rankin [79,119] have performed a study identifying the relative contributions of the various nonlinear elements of MESFETs valuable for harmonic generation. Their work emphasizes harmonic generation at the second-harmonic using computer simulations and

identifies the major contributors to the nonlinear behavior of the MESFET as (1) C_{gs} and C_{gd} ; (2) drain current nonlinearity, which results from the drain current clipping when V_{gs} swings below pinchoff or into forward conduction; (3) the nonlinearity of the drain current equation representing I_{ds} ; and (4) output resistance nonlinearity.

On the basis of computer analysis, Gopinath and Rankin conclude that, in the absence of other nonlinear contributions, the second-harmonic power level due to C_{gs} is on the order of 18–11 dB below the output power at the fundamental. In evaluating the effect of I_{ds} clipping, they neglect the transfer characteristic of I_{ds} and perform a Fourier analysis of the half-wave rectified waveform with $V_{gs} = 0$ V. They find that the second-harmonic output power level is 7.4 dB below the output power level at the fundamental. Gopinath and Rankin analyze the nonlinear contributions from the I_{ds} current equation nonlinearity and the output resistance by simulating the harmonic response of the FET with the drain current represented by Eqs. (65) and (66), respectively. The simulations show that the second-harmonic output power level is 16 dB below the output power level at the fundamental using Eq. (65) to represent I_{ds} , and that the second-harmonic output power level is 15 dB below the output power level at the fundamental when using Eq. (66) to represent I_{ds} :

$$I_{ds} = I_{dss} \left(1 - \frac{V_{gs}}{V_p} \right)^2 \quad (65)$$

$$I_{ds} = I_{dss} \left(1 - \frac{V_{gs}}{V_p} \right)^2 \left(1 + \frac{V_{ds}}{R_{do} I_{dss}} \right) \quad (66)$$

The conclusion is that the major contributor to the nonlinearity of the FET is the I_{ds} nonlinear clipping effect, which produced second-harmonic output power 7.4 dB below the output power at the fundamental. Slight contributions to the nonlinearity of the FET came from the C_{gs} nonlinearity, output conductance nonlinearity, and I_{ds} transfer nonlinearity. It should be noted, however, that the study uses approximations in the computer simulations. The computer model neglects the gate-to-drain branch of the circuit (C_{gd} and D_{gd}), the authors use a predetermined unknown resistive load (R_L), and they indicate that the results are valid only for $R_L \ll R_{do}$, where R_{do} is the output resistance. A final observation of this study is that measured data indicating the accuracy and practicality of the results are not presented.

With reference to the earlier work of Camargo [98], Dow [97] discusses the nonlinear contributions of the MESFET transistor using a graphical approach. He develops an equivalent-circuit model from measured S parameters to evaluate the bias-dependent nonlinear intrinsic circuit elements, and, afterward, presents curves representing g_m , C_{gs} , and G_{ds} versus V_{gs} and V_{ds} to show the nonlinear behavior of these parameters. Examining the curves, Dow identifies particular bias regions of V_{gs} and V_{ds} , where the nonlinear variation of g_m and G_{ds} is more prominent and significant for harmonic generation. With regard to the contribution from C_{gs} , Dow references the study performed by Gopinath and Rankin, as previously discussed,

in stating that second-harmonic generation is weakly dependent on C_{gs} nonlinearity. In summary, Dow's study concludes that harmonic generation is obtained from three sources of the MESFET: (1) nonlinearity of the intrinsic parameters C_{gs} , g_m , and G_{ds} ; (2) current rectification, which occurs when the gate voltage swings into forward conduction; and (3) current clipping occurring when the gate voltage swings below pinchoff.

The previous discussions have stressed the determination of the nonlinear elements responsible for harmonic generation in MESFETs. Focusing on the HEMT transistor, Golio [49] indicates that the major nonlinear elements of the HEMT device are (1) the drain-to-source current I_{ds} , from which the transconductance and output conductance are derived; (2) the gate-to-source and gate-to-drain capacitors (C_{gs} and C_{gd}); and (3) the gate-to-source and gate-to-drain diodes (D_{gs} and D_{gd}).

3.3.2. HEMT Characteristics. Modeled drain-to-source current, transconductance, and output conductance data for a Fujitsu FHX35LG HEMT are shown below to demonstrate the nonlinear characteristics of these types of active devices. Static I - V curves are shown in Figs. 26 and 27 for the transistor using the modeling techniques previously discussed and the equivalent nonlinear model shown in Fig. 28. From the static I - V curves, the transconductance and output conductance are derived and plotted against the drain-to-source (V_{ds}) and gate-to-source (V_{gs}) voltages as shown in Figs. 29–32. These plots graphically display the nonlinearity of the transconductance and output conductance of the HEMT transistor as functions of the DC bias voltages. As shown in these plots, these elements show varying degrees of nonlinearity, which are dependent on the drain-to-source (V_{ds}) and gate-to-source (V_{gs}) voltages bias. The exploitation of these nonlinearities with respect to the optimum bias conditions will be discussed in the following section.

3.4. Nonlinearities Utilized for Frequency Multiplication

The preceding sections presented a general synopsis of device nonlinearities. This section delineates the nonlinearities of specific importance for frequency multiplication applications, given certain optimum bias conditions. Additionally, the impact of terminating impedances on multiplier performance is detailed.

Figure 26. Modeled drain current of HEMT transistor versus drain-to-source voltage.

Figure 27. Modeled drain current of HEMT transistor versus gate-to-source voltage.

3.4.1. Optimum Bias Selection. Golio [49] has noted that the drain-to-source current (I_{ds}) contributes to the nonlinear behavior of the HEMT transistor. In this accord, static I - V curves representing the drain-to-source current are utilized to characterize two dominant nonlinear circuit elements previously identified: the transconductance (g_m) and the output conductance (g_{ds}). These parameters plotted versus the drain-to-source (V_{ds}) and gate-to-source (V_{gs}) voltages as shown in Figs. 26–32, show the nonlinearity of the elements displayed as a function of the DC bias voltages.

For the class of multipliers under consideration, the nonlinear behavior of the drain-to-source current (I_{ds}) produces harmonic generation through its clipping effect [79,98]. In the case of harmonic generation, the conclusion has been advanced that optimum harmonic generation occurs for either $V_{gs} = 0$ or $V_{gs} = V_p$ [97,98,102,127].

If the FET is biased at $V_{gs} = 0$, the input voltage waveform appearing across the gate-to-source capacitance (C_{gs}) is clipped and will be half-wave rectified because of the conduction cycles experienced by the gate-to-source diode. This rectified waveform is transferred to I_{ds} through the device's transfer properties as reflected by the analytical relation between I_{ds} and V_{gs} [55]. When the device is biased at the pinchoff voltage ($V_{gs} = V_p$), however, the input voltage at the gate causes the FET to turn on during the positive half-cycle of the input voltage, and the output voltage again becomes a half-wave rectified waveform.

Figure 28. HEMT/PHEMT nonlinear equivalent model.

Figure 29. Modeled transconductance of HEMT transistor versus drain-to-source voltage.

When the gate voltage is biased between 0 V and pinchoff ($0 \geq V_{gs} \geq V_p$), and the input voltage swing is large enough to cause clipping on both ends, the output current at the drain will resemble a square wave. If the square wave is symmetric, the second-harmonic component will be small, but the third harmonic will be large, allowing frequency tripling [97].

It has been shown that rich harmonic generation will result for class A and class B operation of the transistor [96,97,98]. Class A operation occurs for $V_{gs} = 0$ V and causes drain current (I_{ds}) rectification when the gate diode swings into forward conduction. Class B operation occurs for $V_{gs} = V_p$, where V_p is the pinchoff voltage, and causes the drain current to clip when the gate voltage swings below pinchoff.

Dow [97] and Camargo [98] conclude that class A FET multipliers provide good multiplication gain and poor DC-to-RF efficiency, while class B FET multipliers have poor multiplication gain and good DC-to-RF efficiency.

Using the DC-to-RF efficiency expression [Eq. (63)], the efficiency for typical HEMT frequency doublers, which was simulated with $V_{gs} = V_p$ and $V_{gs} = 0$ V, respectively, can be computed. As an example, evaluating various simulation data for $V_{gs} = V_p$, the DC-to-RF efficiency is 23.5%, and for typical simulations for $V_{gs} = 0$ V, the DC-to-RF efficiency is 0.03%. In each simulation the DC supply voltage (V_{ds}) was 3 V, which causes the DC power for the simulation with $V_{gs} = 0$ V to be considerably higher and, subsequently, to reduce the DC-to-RF efficiency. Usually, for class A

Figure 31. Modeled output conductance of HEMT transistor versus drain-to-source voltage.

operation the device is biased at a lower V_{ds} voltage than the case presented here, thus reducing the DC power and increasing the DC-to-RF efficiency.

More recent research has shown, however, that other V_{gs} values may provide better and more optimum results [166,172]. These results demonstrate that other biases provide improved performance from an output harmonic power perspective. This conclusion was based on the use of rather basic device models that contained no feedback, parasitic elements, or nonlinear G_d . Employing their analytical approach, which was a revision of Maas [44], O’Ciardha et al. [172] predict potentially realistic 8% improvement in output doubler power utilizing only modest changes in bias and input power. Theoretical improvements are shown to be up to 15%.

An investigation by Johnson [171] reveals that, while this is true, these new biases require greater input power and have inferior conversion gain.

Focusing on the Fujitsu FHX35LG HEMT device, measured and modeled measurements provide static I - V curves as shown in Fig. 33. From these data, measured and modeled transconductance and output conductance are derived.

Figures 34–37 show the transconductance and output conductances plotted as functions of the gate-to-source (V_{gs}) and drain-to-source (V_{ds}) voltages. Recalling that the optimum bias conditions are either $V_{gs} = 0$ or $V_{gs} = V_p$, the HEMT transconductance and output conductance plots of Figs. 34–37 show the nonlinear behavior of the

Figure 30. Modeled transconductance of HEMT transistor versus gate-to-source voltage.

Figure 32. Modeled output conductance of HEMT transistor versus gate-to-source voltage.

Figure 33. Modeled transconductance of HEMT transistor versus drain-to-source voltage.

transconductance and output conductance at the optimum bias regions.

In Figs. 34 and 36, oval circles representing the regions (region I) of optimum nonlinearity are indicated for $V_{gs} = 0$ V. These regions are identified as areas where the nonlinear variation in the transconductance and output conductance is greatest. In Fig. 34, the variation in the transconductance is actually greatest for $V_{ds} < 0.5$ V, but in this area of operation the transistor does not supply appreciable gain, thus limiting its usefulness at these bias levels for significant conversion gains. For $V_{ds} > 1$ V, the transconductance tends to flatten with no significant variation for $V_{gs} = 0$ V. This behavior is observed again in Fig. 36 with the output conductance.

In Figs. 35 and 37, regions (region II) for optimum nonlinearity are represented for $V_{gs} = V_p$. Again, areas where the nonlinear variation in the magnitudes of the transconductance and output conductance is greatest are indicated by oval circles. In Fig. 37, significant nonlinear variation in the transconductance is also seen in the vicinity of $V_{gs} = -0.3$ V. Operating in this vicinity is optimum for frequency multipliers, where the third harmonic (frequency tripler) is of interest [97]. Biasing in this vicinity with large voltage swings at the gate of the FET causes the I_{ds} waveform to clip at both pinchoff and forward conduction and causes I_{ds} to resemble a square wave, which enhances the third harmonic frequency [97]. In Fig. 37 significant variation in the output conductance also occurs for V_{gs} 0 to -0.1 V for lower V_{ds} values (V_{ds} 0.6 V). As mentioned previously, the gain of the transistor diminishes significantly in these bias areas, thus causing the

Figure 34. Measured and simulated transconductance of FHX35LG (region I).

Figure 35. Measured and simulated transconductance of FHX35LG (region II).

conversion gain of the frequency multiplier to reduce as well. From these curves the prominent nonlinearity regions for $V_{gs} = 0$ is region I of Fig. 36, where g_{ds} is dominant and for $V_{gs} = V_p$, region II of Fig. 35, with g_m showing the dominant effect.

3.4.2. Detrimental Parasitics: Definition of the Parasitics. The equivalent-circuit topology for the nonlinear FET transistor as given in Fig. 25 includes the parasitic elements ($L_s, L_g, L_d, R_s, R_d,$ and R_g). These parasitics arise from the fabrication process in the development of semiconductor transistors and influence the performance of the transistor and thus warrant inclusion into the equivalent-circuit model. The parasitic inductors ($L_s, L_g,$ and L_d) primarily represent the inductance associated with the metal contact pads deposited on the active-channel layer of the FET. The source and drain parasitic resistors (R_s and R_d) represent the contact resistance of the ohmic contacts underneath the metal contact pads and any bulk resistance leading up to the active channel, and the gate parasitic resistance (R_g) represents the metallization resistance of the gate Schottky contact [49].

3.4.3. Optimum Bias Selection Referencing Harmonic Terminations. A primary factor affecting optimum performance of microwave multipliers employing nonlinear devices is the proper termination of the fundamental and other harmonic frequency components with regard to bias selection. This section presents a quantitative analysis leading to the assessment of optimum terminating impedances in the design of active frequency multipliers, with

Figure 36. Measured and simulated output conductance of FHX35LG (region I).

special attention given to harmonics other than those desired. The analysis includes computer modeled HEMT data and supporting measured data for corresponding circuit realizations. Circuit designs are presented utilizing HEMT transistors as the active element to verify modeled results. From the available literature, the results demonstrate, for the first time, the quantitative effects of harmonic termination on active multiplier conversion gain and fundamental and higher-harmonic suppression. An experimental design, which will be discussed later, reveals an improvement in multiplier gain of 77% over the conventional approach, and data are presented that quantitatively illustrate the advantages of impedance termination considerations under optimal bias conditions.

3.5. Background and Motivation

Numerous techniques exist for the realization of frequency multipliers, as will be discussed below [87–88,91–128, 130–132,137–139]. At radiofrequencies, these techniques typically employ a nonlinear device to generate the desired frequency multiple. In the design of passive multipliers, the nonlinear element is typically a varactor diode. In the active case, the nonlinear element typically includes any of several transistor classes such as BJT and FET.

In many frequency multiplier design approaches, the operating performance is improved by the proper selection of input and output circuits terminating impedances at the fundamental and harmonic frequencies [91–95, 109,145].

This section presents a quantitative analysis of the optimization of active multiplier conversion gain and spectral purity, as governed by fundamental and harmonic terminating impedances and regions of nonlinearity. It is believed that access to this quantitative information will be of use for designers of future circuits. HEMT transistors are employed to represent the class of nonlinear elements to illustrate the approach. The optimum terminating impedances are determined for the input and output ports of the active device, utilizing a more recent nonlinear circuit model for HEMT transistors. This is in marked contrast with earlier studies, which used approximations in the simulated performance predictions [79,93,98]. The results presented in this section incorporate dependences between the input and output harmonic terminating impedances that are not found in previous studies. For the multipliers examined in this section, these impedances include terminations at the fundamental, second-harmonic, and third-harmonic frequencies. Measured data are presented that validate the practicality of the designs and the accuracy of the simulations.

3.5.1. Nonlinear Model. An accurate nonlinear circuit model is required for the quantitative assessment of optimum terminating impedances in the design of active frequency multipliers. Such an equivalent-circuit model permits supporting simulated data to accompany any measured data that further authenticate results. An accurate nonlinear model was presented earlier for the Fujitsu FHX35LG HEMT, which will be employed below for analyzing bias selection with regard to harmonic

terminations (case parasitics are included in the model but not shown in the figure).

Static I - V curves for this HEMT, obtained from the model of Fig. 25 and laboratory measurements, are employed to characterize two dominant circuit element nonlinearities: transconductance (g_m) and the output conductance (g_d). These parameters (modeled and measured), which were derived from the above mentioned sources, are plotted versus the drain-to-source (V_{ds}) and gate-to-source (V_{gs}) voltages shown in Figs. 33–37. These plots graphically display the nonlinearity of the corresponding HEMT elements as a function of the DC bias voltages. The conclusions for the HEMT multiplier are presented quantitatively below.

Utilizing the HEMT transconductance and output conductance plots of Figs. 33–37, the prominent nonlinear regions for the optimum DC bias points (either $V_{gs} = 0$ or $V_{gs} = V_p$) were identified in previous sections. Fundamental load-line analysis indicates that the optimum impedance for region I ($V_{gs} = 0$) is an open-circuit impedance that allows a maximum V_{ds} voltage swing, and for region II ($V_{gs} = V_p$) the optimum impedance is a short-circuit impedance that allows a maximum I_{ds} current swing [145]. These qualitative assertions will be substantiated quantitatively in the ensuing discussion.

3.5.2. Harmonic Terminations. The preceding analysis provides motivation for development of an optimal design approach. We employ the following multiplier design as an illustration. The basic topology of the frequency multiplier used is illustrated in Fig. 38. In this configuration, SC_i , $i = 1 \dots n$, and OC_j , $j = 1 \dots m$, represent short-circuit and open-circuit terminating impedances, respectively, for the multiplier input network at the respective frequencies. Similarly, SC_k , $k = 1 \dots o$, and OC_l , $l = 1 \dots p$, represent short- and open-circuit terminating impedances for the multiplier output network. An infinite number of circuit realizations exist that conform to the configuration of Fig. 38. This provides the motivation for development of a matrix of various circuit configurations as illustrated in Table 1, which displays various harmonic terminating impedances on the input and output ports of the multiplier realization depicted in Fig. 38. Tables have been constructed for multiplier operation (up to the third harmonic) utilizing the precision HEMT computer model with case

Figure 37. Measured and simulated output conductance of FHX35LG (region II).

Figure 38. Frequency multiplier realization.

parasitics. In Table 1, the left-hand vertical column represents various impedance terminations of the input network at the fundamental, second-harmonic, and third-harmonic frequencies. The top horizontal row represents various impedances of the output network at the fundamental, second-harmonic, and third-harmonic frequencies.

To assess performance under various load terminations, several load configurations were analyzed. On the basis of previous discussions, fundamental and harmonic loads of interest may be short-circuited, open-circuited, matched, or 50.

As a first case, the options shown in Tables 1 and 2 were selected. Since only 50, short, and open loads are used, this choice of terminations would appear to provide a concrete basis for assessing the effects of a variety of other input and output harmonic load conditions. Table 1 illustrates the conversion gains obtained employing the FHX35LG HEMT utilizing a harmonic balance program with input and output networks synthesized with lumped elements to realize the indicated harmonic terminations with $f_0=3$ GHz. The HEMT in this table is biased at pinchoff $V_{gs}=V_p$ and driven with 0 dBm at the gate terminal (region II; Figs 35 and 37). This table is presented as a basis by which to measure the quantitative impact of a

variety of terminations on multiplier conversion gain. The numbers to the right of each entry in the table represent the powers obtained at respective harmonics. It is instructive to consider a typical entry of interest in this table. The entry located in the second row and second column, for example, shows that a conversion gain of 1.5 dB is obtained if the input network terminates the fundamental f_0 and third harmonic $3f_0$ in 50, while the second-harmonic $2f_0$ is short-circuited. The output network for this entry terminates the fundamental in a short circuit and all other harmonics in 50. Several authors [93,98,99,102] have reported that the input network should terminate the second-harmonic in a short circuit. For lumped input circuit realizations, however, this table reveals that this provides a 1.5 dB improvement over a 50 or an open-circuit termination at $2f_0$ (row 1, column 2 and row 5, column 2, respectively). While the conversion gains represented in this table are not large and the dB values do not show great

variation, several trends are seen to emerge, and subsequent results will substantiate their implications. In particular, the impact of input network terminations from the data in rows 2 and 3 show, that for doubler operation, a short-circuit termination at $2f_0$ provides the best conversion gain in all cases considered.

Furthermore, a perusal of output network termination responses shows that a short circuit at f_0 provides the best performance using conversion gain as a basis.

Table 2 shows similar data when the HEMT is biased at $V_{gs} = 0$ (region I). This V_{gs} value was chosen in accordance with our previous discussion on optimum bias regions. While an important outcome of the $V_{gs} = 0$ table was typically lower conversion gains in comparison with Table 1, where $V_{gs} = V_p$, an even more significant observation is the dramatic improvement (~ 12 dB) obtained by employing an *open*-circuit termination at f_0 in the output network, in contrast with a short circuit, which was the

optimum case for region II. Note that Table 1 predicts only a 1.6 dB improvement for the analogous comparison.

On the basis of the observations above, we present results only for the specific case where the input network is short-circuited at $2f_0$ in the ensuing discussion.

Table 3 presents the results obtained for region II operation ($V_{gs} = V_p$) when the input network was synthesized to provide a matched load at the fundamental frequency f_0 and a short circuit at $2f_0$. In comparison with its counterpart in row 2 of Table 1, which had a 50 termination at f_0 , it is seen that, as expected, significant improvements occur in conversion gains for all output network impedance terminations. A perusal of the values indicates that significant increases in conversion gain of over 5 dB are typical in each case. Furthermore, the following quantitative results may be observed for various output network terminations: (1) 3.0 dB better conversion gains are obtained by short circuiting as compared with

open circuiting the fundamental (i.e., 8.0 dB vs. 5.0 dB), (2) 1.5 dB better conversion gain will be obtained for a short circuit at f_0 in comparison with a 50 ohm termination (notwithstanding the fact that the 50 ohm case would require some form of output circuit fundamental suppression), (3) 1.2 dB of additional conversion gain is obtained if the third harmonic is open-circuited in contrast with the frequently used short-circuited third harmonic (8.6 vs. 7.4 dB), and (4) 3.8 dB additional conversion gain is obtained over the case where an open-circuit fundamental and short-circuit third-harmonic output network are employed (i.e., 8.6 dB vs. 4.8 dB).

Table 4 presents the results obtained for region II operation when the output network is synthesized to provide a matched load at the second-harmonic ($2f_0$) versus the previous cases where a simple 50 ohm load was employed. On the basis of these results, it can be seen that for output network terminations, where the fundamental has been

short-circuited, an additional 2 dB has been obtained over the results in Table 3 and approximately 9 dB over Table 1 results.

Tables 5 and 6 display the results obtained utilizing microstrip-line circuits that were synthesized to provide short-circuited, open and 50 terminations at respective fundamental and harmonic frequencies as employed in many traditional designs [79,92,95,97,98,100–110].

With reference to Table 5 (region II, $V_{gs} = V_p$), a comparison of the effect of the distributed input network (row 2, column 1) with a 50 input network at f_0 , $2f_0$, and $3f_0$ (row 1, column 1) shows that 5.2 dB improvement in conversion gain performance may be obtained by employing the distributed structure with a short circuit at $2f_0$. Some additional conclusions obtained from a further perusal of this table are as follows: (1) 8.6 dB conversion gain improve-

ment may be obtained by providing a distributed output network that is short-circuited at f_0 and $3f_0$ as compared with 50 ohm input and output terminations (row 1, column 1 vs. row 2, column 4); (2) with the distributed input network terminated in a short circuit, 1.3 dB improvement in conversion gain may be obtained by short-circuiting the output network at f_0 and $3f_0$ (column 4) as compared with open circuits at f_0 and $3f_0$ (column 5); (3) the difference in termination in the output network between open and short circuits at f_0 is on the order of 1 dB; and (4) an additional 2.3 dB of conversion gain is obtained by introducing an additional short-circuited stub at $3f_0$.

Table 6 presents similar results for region I ($V_{gs} = 0$) operation. Several significant conclusions are evident from these results: (1) optimal performance is considerably less (2.8 vs. 7.7 dB) than that for region II operation,

Table 6. Simulated Doubler Response with Microstrip Elements (Region I; ($V_{gs} = -0\text{ V}$, $P_{in} = 0\text{ dBm}$, $V_{ds} = 3\text{ V}$))

$\begin{pmatrix} 50 \\ 0 \\ 50 \end{pmatrix}$		$\begin{pmatrix} 14.7 \\ -12.5 \\ -8.4 \end{pmatrix}$	$\begin{pmatrix} -18.4 \\ -13.1 \\ -18.4 \end{pmatrix}$	$\begin{pmatrix} -14.4 \\ 1.8 \\ -25.6 \end{pmatrix}$	$\begin{pmatrix} -21.3 \\ -10.4 \\ -41 \end{pmatrix}$	$\begin{pmatrix} -11.1 \\ 2.8 \\ -52 \end{pmatrix}$	$\begin{pmatrix} 13.2 \\ -10.6 \\ -2.8 \end{pmatrix}$

$$^a \text{At } \begin{pmatrix} f_0 \\ 2f_0 \\ 3f_0 \end{pmatrix}.$$

^b0 = short circuit; ∞ = open circuit.

(2) significant conversion gain improvement is obtained when the output network is open circuited at f_0 in comparison with the short-circuited condition (1.8 vs. -13.1 to -15 dB, and (3) 1 dB of conversion gain performance improvement is achieved by introducing an additional open-circuited stub at the third harmonic.

This topic will be revisited in the next section in the discussion of active multiplier design. Specific multiplier designs are illustrated demonstrating the efficacy of harmonic terminations and optimum bias selection.

4. ACTIVE MULTIPLIER DESIGN TECHNIQUES

4.1. Existing Active Multiplier Design Techniques

Since the 1980s, numerous researchers have discussed numerous design approaches leading to various design procedures utilizing various active devices and topologies in different media and frequency ranges. This section presents various existing design techniques and other techniques implemented by the author.

A fundamental topological representation for realization of active microwave multiplier circuits is shown in Fig. 39. While this is not the most generalized topology, it is one of the most frequently used. The physical realization of an efficient frequency multiplier subject to design criteria utilizing this configuration is strongly reliant on the synthesis of networks N_1 , N_2 , and N_3 , which are typically, but not always, passive. The criteria for specification of N_1 , N_2 , and N_3 rely, heavily as usual, on fundamental active-device parameters. In the case of multipliers, this is heavily dependent upon bias conditions, input power level, and frequency.

Only very seldom have designers intentionally employed feedback (N_3) in multiplier designs in the realization of such circuits [165]. Synthesis of N_3 is typically avoided, due in part to potential stability problems [93,106,147]. This network, however, has the potential of providing useful improvement in conversion efficiency by proper combination of harmonics emerging from the active device with the input fundamental, for example, at the correct phase. The feedback network (N_3) combines a harmonic component from the drain (collector) of the transistor with the fundamental component on the gate (base).

Figure 39. Frequency multiplier realization.

Theoretically, this produces an enhanced component at the desired output harmonic frequency on the drain (collector), assuming that in the ideal case the phase of the feedback is optimal [106,147].

Some designers have selected a balanced version of the topology given in Fig. 39 for doubler design, with expectations of superior doubler performance [91,109,111-113, 148,149]. These seem to have been inspired by the advantages actually realized in the design of diode doublers [150]. Developers of such balanced active multipliers state that these circuits are better because of the natural cancellation of the fundamental and all odd harmonics, thus providing a virtual ground at the output of the active devices and permitting the location of any matching networks closer to the drain (collector) of the devices [99]. Furthermore, they indicate that such designs have the advantage of high conversion efficiency, 3 dB better output power, better isolation, good harmonic suppression, and the elimination of the long ($\lambda/4$) stubs that are common in single-ended designs.

One of the design classes emphasizes the arrangement of two or more transistors in one of several topological configurations as shown in Figs. 40 and 41. The technique shown in Fig. 40 utilizes two identical fundamental frequency signals, which are fed 180° out of phase to transistors T_1 and T_2 . The circuit functions as a type of active full-wave rectifier in that when the voltage at port 1 is positive, T_1 conducts and T_2 is turned off and current flows through the emitter of T_1 to the load Z_L . When the polarity of the input signal $V(f_1)$ is reversed, T_2 conducts and T_1 is turned off and current flows through the collector of T_2 , providing an output to Z_L . This process effectively provides a rectified output at Z_L with the corresponding strong second-harmonic content. This approach has been demonstrated for doubler action over a broad frequency range (1-7 GHz) in MMIC topology. Conversion gains range from 0 to 12 dB, utilizing input and output amplification stages. Fundamental rejections of less than 10 dB appear to be realizable.

A block diagram of a typical balanced multiplier design is shown in Fig. 41. At the input, the input signal of the multiplier is fed through a powerdivider-phase shifter,

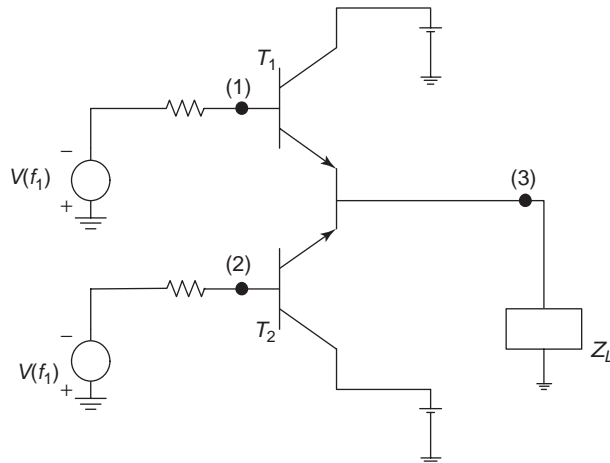

Figure 40. Block diagram of push-push topology of frequency multiplier.

Figure 41. Block diagram of typical balanced frequency multiplier.

which divides the power between the two transistors with 180° phase difference between the input ports of the transistors. The drains (collectors) of the transistors are connected on the output by a combiner. At the output, the fundamental and odd harmonic signals have opposite phase, and, by destructive interference, cancel, giving good harmonic suppression. The second-harmonic signals from the transistors have the same phase and thus interfere constructively.

A perusal of the published literature on such balanced designs reveals, however, that they require complex components in their realization. In addition to two matched active devices (some designers use more in their active matching stages), balanced designs typically require large baluns or powersplitter–phase shifter combinations, T junctions, and in some cases airbridges. Some realizations also require complex transitions and additional lengths of transmission lines to rotate the active device outputs to achieve a pure reactance output. Finally, only frequency doubler designs are typically reported; however, Fudem and Niehenke [166] have realized a balanced tripler. It is found that, with due consideration of the importance of the particular active device characteristics and frequency bands, these designs in almost all cases are narrowband (10%) (Ref. 112, with -9 dB conversion gains, is one exception; it uses an additional active device), have modest conversion gain (-5 to $+5$ dB; 3 to 12 dB in one case), and frequently yield sparse data on fundamental suppression (typically between 12 and 30 dB).

Hiraoka [148], for example, developed a broadband MMIC balanced frequency doubler with a fundamental frequency of 5 GHz, consisting of a common-gate FET and a common-source FET directly connected in parallel, followed by an output-matching network. A phase shifter network precedes the common-gate FET to compensate for the phase error between the outputs from the common-gate FET and the common-source FET. A conversion loss of 8–10 dB was achieved for output frequencies between 6 and 16 GHz. Fundamental frequency isolation (suppression) better than 17 dB up to output frequencies of 20 GHz was obtained. Unfortunately, the author did not provide any data on the third-harmonic isolation (suppression).

Angelov [113] discusses a 20–40-GHz balanced doubler where two common-source PHEMTs are connected in parallel followed by sections of transmission lines on the gates before combining into a 3-dB coupler. The input signal to the doubler is fed to a power divider, which divides the power equally between the two input ports with 180°

phase difference between the input ports. Sections of transmission lines connect the power divider to the drain of the PHEMTs. The completed doubler circuit provides approximately -1 dB of conversion gain with a -3 dB bandwidth of approximately 5%. The author notes that the bandwidth is limited mainly by the 180° ratrace coupler. The author does not provide data on the fundamental and the third-harmonic suppression.

Takenaka and Ogawa [111,112] developed a wideband MMIC balanced frequency multiplier utilizing line-unified HEMT configurations. In line-unified HEMT configurations, coplanar lines such as slotlines and coplanar waveguides are used to connect the circuit electrically. A coplanar waveguide precedes a common-gate HEMT followed by a slotline series T junction, which acts as an out-of-phase divider to drive two parallel, common-drain HEMTs. The output of the two HEMTs is connected to a coplanar waveguide followed by the load resistance. This topology yields conversion loss of 8–10 dB in the 4–40 GHz output frequency range, and fundamental frequency signal isolation of better than 21 dB above the input frequency of 7 GHz. The authors do not provide any data on third-harmonic isolation.

One final observation on balanced designs is the almost universal disregard for the deleterious effects of channel imbalances. It has been reported that for phase imbalances of 10° , the output conversion gain at the second-harmonic will decrease by 1 dB in a 4-dB design, while an amplitude imbalance of 0.3 dB produces the same 1 dB decrease. A combination of imbalances of 10° and 0.3 dB together results in a 3 dB decrease in a 4-dB conversion gain design [113,151,167]. For these reasons, balanced realizations are not considered further in this article, although obviously some principles presented are directly transferable to balanced circuits.

Numerous investigators have reported designs for single-ended microwave multipliers. Referring to Figs. 25 and 39, these designs include networks N_1 and N_2 but exclude an external network N_3 . Thus, single-ended designs are based primarily on the realization of N_1 and N_2 . Traditional synthesis of N_1 and N_2 have followed the lines of the passive case where N_1 is traditionally composed of a bandpass or lowpass filter or matching network tuned to a fundamental frequency, and N_2 is similarly a matching network or bandpass or highpass filter tuned to the appropriate harmonic frequency of interest. Synthesis of these networks includes the use of cascades of filters and matching networks [87,88,97,99,108,110,116–123,124,125,128,147,152–154], and such methods have been realized utilizing transmission lines and stubs to open-circuit-, or short-circuit-specific harmonics [88,108,110,154], while some authors have additionally considered these networks as a cascade of matching and reflection networks [95,104,110,154]. Many of these techniques determine optimal networks by utilizing load-line analysis [91,92], intuitive reasoning based on previous results [92,124], computer optimization of generalized models [106,108], and experimental techniques based on stub tuner measurements [88,154].

The following paragraphs illustrate some specific examples of these classes of realizations. Dow [97]

developed a FET frequency doubler with a fundamental frequency of 20 GHz utilizing matching networks and tuners. Network N_1 includes a matching network at the gate designed to match the fundamental frequency and an output-matching network N_2 at the drain that was designed to match the second-harmonic. In addition to the matching networks, tuners were also included in both N_1 and N_2 to optimize the performance of the frequency doubler. A maximum conversion gain of -1.8 dB was achieved utilizing this topology.

Chen [87] developed a MESFET frequency doubler utilizing filters and matching networks. A lowpass filter was placed on the input of the circuit, which allows the fundamental frequency to pass through to the gate of the device, and a highpass filter was placed on the output of the device to allow the desired second harmonic to pass. A matching network designed to match the second-harmonic frequency was placed in series with the highpass filter. Utilizing this topology, Chen achieved 8 dB of conversion gain.

Borg [95] has developed BJT frequency doubler designs utilizing transmission lines and stubs. In one of these, a 50 transmission line is placed on the input of the circuit, and short-circuited stubs are employed on the output of the device. This design produces 2.5 dB of conversion gain. Rauscher [93] provides an FET frequency doubler utilizing transmission lines and stubs as well. On the input of the device, transmission lines are utilized to form impedance transformations and an open-circuited stub. On the output, they are utilized to provide an open-circuited stub at the fundamental frequency. Rauscher's data show that -0.5 dB of conversion gain was achieved in this design.

Stancliff [91] and Gilmore [92] determine optimal networks utilizing load-line analysis for their FET multiplier designs. Using the $I_{ds}-V_{ds}$ curves, they employ fundamental load-line analysis to demonstrate the output characteristics for a fundamental frequency open-circuited load line placed on the output of the FET. Stancliff utilizes this approach in a balanced configuration, whereas Gilmore uses it for the development of a single-ended multiplier.

Various authors have used computer optimization techniques for generalized large-signal device models to develop frequency multipliers [106,108]. El-Rabaie [108] uses a harmonic balance analysis technique to optimize a MESFET frequency doubler utilizing a large-signal MESFET device model. This technique determines the terminating impedance value that should be presented to the multiplier for optimum performance, while the approach utilized by Guo [106] determines optimum bias voltages and optimum load impedances.

Le [88] utilizes experimental techniques based on stub tuner measurements to design frequency multipliers. In this approach, load-pull measurements are performed to measure impedances at various harmonics at various bias voltages, and utilizing these data, frequency multipliers are designed optimizing conversion gain and efficiency.

Le uses this approach in the development of a frequency tripler, which provided a conversion gain of -2.4 dB.

Single-ended designs using the previously mentioned design techniques have exhibited excellent performance. Conversion gains approaching 9 dB, harmonic suppression exceeding 40 dBc, and bandwidths approaching 35% have

been reported [140,142,168]. A significant drawback of some single-ended designs is the potentially large size constraints required by matching networks and harmonic terminating stubs. Long stubs of lengths approaching $\lambda/4$ are commonly used. Even though the performance of frequency multipliers using these design techniques is excellent, they are unsuitable for applications where size constraints are specified. In certain cases, however, it has been shown that discrete networks are feasible for significant size reduction.

4.2. A Unified Design Technique

Existing frequency multiplier design techniques are presented in the previous sections. While these approaches suffice to produce multipliers that work, they are not necessarily efficient in that proper synthesis of N_1 and N_2 can yield significant improvements in performance as measured by conversion gain. In this section, a consistent design technique is proposed for the design of active frequency multipliers, using the topology shown in Fig. 42 stemming from research on terminating-impedance effects on active devices.

Because of the extraordinary complexity of nonlinear circuit problems, it is proposed that the technique, while heavily reliant on experimental measurements, be based on in-depth computer-aided design. From a perusal of the literature, there appears to be little discussion on this topic for active multipliers other than an occasional reference to power limitation in overdriving the drain in MESFET/HEMT realizations. As with any such active design, the first step requires the selection of an active device possessing the appropriate performance characteristics [113], and particularly, in this case, developing accurate nonlinear computer oriented device models. (In the present case, a particular device on hand has been selected for convenience.) Here, for example, we consider the effects of each devices nonlinearity (e.g., C_{gs} , C_{gd} , g_{ds} , I_{ds} , V_{gs} , V_{ds}) on augmenting a particular device harmonic [97]. At this point the nonlinear device model should be accurately developed, based on both DC and AC characteristics, to match the measured performance of the transistor [48,109,146].

The next step requires utilizing the device model and/or measured data to determine optimum bias points and input power levels, using both static and P_{in} versus P_{out} data. Examples of this process may be found in previous publications [97,147]. At this stage, it is important to develop the requirements on the termination networks N_1 and N_2 of Fig. 39 leading to optimum multiplier performance. This process requires the use of extensive

Figure 42. Topology of active microwave multiplier.

computer analysis to be efficient timewise, although, as has been done by several researchers [88,108], some limited results can be achieved by extensive time-consuming measurements. As mentioned previously, El-Rabaie [108] and Le [88] used computer optimization of generalized

nonlinear models to optimize frequency multipliers. The outcome of this process is the prescribed driving-point responses for networks N_1 and N_2 when terminated in R_g and R_L , respectively, where R_g is the source resistance and R_L is the load terminating impedance.

in a previous section where measured and modeled data were presented showing the accuracy of the nonlinear model subsequent to performing the first step described above.

We need to determine the optimum bias points and input power levels from either measured or modeled data. Figures 43–47 show simulated data for various bias conditions and input power levels of the FHX35LG transistor. Figure 43 shows the simulated output power at 3 GHz versus the gate-to-source voltage V_{gs} at the fundamental frequency and the second-harmonic frequency, Fig. 44 shows the simulated output power at the second-harmonic frequency versus the drain-to-source voltage V_{ds} , Figs. 45 and 46 show the conversion gain at the second-harmonic versus V_{gs} for various input power levels, and Fig. 47 shows the simulated output power versus input power. Figures 43, 45, and 46 show that good second-harmonic generation occurs for $V_{gs} = 0\text{ V}$ and $V_{gs} = V_p = -0.7\text{ V}$. However, in the

present case, the conversion gain is greater by approximately 9 dB (–1 dB vs. –10 dB) when operating at $V_{gs} = V_p$ with $P_{in} = 0\text{ dBm}$ (Fig. 46) than when operating at $V_{gs} = 0\text{ V}$. The results indicate that the optimum bias and input power values for the doubler are $V_{gs} = V_p = -0.7\text{ V}$ and $P_{in} = 0\text{ dBm}$.

The next step requires the generation of matrix tables for the design of a frequency doubler operating at 3 GHz input. These matrix tables represent the simulated output powers of the HEMT frequency doubler for various combinations of the input and output impedances (Z_{N_1} and Z_{N_2}) presented to the HEMT. In this case extensive terminating tables were generated for both $V_{gs} = 0\text{ V}$ and $V_{gs} = V_p = -0.7\text{ V}$ [79]. Several matrix tables are shown in Tables 1–4.

Tables 1 and 2 show the output power simulations where lumped elements (not always practical values) were utilized to present the various impedances to the

input and output ports of the HEMT for $V_{gs} = 0$ V and $V_{gs} = V_p$. As an example, Table 2 shows an analysis with the HEMT biased at $V_{gs} = 0$ V. The table illustrates the wide variation in the conversion gain based on resistive termination and pole-zero placement for both N_1 (Z_{N_1}) as the input network and N_2 (Z_{N_2}) as the output network. In particular, it is seen that if the device is driven from an N_1 that admits a real 50 ohm impedance presented to the gate and is terminated in a real 50 ohm impedance for N_2 seen from the drain, then the conversion gain will have a value of -10.1 dB for operation as a doubler or -13.9 dB as a tripler, with due consideration of unwanted harmonics. However, if N_1 presents an impedance to the gate of the HEMT of 50 at f_0 , a pole at $2f_0$, and 50 at $3f_0$, and N_2 presents a pole f_0 , 50 at $2f_0$, and a pole at $3f_0$, then the conversion gain increases 8.4 dB to a value of -1.7 dB.

In efforts to realize impedances with transmission lines, ideal transmission lines were used to present the

various ideal impedances to the HEMT, without considering losses, to obtain a best-case scenario before proceeding to practical microstrip lines. Tables 7 and 8 show the simulations of the output power of the doubler for $V_{gs} = 0$ V and $V_{gs} = V_p$, utilizing ideal transmission lines. Variations in the conversion gain, as observed in the previous matrix simulation tables, are observed in the simulations that utilize ideal transmission lines as well.

Doubler simulations utilizing practical microstrip lines are considered next. Figures 44–48 show simulations utilizing microstrip lines for $V_{gs} = 0$ V and $V_{gs} = V_p$ for input powers of 0 and -4 dBm.

A perusal of the matrix tables (specifically Tables 9–12) provides requirements for both input and output network impedances to provide optimal conversion gain performance for a frequency doubler. In Table 9, the optimum conversion gain is shown to be 8.6 dB (row 2, column 4), where the required input termination is a short circuit at

^b0 = short circuit; ∞ = open circuit.

the second-harmonic frequency and the output network consists of an open-circuit termination at the third-harmonic frequency along with a short-circuit termination at the fundamental.

After the optimal impedances (Z_{N_1} and Z_{N_2}) have been determined, the impedances have to be synthesized in order to construct a physical frequency doubler to evaluate the efficacy of the results. In this analysis, the synthesis is performed using microstrip transmission lines. Figures 48 and 49 show the transmission response of the input network (short circuit at the second-harmonic) and the output network (short circuit at the fundamental and open circuit at the third harmonic), respectively. The measured and simulated responses for $|S_{21}|$ indicate that the desired short-circuit effect is established at the second-harmonic (6 GHz) for Z_{N_1} as shown in Fig. 48, and similarly for the measured and modeled response of Z_{N_2} in Fig. 49.

The complete experimental frequency doubler was realized on 50 m (20 mil) duroid, and its response is shown in Figs. 50 and 51. Figure 50 shows the conversion gain of the doubler using the technique outlined here, and Fig. 51 shows the harmonic suppression. Figure 50 shows that the maximum conversion gain is 8.5 dB with a -3 dB bandwidth of approximately 8% and with harmonic suppression greater than 20 dBc.

Conventional doubler designs have employed a short-circuit termination at the second-harmonic frequency on the input network along with a short-circuit termination at the fundamental on the output network. This conventional design approach (row 2, column 2 of Table 9) shows the simulated conversion gain as 3.2 dB less than the optimal case outlined by this new approach. For comparison, a frequency doubler utilizing the conventional approach mentioned is developed on 20 mil duroid as well. The

measured and simulated conversion gain for the HEMT doubler utilizing this conventional approach is shown in Fig. 52. The circuit is seen to have a conversion gain of approximately 5 dB around the center frequency of 3 GHz,

rising to 6.7 dB at 3.08 GHz. As indicated previously, the conversion gain produced by the conventional design approach exhibits approximately 3 dB less conversion gain than doublers designed with the unified approach.

Figure 49. Transmission magnitude for output network (Z_{N_2}).

Figure 50. Conversion gain of HEMT doubler using the unified technique ($P_{in} = 0$ dBm, $V_{gs} = -0.7$ V, $V_{ds} = 3.0$ V).

4.3. Reflector Method

Another single-ended design technique [93,95,104,109, 141–145,168–171] is based on the use of reflector networks. This section presents examples of doubler designs operating in the S and C frequency bands incorporating such reflector networks to provide optimized performance. In this presentation, reflector networks are employed simultaneously on both the input and output of HEMT-based designs. In a common-source configuration, the input reflector network passes the fundamental frequency but reflects the desired higher-harmonic signal back into the gate of the device at an optimum phase. The output reflector network passes the desired harmonic while reflecting the fundamental frequency back into the drain of the device at the proper phase angle for maximizing the conversion gain. Measured and simulated results are given to strengthen this design philosophy.

Figure 51. Harmonic suppression of HEMT doubler using the unified technique ($P_{in} = 0$ dBm, $V_{gs} = -0.7$ V, $V_{ds} = 3.0$ V).

Figure 52. Conversion gain of HEMT doubler using conventional design ($P_{in} = 0$ dBm, $V_{gs} = -0.7$ V, $V_{ds} = 3.0$ V).

Figure 53. Fundamental output (input) reflector network.

4.3.1. Reflector Networks. Numerous techniques exist for the realization of frequency multipliers. All techniques at radiofrequencies employ a nonlinear device to generate the desired frequency multiple. The basic configuration of the single-ended frequency multiplier realization is illustrated in Fig. 24. As mentioned previously, the input network allows the fundamental frequency to pass through to the gate of the transistor, in a common-source configuration, while suppressing higher-harmonic frequencies. Similarly, the output network suppresses the fundamental and other unwanted harmonics, while allowing the desired harmonic to pass. The frequency multiplier reflector network design philosophy implemented in this section is applied to an HEMT (Fujitsu FHXLG) frequency doubler with a fundamental frequency of 3 GHz.

As stated above, a primary objective of the output and input networks is to suppress select harmonics. In the process of suppressing the undesired signals, it appears that relatively little attention is given to the possibility that the unwanted signals can be reflected back into the device from the input and output networks simultaneously. The nonlinearity of the device causes these harmonics and the fundamental to mix with other frequency

Figure 54. Wideband HEMT doubler design ($P_{in} = 0$ dBm, $V_{gs} = 0.6$ V).

components. This mixing process can either enhance or degrade the signal at the desired second harmonic. Therefore, it is important for the reflected signal to be properly phased, such that it interferes constructively with the desired harmonic (second harmonic in the case of the frequency doubler examples presented below). Thus, the input and output networks of Fig. 24 can be designed in such a way that in addition to their primary function of filtering, they are reflector networks meeting the above criteria. Owing to the complexity in calculating the actual effects of the reflector networks, there has not been a significant amount of analytical discussion on this topic until 2000 [157,168,169,171].

4.3.2. Consideration of Reflection Phase Angle. As stated, the input and output networks of Fig. 24 should be designed such that they are reflector networks, in addition to their primary function of filtering. The reflector networks developed in this section are analyzed on a frequency doubler with a fundamental frequency of 3 GHz. For a frequency doubler, the input network of Fig. 24 should be designed to reflect the second-harmonic back into the gate of the HEMT at the proper phase angle for constructive interference and optimum conversion gain. Similarly, the output network is designed such that it reflects the fundamental signal back into the drain of the HEMT at the optimum phase. The network of Fig. 53 is a logical choice for the output and input reflector functions described above, although it is not optimal in the input case. In this figure, Z_{in_2} , Γ_{out} , l_1 , l_2 , R_L and Z_{in_1} , l_3 , l_4 , R_g denote output and input reflector networks, respectively [157], and l_1 and l_3 are fixed at a quarter wavelength of the fundamental frequency and a quarter-wavelength of the second-harmonic frequency, respectively.

4.3.3. Effect of Reflection Angle on Conversion Gain. Optimization of the conversion gain of a HEMT (FHXLG) doubler can be obtained by varying the reflection angles on both input and output, using l_4 and l_2 , respectively. Computer analyses, substantiated by experimental measurements, show that conversion gain variation of over 20 and 27 dB result by changes of l_4 and l_2 , respectively. Maximum to minimum gain variations have been found to occur for l_4 , varying from 0 to 200° and l_2 varying from 0 to 180°.

4.4. Doubler Designs Based on Prior Analysis

It has been shown that optimum multiplier designs in terms of conversion gain can be developed. These designs are based on the proper synthesis of input and output networks with the requisite transfer, input magnitude $|Z_{in_2}|$, and phase $\angle Z_{in_2}$. Narrow, medium, and wideband designs have been demonstrated employing this approach [136,157]. Figure 54 shows a wideband design employing this technique.

4.5. Summary

This section has presented design techniques for single-ended frequency multiplier designs. These techniques incorporate reflector networks providing excellent performance characteristics, which includes effective conversion gain and harmonic suppression as demonstrated by the results. These results show the improvement in conversion gain using reflector networks with proper phase angles on the input and output networks simultaneously, which are useful for narrowband and wideband applications. Because of bandwidth constraints imposed by the use of single stubs, incorporating filters into the designs achieves bandwidth extension and improves harmonic suppression. This improvement in bandwidth and harmonic suppression, however, comes at the expense of conversion gain, as shown by the wideband designs. Another advantage of these designs is that they are single-ended, thus alleviating the requirement for complex baluns or transformers.

MICROWAVE CIRCUITS

K. C. GUPTA
HAKI CEBI
CHOONSIK CHO
ZHIPING FENG
University of Colorado at
Boulder

The term “microwave circuits” is used to identify the electrical circuits used at microwave frequencies for performing signal processing functions like amplification, frequency conversion, mixing, detection, phase shifting, filtering, and power dividing. By “microwave frequencies,” we refer to electromagnetic signals whose wavelength is in centimeters, roughly from 30 cm to 1 mm with the corresponding frequencies ranging from 1 GHz ($\text{GHz} = 10^9 \text{ Hz}$) to 300 GHz. The frequency range from 30 to 300 GHz is also known as the *millimeter-wave band*. Microwave frequencies present several interesting and unusual features not found in other portions of the electromagnetic frequency spectrum. These features make microwaves uniquely suitable for several useful applications in telecommunications, radar, industrial heating and sensors, and so on. The most common consumer application of microwaves is the domestic microwave oven used for food processing.

Microwave circuits differ from lower-frequency electronic circuits for several reasons. Active devices (transistors, diodes, etc.) used at microwave frequencies are special designs and in several cases operate on entirely different physical principles. Parasitic reactances associated with passive and active circuit elements used at lower frequencies become significant and can cause disastrous effects on performance of circuits at microwave frequencies. Dimensions of lumped elements used in low-frequency electronics can become comparable to the wavelengths at microwave frequencies and cause what are known as distributed circuit effects. Transmission lines (and other structures) used for transmission of signals from one location to another inside a circuit need to be designed differently from those at lower frequencies. All these features make the design, technology, and operation of microwave circuits significantly different from their lower-frequency counterparts.

1. TYPES OF MICROWAVE CIRCUITS

Types of microwave circuits may be classified in several different ways. Depending on the type of active devices used, there are vacuum-tube circuits and solid-state circuits. Depending on the technology used, there are printed circuits, hybrid integrated circuits, monolithic circuits, and so on. Depending on the circuit functions, there are amplifier circuits, filter circuits, mixer circuits, power divider circuits, and so on. Depending on the special performance features, there are low-noise circuits, high-power circuits, and so on. Depending on the transmission structures whose sections form the basic building blocks for

circuit design, there are waveguide circuits, coaxial circuits, stripline circuits, microstrip circuits, coplanar waveguide (CPW) circuits, finline circuits, slotline circuits, dielectric waveguide circuits, and so on. Depending on the special material properties used, there are ferrite circuits, surface acoustic wave (SAW) circuits, and so on.

This article provides a brief overview of the important types of microwave circuits. Several specific types of microwave circuits are described in more detail in other articles in this encyclopedia. These include articles on frequency converters/mixers, microwave signal amplifiers, microwave couplers, microwave detectors, microwave filters and multiplexers, microwave oscillators, microwave phase shifters, microwave switches, power combiners/dividers, and stripline components.

2. LUMPED AND DISTRIBUTED CIRCUITS

All electronic circuits can be grouped into five classes depending on their physical dimensions compared to the wavelength at the frequency of operation. When all three physical dimensions of a component or a circuit are much smaller than the wavelength at the frequency of operation, we call it a “lumped circuit.” These are most extensively used components and circuits at lower frequencies. Lumped components are used at microwave frequencies also, but their dimensions have to be proportionately smaller. When one of the physical dimensions of a component is comparable to the wavelength (other two being still small), we refer to these as one-dimensional components, and the circuits using these components are called one-dimensional circuits. Circuits using sections of transmission lines as components, commonly known as transmission-line circuits, are one-dimensional. Transmission-line circuits are used extensively at microwave and millimeter-wave frequencies. Components and circuits with two of their dimensions comparable to the wavelength at the operating frequency are appropriately called “two-dimensional components.” Thin-film components, planar components and circuits fabricated on thin substrates, microstrip patch antennas, and reduced-height waveguide components belong to this class. These planar components are the important building blocks in microwave integrated circuits. The fourth class of electronic circuits have all three of their dimensions comparable to the wavelength at the operating frequency. These are known as three-dimensional components. Waveguides, hollow metallic cylindrical tubes used as transmission structures in place of conventional transmission lines, have both of their transverse dimensions comparable to the wavelength. Circuits using these waveguide sections and resonant cavities made out of these waveguides are examples of three-dimensional components and circuits used at microwave frequencies. Finally, the fifth class of electronic circuits (classified by their size) have at least one of their dimensions much larger than the wavelength at the operating frequency. These are known as quasioptical circuits. The term “quasioptical” is derived from their likeness to optical circuits that are orders of magnitude larger than the submicron wavelengths at optical frequencies.

3. EVOLUTION OF MICROWAVE CIRCUITS

For a long time the term “microwave circuits” was synonymous with “waveguide circuits.” A waveguide was recognized as a useful transmission structure for microwave frequencies in the early 1930s. The work of Southworth and others [1–3] at Bell Telephone Laboratories deserves mention in this respect. It was soon realized that a short length of waveguide, with suitable modifications, might function as a radiator and also as a reactive element. Resonant cavities and horn antennas are mentioned in a 1936 article by Southworth [1]. Modern waveguide circuitry had its beginning in the efforts to obtain both a more efficient transfer of microwave power from a source to a waveguide transmission line, thereby providing the elements of a transmitter, and again in the efficient recovery of microwave power at the receiving end, thereby providing the elements of a receiver. These efforts led to the development of several components like traveling detectors, wavemeters, terminations, and so on. Some idea of the techniques used in 1934 can be obtained by recalling that optical benches were commonly used to set up microwave experiments [4]. Several photographs of equipment of those days are available in an interesting article surveying the history of the progress of microwave arts published in the fiftieth anniversary issue of *Proceedings of the IRE* [4].

The principle of multiple reflections from discontinuities and the associated principle of cavity resonance played an important role in the development of microwave technology. In some cases, these principles were used to match a source of microwave power to a waveguide. In others, they served to match a waveguide to a receiver, such as a crystal detector. In still others, they served to pass freely a band of frequencies. Together, these principles formed the foundations of microwave circuits. One of the key features of microwave circuits has been the empirical adjustment or tuning of characteristics by screws and irises (and even by denting) in waveguides. In the beginning it was an art that was learned by trial and error. This came to be known as “plumbing” and had been for quite a long time a practical tool for microwave engineers.

Perhaps the greatest single contribution to the engineering analysis of microwave circuits was by Phillip H. Smith [5], who provided a graphical tool for solving otherwise complicated transmission-line problems. Not only were laborious calculations avoided, but, while solving the problems on a Smith chart, one could visualize the step-by-step processes underway. Few gadgets of microwave circuitry have been more useful than the Smith chart. Rapid developments in microwave circuits took place during World War II, when special laboratories were set up at the Massachusetts Institute of Technology and at Columbia University to apply microwave techniques to radar problems. Many significant developments in microwave circuits took place during these years, but were published later. A few of those deserve mention. Fox [6] developed devices by which phase could be added progressively to a waveguide. Another product was a hybrid tee (or magic tee) [7] and still another equally significant one was the

first directional coupler [8]. All these devices found practical uses immediately. Another direction of wartime evolution was the extension of filter techniques to higher frequencies, leading to transmission line filters. Simultaneously, analytical tools were also developed. The classical description of network performance in terms of voltages, currents, impedance, and admittance matrices was replaced by a description based on the transmitted and the reflected wave variables, leading to the concept of scattering matrix.

The scattering matrix formalism allows simpler representation of multiport microwave networks. At this stage in the development of microwave circuits, two basic transmission structures were employed frequently. These were the waveguide and the coaxial TEM-mode line. Waveguides provided higher power capability and low loss that lead to high- Q resonant cavities. Coaxial lines provided inherently wider bandwidth because of the absence of dispersion effects. Also, the concept of impedance could be easily interpreted in the case of coaxial lines. This simplified the design of components. These two transmission structures (waveguides and coaxial lines) grew as important components for microwave circuits. Often their roles have been complementary; sometimes they appear in the same module. It was at this stage that a very useful microwave technique emerged from a special adaptation of two-conductor transmission-line theory. Introduced by Barrett and Barnes [9] in 1951, this structure, as used presently, consists of a thin strip of conductor sandwiched between two dielectric plates metalized on the outside. This structure is known as a stripline. Early stripline work used razor blades and glue to cut the thin strips and paste them on dielectric sheets. With the availability of copper-clad laminates (first introduced for printed circuits) the stripline techniques have developed into a predictable and precise batch process technology. The first detailed account of stripline circuits was made available by the Sanders *Tri-plate* manual [10], published in 1956. A comprehensive account of stripline circuits was made available in a book by Harlan Howe, Jr. [11]. The most significant feature of a stripline transmission structure is that the characteristic impedance of the line is controlled by the width of the central strip, which is fabricated by photoetching a copper-clad dielectric substrate. The two-dimensional nature of the stripline circuit configuration permits the interconnection of many components without the need to break the outer conductor shielding. This also allows the placement of the input and output ports with a high degree of flexibility. Striplines were found to be very convenient for use in parallel-line couplers because of the natural coupling between two strips placed close to each other. The principles of the coupled-line directional coupler were introduced by Wheeler [12] in 1952. Even today a vast majority of directional couplers use a stripline configuration.

In the early 1950s, another type of transmission structure was conceived [13,14], consisting of a single dielectric laminate with a conducting strip on one side and a complete conducting coating on the other side. This structure is known as a microstrip line. Microstrip lines enjoyed a brief spell of popularity and intensive investigations in the

1950s, but were not readily accepted at that time for microwave use because of the high loss per unit length caused by radiation. This was largely a result of the low dielectric constant (about 2.5) of the substrate materials then in use. Further developments were prevented by the lack of availability of both the high-dielectric-constant, low-loss materials and suitable methods for processing and production.

Ever-increasing demands for miniaturized microwave circuitry for use in weapons, aerospace, and satellite applications led to renewed intense interest in microstrip circuits in the 1960s. An elegant analysis of microstrip structure based on conformal mapping transformation was presented by Wheeler [15,16]. The technology of high-dielectric-constant, low-loss dielectric materials and that of deposition of metallic films were perfected [17] and became easily available in the late 1960s. This led to rapid developments in the use of microstrip lines in microwave circuits. Today, microstrip line is the most common transmission structure used in hybrid and monolithic microwave integrated circuits.

The availability of a planar microwave transmission-line structure like microstrip line, coupled with the rapid developments in microwave semiconductor devices and the techniques of thin-film deposition and photolithography, eventually resulted in the technology of microwave integrated circuits [18–21]. Microwave integrated circuits (MICs) represent an extension of thin-film hybrid integrated circuit technology to microwave frequencies. These hybrid MICs consist mostly of passive components and circuits in the form of conducting patterns deposited on ceramic or dielectric substrates plus active devices mounted on these circuits in the form of chips or in specially designed packages. In addition to microstrip, other types of lines called slotline and coplanar lines [22,23] have been used in some MICs. Slotline consists of a slot in the conducting pattern on one side of a dielectric substrate. The other side of the substrate does not contain any metallization. Coplanar lines also involve a metallization pattern, but only on one side of the substrate.

Another trend in microwave circuits is the use of lumped elements. Previously, lumped elements could not be used because the size of available lumped elements was comparable to the wavelength at microwave frequencies. With the use of photolithography and thin-film techniques, the size of elements (capacitors, inductors, etc.) can be reduced so much that these elements can be used up to J-band (10–20 GHz) frequencies [24,25]. Use of lumped elements on dielectric substrates, along with semiconductor devices in chip form mounted thereon, is an attractive option for microwave integrated circuits. Cost reduction of the order of one-fiftieth or more has been predicted with the use of these types of circuits [24]. Apart from reduction in size, there is another advantage of lumped elements—circuit design and optimization techniques perfected at lower frequencies can now be directly used in the microwave frequency range. In addition to lumped elements and one-dimensional transmission-line components, two-dimensional planar components have also been proposed for use in microwave circuits [26]. These components are compatible with stripline and

microstrip line and provide a useful alternative in microwave circuit design.

The current generation of MICs is monolithic microwave integrated circuits (MMICs) using semiconductor substrates [27,28]. Semiconductor substrates used are high-resistivity gallium arsenide and, to a limited extent, high-resistivity silicon. Difficulties arise from the need to use a variety of microwave semiconductor devices that cannot be fabricated by a common process, as well as because of the requirement of large substrate areas when distributed elements (transmission-line sections) are used for passive functions. GaAs technology [29] and GaAs metal semiconductor field-effect transistors (MESFETs) [30] play the key role in microwave monolithic integrated circuits.

Microwave integrated circuits (hybrid or monolithic) exhibit almost the same advantages as those available in the case of integrated circuits at lower frequencies [31], namely: (1) improved system reliability, (2) reduced volume and weight, (3) batch production, and (4) eventual cost reduction when a large number of standardized items are required.

As in the case of low-frequency integrated circuits, the MICs are responsible for both the expansion of present markets and the opening of many new applications, including a host of nonmilitary uses.

There are some difficulties associated with the use of MICs [31]. Before MICs became popular, the microwave circuit designers and users had the flexibility to incorporate tuners and adjustment screws in circuits in order to optimize the performance of the circuit after fabrication. MICs, especially if they have to meet high reliability standards, lack these trimming arrangements. Consequently, devices used in MICs need to be characterized precisely and the circuits have to be designed more accurately. Computer-aided design, simulation, and optimization [32,33] techniques have therefore become a necessity.

The current state of the art in microwave circuits is summarized in several recent books [34–36].

4. WAVEGUIDE CIRCUITS

As pointed out in Section 3, hollow metallic single-conductor waveguides of rectangular and circular cross section were among the earliest forms of transmission structures used at microwave frequencies (see Fig. 1). A rectangular waveguide has been more popular and is still used today for many applications. A large variety of waveguide circuit components such as couplers, detectors, isolators, attenuators, and slotted lines are commercially available for various standard waveguide frequency bands ranging from 1 GHz to over 220 GHz [37,38,42]. Because of the more recent trend toward miniaturization and integration, more and more microwave circuits are currently fabricated using planar transmission lines (such as microstrip line and coplanar waveguides) discussed later in this article. However, there is still a need for waveguide circuits in many applications such as high-power systems, millimeter-wave systems, and some precision test/measurement applications [38,42]. Also waveguides can be

Figure 1. Hollow metallic single-conductor waveguides: (a) rectangular waveguide; (b) circular waveguide. Waveguides were the earliest form of transmission structures used at microwave frequencies and are still used today for special applications.

combined with other kinds of transmission lines [39] for some special applications.

4.1. Modes in a Waveguide

Unlike most of the other transmission structures discussed later in this article, waveguides do not support the transverse electromagnetic (TEM) mode of wave propagation. Waveguides support two other kinds of modes known as the transverse electric (TE) and transverse magnetic (TM) modes. TE modes have their electric field components only in a plane transverse to the direction of propagation along the waveguide, and for TM modes the magnetic field components are totally in the transverse plane. Both of these types of modes have cutoff frequencies below which wave propagation is not possible. For a rectangular waveguide the mode with the lowest cutoff frequency is the TE_{10} mode. Field patterns of the TE_{10} mode for a rectangular waveguide are shown in Fig. 2. Various field components for this mode can be expressed as [34, pp. 145–146]

$$\begin{aligned} E_y &= E_{y0} \sin(\pi x/a) e^{-j\beta z} \\ H_x &= H_{x0} \sin(\pi x/a) e^{-j\beta z} \\ H_z &= H_{z0} \cos(\pi x/a) e^{-j\beta z} \end{aligned} \quad (1)$$

where a is the waveguide width (in the x direction) and β is the phase constant of the wave along the z direction given by

$$\beta = \sqrt{\kappa^2 - \left(\frac{\pi}{a}\right)^2} \quad (2)$$

Figure 2. Field patterns of TE_{10} mode in a rectangular waveguide. Dashed lines show the H field, and solid lines show the E field. Note that there is no z component of electric field.

where κ is the wavenumber ($\kappa = \omega\sqrt{\mu\epsilon}$). The cutoff frequency for the dominant TE_{10} mode is given by

$$f_{c10} = \frac{1}{2a\sqrt{\mu\epsilon}} \quad (3)$$

4.1.1. Dispersion Characteristics. The fact that the propagation constant for individual waveguide modes is a nonlinear function of frequency, and that the different modes start to propagate at different frequencies, leads to wave dispersion in a waveguide [38, pp. 106–107].

4.1.2. Power-Handling Capability. The power-handling capability for a transmission medium needs to be characterized for high-power microwave circuits. Metallic waveguides can handle very high power because of their physical structure. In a rectangular waveguide operating in the fundamental mode, the maximum peak power that the waveguide can handle is given by [40]

$$P_{\max} = 416(ab) \text{ (kW/cm}^2\text{)} \quad (4)$$

where b is the waveguide dimension in the y direction.

4.2. Waveguide Circuit Components

Circuits for all kinds of signal processing functions have been designed using waveguides. A few of these are reviewed here.

4.2.1. Waveguide Phase Shifters. A phase shifter is a circuit that produces an adjustable shift in the phase angle of the wave transmitted through it. There are different types of waveguide phase shifters. Two of these, linear and rotary phase shifters, are described here:

Linear Phase Shifter. An example of linear phase shifters is the circuit consisting of three dielectric slabs placed in a rectangular waveguide [41] as shown in Fig. 3. The center slab is free to move longitudinally, and it is moved by a suitable drive mechanism to

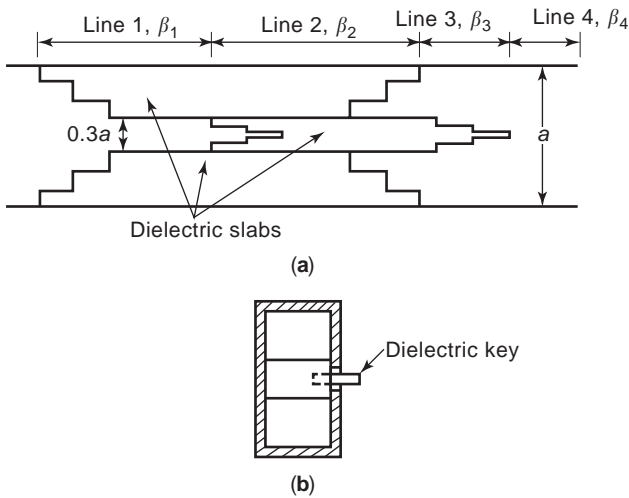

Figure 3. A linear phase shifter in a waveguide configuration. The dielectric key is used to move the central dielectric slab and thereby change the phase shift. (From Ref. 42, © Ellis Horwood Limited, reprinted with permission.)

which it is keyed by means of a dielectric key that protrudes through a long centered slot cut in one broad face of the guide. Each end of the dielectric slab is cut stepwise to provide a broadband multisection quarter-wave transformer to match the partially filled guide to the empty and completely filled guide. If the center slab is displaced a distance x to the right, the effect is to lengthen lines 1 and 3 by an amount x and to shorten lines 2 and 4 by the same amount x . Therefore, the phase shifter change undergone by a wave propagating through the structure is

$$\Delta\phi = [(\beta_1 + \beta_3) - (\beta_2 + \beta_4)]x \quad (5)$$

The phase shift $\Delta\phi$ is proportional to the displacement x . The amount of phase shift increases if the dielectric constant of the slab is increased. If a material whose ϵ_r equal to 2.56 is used in a 3-cm waveguide of dimensions $a = 2.25$ cm, the phase shift obtained is about 0.4 rad/cm of displacement. About 16 cm of displacement gives a phase shift of more than 360° .

Rotary Phase Shifter. The rotary phase shifter [42, pp. 262–266] is a better precision instrument than the linear phase shifter. It consists of a half-wave plate and two quarter-wave plates (see Fig. 4). The quarter-wave plate on the left converts a linearly polarized TE_{11} mode into a circularly polarized mode, and the quarter-wave plate on the right produces a linearly polarized wave when a circularly polarized wave is incident on it. Rotation of the half-wave plate through an angle θ changes the phase of the transmitted wave by an amount 2θ . This simple dependence of the phase change on mechanical rotation is the main feature of the rotary phase shifter.

4.2.2. Microwave Hybrid Junction. A rectangular waveguide hybrid, which is more popularly known as

Figure 4. (a) A rotary phase shifter consists of a $\lambda/2$ plate and two $\lambda/4$ plates (rotation of the $\lambda/2$ plate changes the phase; $\lambda/4$ plates convert circular polarization into linear and vice versa); (b) details of the $\lambda/4$ plate. (From Ref. 53, © McGraw-Hill, 1992, reprinted with permission.)

“magic tee,” is shown in Fig. 5. If a wave in the dominant TE_{10} mode is incident at the port 4, the structure is symmetrical with respect to this wave, and hence equal powers are transmitted to port 1 and 3. If E_n^n represents the transmitted electric field in the n th port when the incident wave is in the m th port, then $E_4^1 = E_4^3$. Besides, it can be seen that no power is transmitted to port 2 from port 4, that is, $E_1^2 = 0$. On the other hand, if a TE_{10} wave is incident at port 2, the E field has an odd symmetry about the plane of symmetry and therefore excites fields in ports 1 and 3 which are 180° out of phase. Hence, $E_2^1 = -E_2^3$. Also, power incident at port 2 is not transmitted to port 4. Therefore, $E_2^4 = 0$. The power coupling factor may not be exactly one-half if ports 2 and 4 have reflections. To ensure a coupling of exactly one-half, which is desirable, the junction needs to be matched by irises or probes.

Figure 5. A microwave hybrid or magic tee in a rectangular waveguide configuration. The magic tee is a directional coupler with 3 dB coupling and is commonly used in balanced mixers.

Figure 6. A waveguide directional coupler is a widely used circuit component used to sample the waves traveling in one particular direction (say, from 1 to 2) independent of the reflected wave traveling in the opposite direction (from 2 to 1).

4.2.3. Directional Couplers. A directional coupler is a four-port circuit. An example is shown in Fig. 6. A portion of the wave incident at port 1 couples into the bent waveguide through the hole a_1 . The remaining wave travels to the hole a_2 in the main waveguide (ports 1, 2), and a portion of it again couples into the bent waveguide. If the magnitudes of the energy coupled through holes a_1 and a_2 are equal, and if the distance between a_1 and a_2 is $\lambda_g/4$, then the two coupled signals are reinforced at port 4 because they arrive with equal phase. On the other hand, the two coupled signals cancel each other at port 3, because they are 180° out of phase. Similarly, a wave incident on the junction from port 2 travels to ports 1 and 3, but no signal travels to port 4. The ratios of signal flow between ports 1 and 4 and between ports 2 and 3 are known as the *coupling coefficient* of the directional coupler. In general, the leakage of energy through holes a_1 and a_2 is kept quite small. A directional coupler can be used as a standing-wave detector and forms an important component in microwave and millimeter-wave network analyzers. Some other designs [37, Sect. 7.2, 42, pp. 267–271] of typical waveguide directional couplers are shown in Fig. 7.

4.2.4. Waveguide Filters. Design procedures for filters using waveguides and other transmission structures have certain common features. These filters can be designed using the low-frequency prototype filter synthesis techniques. One such technique, called the *insertion-loss* method, begins with a complete specification of the attenuation characteristics of the filter and develops a basic prototype lowpass filter having the desired passband characteristics. Using suitable frequency transformations and element realizations, the required type of filter (lowpass, bandpass, highpass, or bandstop filters) is derived. The lumped element values of these filters are then realized in terms of the distributed circuit elements. Special features for implementing filters in waveguide configuration are reviewed in this section:

Waveguide Stub Filters. One of the simplest realizations of waveguide bandpass (or bandstop) filters is a waveguide stub filter [38, pp. 185–190] shown in Fig. 8. For bandpass filters, the short-circuited E -plane stubs are a half-wavelength long at the center frequency of the filter, and are connected in cascade with $\lambda/4$ separations. Band rejection filters use

Figure 7. Two other designs of waveguide directional coupler circuits. In both of these cases, coupling takes place through holes in the common wall of the two waveguides.

stubs that are an odd multiple of quarter-wavelength, also separated by $\lambda/4$ distance. The stubs can be asymmetric or symmetric along the main waveguide and with or without steps. The selection of the stub configuration depends on the required bandwidth and power-handling capability. Filters with stepped stubs can be designed to yield narrower bandwidth. Filters with stubs on both sides of the waveguide broadwall have large power-handling capability.

E -Plane Filters. E -plane filters have been developed as compatible filtering structures for integrated millimeter-wave circuits [43,44] and are most often realized in finline techniques or as all-metal structures. Their common feature is that the filter metallization pattern is obtained using photolithographic techniques. Thus, the geometry of the component is realized with very small manufacturing errors, which is very important at millimeter-wave frequencies. Four different configurations of E -plane waveguide filters are shown in Fig. 9. All of types are designed as bandpass filters [43,45,46]. In Fig. 9, the shaded part is dielectric substrate to support the thin metallization structures; t_m is the thickness of the metal layer and t_d is the thickness of the dielectric substrate; and l_c is the length of the metal strip and l_r is the gap between metal strips.

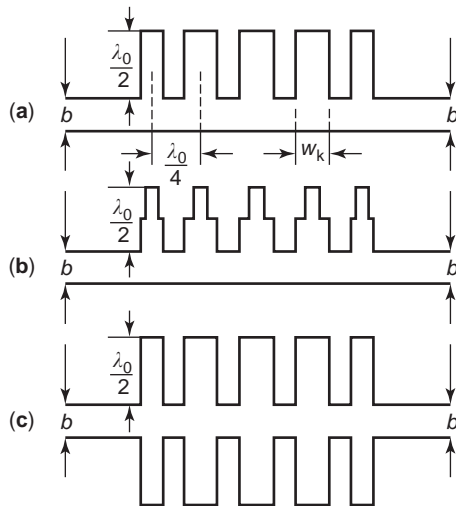

Figure 8. Waveguide stub filters: (a) asymmetric stubs without steps; (b) asymmetrical stubs with steps; (c) symmetric stubs without steps. Both bandpass and bandstop characteristics can be designed in these circuits.

Corrugated Waveguide Filters. Corrugated waveguide structures similar to that shown in Fig. 10 are used as lowpass filters in numerous antennas feed system to reject the spurious harmonics from transmitters [38, pp. 200–207; 49]. They can also be designed as bandpass filters, with a wide or narrow passband response [47,48].

Evanescent-Mode Waveguide Filters. Evanescent-mode waveguide filters (Fig. 11) can be designed [50–52] to provide a very wide stopband with low passband

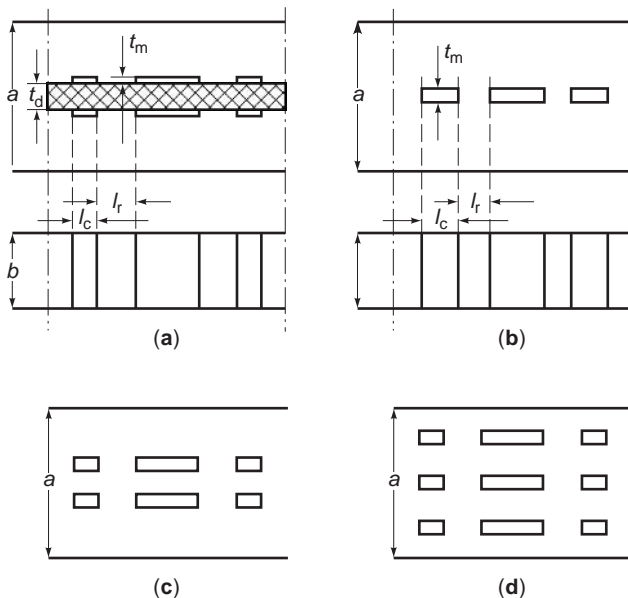

Figure 9. *E*-plane bandpass filters: (a) large gap finline filter; (b) single metal insert filter; (c) double metal insert filter; (d) triple metal insert filter. In these designs, fin dimensions and hence RF performance can be controlled accurately by photolithography techniques. (From Ref. 38, © Artech House, 1993, reprinted with permission.)

Figure 10. Longitudinal cross section of a corrugated waveguide filter.

insertion loss. Their size is compact, even when the passband is located in the lower microwave frequency region. For these reasons the evanescent-mode waveguide structures are often used as pseudolowpass filters, or as bandpass filters in a wide microwave spectrum. Because of the high skirt selectivity achievable in this filter type, they can also be used in duplexers and multiplexers.

4.3. Multiplexers

Multiplexer circuits are required for combination or separation of communication channels at different frequencies. The multiplexer for the antenna feed systems must provide separation of the receive and transmit bands and combination of the individual transmission channels that cover only a small portion of the frequency band. There are four different multiplexing methods that are applied in feed systems [38, pp. 252–307]: (1) the circulator/filter chain, (2) the directional filter approach, (3) the manifold multiplexing techniques, and (4) the branching filter concept. Each of these has its own particular properties and applications.

4.3.1. Waveguide Circuits Using Active Devices. Waveguide circuits using active devices can be designed for various applications, such as oscillator, mixer, detector, and so on [37, pp. 325–490]. A waveguide cavity Gunn oscillator [53] is shown in Fig. 12 as an example. In this design the high impedance of the waveguide is transformed into low impedance at the location of the Gunn device by means of quarter-wave transformers. The cavity resonant frequency can be adjusted by changing the location of the

Figure 11. Ridged waveguide evanescent mode bandpass filter: (a) top view; (b) side view. These designs provide compact filters at lower microwave frequencies.

Figure 12. A Gunn oscillator waveguide circuit that uses two quarter-wave sections to transform the high impedance of the waveguide to a low impedance at the Gunn device. (From Ref. 53, © McGraw-Hill, 1992, reprinted with permission.)

short circuits. A tuning screw can be used for fine tuning of the cavity. More examples of active wave guide circuits can be found in Refs. 37 and 53.

4.4. Computer-Aided Design of Waveguide Circuits

Waveguide circuits require an approach for computer-aided design (CAD) different from that used for transmission-line circuits at microwave frequencies. The traditional CAD methods for waveguide circuit are usually based on the network analysis, with various discontinuities in the waveguide modeled separately by a combination of equivalent reactances [54]. This equivalent circuit approach has some drawbacks. The models are valid only for a specified geometry and only within a certain range of parameters. Another problem associated with using the equivalent circuit models is their inability to account for higher-order mode-coupling effects, which can occur if discontinuities are in close proximity. A field-theory-based approach [55] overcomes these limitations. Some features of this approach are a very accurate prediction of frequency responses, higher-order mode effects taken into account, no restrictions on the wavelength (or frequency range), and straightforward extension in millimeter-wave bands. Several numerical methods are used for field analysis of waveguide circuits; the most popular are the finite-different time-domain method (FDTD) [56] finite-element method (FEM) [57], transmission-line matrix method (TLM) [58], mode-matching techniques (MMT) [59], and the method of integral equations [60]. For automated design and yield analysis of waveguide circuits, modal analysis [61] has emerged as the most useful electromagnetic simulator, either in the generalized scattering matrix (GSM) formulation or in the generalized admittance matrix (GAM) form. It has been demonstrated [61] that for waveguide circuits the GAM approach requires only half the number of unknowns at the internal ports and hence is much more efficient than the GSM representation.

5. COAXIAL-LINE CIRCUITS

Coaxial line is the most commonly used transmission structure over a very wide range of frequencies from

Figure 13. Geometry of a coaxial line. The ratio of the outer to inner conductor radii (b/a) determines the characteristic impedance Z_0 of the line.

very low frequencies through microwave frequencies and extending into the millimeter-wave frequency range. However, because of the convenience of physical size, coaxial line circuits are popular only in the microwave frequency range. They are too bulky at lower frequencies and very difficult to fabricate (as well as very lossy) at millimeter-wave frequencies.

The geometry of a coaxial line is shown in Fig. 13. One can derive the expressions for electromagnetic fields in this line solving Laplace equation for scalar potential. As shown in Fig. 13, the inner conductor is considered to be at V_0 volt potential and the outer conductor is at 0V. The electric and magnetic field vectors, can be derived as [34]

$$\bar{E}(\rho, \phi, z) = \frac{V_0 \hat{\rho} e^{-j\beta z}}{\rho \ln b/a} \quad (6)$$

$$\bar{H}(\rho, \phi, z) = \frac{V_0 \hat{\phi} e^{-j\beta z}}{\eta \rho \ln b/a} \quad (7)$$

where $\beta = \omega \sqrt{\mu\epsilon}$ and $\eta = \sqrt{\mu\epsilon}$ are the phase constant and the intrinsic impedance of the medium, respectively.

Coaxial lines possess general properties of TEM-mode transmission lines. Characteristic impedance Z_0 of a coaxial line filled with a dielectric material of relative dielectric constant ϵ_r as shown in Fig. 13, is

$$Z_0 = \frac{60}{\sqrt{\epsilon_r}} \ln \frac{b}{a} \Omega \quad (8)$$

In addition to TEM modes, coaxial lines can also support TE and TM waveguide modes. When coaxial line dimensions are selected appropriately for the operating frequency range; these modes are evanescent modes and they are excited only near discontinuities or sources. In practice, it is essential to know the cutoff frequencies of the lowest-order waveguide mode and use the coaxial line below this frequency. Various types of microwave circuits can be realized using coaxial lines [62,63]. However, with the more recent advances in planar circuit technology and because of their size and fabrication difficulties, they are not used commonly. In the past, coaxial lines have been widely used to design passive filter circuits. A common type of high-pass filters constructed by coaxial lines as shown in Fig. 14

Figure 14. A highpass filter constructed by coaxial lines. Lumped series capacitors and shunt inductors provide the filter operation. (From Ref. 62, © Artech House, 1980, reprinted with permission.)

has been described in the classic book by Matthaei et al. [62]. In this configuration, coaxial stubs present shunt inductances, and disks spacers constitute series capacitors.

Another coaxial filter example described by Matthaei [62] is a series capacitance-coupled half-wave resonator circuit shown in Fig. 15. This filter is realized by breaking the inner conductor at several locations. The gap spacing needed to produce a desired coupling can be found either experimentally or theoretically.

Coaxial-line components are also used extensively as coaxial probes connectors in between various circuit assemblies and for connecting circuits to instrumentation, and so on. Most of the coaxial lines that are used as cables and connectors have a $50\ \Omega$ characteristic impedance except for $75\ \Omega$ coaxial cable used for television systems. Coaxial connectors must have low standing-wave ratio (SWR), no spurious higher-order modes, mechanical strength, and repeated usability. Some of the most common microwave coaxial connectors are popularly known as type N connector (originally named after P. Neill), (SMA) SubMiniature Amphenol connector, (SSMA) Scaled SubMiniature Amphenol connector, and (APC-7) Amphenol Precision Connector, 7-mm connector. These connector types are shown in Fig. 16. The type N connector is a relatively large connector with an outer diameter of 0.625 in. The recommended upper operating frequency ranges from 11 to 18 GHz. The SWR is typically less than 1.07. The SMA connector is small compared to the type N connector with an outer diameter of the female end of 0.210 in. and can be used up to 25 GHz. SMA connectors modified to work up to 40 GHz are known as K connectors. An SSMA connector is even smaller. The outer diameter of the female end is about 0.156 in. and the maximum operating frequency is about 38 GHz. The APC-7 connector is a precision connector which has an SWR less than 1.04 and an

operating range of up to 18 GHz. Coaxial connectors are described in Refs. 34 (pp. 169–170) and 64.

6. STRIPLINE CIRCUITS

6.1. Striplines

A stripline [11,65] is a planar-type transmission line that lends itself well to microwave integrated circuitry and package feedthroughs. The geometry of a stripline is shown in Fig. 17a. A thin conducting strip of width W is centered between two wide conducting ground planes with a separation b . The entire region between the ground planes is filled with a dielectric.

Unlike microstrip lines and other open planar transmission lines described later in this article, a stripline can support a pure TEM mode because it has a homogeneous dielectric medium. The stripline, however, can also support higher-order TM and TE modes. These modes can be suppressed with shorting screws between the two ground planes and by restricting the ground planes spacing to less than one quarter wavelength. A sketch of the field lines for the TEM stripline mode is shown in Fig. 17b.

Figure 17. (a) Geometry of stripline—a thin strip of width W is inserted in a dielectric with ground planes on the top and the bottom; (b) electric and magnetic fields in a stripline. Striplines support a pure TEM mode.

6.2. Stripline Parameters

An exact solution of Laplace equation of electromagnetic fields in a stripline can be obtained by the conformal mapping approach [66]. However, closed-form expressions that give a good approximation of the exact results are used in circuit design [34].

The phase constant for a stripline is given (by the usual relation for homogeneously filled lines) as

$$\beta = \frac{\omega}{v_p} = \omega \sqrt{\mu_0 \epsilon_0 \epsilon_r} = \sqrt{\epsilon_r} k_0 \quad (9)$$

where ω is the angular frequency, v_p is the velocity of the wave along the line, μ_0 is the permeability of free space, ϵ_0 is the permittivity of free space, ϵ_r is the dielectric constant of the stripline dielectric, and k_0 is the phase constant of free space.

The characteristic impedance of a transmission line is given by

$$Z_0 = \sqrt{\frac{L}{C}} = \frac{1}{v_p C} \quad (10)$$

where L and C are inductance and capacitance per unit length of the line. An approximate expression for characteristic impedance [34] of striplines is

$$Z_0 = \frac{30\pi}{\sqrt{\epsilon_r}} \frac{b}{W_e + 0.441b} \quad (11)$$

where

$$\frac{W_e}{b} = \frac{W}{b} - \begin{cases} 0 & \text{for } W/b > 0.35 \\ (0.35 - W/b)^2 & \text{for } W/b < 0.35 \end{cases}$$

Since the stripline is a TEM-mode line, the attenuation due to the dielectric loss is obtained by the procedure commonly used for other TEM lines [67]. The attenuation due

to the conductor loss is approximated as

$$\alpha_c = \begin{cases} \frac{2.7 \times 10^{-3} R_s \epsilon_r Z_0}{30\pi(b-t)} A & \text{for } \sqrt{\epsilon_r} Z_0 < 120 \text{ Np/m} \\ \frac{0.16 R_s}{Z_0 b} B & \text{for } \sqrt{\epsilon_r} Z_0 > 120 \text{ Np/m} \end{cases} \quad (12)$$

with

$$A = 1 + \frac{2W}{b-t} + \frac{1}{\pi} \frac{b+t}{b-t} \ln \left(\frac{2b-t}{t} \right)$$

$$B = 1 + \frac{b}{0.5W + 0.7t} \left(0.5 + \frac{0.414t}{W} + \frac{1}{2\pi} \ln \frac{4\pi W}{t} \right)$$

where t is the thickness of the strip metallization.

6.3. Examples of Stripline Circuits

Design procedures for stripline circuits are identical to those for other TEM mode transmission line circuits. The main difficulty in transferring the design from one kind of transmission line (say, coaxial line) to another (say, stripline) arises from the fact that discontinuity and junction reactances are different for different kinds of transmission structures. Quite often, the first-order designs are carried out without considering the effect of discontinuity/junction reactances. Then the circuit performance is computed taking discontinuity/junction reactances into account, and designable parameters of the circuit are optimized to compensate for discontinuity/junction effects. This design methodology is common to microwave circuit design using any kind of transmission structure.

6.3.1. Branchline Directional Couplers. These couplers, similar to the one shown in Fig. 18 [68], are essentially power division networks with two important features—namely, the two ports are mutually isolated (ports 1 and 4 in Fig. 18 when the input signal is connected to port 1), and the output signals at the other two ports (ports 2 and 3 in Fig. 18) are out of phase by 90° . These circuits form building blocks of several other circuits such as balanced mixers, variable attenuators, pin-diode phase shifters, directional filters, diplexers, multiplexers, and transmit-receive (TR) switches. Branchline couplers are also used

Figure 18. A branchline coupler using striplines. Port 1 is the input port, ports 2 and 3 are output ports, and port 4 is the isolated port. Output signals at ports 2 and 3 are 90° out of phase.

extensively in antenna array feed networks in preference to Y-junction-type power dividers and as impedance transformers. In active circuits, they provide the advantage of direct-current (DC) coupling for biasing. Branchline couplers are forward-wave couplers and hence can be cascaded without crossing lines.

6.3.2. Parallel-Coupled-Line Directional Couplers. Parallel-coupled-line directional couplers shown in Fig. 19 [69] offer much larger bandwidths as compared with the branchline couplers. They are mostly backward-wave couplers, although forward-wave couplers are also possible using an inhomogeneous medium. The most commonly used parallel-coupled directional coupler is the TEM-mode single-section backward-wave coupler. As the term “backward-wave coupler” implies, the electric and magnetic field interaction between the parallel-coupled conductors causes the coupled signal to travel in a direction opposite to that of the input signal. Maximum coupling occurs when the length of the coupling region is equal to one-quarter wavelength (or an odd multiple of quarter wavelength). Analysis of the couplers is carried out in terms of two normal modes of propagation known as *even* and *odd* modes for symmetrical couplers. Even and odd modes exhibit even and odd symmetry of fields with respect to the plane of symmetry. These couplers offer a perfect match and infinite directivity at all frequencies because of the inherent property that the even- and odd-mode phase velocities are equal when the propagating mode is a pure TEM.

6.3.3. Hybrid Rings. The branchline coupler as well as the coupled-line backward-wave coupler provides a phase difference of 90° between the two outputs. For hybrid ring couplers shown in Fig. 20 [70], the two output signals are either in-phase or 180° out of phase depending on the choice of the input port. The circumference of the ring is $3\lambda/2$, where λ is the wavelength in the stripline at mid-band frequency. For an input at port 1, outputs at ports 2 and 4 are 180° out of phase and the port 3 is isolated (with no output). When the input is at port 2, the two outputs at ports 1 and 3 are in phase and the port 4 is isolated.

6.3.4. Power Dividers. In several microwave applications (as, e.g., a feed for a phased-array antenna) the input signal is required to be divided into several

Figure 19. A parallel-coupled-line coupler realized in stripline structure. Equal widths are used for two strips. When a signal enters into port 1, port 2 is the direct output and port 3 is the coupled point. No signal comes out of port 4, which is called the “isolated port.”

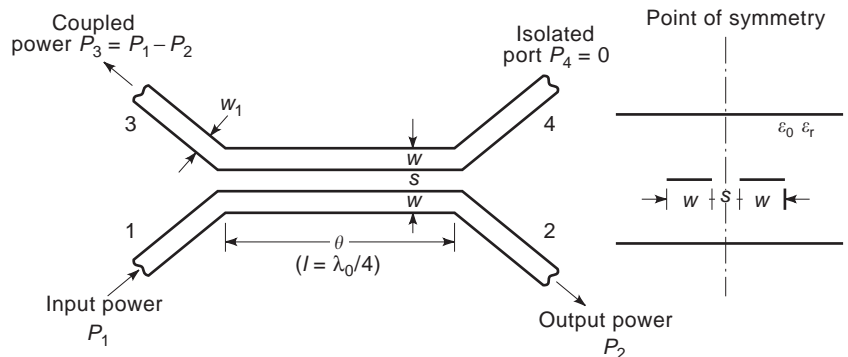

Figure 20. A stripline ring hybrid. The circumference is $3/2$ wavelengths. When a signal is fed to port 1, output signals at ports 2 and 4 are 180° out of phase, and port 3 is isolated. For an input signal fed to port 3, output signals at ports 2 and 4 are in phase and port 1 is isolated.

equiamplitude, equiphase output signals. A matched, symmetric n -way power divider has the advantage that it gives neither amplitude nor phase imbalance at any frequency. Such a power divider can also be used as an n -way power combiner by simply reversing the input and output ports. Using such combiners, output powers of a number of solid-state amplifiers and oscillators can be combined over a wide frequency range. A two-way power divider stripline circuit is shown in Fig. 21 [71]. The resistor R between the output port ensures input match at ports 2 and 3 when the circuit is used as a power combiner.

6.3.5. Filters. Stripline filters generally make use of a cascade of distributed circuit elements in the form of coupled resonators, stubs, and so on. As pointed out in the discussion for waveguide filters, stripline filters are also designed using low-frequency prototype filter synthesis techniques. A coupled-line bandpass filter is shown in Fig. 22 [72]. This configuration is also commonly used for other filters using planar lines such as microstrip lines and coplanar waveguides.

6.3.6. Pin-Diode Switches. A pin diode (which consists of an intrinsic layer sandwiched between p- and n-type

Figure 21. A matched stripline two-way power divider. Input power at port 1 splits equally into output ports 2 and 3. A resistor ($R = 2Z_c$) ensures that the circuit is matched at ports 2 and 3.

layers) acts as an electronic switch when operated at the forward and reverse bias states [73]. As a basic switching element, it is extensively used in the realization of multiple-throw switches, phase shifters, modulators, limiters, and duplexers. A single-pole single-throw switch using a pin diode is shown in Fig. 23 [65]. With a variable forward bias, the forward bias resistance of the pin diode can be varied over a wide range. This property is used in realizing electronically variable attenuators. Pin-diode circuits can also be used as attenuators by varying the forward bias current of the diodes. Pin-diode attenuators with constant input impedance characteristic can be built by incorporating a circulator or a hybrid coupler in the circuit. Figure 24 shows a hybrid-coupled pin-diode attenuator [65].

6.3.7. Phase Shifters. Phase shifters can be built using pin diodes, varactors, or GaAs field-effect transistors (FETs). Of these three semiconductor devices, pin diodes are the most commonly used because of reproducibility of their characteristics and high power-handling capability. Digital phase shifters are extensively employed in phased arrays to electronically scan the radiated beam. These phase shifters can be broadly classified as either the reflection type or the transmission type. The reflection-type phase shifters can be realized using a circulator or a hybrid coupler. Some common designs for transmission-

type phase shifters are the switched line, the loaded line, and the lowpass highpass. For phased array applications, several of these circuits are cascaded to form multibit phase shifters.

Microwave phase shifters can be designed using various different kinds of transmission lines. Figure 25 shows a switched-line phase shifter with series-mounted diodes [74].

6.3.8. Mixers. A mixer circuit is an essential component of almost all receivers used in communication, radar, and radioastronomy applications. Microwave mixers make use of nonlinear semiconductor devices, usually Schottky barrier diodes for mixing operation. A typical mixer consists of a nonlinear mixer diode together with coupling networks for feeding the signal [radiofrequency (RF)] and local-oscillator (LO) power and for extracting the (IF) signal. Practical mixer configurations can be broadly divided into three categories: single-ended mixers, balanced

Figure 24. A hybrid-coupled pin-diode attenuator. The attenuation is controlled by varying the forward bias current of the diodes. Two identical diodes are mounted symmetrically in the two output arms of the 3 dB, 90° hybrid coupler and are shunted by matched loads. (From Ref. 65, © New Age Int. Ltd., 1989, reprinted with permission.)

mixers, and double-balanced mixers. Of the various types of mixers, the balanced mixer employing Schottky barrier diodes is the most commonly used configuration in practical application. Figure 26 shows a hybrid ring balanced mixer [65].

Several other types of stripline circuits have been reported in literature [11,34,65]. Microwave circuits described in this section can also be realized in microstrip configuration, described in the next section.

7. MICROSTRIP CIRCUITS

Microstrip line is the most frequently used planar transmission structure and forms the basic building block for almost all hybrid microwave integrated circuits (MICs) and monolithic microwave integrated circuits (MMICs). The physical geometry of a microstrip line is shown in Fig. 27a, and the approximate field distribution is depicted in Fig. 27b. Microstrip line consists of a single dielectric substrate with a complete conducting coating (ground plane) on one side and a conductor strip on the other side

Figure 25. A switched-line phase shifter with series mounted diode to switch between two fixed transmission-line paths. The differential phase shift is $\beta(l_1 - l_0)$.

Figure 26. A hybrid ring balanced mixer where D_1, D_2 are mixer diodes; F_1, F_2 are image reject filters; and T_1, T_2 are matching transformers. The RF power fed to port 1 and the LO power fed to port 3 are split equally between the output ports 2 and 4. At the two mixer diodes, the RF signals appears 180° out of phase with each other whereas the LO signals appear in phase. (From Ref. 65, © New Age Int. Ltd., 1989, reprinted with permission.)

of the substrate. In contrast to a stripline, the top surface of the microstrip circuitry is open. Because of the nonhomogeneous dielectric medium surrounding the conductor strip (the substrate and the air above), the microstrip line cannot support a pure TEM mode. However, a quasi-TEM mode approximation is used for analysis of microstrip lines and is adequate for design of microstrip circuits [23].

Popularity of microstrip circuits is due to an increasing trend in miniaturization of, and cost considerations for, microwave circuits. Compared to waveguides, and coaxial lines, and striplines, it is easier to fabricate microstrip circuits and integrate them with other active and passive microwave devices. The open nature of the microstrip lines allows easy access to circuitry to mount active devices and lumped element components such as resistors,

Figure 27. Geometry of a microstrip line: (a) geometry (h is substrate height, W is the width of the conducting strip, and ϵ_r is relative dielectric constant); (b) electric and magnetic field distribution in a microstrip-line quasi-TEM mode.

capacitors and inductors. However, microstrip line circuits have some disadvantages such as higher loss, radiation, dispersion, and spurious coupling among components when compared to coaxial-line circuits.

7.1. Design Formulas for Microstrip Lines

Analysis and design considerations for microstrip lines are very well documented in the literature [16,23,75,76].

7.1.1. Effective Dielectric Constant ϵ_{eff} . Because of the nonhomogeneous dielectric structure of microstrip lines, the concept of effective dielectric constant has been introduced [16] and is commonly used for calculating line wavelength and phase velocity as needed in microstrip circuit design. A formula that is commonly used for calculation of ϵ_{eff} is [75]

$$\epsilon_{\text{eff}} = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} (1 + 10h/W)^{-1/2} \quad (13)$$

where h is height of the dielectric substrate, W is the width of the conducting strip, and ϵ_r is the dielectric constant of the substrate.

7.1.2. Characteristic Impedance (Z_0). As for any other transmission line, the characteristic impedance for the quasi-TEM mode is the most important parameter in microstrip circuit design. Given the dimensions h and W and the value of ϵ_r , the characteristic impedance of a microstrip line can be found by using the following formulas [35, pp. 52–53]:

For narrow strips ($W/h < 3.3$):

$$Z_0 = \frac{119.9}{\sqrt{2(\epsilon_r + 1)}} \left[\ln \left(4 \frac{h}{W} + \sqrt{16(h/W)^2 + 2} \right) - \frac{1}{2} \left(\frac{\epsilon_r - 1}{\epsilon_r + 1} \right) \left(\ln \frac{\pi}{2} + \frac{1}{\epsilon_r} \ln \frac{4}{\pi} \right) \right] \quad (14)$$

For wide strips ($W/h > 3.3$):

$$Z_0 = \frac{119.9\pi}{2\sqrt{\epsilon_r}} \left[\frac{W}{2h} + \frac{\ln 4}{\pi} + \frac{\ln(e\pi^2/16)}{2\pi} \left(\frac{\epsilon_r - 1}{\epsilon_r^2} \right) + \frac{\epsilon_r + 1}{2\pi\epsilon_r} \left(\ln \frac{\pi e}{2} + \ln \left(\frac{W}{2h} + 0.94 \right) \right) \right]^{-1} \quad (15)$$

where e is the exponential base; $e = 2.71828$. For given values of characteristic impedance and ϵ_r , the W/h ratio can be found by using the following expressions.

For narrow strips (when $Z_0 > 44 - 2\epsilon_r\Omega$):

$$\frac{W}{h} = \left\{ \frac{e^A}{8} - \frac{1}{4e^A} \right\}^{-1} \quad (16)$$

where

$$A = \frac{Z_0 \sqrt{2(\epsilon_r + 1)}}{119.9} + \frac{1}{2} \left(\frac{\epsilon_r - 1}{\epsilon_r + 1} \right) \left(\ln \frac{\pi}{2} + \frac{1}{\epsilon_r} \ln \frac{4}{\pi} \right)$$

For wide strips (when $Z_0 > 44 - 2\epsilon_r\Omega$):

$$\frac{W}{h} = \left(\frac{2}{\pi} \right) \{ (B - 1) - \ln(2B - 1) \} + \frac{\epsilon_r - 1}{\pi\epsilon_r} \times \left\{ \ln(B - 1) + 0.293 - \frac{0.517}{\epsilon_r} \right\} \quad (17)$$

where $B = 59.95\pi^2 / (Z_0 \sqrt{\epsilon_r})$.

7.2. Microstrip Discontinuities

Microstrip circuits, like other types of microwave circuits, contain transmission line discontinuities such as bends, width changes, gaps, and junctions. These discontinuities introduce parasitic reactances and cause a degradation in circuit performance. Various types of microstrip discontinuities which are encountered in microwave circuits are shown in Fig. 28. This figure also includes approximate lumped-element models for these discontinuities. At higher microwave frequencies, these discontinuity reactances become significant and need to be taken into account. Closed-form relations for discontinuity model elements

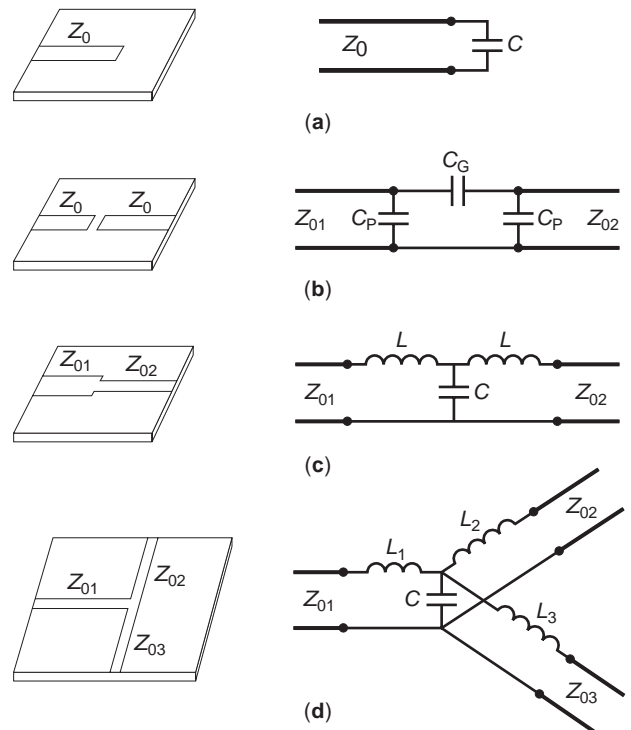

Figure 28. Some common types of microstrip discontinuities and their equivalent lumped-element models: (a) open-ended microstrip; (b) gap in microstrip; (c) change in width. (d) T junction.

and their values form a key part of any microwave circuit computer-aided design (CAD) software. However, equivalent lumped circuit models are not available for all types of discontinuities and substrate types. Another difficulty is that the accuracy for discontinuity models degrades at higher frequencies. Lack of accurate discontinuity models at millimeter-wave frequencies is still the main bottleneck in the CAD for millimeter-wave circuits [77].

In order to compensate for the discontinuity effects, one can construct the equivalent circuit for the discontinuity and take it into account in the design process. The second approach is to minimize the discontinuity effect by modifying the geometry of the discontinuity, such as chamfering or mitering the strip conductor in case of microstrip right-angle bends. Compensation techniques for discontinuities have been reported in the literature [35, pp. 140–165].

7.3. Passive Microstrip Circuits

Some commonly used microstrip passive circuits are couplers, power dividers, impedance matching circuits, and filters. Design process for these circuits is similar to that for stripline circuits.

7.3.1. Couplers. As in case of stripline circuits, the two common types of microstrip line couplers are also coupled line directional couplers and branchline directional couplers. Layouts of these couplers are similar to those of stripline couplers. Even and odd mode analysis technique is also applied in the design of microstrip couplers. For coupled line couplers in microstrip configuration, the phase velocities for even and odd modes are not equal. This factor limits the directivity of these couplers. Design of these couplers is well explained in Refs. 34 and 35 .

Branch line couplers are also similar to corresponding circuits in stripline configurations. They can be designed for different values of the coupling factor and may have more than two branches [34,35] in order to increase the circuit bandwidth.

7.3.2. Filters. Various types of filters [34,35] can be realized by using microstrip lines. Again, their design methodology is similar to those of stripline filters. Lowpass filters can be formed with cascaded sections of microstrip lines. One first designs the prototype filter using lumped elements and then substitutes these elements with their microstrip-line equivalents. A short ($< \lambda_g/4$) length of a high-impedance line behaves like a series inductance. Also a very short ($\ll \lambda_g/4$) length of low-impedance line behaves like a shunt capacitance. An example of a lowpass filter constructed by microstrip line elements is shown in Fig. 29.

Microstrip bandpass and bandstop filters can also be realized by using coupled sections of microstrip lines. Two popular types of microstrip bandpass filters are end-coupled and parallel (edge)-coupled bandpass filters. Figure 30 shows a general layout for an end-coupled microstrip bandpass filter. In this circuit, coupling gaps are located in between and couple the cascaded microstrip resonator elements. The gap width is usually much smaller than

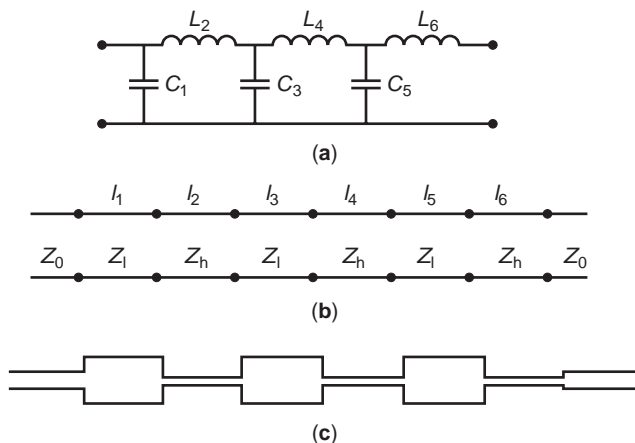

Figure 29. Filter design example: (a) lowpass filter prototype circuit using lumped elements; (b) stepped-impedance implementation; (c) microstrip layout of final filter; high-impedance lines (narrow lines) behave like inductances, and low-impedance lines (wide lines) behave like capacitances.

the substrate height to ensure the required coupling between the two adjacent resonators. Parallel-coupled bandpass microstrip filters are similar to the stripline filter shown in Fig. 22. Bandpass and bandstop filters [34,35] can also be realized using quarter-wave open-circuited or short-circuited microstrip line resonators.

7.4. Active Microstrip Circuits

Microstrip lines have been used in practically all possible types of active circuits used at microwave frequencies.

7.4.1. Microstrip Amplifiers. Microstrip lines are extensively used in various types of microwave amplifier circuits [34,78,79]. All microwave amplifier circuits require some type of matching circuits both at the input and output sides in order to obtain specified gain characteristics over a desired frequency range. Microstrip lines are used for realizing matching networks as well as for biasing networks for microwave amplifiers. Microstrip lines are also used in distributed amplifiers with multioctave bandwidths [78,79]. Various types of microstrip matching networks are: single-stub matching network, double-stub matching network, quarter-wave transformer, multisection transformer, and tapered line. Microstrip amplifier circuit design examples including matching and biasing network design considerations are available in Refs. 34, 78, and 79.

7.4.2. Microstrip Oscillators. There are numerous types of oscillator circuits. One of the most common types of

Figure 30. General microstrip layout for an end-coupled bandpass filter (series coupling gaps are located in between cascaded straight resonator elements).

Figure 31. Microstrip implementation of the parallel feedback DRO. A dielectric resonator is coupled to two microstrip lines used to provide a feedback path from the drain to the gate of a MESFET [80].

microstrip oscillator circuits is the “dielectric resonator oscillator” (DRO). Layout of a microstrip DRO oscillator [35,80] is shown in Fig. 31. In this circuit, the dielectric resonator is coupled to two microstrip lines used to provide a feedback path from the drain to the gate of the MESFET. A microstrip single-stub matching circuit is used for the output matching.

7.4.3. Active Microwave Filters. Active microwave tunable filters have been reported in the literature [35,81]. Figure 32 shows a layout of a varactor-tuned, multipole active microwave bandpass filter described in Ref. 81.

7.4.4. Microstrip Circuits for High-Speed Digital Circuits. Microstrip lines are also used in ECL high-speed circuits or GaAs integrated circuits (ICs) for interconnection among the components and/or device chips. These

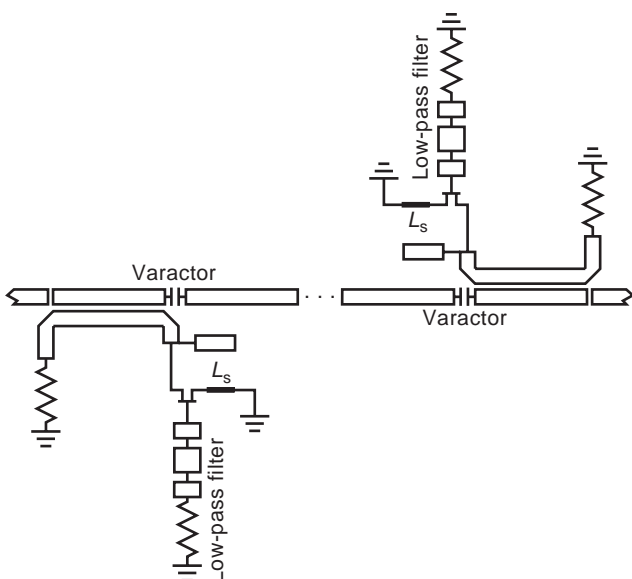

Figure 32. The multipole active tunable filter. The negative resistance is realized by the MESFET circuit. (From Ref. 81, © IEEE, 1990, reprinted with permission.)

microstrip lines are formed by the conductors of integrated circuits printed on a circuit board. At high frequencies or high speeds, it is essential to minimize reflection at the interconnections. Also, crosstalk between two parallel interconnects can become significant. Various design techniques for microstrip interconnections in high-speed digital circuits are described in the literature [35,82].

7.5. Monolithic Microstrip Circuits

Monolithic microwave integrated circuits (MMICs) are microwave circuits in which all circuit components (active and passive) are fabricated on the same semiconductor substrate [83]. MMIC circuits are used in many areas of microwave circuits with an increasing popularity because of their significant advantages over hybrid MICs in terms of lower cost, smaller size, better performance, and higher reliability. In the lower microwave frequency range, lumped elements are used for realizing microwave matching networks. However, in the higher frequency range (over 20 GHz), lumped elements become lossy and difficult to design, and distributed elements such as microstrip and coplanar waveguides are used.

Monolithic microwave circuits are described in a separate article in this encyclopedia.

8. COPLANAR WAVEGUIDE CIRCUITS

8.1. Coplanar Waveguides

Unlike microstrip lines, the ground plane in a coplanar waveguide (CPW) [84–86] is located on the same side of the substrate that contains the strip conductor. CPWs, coplanar strips, and slotlines are categorized as coplanar lines or uniplanar lines [85] because all the metallization is contained in a single layer. CPW configurations have been widely utilized to realize a variety of microwave circuits including capacitors, inductors, magic tees, mixers, filters, oscillators, resonators, distributed amplifiers, and so on. Configurations of coplanar strips, CPW, and slotlines are shown in Fig. 33.

8.1.1. Field Distribution in Coplanar Lines. Knowledge of field distribution in transmission lines is useful to microwave circuit designers because it helps in configuring location and orientation of lumped active and passive elements in transmission line circuits. Approximate electric field and magnetic field distributions in three coplanar transmission structures are shown in Fig. 34. The field distributions are different from those in a microstrip line, and they lead to some advantages these lines exhibit compared to microstrip lines.

8.2. Advantages of CPW Circuits

One of the advantages of CPW circuits over microstrip circuits arises from the fact that mounting of lumped components in shunt connection is easier in a CPW. In this case, drilling of holes through the substrate is not needed to reach the ground plane. Also, transition from a CPW to a slotline is easier to fabricate. This allows a great flexibility in the use of mixed transmission media.

Figure 33. Various types of coplanar lines. (a) Coplanar strip. (b) Coplanar waveguide. (c) Slotline.

CPW circuit configurations can be designed to exhibit a lower sensitivity to substrate thickness, less dispersion effect, and lower losses than the corresponding microstrip circuits. Implementation of circuits in CPW configurations allows thick substrates to be used, thus avoiding the need to use fragile thin substrates at higher microwave and millimeter-wave frequencies, as occurs for microstrip circuits. Since active components can easily be inserted in CPW circuits also, CPW configurations are used increasingly in monolithic microwave and millimeter-wave integrated circuits. As strip width and gap dimensions in CPW can be reduced without changing the CPW characteristic impedance, CPW circuits can be designed to radiate much less energy than the corresponding microstrip circuits. In addition, dispersive effects in the CPW can be reduced by choosing smaller transverse dimensions.

The CPW configurations, however, have some disadvantages such as possible excitation of the slot mode, lower power-handling capability, and field nonconfinement. Slot mode is an alternative mode possible in a CPW when two ground planes are not at the same potential and E fields in two slots are oriented in the same direction. This

Figure 34. Electrical and magnetic field distributions in (a) coplanar strips, (b) a coplanar waveguide, and (c) a slotline.

mode can be excited by a nonsymmetric excitation (such as caused by a tee-junction discontinuity). Airbridges are needed to suppress excitation of the slot mode. The fields in a CPW are less confined than those in microstrip lines, and therefore they make the CPW circuits more sensitive to packaging covers or shields placed above the circuit.

8.3. CPW Circuit Design Considerations

The main difference in the design of CPW circuits as compared to microstrip circuits is the different characteristics of discontinuities occurring in CPW circuits. As the density of active and passive devices in CPW circuits increases, the population of discontinuities also increases. Thus, the slot mode can be excited more frequently because of asymmetric structure. When MMICs are composed of more than one kind of transmission lines, there is the need for appropriate transitions such as CPW to slotline or CPW to microstrip line. In the design of CPW circuits, characterization of these discontinuities and transitions needs to be taken into account for obtaining the desired performance. For the analysis and modeling of CPW discontinuities, several numerical methods like mode-matching method [87], finite-difference method [88], spectral domain analysis [89], transmission-line method [90],

integral equation method [91], and method of lines [92] have been used.

In addition to discontinuities, other factors such as dispersion, metallization thickness, dielectric loss, conductor loss, radiation, and surface wave loss also affect the performance of CPW circuits. All these factors need to be taken into account in the design of CPW circuits.

8.4. Examples of CPW Circuits

Most of microwave circuits developed using microstrip lines and other transmission lines can be realized in CPW configurations also. Some examples of CPW circuits are reviewed in this section.

8.4.1. Capacitors and Inductors. CPW circuits need the basic reactive elements, namely capacitors and inductors, to be realized in CPW configurations. Due to the flexibility provided by CPW configurations to accommodate lumped elements both in series and the shunt connections, capacitors and inductors may be implemented in many ways. Series or shunt circuits for capacitors or inductors are possible using CPW or CPW-slotline transitions, and some of these are shown in Fig. 35 [23].

8.4.2. Filters. Parallel-coupled-line filters and end-coupled bandpass filters can be realized in CPW configurations also [93,94]. Usually, the implementations of these filters utilize a single-layer configuration that is much easier to fabricate. Sometimes a double-layer geometry is used for a wide bandwidth [95]. Inductively coupled bandpass filters can also be realized using CPW. These filter configurations eliminate the need for via holes to the

Figure 36. Layout of an inductively coupled multiresonator bandpass filter realized in a CPW configuration.

ground. The layout of an inductively end-coupled bandpass filter in a CPW configuration is shown in Fig. 36.

8.4.3. Hybrid Ring Couplers and Ring Resonators. The hybrid ring coupler can be realized in a CPW-slotline configuration [96] as shown in Fig. 37a. This circuit makes use of the properties of a slotline T junction and a CPW-slotline T junction together with the usual operation of a ratrace hybrid ring [97]. The circumference of the slot ring is one wavelength divided equally into four quarter-wave sections.

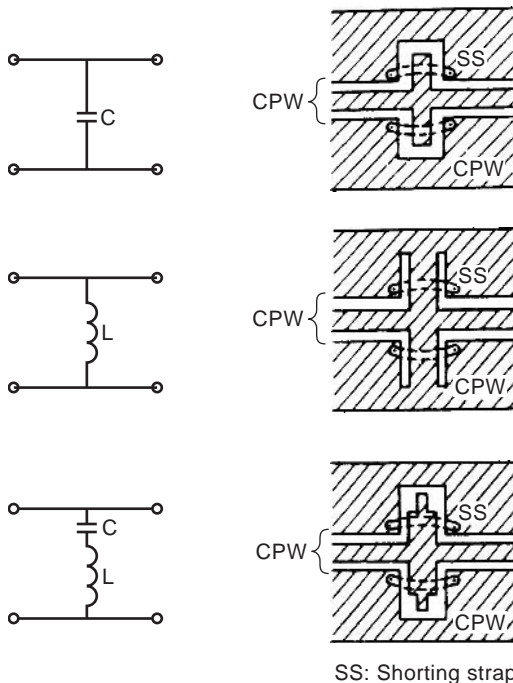

Figure 35. Capacitor and inductor elements realized in CPW configuration. *C* represents a capacitor and *L* represents an inductor.

Figure 37. (a) Layout of a hybrid ring coupler in a CPW configuration where the slot ring is one wavelength (λ) and divided equally into four quarter-wave sections; (b) circuit configuration of a slotline ring resonator with different coupling schemes such as CPW, slotline, or microstrip line.

Ring resonators can also be realized using CPW or slot-line feed as shown in Fig. 37b [98]. The resonator can be easily integrated with shunt and series active devices and used for several applications [99,100]. The CPW-fed slot-line ring resonators show characteristics similar to those of microstrip-fed slotline ring resonators.

8.4.4. Mixers. Most of the microwave mixers use Schottky barrier diodes for mixing operation. A typical mixer circuit consists of a mixer diode together with coupling networks for feeding the RF signal and local oscillator (LO) power and for extracting the IF signal. One of the commonly used mixers is the balanced mixer.

Balanced mixers realized in a CPW configuration [101] use a balanced local oscillator input and an unbalanced signal input. One of the mixer configurations is shown in Fig. 38. Local-oscillator voltage is applied via the slotline, and the signal is fed through the coaxial line. Connection to the slotline is made by a small copper coaxial cable (not shown) at right angles to the slot, while a coaxial line connection to the CPW is made directly along as shown. The IF connecting wires are brought through holes in the substrate to mixer diodes.

8.4.5. Oscillators. A three-port MESFET oscillator designed in a CPW configuration [102] is shown in Fig. 39. The gate of the device is self-biased in order to minimize the number of bias points. The source and the drain are connected to 50Ω CPW transmission lines.

8.4.6. Distributed Amplifiers. A low-noise distributed CPW amplifier [103] is shown in Fig. 40. The distributed amplifier topology offers not only typically greater than octave bandwidth, but also an excellent phase linearity due to the transmission line characteristics inherent in its topology. A distributed amplifier is made up of a set of

Figure 39. The circuit layout of an oscillator using CPW configurations where the gate of the MESFET is self-biased and is connected to a resonant section of open-circuited transmission line. The dashed line shows the possible position of optical waveguides in a Mach-Zehnde modulator. All CPW lines were designed to have an impedance of 50Ω. (From Ref. 102, © IEEE, 1993, reprinted with permission.)

cascaded devices, which act as shunt capacitances, connected together by high-impedance transmission lines that simulate inductances. The CPW configurations offer simplified fabrication processing and hence lower cost compared to similar microstrip amplifiers.

Various CPW circuit examples mentioned above provide a sampling of microwave circuits that can be designed in CPW configurations. Several other CPW circuit examples have been reported in the literature [104–107].

9. LUMPED-ELEMENT CIRCUITS

Circuits employing lumped elements, such as inductors and capacitors, are used extensively at lower frequencies. Lumped elements, by definition, are much smaller than the wavelength ($< \lambda/10$) at the operating frequency and exhibit small phase shift across any physical dimension. Thus, the frequency limit for lumped elements is dependent on the size of the element. With improving technology and with the development of monolithic microwave circuits, miniaturization of electronic elements becomes a possibility, and lumped-element circuits are used up to about 20 GHz. In millimeter wave monolithic circuits, lumped resistors and MIM capacitors are commonly used. Spiral inductors can be designed with self-resonance frequencies up to 40 GHz. There are several advantages of lumped-element circuits compared to distributed element transmission-line circuits [108, p. 118]. First, lumped elements have smaller frequency-dependence and are therefore good for wideband circuits. Second, the use of lumped elements affords a considerable size reduction (a factor of 10 in area) compared with distributed element circuits in microwave integrated circuits. Third, since the substrate area required is smaller and many lumped-element MICs can be processed simultaneously, the lumped elements are less costly.

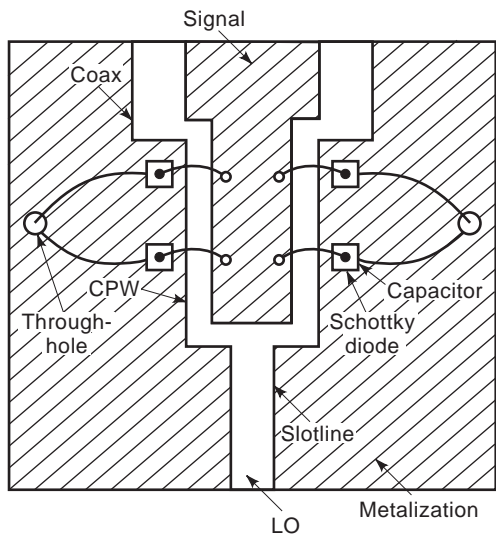

Figure 38. A circuit arrangement for a double balanced mixer using CPW where RF signal is fed through the coaxial line, LO voltage is applied via the slotline, and IF signal is brought out from the through-holes. (Based on Ref. 101.)

Figure 40. The circuit schematic of a 2–20-GHz CPW distributed amplifier using high-electron-mobility transistors (HEMTs) and CPW lines. (From Ref. 103, © IEEE, 1993, reprinted with permission.)

9.1. Lumped-Element Components

9.1.1. Inductors. Depending on the value of the inductance required, lumped inductors can be realized either as straight narrow strips (ribbon inductors), as single-loop inductors, or as multiturn spiral inductors:

Ribbon Inductors. A microstrip ribbon inductor and its equivalent circuit are shown in Fig. 41. For short lengths ($< \lambda_g/4$) the inductance L and shunt capacitances C at the two ends can be calculated [35]:

$$L = \frac{Z_0}{2\pi f} \sin\left(\frac{2\pi l}{\lambda_g}\right) \tag{18}$$

$$C = \frac{1}{2\pi f Z_0} \tan\left(\frac{\pi l}{\lambda_g}\right) \tag{19}$$

A narrow strip with high Z_0 is needed to achieve a high inductance value with low parasitic capacitance. However, in practice the choice of the strip width is determined by fabrication limits, by the direct-current-carrying capacity, and by the high resistance of very narrow strips. The strip length is limited simply by the need to ensure a realistic and economical chip size. The ribbon inductor is thus limited to values of less than 1 nH, but is a relatively “pure” inductor with low parasitic capacitances.

Figure 41. The ribbon inductor consisting of a high-impedance transmission line section: (a) physical layout; (b) equivalent circuit.

Loop Inductors. An example of a single-loop inductor is shown in Fig. 42. Because of their inefficient use of the chip area, loop inductors have been used very little in MMICs. However, design information can be found in a number of references [109–111].

Spiral Inductors. Spiral inductors with multiple turns are essential for inductance values above approximately 1 nH. There are two kinds of spiral inductors: circular spiral and square spiral (see Fig. 43). Circular (approximately) spirals have a slightly better quality factor at the cost of layout complexity and have a less convenient shape for integration with other components. So the square spirals are used more often in MMICs. Design equations can be found in Refs. 112–115. The drawback of the spiral inductors is that the need to connect the center turn back to the outside circuit dictates that either airbridge or dielectric crossovers must be used. There are a number of different solutions for this connection problem, and these are illustrated in Fig. 44.

Stacked Spirals. Stacked spiral inductors [83] comprise a pair of interwound spirals placed on separate metal layers. The major advantage is that the turns are much more tightly packed than what normal photolithography and metal patterning would allow for a single-layer spiral. Since the turns are separated vertically, there is less capacitance between adjacent turns than there would normally be with such small gaps. However, since the lower metal thickness is limited to 1 μm or less, stacked spirals have higher series resistances. They are generally used at frequencies below 5 GHz or so.

Figure 42. Layout of a single-loop inductor (not used much because of inefficient use of substrate area).

Figure 43. Spiral inductors: (a) circular spiral; (b) square spiral. Square spirals allow a more compact layout of components in MMICs.

9.1.2. Capacitors. Both overlay metal–insulator–metal (MIM) capacitors and interdigital capacitors are used in microwave circuits. Interdigital capacitors can be used for values up to approximately 1 pF, above which their size and the resulting distributed effects prevent their use. Overlay capacitors are therefore needed for most of applications, such as direct-current blocking and decoupling, where large capacitor values are required:

Overlay Capacitors. These consist of an MIM, with the most common insulators being silicon nitride, silicon

Figure 44. Different interconnection schemes for spiral inductors: (a) single airbridge; (b) airbridges over an underpass; (c) formed entirely of airbridges; (d) using two metal levels for an underpass. (From Ref. 83, © IEE, 1995, reprinted with permission.)

Figure 45. Overlay capacitors: (a) using a dielectric via; (b) with an airbridge; (c) without an airbridge or spacer dielectric.

dioxide, and polyimide. Silicon nitride is popular since it has a fairly higher ϵ_r compared to silicon dioxide and polyimide. The type of connection used from the capacitors to the rest of the circuit depends on whether an airbridge or a polyimide-based two-metal level process is used. Three types of overlay capacitors with connections are shown in Fig. 45. Design equations for C and capacitor quality factor Q can be found in Ref. 108, pp. 161–165.

Interdigital Capacitors. A capacitor, simpler than the MIM capacitors, is the single-layer interdigital capacitor. The interdigital capacitor consists of a number of interleaved microstrip fingers coupled together and is fabricated in a single-layer structure. Its structure and equivalent circuit are shown in Fig. 46. The maximum value of capacitance of an interdigital capacitor is limited by its physical size. It can be fabricated with values of 0.1 pF to 15 pF in a reasonable size. Because of the long length of gap between lines, large capacitors resonate at low frequency. Therefore only small value capacitors (less than 2 pF) are practical at higher frequencies. Since interdigital capacitors do not use a dielectric film, their capacitance tolerance is very good and is limited only by the accuracy of the metal pattern definition. Hence, they are ideal as tuning, coupling, and matching elements where small capacitor values are required but precise values are necessary. Design equations for these capacitors are available in Refs. 116 and 117.

9.1.3. Resistors. Because of the signal loss associated with resistances, the resistors are not used as much at microwave frequencies as in the low-frequency circuits. They are, however, irreplaceable in many cases such as for reflectionless terminations, for suppressing undesirable signals, for damping elements providing the isolation of circuits from each other, or for reducing the power level. Resistors can either use doped semiconductor layers (mesa resistors or implanted planar resistors) or sputtered thin-film resistive layers. Figure 47 shows the two

Figure 46. Interdigital capacitor layout and equivalent circuit. N is the number of fingers, $4X$ is the width of a unit cell. (From Ref. 116, © IEEE, 1970, reprinted with permission.)

resistor examples. In either case, since the layer or film thickness is fixed, it is very convenient to quote resistivity in terms of an ohm-per-square figure. Hence, the value of the resistor is chosen by selecting a suitable aspect ratio. A practical limit is imposed by the higher parasitic capacitance of large pads and the resistors physical size.

GaAs Mesa Resistors. The term “mesa” refers to the configuration where the whole wafer is doped and subsequently etched selectively so that active regions remain only where required. Figure 48 shows the details of a mesa resistor with passive and negative mesa edges [83, pp. 77–78]. The GaAs resistor relies on the linearity of the semiconductor’s current-field characteristic at low electric field values. Hence it is important to consider how much current is to be passed through the resistor. The maximum electric field allowed in the resistor is normally given as a

Figure 47. Lumped resistor examples: (a) small value ($= 50 \Omega$); (b) large value ($= 3000 \Omega$). (From Ref. 83, © IEE, 1995, reprinted with permission.)

Figure 48. Mesa resistor view showing positive and negative mesa edges.

“volts per unit length” value for a certain permissible percentage deviation from perfect linearity.

Thin Film Resistors. Sputtered thin-film resistors offer improved linearity and lower temperature coefficients compared with the mesa types. In addition, the ohm-per-square figure can be optimized for the circuit designer without any limitations imposed by the requirements of the active devices. The most commonly used materials are tantalum nitride, cermet, and nickel chrome. Their temperature coefficients of resistance are less than one-tenth that of GaAs, and ohm-per-square figures of 50Ω can be produced, which is convenient for the circuit designers [118, pp. 158–159].

9.2. Examples of Lumped-Element Circuits

Planar Spiral Transformers. A lumped element transformer with spiral inductors offers direct-current (DC) blocking, matching, and DC bias injection functions in a very small size [120,121]. A planar spiral transformer, whose layout and equivalent circuit are shown in Fig. 49, is used as a lumped transformer up to 4 GHz or so [83, p. 73]. The two-coupled inductors have self-inductance and mutual inductance. There are series resistances in the conductors, interturn capacitance, and shunt capacitance to ground. The most serious parasitic is usually the capacitance between the two spirals since this makes the transformer resonant as the capacitive coupling becomes dominant at higher frequencies. To minimize this parasitic capacitance while achieving a high mutual inductance, the turns need to be very narrow and close together. Typically a transformer would have $5 \mu\text{m}$ conductor widths and $5 \mu\text{m}$ gaps.

Lumped-Element Matching Circuits for MMIC Amplifiers. A lumped-element amplifier circuit [83, p. 19] is shown in Fig. 50. Lumped-element matching networks (using spiral inductors or overlay capacitors) provide an appropriate arrangement at frequencies below 20 GHz. The chip is a 1–2 GHz single-stage amplifier. When operation frequency is higher than 20 GHz, the performance of spiral inductors degrades because of their self-resonances.

(a)

(b)

Figure 49. A lumped-element spiral transformer: (a) layout; (b) equivalent circuits. (From Ref. 83, © IEE, 1995, reprinted with permission.)

Lumped-Element Resonators. Series and parallel lumped-element resonators using interdigital capacitors are shown in Fig. 51 [117]. These kinds of resonators can be used at frequencies of 7 GHz and higher. A 0.3-pF capacitor with a 20 μm gap had a capacitance tolerance of less than 25% from sample to sample. These resonators are fabricated on one side of alumina or quartz substrate.

Filters. Figure 52 depicts a lumped element filter with bandstop loss of 30 dB at 9 GHz (117). The equivalent circuit is also shown. Interdigital capacitors are of practical use and allow the attainment of the few picofarad capacitor values required for the design of these filters at the higher microwave frequencies. Several other types of lumped element microwave circuits have been reported in the literature [83,118,119,121].

10. MULTILAYER MICROWAVE CIRCUITS

10.1. Multilayer Configurations

Portable microwave systems require circuits to be fabricated in smaller sizes and volumes. Multilayer configurations have begun to be adapted for microwave circuits to meet these size requirements [122–125]. Also, multilayer

(a)

(b)

Figure 50. A lumped-element 1–2-GHz MMIC amplifier: (a) layout; (b) circuit diagram. (From Ref. 83, © IEE, 1995, reprinted with permission.)

designs exhibit more flexibility and, in several cases, yield better performance than the corresponding designs in single-layer configurations [126]. A tight coupling is an outstanding characteristic that multilayer circuits can provide. Since a physical geometry with very narrow spacing is necessary to produce a tight coupling in single-layer directional couplers, directional couplers realized in two layers are well suitable for providing a tight coupling and high directivity [127]. This tight coupling also makes it possible to obtain wide bandwidth in filter circuits [123]. In addition, the circuits designed using symmetrical planar structures in traditional single-layer configurations can now be implemented in asymmetrical geometry. This asymmetry produces more design flexibility, leading to conveniently realizable physical geometries.

Multilayer configurations have also been utilized to integrate a number of passive components and active devices into a module to reduce the size and the volume of the whole system. This kind of use of multilayer structures has resulted in the development of multichip module (MCM) technology at microwave frequency [128,129]. However, multilayer configurations inherently require

Figure 51. Series and parallel lumped-element resonator networks using interdigital capacitors: (a) series LC ; (b) parallel LC . The size $AA'BB'$ fits across a standard coaxial connector. (From Ref. 117, © IEEE, 1971, reprinted with permission.)

Figure 52. Bandstop filter and equivalent circuit. Bandstop loss at 9 GHz was 30 dB. (From Ref. 117, © IEEE, 1971, reprinted with permission.)

vertical interconnections between adjacent layers. Also, there is a possibility of air gap and misalignment between different dielectric layers, and these can affect the circuit performance.

10.2. Multilayer Microwave Circuit Technologies

10.2.1. Multilayer MMICs. Multilayer MMICs [130–132] are constructed using multilayer passive circuits integrated with active devices on the semiconductor substrate. Active devices, resistors, and MIM capacitors are formed on the surface of a semiconductor wafer. Dielectric films and conductors are stacked on the wafer, and transmission lines and the ground layers are connected through holes. This structure allows transmission lines with reduced linewidths, vertical interconnections with short signal delays, and miniaturized connections in a small area. In addition, this provides miniature but low-loss transmission lines and increased design flexibility.

For examples using this multilayer structure, several miniature passive circuits such as directional couplers, Wilkinson power dividers, transmission lines, and planar baluns have been designed and fabricated. Active circuits such as mixers, amplifiers, phase shifters, and upconverters are integrated with passive circuits in planar forms. Figure 53 [131] shows the typical configuration of a multilayer MMIC. In Fig. 53, a three-dimensional MMIC fabricated on a GaAs substrate integrates active devices, resistors, and MIM capacitors on the surface of a semiconductor wafer. A thin-film microstrip (TFMS) line offers a compact meanderline configuration while thin polyimide films and conductors are stacked on the wafer and ground metal is inserted between layers.

10.2.2. Multichip Modules. A multichip module (MCM) [129] is defined as multilayer sandwiches of dielectric and conducting layers, on which integrated circuits and passive components (if any) are mounted directly on (or inside of) the sandwich structure, without separate packaging for each of the active components. That is, the chips are mounted bare onto the MCMs, which then provide the

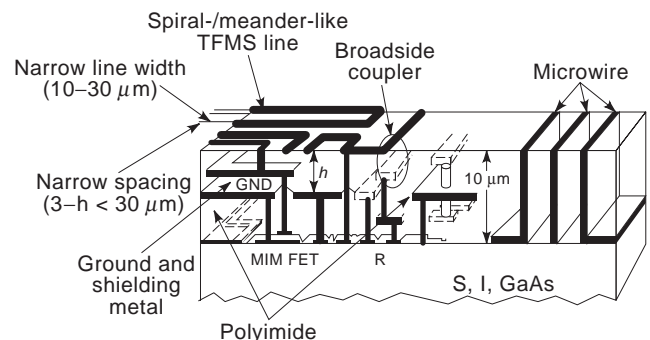

Figure 53. Structure of the three-dimensional multilayer MMIC fabricated on GaAs substrate. Active devices and an MIM capacitor are placed on the surface of a wafer, thin polyimide films and conductors are stacked on the wafer, and thin-film microstrip (TFMS) lines and ground layers are connected through via holes. (From Ref. 131, © IEEE, 1996, reprinted with permission.)

required power and ground, as well as all the signal interconnect and the electrical interface to the external environment. The entire MCM, including chips and passive components, may be placed in a hermetic package much like a large single-chip carrier, or it may be directly covered with a sealant material (such as epoxy or a glass passivation coating) to protect the components from physical damage.

Three general categories of MCMs are MCM-C (ceramic), MCM-L (laminated), and MCM-D (deposited). MCM-Cs are manufactured by stacking unfired layers of ceramic dielectric, onto which liquid metal lines are “silk-screened” using a metal ink process. The individual inked layers are then aligned, pressed together, and cofired into a solid planar structure, onto which integrated circuits can be installed. MCM-Ls are manufactured through the lamination of sheet layers of organic dielectric, and they are very similar to traditional printed circuit-board technology. MCM-Ds are manufactured through the deposition of organic or inorganic dielectrics onto a silicon or alumina support substrate. After each dielectric layer is deposited, one of several techniques is used to pattern metal lines as well as metal vias. The chips are then installed on the upper surface.

MCM-D technology can provide a versatile platform for the integration of GaAs MMICs and silicon devices for microwave circuits where performance, size, and weight are critical factors. Multilayer circuits such as spiral inductors, baluns, directional couplers, Lange couplers, transmission line transformers, filters, amplifiers, and voltage-controlled oscillators have been realized using this technology [129]. Figure 54 shows a typical configuration that can be fabricated by MCM-D technology suitable for design of multilayer microwave circuits.

10.3. Design of Multilayer Circuits

Multilayer microwave circuits can be divided into two groups, the first of which consists of planar components employing multilayer transmission structures, while in the second group, one integrates various circuits into a single multilayer module.

Multilayer couplers, filters, baluns, inductors, and so on, belong to the first group because these employ multilayer transmission structures to overcome difficulties occurring in single-layer designs. It is well known [62] that

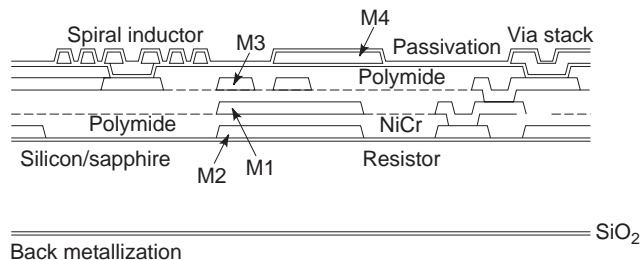

Figure 54. Multichip module (MCM-D) technology used for RF integration. Polymide dielectrics are deposited onto a silicon sapphire substrate; then the chips are installed on the upper surface, and transmission lines and vias are fabricated.

coupled lines realized in single-layer structures produce a weak coupling. Thus, when a tight coupling is required, coupled lines can be implemented in multilayer configurations because overlapping geometry between coupled lines is possible. Coupled-line couplers requiring a tight coupling and those requiring high directivity are designed [127] using this advantage. For the design of parallel coupled-line filters and end-coupled filters, a wide bandwidth is frequently required. For this purpose, multilayer structures used in coupled-line filters [133] and end-coupled filters [95] allow overlapping geometry in the design, which leads to a wide bandwidth and flexibility in selection of physical dimensions. Baluns using multilayer coupled lines [134] can also be designed for wideband operation and with compact dimensions because a tight coupling can easily be obtained in multilayer configurations. Apertures in the ground plane can be employed to achieve interconnection between different layers in multilayer circuits [135] such as aperture-coupled couplers and magic tees.

For the multilayer circuits in the second group, passive components and/or active devices are integrated into a single module for miniaturization and cost-effective production [131]. When these are integrated, vertical vias between different layers and apertures in the ground plane are placed appropriately considering miniaturization, crosstalk, and productivity.

10.4. Examples of Multilayer Circuits

Some examples of multilayer microwave circuits are discussed in this section.

10.4.1. Couplers. Since single-layer structure is not convenient for couplers requiring a tight coupling, multilayer configuration has been explored to overcome this difficulty. As a result, coupled-line directional couplers in two layers [136] and reentrant type couplers [137] designed for a tight coupling have been reported. Figure 55 shows a two-layer coupler [136]. Two conductors with unequal widths are placed on different layers to yield a tight coupling. Different port impedances can be used at the four external ports.

Figure 56 shows a reentrant-type coupler where two identical conductors placed on the top layer with a wider conductor on the bottom layer produce a tight coupling. The spacing between the two conductors on the top layer is wide, not leading to tight tolerance requirement of a narrow gap in fabrication.

10.4.2. Filters. Multilayer configurations have been used for wideband parallel coupled-line filters [138] and

Figure 55. Two-layer coupled-line coupler. Conductors are placed on different levels. A tight coupling can be obtained.

Figure 56. Reentrant-type coupler. Two identical conductors are placed on top layer with a wide spacing, a wide conductor is placed on the bottom layer. This coupler provides a tight coupling.

end-coupled bandpass filters [95] because filters in single-layer configurations cannot yield a wide bandwidth. Aside from the wide bandwidth, enhanced freedom in circuit layout in multilayer designs makes multilayer configurations more attractive. Parallel coupled-line filters and end-coupled bandpass filters have been developed in multilayer structure and also in multilayer coplanar waveguide structure. Examples of these filter circuits are shown in Figs. 57 and 58.

In Fig. 57, coupled lines, which can be placed on different layers, constitute a bandpass filter where each coupled line can have nonsymmetric geometry leading to flexibility in design. Due to these coupled lines offering tight coupling, multilayer coupled-line bandpass filters provide wide bandwidths which are not achievable in single-layer configurations. In Fig. 58, gap-coupled sections constitute a bandpass filter in two-layer configuration. Since this structure allows overlapping conductors in each gap-coupled section, this can also be used for obtaining a wide bandwidth.

10.4.3. Baluns. Due to the requirement for a wide bandwidth and compact design, planar Marchand baluns have been developed [134] using coupled lines in two-layer configurations. These baluns provide wide bandwidth (more than one octave) and compaction of physical dimensions. Figure 59 shows one such circuit reported in the literature. In Fig. 59, two kinds of coupled-line sections in two layers constitute a planar Marchand balun. An unbalanced signal entering port 1 is transformed into a balanced signal coming out of ports 2 and 3.

Three-line baluns using three-coupled lines have also been designed [139] in a two-layer structure, leading to compact design and good performance. Figure 60 shows one of such balun designs. In this design, one of the conductors is placed on one layer while two other conductors are placed on the second layer. With appropriate termi-

Figure 57. Multilayer parallel coupled-line filter. Various conductors can be placed on different levels; each coupled section produces tight coupling, leading to broad bandwidth for the filter.

Figure 58. Two-layer end-coupled bandpass filter. Half-wave resonators shown in dotted lines are at lower layer. Each gap-coupled section can have overlapping geometry for tight coupling and therefore broad bandwidth of the filter.

nations at the ports, this balun transforms an unbalanced signal at port 1 to a balanced signal at ports 2 and 3.

10.4.4. Hybrids. Branchline couplers [140] and magic tees [135] have been developed using multilayer configurations to produce better performance than what can be obtained in single-layer configurations. Figure 61 [140] shows a multilayer branchline coupler where the two output ports are mutually isolated, and the signals at these two ports are out of phase by 90° . The distance between two microstrips or slotlines is one quarter-wavelength. It is possible to make 3 dB branchline couplers by suitably choosing the values of Z_m and Z_s .

Figure 62 shows [135] a multilayer magic tee where the microstrip line (difference arm) on the lower substrate is coupled to a slot-aperture and is terminated on the same layer by an open-circuit stub. The other three magic tee ports are located at the top layer. With the excitation at port 1 (difference port), signals at ports 2 and 3 are equal in magnitude and out of phase by 180° . When the sum port (port 4) is fed, signals at ports 2 and 3 are in phase and equal in magnitude. In addition to the circuits described above, there are many other multilayer circuits like transmission-line transformers [141], aperture-coupled multilayer circuits [142], and aperture-fed and microstrip patch antennas [143].

11. DESIGN OF MICROWAVE CIRCUITS

As is true also for design processes in other domains of engineering, the computer-aided design (CAD) approach [144–146] is being used extensively for the design of microwave circuits and is also being refined further. In order

Figure 59. Planar Marchand balun. Two kinds of coupled lines constitute a balun transforming an unbalanced signal entering into port 1 to a balanced signal coming out of ports 2 and 3. (From Ref. 134, © IEEE, 1990, reprinted with permission.)

Figure 60. Two-layer three-line balun. One conductor is placed on one layer while two other conductors are placed on the other layer. With appropriate terminations at different ports, this circuit works as a balun.

to appreciate the CAD methodology, it is necessary to review the conventional design process that designers used before the CAD methods and software were developed.

11.1. Conventional Design Procedure

A flow diagram depicting the conventional design procedure is shown in Fig. 63. One starts with the desired circuit specifications and arrives at an initial circuit configuration. Available design data and previous experience are helpful in selecting this initial configuration. Analysis and synthesis procedures are used for deciding values of various parameters of the circuit. A laboratory model is constructed for the initial design, and measurements are carried out for evaluating its characteristics. Performance achieved is compared with the desired specifications; if the given specifications are not met, the circuit is modified. Adjustment, tuning, and trimming mechanisms incorporated in the circuit are used for carrying out these modifications. Measurements are carried out again and the results are compared with the desired specifications. The sequence of modifications, measurements, and comparison is carried out iteratively until the desired specifications are achieved. At times the specifications are compromised in view of the practically feasible performance of the circuit. The final circuit configuration thus obtained is sent for prototype fabrication.

The above procedure had been used for the design of microwave circuits for quite some time. However, it became increasingly difficult to use this iterative

Figure 61. A branchline coupler in a two-layer structures. Slotlines are placed on the lower layer while two microstrip lines are located on the upper layer, and two outputs are (at ports 2 and 3) 90° out of phase and equal in magnitude. (From Ref. 140, © IEEE, 1995, reprinted with permission.)

Figure 62. A two-layer microstrip magic-tee junction (ports 2, 3, and 4) coupled through a slot in the ground to a microstrip line (port 1) on the backside. (From Ref. 135, © IEEE, 1997, reprinted with permission.)

experimental method successfully because of the following considerations:

1. Increased complexity of modern systems demands more precise and accurate design of circuits and subsystems. Consequently, the effect of tolerances in the circuit design becomes increasingly important.
2. A larger variety of active and passive components, as described in previous sections, are now available for achieving a given circuit function. The choice of the appropriate device or transmission structure becomes difficult if the iterative experimental approach is used.

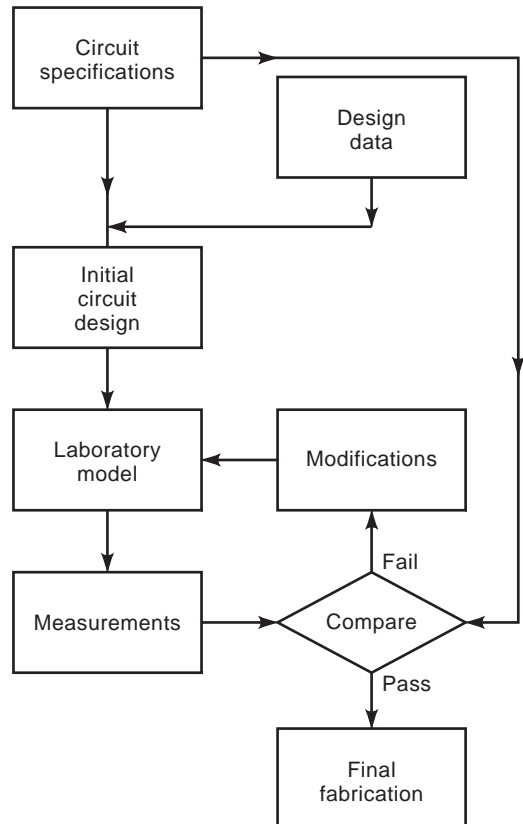

Figure 63. The conventional design procedure that was used for microwave circuits before CAD methods were developed.

- It is very difficult to incorporate any modifications in the circuits fabricated by MIC technology.

The method developed for dealing with this situation is known as “computer-aided design (CAD)”. Computer-aided design in its strict interpretation may be taken to mean any design process where the computer is used as a tool. However, usually the term CAD implies that without the computer as a tool, that particular design process would have been impossible or much more difficult, more expensive, more time-consuming, and less reliable and more than likely would have resulted in an inferior product.

11.2. CAD of Microwave Circuits

A typical flow diagram for the CAD procedure is shown in Fig. 64. As before, one starts with a given set of specifications. Synthesis methods and available design data (at times prestored in computer memory) help to arrive at the initial circuit design. The performance of this initial circuit is evaluated by a computer-aided circuit analysis. Numerical models for various components (passive and active) used in the circuit are needed for the analysis. These are called from the library of subroutines developed

for this purpose. Circuit characteristics obtained as results of the analysis are compared with the given specifications. If the results fail to satisfy the desired specifications, the designable parameters of the circuit are altered in a systematic manner. This constitutes the key step in the optimization. Several optimization strategies include sensitivity analysis of the circuit for calculating changes in the circuit parameters. The sequence of circuit analysis, comparison with the desired performance, and parameter modification is performed iteratively until the specifications are met or the optimum performance of the circuit (within the given constraints) is achieved. The circuit is now fabricated and the experimental measurements are carried out. Some modifications may still be required if the modeling and/or analysis are not accurate enough. However, these modifications, hopefully, are very small, and the aim of the CAD method is to minimize the experimental iterations as far as practicable.

The process of CAD, as outlined above, consists of three important segments:

- Modeling
- Analysis
- Optimization

Modeling involves characterization of various active and passive components to the extent of providing a numerical model that can be handled by the computer. In the case of microwave circuits, one comes across a variety of active and passive elements. Semiconductor devices used include bipolar and MESFET transistors, point contact and Schottky barrier detectors, varactor and pin diodes, and transferred electron and avalanche devices. Passive elements used in microwave circuits include sections of various transmission structures, lumped components, YIG and dielectric resonators, nonreciprocal components, and planar (two-dimensional) circuit elements. Transmission structures could be coaxial line, waveguide, stripline, microstrip line, coplanar line, slotline, or a combination of these. As mentioned earlier in article, not only do these transmission structures need to be characterized fully for impedance, phase velocity, and so on, it also becomes necessary to model the parasitic reactances caused by geometrical discontinuities in these densely packed transmission lines.

Modeling of components in microwave circuits had been the main difficulty in successful implementation of CAD techniques at microwave frequency. However, the development of electromagnetic (EM) simulation techniques developed since the late 1980s has helped to construct adequate models and bring microwave hybrid and monolithic circuit CAD software to level of maturity. Modeling still remains the major bottleneck for CAD of certain classes of microwave circuits [such as coplanar waveguide (CPW) circuits, multilayered circuits, and integrated circuit-antenna modules] and most of the millimeter-wave (above ~ 40 GHz) circuits. Current research in efficient use of EM simulation techniques and in use of artificial neural network models [77] will lead to further improvement in CAD tools for microwave and millimeter-wave circuits.

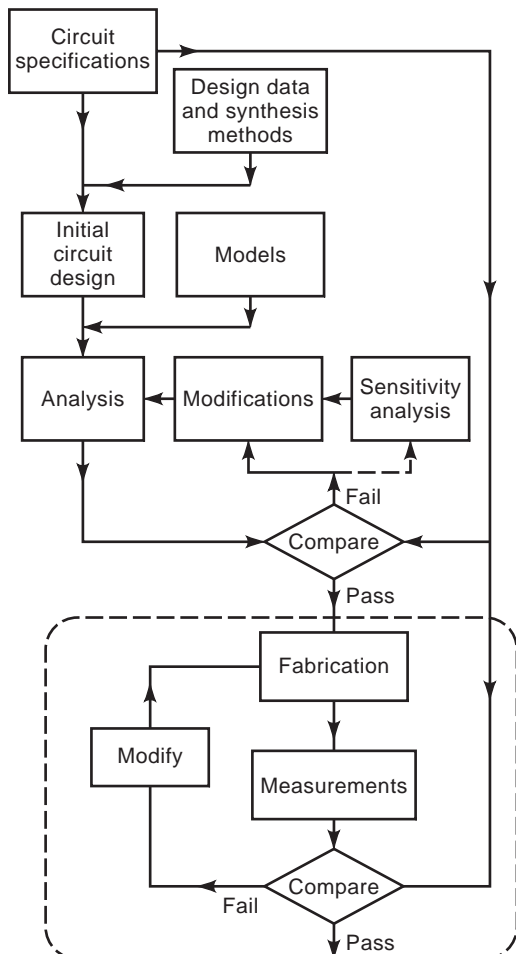

Figure 64. Computer-aided design methodology used for microwave circuits. Recent developments have brought microwave CAD tools to a level of maturity.

12. EMERGING TRENDS IN MICROWAVE CIRCUITS

Even after going through developments over almost a century, the field of microwave circuits continues to see developments in full swing even today; particularly in the areas of multilayered circuits, integrated circuit–antenna modules, quasioptical circuits and systems, and exotic methodologies for CAD.

12.1. Multilayered Circuits

Microwave multilayered circuits were described earlier in Section 10. Multilayered circuit technology is responsible for two novel innovations in monolithic microwave circuits. The first one of these is the development of three-dimensional passive circuit technology [147] as an evolution from the two-dimensional planar microwave circuit technology, which has been the cornerstone of integrated microwave circuit technology so far. Three-dimensional microwave circuits make use of multilayered configurations combined with vertical wall-like microwave structures. This technology can reduce the sizes of inductors and transmission lines to one-third or one-fourth of the size of two-dimensional configurations.

Another novel concept that has emerged from the application of multilayer circuit technique is that of master slice MMIC [148]. The basic idea is similar to that of gate arrays used for semiconductor application-specific integrated circuits (ASICs). In an MMIC master slice, many units that contain transistors, resistors, and lower electrodes for MIM capacitors are located repeatedly (nearly 6 units/mm²) on a GaAs or Si wafer to form a master array. Additional upper layers provide custom design interconnects and top conductor for capacitors to yield semi-custom-designed circuits.

12.2. Integrated Circuit-Antenna Modules

Another very interesting trend in microwave and millimeter-wave design is the integration of conventional circuit and antenna functions in single components. This integration has been made possible by common fabrication technology used for planar circuits and printed antennas. Various design approaches applicable to integrated circuit–antenna modules have been developed [149]. Quasioptical systems [150] designed to generate high power at millimeter-wave frequencies by employing a grid array of sources are important examples of integrated circuit–antenna modules.

12.3. Knowledge-Aided Design (KAD)

Emerging innovations in design techniques [77] for microwave circuits include use of artificial neural networks and development of knowledge-based design tools.

Artificial neural networks (ANNs) are neuroscience-inspired computational tools that learn from experience (training), generalize from previous examples to new ones, and abstract essential characteristics from inputs containing noise or irrelevant data. A significant application of ANN computing to microwave design has been for development of component models [151]. These models are

as accurate as results for EM simulators used for training them but are as efficient as network models. ANNs are expected to play a significant role in microwave design in areas of modeling and optimization and possibly as a means of embedding knowledge in design tools.

Any design process involves several steps starting from problem identification and going through specification generation, concept generation, initial analysis and evaluation, and initial design to a detailed optimized design. It is for the last of these steps (from initial design to detailed optimized design) that the current microwave CAD tools have been developed. The earlier steps in the design process are not at all trivial. We need a technology to aid the earlier stages of design where designers make important and expensive decisions. Knowledge-based system seems to be the most appropriate technology for this purpose.

MICROWAVE DETECTORS

RONALD E. HAM
Consultant

Microwave energy cannot be efficiently detected with equipment used for lower-frequency applications. Microwave-frequency voltage changes are too rapid to be captured on any but the fastest sampling oscilloscopes, and response time and parasitics of common test meters render them useless. Microwave detectors generally measure power in the controlled impedance environments afforded by transmission lines and waveguides. The system impedance is known, so voltage and current magnitudes can be derived. With the judicious application of other microwave components such as power splitters and quadrature couplers, phase information can be extracted from multiple power measurements; therefore, full characterization of a system or component is possible with only the microwave detector to convert microwave signal characteristics to the readily observable and measurable quantities of low-frequency voltages and currents.

Microwave detectors sense the amplitude or power of a signal, or the change in the amplitude or power of a signal. They are used for the determination of signal power level and for recovery of information placed upon the microwave signal amplitude. The microwave detector circuit (Fig. 1) consists of a matching circuit to match the impedance of the circuit being measured to the impedance of the detector itself, along with an output signal conditioning circuit to convert the detector output to a voltage or current that is proportional to the microwave signal input. Ideally, the detector impedance directly matches the system impedance, and the matching circuit is not required.

Microwave detectors can be separated into two categories: thermally dependent detectors and diode detectors.

Thermally dependent detectors absorb the incident microwave signal in a detector element, and the microwave energy is converted into heat energy. The increase in temperature of the detector element is directly detected, or a change in a physical parameter of the detector element due to the change in temperature, normally resistance, is detected. The diode detector rectifies the microwave signal, clipping either the positive or negative voltage of the alternating voltage waveform, and averages the resultant monopolar signal in a capacitive circuit to produce a DC signal with an amplitude related to the microwave signal amplitude.

The response time of the thermally dependent detector is a function of the thermal mass being heated by the incident energy and the thermal resistance of the detector to its surrounding environment. In general, the response time of a thermally dependent detector is slow compared to the response time of a diode detector and is on the order of milliseconds to seconds. Thermally dependent detectors are used primarily for the measurement of the power level of steady-state signals or to measure the average value of the power of a time-varying signal such as a pulsed radar transmitter output.

The response time of a diode detector can be within a few periods of the microwave signal being detected; hence, diode detectors can recover information placed in amplitude variations on a signal in addition to measuring the power of steady-state signals.

Small-signal thermally dependent detectors with a bandwidth of less than 100 Hz typically operate over a power range of +10 dBm to about –50 dBm, while diodes limited to the same bandwidth are useful from about +10 dBm to less than –80 dBm. Insertion of attenuators or couplers between the power source and the detector facilitates measuring much higher powers; however, measurement of very small amounts of power generally necessitates insertion of amplifiers or frequency conversion to lower frequencies where more sensitive techniques can be used to detect the signal.

1. THERMALLY DEPENDENT DETECTORS

Thermally dependent detectors depend on the heating of the detector element by the incident microwave energy. The heating is proportional to the electrical energy dissipated in the detector element. Bolometers and thermocouples are typical of thermally dependent microwave detectors. Because absorption of the available power in the incident signal depends on a proper impedance match between the transmission media and the absorbing detector circuit, the detector must have a well-established and controlled impedance.

Figure 1. The impedance of the microwave detector should be matched to the impedance of the system being measured.

MICROWAVE DETECTORS

RONALD E. HAM
Consultant

Microwave energy cannot be efficiently detected with equipment used for lower-frequency applications. Microwave-frequency voltage changes are too rapid to be captured on any but the fastest sampling oscilloscopes, and response time and parasitics of common test meters render them useless. Microwave detectors generally measure power in the controlled impedance environments afforded by transmission lines and waveguides. The system impedance is known, so voltage and current magnitudes can be derived. With the judicious application of other microwave components such as power splitters and quadrature couplers, phase information can be extracted from multiple power measurements; therefore, full characterization of a system or component is possible with only the microwave detector to convert microwave signal characteristics to the readily observable and measurable quantities of low-frequency voltages and currents.

Microwave detectors sense the amplitude or power of a signal, or the change in the amplitude or power of a signal. They are used for the determination of signal power level and for recovery of information placed upon the microwave signal amplitude. The microwave detector circuit (Fig. 1) consists of a matching circuit to match the impedance of the circuit being measured to the impedance of the detector itself, along with an output signal conditioning circuit to convert the detector output to a voltage or current that is proportional to the microwave signal input. Ideally, the detector impedance directly matches the system impedance, and the matching circuit is not required.

Microwave detectors can be separated into two categories: thermally dependent detectors and diode detectors.

Thermally dependent detectors absorb the incident microwave signal in a detector element, and the microwave energy is converted into heat energy. The increase in temperature of the detector element is directly detected, or a change in a physical parameter of the detector element due to the change in temperature, normally resistance, is detected. The diode detector rectifies the microwave signal, clipping either the positive or negative voltage of the alternating voltage waveform, and averages the resultant monopolar signal in a capacitive circuit to produce a DC signal with an amplitude related to the microwave signal amplitude.

The response time of the thermally dependent detector is a function of the thermal mass being heated by the incident energy and the thermal resistance of the detector to its surrounding environment. In general, the response time of a thermally dependent detector is slow compared to the response time of a diode detector and is on the order of milliseconds to seconds. Thermally dependent detectors are used primarily for the measurement of the power level of steady-state signals or to measure the average value of the power of a time-varying signal such as a pulsed radar transmitter output.

The response time of a diode detector can be within a few periods of the microwave signal being detected; hence, diode detectors can recover information placed in amplitude variations on a signal in addition to measuring the power of steady-state signals.

Small-signal thermally dependent detectors with a bandwidth of less than 100 Hz typically operate over a power range of +10 dBm to about –50 dBm, while diodes limited to the same bandwidth are useful from about +10 dBm to less than –80 dBm. Insertion of attenuators or couplers between the power source and the detector facilitates measuring much higher powers; however, measurement of very small amounts of power generally necessitates insertion of amplifiers or frequency conversion to lower frequencies where more sensitive techniques can be used to detect the signal.

1. THERMALLY DEPENDENT DETECTORS

Thermally dependent detectors depend on the heating of the detector element by the incident microwave energy. The heating is proportional to the electrical energy dissipated in the detector element. Bolometers and thermocouples are typical of thermally dependent microwave detectors. Because absorption of the available power in the incident signal depends on a proper impedance match between the transmission media and the absorbing detector circuit, the detector must have a well-established and controlled impedance.

Figure 1. The impedance of the microwave detector should be matched to the impedance of the system being measured.

Figure 2. The bolometer *B* is a temperature-sensitive resistor.

The bolometer detects electromagnetic radiation by converting the energy in the transmission media to heat. It is placed across transmission line terminals, as shown in Fig. 2, or in the electric field of a waveguide. The nominal resistivity of the bolometer should be equal to the impedance of the transmission line or waveguide at the point of measurement, or the transmission media impedance should be matched to that of the bolometer. One method of making a detector that matches a 50 Ω coaxial system impedance while maintaining a relatively large 200 Ω DC resistance is to place two 100-Ω resistive elements in parallel for the microwave measurement but in series for the dc measurement, as shown in Fig. 3. Under matched conditions all the incident energy is dissipated and appears as heat in the bolometer. The change in the bolometer element resistivity is measured and equated to the magnitude of the incident electromagnetic radiation.

A significant change in the resistivity of a bolometer as power is absorbed can result in an impedance mismatch to the circuit being measured. This can result in unacceptable errors. A measurement circuit usually facilitates a method for accommodating the change in a bolometer element resistivity with the change in incident power. The most common is to use a power substitution technique. A bias current is passed through the bolometer as shown in Fig. 4. The bias current feeds more bias power to the element than the microwave energy that is to be measured. The bolometer element is designed to have an impedance equal to the characteristic impedance of the system being measured while the bias is at the quiescent level with no applied microwave energy. The resistance of the bolometer element becomes part of the resistive bridge. As microwave power is fed to the detector, its resistance changes;

Figure 4. A bridge circuit is used to detect change in the bolometer resistance.

however, the bias power to the circuit must be reduced to balance the bridge. The reduction in bias power to the bolometer is equal to the applied microwave power; therefore, the external circuit measures this change in power, and the detector impedance remains matched to the system being measured. Numerous schemes for automatically balancing the bridge and deriving the change in bias power are used.

Bolometers are, by definition, temperature-sensitive. The more sensitive a bolometer detector is to incident microwave power, the more sensitive it will be to small ambient temperature variations; therefore, temperature compensation is virtually imperative for low-level power measurements. This is accomplished as shown in Fig. 5 by mounting two identical bolometer sets in the same detector package so that the thermal resistance path from each element is to the same heat sink. This forces changes in ambient temperature to cause identical temperature variations in both elements. Only one of the bolometer sets has microwave power applied. By effectively connecting the bolometers in a differential circuit, the common mode variations, introduced by ambient environmental temperature variations through the thermal resistance paths, are canceled.

The bolometer measures the power absorbed in its resistance. In many microwave circuits, unlike those at lower frequencies, current and voltage have little meaning because of the difficulty of their measurement. It is common in microwave applications to make power measurements in a controlled impedance environment; hence, the same circuit information is obtained but with different types of measurement.

A barretter is one form of bolometer. It is a small wire that increases its resistance because of the resultant heating when a microwave signal potential is placed across the ends of the wire. The wire is usually either platinum or tungsten. The response characteristic of a barretter is nominally

$$R - R_0 = JP^n \tag{1}$$

where R_0 is the room temperature resistance of the wire, R is the resistance of the wire with the power P being dissipated, and J and n are constants.

Figure 3. Using two bolometers increases detection sensitivity.

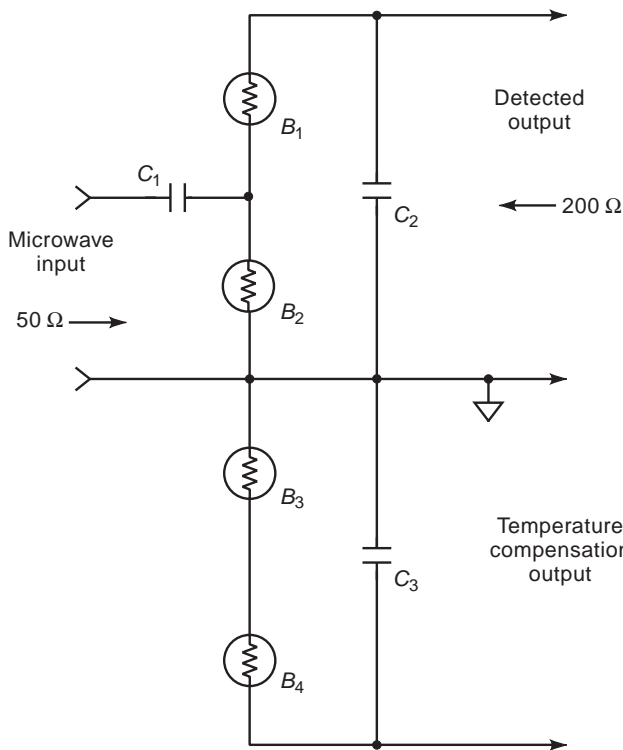

Figure 5. Bolometer set B_1, B_2 are detectors, and set B_3, B_4 are for temperature compensation.

For a specific commercial barretter intended for low-power measurements, $R_0 = 155 \Omega$, $n = 0.9$, and $J = 7.57$. The power sensitivity S is found by differentiating the resistance with respect to the absorbed power giving

$$S = \frac{dR}{dP} = \frac{n(R - R_0)}{P} \quad (2)$$

This unit has a recommended operating point of $R_{op} = 200 \Omega$ at an applied power of $P_{mW} = 15 \text{ mW}$, which is achieved at a bias current of 8.7 mA. Substituting this into the equation yields a sensitivity of 5 Ω/mW . The change e_{out} in the voltage across the unit with the applied power being much less than the bias power will be

$$e_{out} = \sqrt{\frac{P_{bias}}{R_{op}}} \cdot S \cdot P_{mW} \quad (3)$$

Applying 1 μW of power to this detector produces an output voltage of 44 μV . The kTB thermal noise in a 100 Hz bandwidth at the terminals of the unit is about $2.5 \times 10^{-8} \text{ V}$. This indicates that the smallest microwave signal that can be detected in the presence of the noise in the 100 Hz bandwidth is around 10 nW or -50 dBm . This is typical of low-power bolometers.

The thermistor is another form of bolometer. The thermistor consists of a small amount of resistive material with a high temperature sensitivity placed between two connecting wires as shown in Fig. 6. Typically, the material is a semiconductor with a large negative temperature coefficient of resistance; that is, the resistivity of the

Figure 6. A thermistor is a resistor with a high temperature sensitivity.

material decreases with an increase in temperature. Placing a microwave signal potential across the thermistor results in a current that heats the temperature-sensitive material. With the semiconductor thermistor, this results in a reduction in the resistance between the terminals. The thermistor is used in the same bias substitution circuits as the bolometer with changes to allow for the negative change in resistance with increase in applied power. Because the magnitude of the negative temperature coefficient of the thermistor is typically much greater than the positive temperature coefficient of the barretter, the thermistor tends to be more sensitive than the barretter; however, the large volume of the thermistor leads to a larger thermal time constant, making its time response slower than that of the barretter.

Other variations in the construction of bolometers are possible, such as the deposition of thin metal resistive films on insulating substrates. These implementations readily lend themselves to varied microwave construction techniques such as monolithic and thin-film integrated circuits, stripline, slotline, coplanar waveguide, and microstrip. Note that such construction also facilitates thermal isolation, cooling, and miniaturization for sensitive millimeter-wave through infrared operation.

A thermocouple is formed by intimately joining two dissimilar pieces of wire, such as copper and constantan. A potential difference appears across the junction related to the temperature. Microwave energy can be detected by using the thermocouple to measure the change in temperature of a resistor that terminates the microwave circuit as shown in Fig. 7. Another method, resulting in a better form factor for microwave measurement, places a carbon resistor between the two dissimilar wires as in Fig. 8. This results in a smaller thermal mass and a resultant faster response time. In both examples, a standard thermocouple measurement system with a reference cold junction is required. Calibration of power into the detector as a function of thermocouple temperature must be experimentally derived.

Other calorimetric methods can be used for large-signal levels. For example, water pumped through an incident microwave energy-to-heat converter (a calorimetric load) increases in temperature. The energy required to change the temperature of the water is the energy in the incident microwave signal. This is illustrated in Fig. 9 and is a common method for measuring the average power output from large radar transmitters.

The ratio of the maximum power detected to the minimum detectable power with the thermal detector is

Figure 7. Microwave power is absorbed in the resistor, and the temperature increase is measured by the thermocouple.

relatively small; however, this is compensated for by measurement accuracy and repeatability. The time response of the thermal detector is a function of the thermal time response of the energy absorbing mass; therefore, barretters typically respond faster than a thermistor, and a thermistor is faster than a thermocouple. An advantage of the slowly responding detector is the ability to measure the average power of a pulsed signal, such as a radar.

Recent developments in temperature-dependent detectors is primarily focused in two areas. Increased miniaturization is intended to increase the frequency of operation up into the millimeter microwave range and to infrared. Arrays of these very small detectors can be used for imaging. There is also active research in cryogenic detectors because they produce less noise than heated detectors and hence yield improved small signal sensitivity.

2. DIODE DETECTORS

Semiconductor diode detectors respond rapidly to changes in the input signal. They rectify the voltage of the incident microwave signal, producing a direct current output that

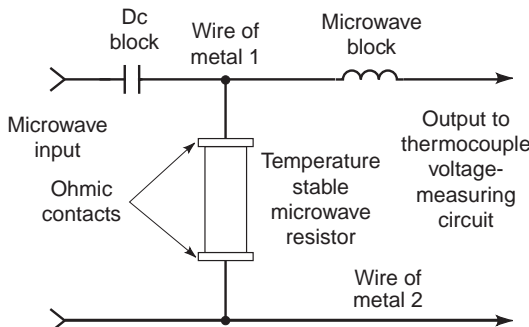

Figure 8. Direct series connection of the thermocouple to the resistor facilitates faster response because of the reduced thermal mass.

Figure 9. A water or calorimetric load can accurately measure large amounts of average power.

is related to the magnitude of the input. This process is illustrated in Fig. 10. The diode curve of current *I* through the diode versus the voltage *V* across the diode is roughly governed by the ideal diode equation

$$I = I_0(e^{qV/kT} - 1) \tag{4}$$

where

*I*₀ = is the diode leakage current with a reverse voltage applied

q = is the charge of an electron (1.60 × 10⁻¹⁹ C)

k = is Boltzmann's constant (8.62 × 10⁻⁵ eV/K) and

T = is the temperature in degrees Kelvin (degrees centigrade + 273)

At room temperature, *kT/q* = 26 mV. By applying a voltage across the diode, a corresponding current is forced through the diode. Using the circuit in Fig. 11, the current

Figure 10. The diode detector rectifies the input signal.

Figure 11. The rectified current through the series diode is averaged in the RC circuit to produce a DC or low-frequency output.

is averaged in a parallel resistor and capacitor to produce a DC output voltage that is related to the magnitude of the input voltage. Note that the microwave voltage component of the output voltage is shorted by the averaging capacitor. This AC short circuit also forces all of the applied high-frequency voltage to appear across the diode.

Two variations of the diode detector circuit are shown in Figs. 12 and 13. In the first, the applied voltage appears directly across the diode. On negative portions of the microwave cycle the voltage is shorted through the diode, resulting in a small negative voltage diode drop that is proportional to the current through the diode. On the positive portion of the cycle, all of the applied voltage appears across the diode. The RC circuit effectively integrates the voltage and produces a net positive output voltage that is proportional to the magnitude of the applied microwave signal. Figure 13 is a combination of the series and shunt connections. Each diode provides the necessary DC return path for the other, eliminating the necessity of the large biasing element.

Real semiconductor diode performance is more closely approximated by the equation

$$I = I_0(e^{qV/nkT} - 1) \tag{5}$$

where n is the ideality factor and is an indication of how close to ideal were the conditions under which the device was fabricated. It usually ranges from 1.0 to 1.06 for a silicon diode. The leakage current I_0 is a function of material, material doping, and various factors involved in the fabrication of the physical diode. The combination of all of these factors produces a distinct V - I curve for various

Figure 12. The rectified voltage waveform across the shunt diode is averaged in the RC circuit.

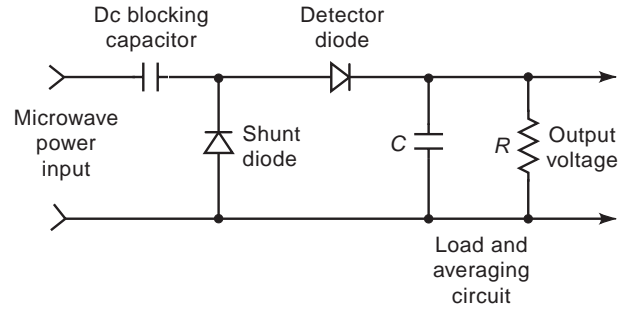

Figure 13. Combining the shunt and series diodes eliminates the inductors as the shunt diode provides the DC return path.

classes of diodes. The most significant physical parameter of these devices is the maximum voltage drop across the diode with a moderate amount of applied current. This is referred to as the *diode voltage*. For silicon pn junctions the diode voltage is nominally 0.7 V. For Germanium it is about 0.3 V. For metal semiconductor junctions, commonly called *Schottky barrier diodes*, the voltage drop can be tailored between nominally 0.2 and 0.6 V by material selection and processing technique variations.

The Schottky barrier is the most commonly used high-frequency detector diode because its relatively low forward voltage drop results in excellent sensitivity to small signals. It also can be switched from forward conduction to reverse isolation faster than a pn junction because there is no charge storage within the device due to diffusion capacitance. Figure 14 is a first-order equivalent circuit for a detector diode. The L , R , and C elements are commonly known as “parasitics.” The series resistance is primarily the bulk loss due to the substrate. The shunt capacitor across the diode proper is the junction capacitance and is a strong function of the diode area. The series inductance represents bondwires, beam leads, or any connections to the semiconductor die. The capacitor surrounding the circuit is plate capacitance between metallized areas and, for a packaged device, the packaging capacitance. Inserting the diode model into any of the diode detector circuits of Figs. 11–13, note that the parasitic capacitors can short out the diode at high frequencies. The smaller the parasitic capacitances, resistance, and inductance, the higher in frequency the diode detector can be made to operate.

Although the equations above roughly describe the transfer characteristic of the metal semiconductor diode, they do not properly define operation for very large input

Figure 14. Parasitics limit the high-frequency performance of a diode detector.

Figure 15. The diode detector follows a square law over most of its dynamic range.

signals. As shown in Fig. 15, the diode detector actually has two operating regions. From very low power until about 0 dBm input, the detector output voltage is proportional to the input power. This is the square-law region and is generally the desired region of operation. Further increasing the input results in an output proportional to the input voltage. This is the linear region.

Planar Schottky barrier diodes can be fabricated by evaporating a metal onto a wafer of doped semiconductor. Small dots or interdigitated patterns are photolithographically defined to establish the area and shape factor of the diodes to be made. The backside of the die is degenerately doped and metallized. Thermal activation of the metal semiconductor junctions results in a Schottky barrier diode on the topside and an ohmic contact on the backside of the semiconductor wafer.

The Schottky barrier diode, made by the deposition of thin metal films, represents an improvement in operational consistency and is a method of mass-producing a type of diode originally requiring considerable fabrication labor. The point contact diode, Fig. 16, was the first microwave metal semiconductor detector. It consists of a small die of semiconductor alloyed to a metal header to form an ohmic contact. A thin “cat whisker” of a stiff metal such as tungsten with a sharp point is brought into contact with the semiconductor. Although a thin layer of oxide contamination probably exists between the metal and the semiconductor, a rudimentary junction similar to a Mott diode is formed. The junction area is nominally increased or decreased by increasing or decreasing the pressure of the cat whisker on the semiconductor. Obviously, aging and

Figure 16. The point contact diode is a pressure contact between a stiff metal wire and a doped semiconductor die.

temperature cycling will change the junction characteristics, and vibration can be a definite hazard; however, there are many of these detectors, made in the early 1940s, still in service and doing an excellent job.

The diode parasitic capacitance is a function of the area of the junction; however, the power-handling capability is also a function of diode area. As the maximum useable frequency of a diode made with a particular fabrication process increases, the maximum power that can be fed to the diode decreases.

Diode detector sensitivity can, to some extent, be increased by supplying a small amount of DC bias current to the diode in addition to the microwave signal that is to be detected. This bias current moves the operating point to the right of the current axis and up the $I-V$ curve. Careful adjustment of this current can set the operating point at a region of maximum curvature, resulting in an increase in the output voltage from the detector for a given microwave power input; however, this does not necessarily indicate adjustment for maximum sensitivity because the diode generates $1/f$ noise due to the bias current. The increase in noise level from zero bias current kTB noise can exceed a factor of 10–1000 while significant amounts of the $1/f$ noise can extend well beyond 20 kHz. In general, maximum signal sensitivity with bias will occur somewhere between zero bias and the region of maximum curvature of the diode $I-V$ curve.

By heavily doping both sides of a pn junction, a diode producing a very small initial voltage drop is obtained. Carriers “tunnel” through the quantum mechanical potential barrier; hence, the diode, referencing Fig. 17, is called a *tunnel diode*. Although this diode, when used as a detector, can suffer from the same charge storage capacitance malady of other pn junctions, judicious matching of the diode area to the maximum applied power can result in a very sensitive zero-bias detector. As seen from the $I-V$ curve, if bias current is increased beyond the usable detector range, the impedance of the diode becomes negative. Biased in this region, the diode can be used as an oscillator or amplifier.

The ratio of the maximum power detectable to the minimum detectable power with the diode detector is

Figure 17. A tunnel diode is a highly doped pn junction with a very small low-current junction voltage.

relatively large; however, the difficulty of compensating thermal drift in the detector limits its use in accurate absolute power measurement applications.

MICROWAVE FERROELECTRIC DEVICES

D. P. PATEL
J. M. POND
J. B. L. RAO
Naval Research Laboratory

Control of reactance in microwave circuits, devices, and systems is a common method by which the response of a microwave circuit such as a filter, resonator, or phase shifter can be tuned. Devices based on a class of voltage-dependent non-linear dielectrics known as ferroelectrics provide an alternative to semiconductor varactor diodes and ferrimagnetic components, which are the most common devices of this type.

After an overview of the relevant materials issues, this article describes microwave devices that exploit the variation of the ferroelectric's permittivity with applied DC electric field. The main feature of these "tunable" microwave devices is the change of their capacitance, impedance, or phase velocity. We will describe varactors, oscillators, tunable filters, and phase shifting devices.

1. FERROELECTRIC MATERIALS

Even though they do not contain iron, the name "ferroelectric" was selected because they possess a response to an electric field that, although not the dual, is analogous to a ferromagnetic material's response to a magnetic field. Ferroelectrics are a subgroup of nonlinear dielectrics. The complex permittivity of a ferroelectric material is a function of both the temperature and an applied DC electric field.

Ferroelectric materials possess spontaneous polarization below a temperature referred to as the "Curie temperature," at which point they undergo a phase transition.

Above the Curie temperature, they are in a paraelectric state where spontaneous polarization disappears, but they still retain a nonlinear dielectric constant with applied electric field. In this article, we will use the term ferroelectric to describe these materials even if they are being operated at temperatures where they are in the paraelectric phase. Unlike ferromagnetic materials, ferroelectric materials in either the ferroelectric or paraelectric state are reciprocal; that is, the transmission coefficient through these devices is the same for different directions of propagation. Until relatively, the dielectric losses in ferroelectric materials excluded them from being used at microwave frequencies. However, the continued improvement of ferroelectric materials suitable for use at microwave frequencies has resulted in the design of many microwave devices.

Tunability can be defined for a ferroelectric as the fractional change in the dielectric constant with applied dc bias voltage or

$$\text{Tunability} = \frac{\epsilon_{r,\max} - \epsilon_{r,\min}}{\epsilon_{r,\max}} \quad (1)$$

where $\epsilon_{r,\max}$ is the dielectric constant when no bias voltage is applied and $\epsilon_{r,\min}$ is the dielectric constant when maximum DC bias is applied. The dielectric constant of a ferroelectric decreases as the bias voltage is increased. Although larger tunability is a desirable feature for most microwave applications, a ferroelectric material with larger tunability usually has a relatively larger dielectric loss. Optimizing material tunability and loss to meet the needs of a particular microwave application remains a challenging task.

Ferroelectrics are inherently broadband; that is, they do not have a low frequency limit like ferrites. Switching time for these materials has been measured to be less than a nanosecond [1], which is sufficient for most microwave applications. Also, these materials are radiation-hardened. Ferroelectrics can be manufactured in bulk, thick-film, and thin-film form.

Like other ceramics, bulk ferroelectric ceramics can handle high peak powers. The limit on the average power is determined by the loss tangent ($\tan \delta$) of the ferroelectric. There are many known ferroelectrics, but the most widely used ferroelectric at microwave frequencies is barium strontium titanate, $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$ (BSTO). BSTO with $x = 0.5$ is frequently used for microwave applications since the Curie temperature is well below room temperature yet a reasonable tunability is retained. Bulk ceramics of this composition typically possess relative dielectric constants on the order of 1000 and loss tangents of 0.02 at 10 GHz [2,3]. BSTO's Curie temperature can be controlled by varying the barium-to-strontium ratio. A bulk composite material can be engineered by adding nonferroelectric oxides to BSTO to reduce the dielectric constant and the loss tangent [2,3]. For room-temperature operation of these composites in the paraelectric phase, tunability ϵ_r , and $\tan \delta$ decrease with decreasing barium content; they also decrease with increasing oxide content. Tunability increases linearly with an increase in bias

voltage. Bulk ceramics can be produced using usual ceramic processing techniques.

Thin films are compatible with integrated circuits, and they need lower bias voltages than does bulk material. Thin films can be manufactured by any of the common thin-film deposition techniques, pulsed-laser deposition, sputtering, metal organic chemical vapor deposition (MOCVD), and so on. In thin films, control of the ferroelectric composition and incorporation of doping is also possible to reduce losses at microwave frequencies [4]. Thin films can potentially be less costly and easier to manufacture, but they cannot handle high power levels. Thin films of the ferroelectric strontium titanate, SrTiO_3 (STO), are used at microwave frequencies because of their compatibility with the high-temperature superconductor (HTS) yttrium barium cuprate (YBCO).

Between bulk and thin-film ferroelectrics lies the realm of thick-film ferroelectrics, which can be produced via tape casting.

Throughout this article, it will be assumed that the ferroelectric is homogeneous and that it is linear with respect to a small, time-varying electric field. The dielectric strength of these ferroelectrics is relatively high. Large DC electric fields (in the range of a few MV/m) can be applied to STO and BSTO before dielectric breakdown occurs. Assuming that a particular ferroelectric composition meets the tunability, ϵ_r and $\tan \delta$ requirements of the application, the next two sections describe the various issues that need to be addressed before designing a microwave ferroelectric device.

2. MICROWAVE DEVICE CONSIDERATIONS

Most microwave devices can be categorized according to their physical size in relation to the wavelength at their upper frequency of operation. Those devices that are very small compared to their operational wavelength are called “electrically small” and can be modeled with discrete circuit components. The term “lumped-element” model is often employed. For devices whose dimensions are larger, it is usually necessary to take into account the frequency-dependent effects. Such devices are described by distributed networks of common circuit elements such as inductors and capacitors. The most common distributed device is the transmission line, which is modeled by a ladder network of series inductors and shunt capacitors. As a lumped element, a capacitor which uses ferroelectric material yields a tunable circuit reactance.

Transmission lines can usually be described by their phase velocity and characteristic impedance, which are given by

$$v_p = \frac{1}{\sqrt{LC}} \quad (2)$$

and

$$Z_c = \sqrt{\frac{L}{C}} \quad (3)$$

respectively, where L is the inductance per unit length and C is the capacitance per unit length. By introducing a

material whose dielectric constant ϵ_r is controlled (or tuned) by a direct-current (DC) bias voltage, the phase velocity and characteristic impedance can be varied by changing capacitance.

An issue to consider when choosing a microwave device topology is the power-handling requirements. For high-power applications, the number of device topologies that are appropriate is limited. Further discussion is offered in the next section.

In any nonlinear material, device, or system, another important practical consideration is the strength of signals generated at other than the desired frequency. Since most systems are bandwidth-limited, the most troublesome condition arises when two desired signals, f_1 and f_2 , both within the passband produce signal at frequencies $2f_1 - f_2$ and $2f_2 - f_1$, also within the passband. A plot of the signal strengths of f_1 , f_2 , $2f_1 - f_2$, and $2f_2 - f_1$ is often used to determine the third-order intercept point (IP3), which is an important figure of merit.

Since ferroelectrics have a high dielectric constant, the circuits that employ these materials tend to have very low impedance. Therefore, impedance matching is also another major issue to be addressed when using ferroelectrics. A consequence of a voltage-dependent capacitance being utilized to tune the phase velocity of a transmission line as given by Eq. (2) is that the characteristic impedance of the transmission line is also tuned per Eq. (3). This further complicates the impedance-matching problem.

3. MICROWAVE GUIDING STRUCTURES

At microwave frequencies, ferroelectrics can be introduced into many different types of rectilinear structures that are used to guide electromagnetic waves. These guiding structures include parallel-plate and rectangular waveguides, which can be loaded (or filled) with ferroelectric material. There are also many planar structures that use the ferroelectric material as a tunable substrate, like microstrip, slotline, coplanar strip, and coplanar waveguide. Each structure has a different set of advantages and disadvantages. For applications where ferroelectrics are used to provide bias-dependent propagation properties, it is convenient to divide the guiding structures into two categories: (1) geometries that can handle high microwave power but require large bias voltages (parallel plate and rectangular waveguide) and (2) those that are compatible with small microwave power levels and require only modest bias voltages (planar structures). Note that the ferroelectric permittivity is a function of the electric field. In a planar structure, the bias voltage is applied across a thinner ferroelectric, and so smaller bias voltage will produce the same variation of the permittivity as a larger bias voltage (which creates a similar electric field intensity) would produce in a parallel-plate or rectangular waveguide.

Planar waveguiding structures contain the metallization defining the waveguiding structure delineated on the one or more plane. Often this metallization layer is on the top surface of a dielectric substrate. Hence, these geometries are compatible with photolithographic processing. Since the metallization delineating the waveguide is at the

interface of two regions (usually dielectric), the guided wave is propagating such that a portion of the field is in each region. The choice of the correct planar transmission line is determined by many factors including (1) orientation of the bias field and microwave field with the ferroelectric region, (2) thickness of the ferroelectric material, and (3) compatibility with other circuit elements. Planar structures are compatible with ferroelectric thin films and with semiconductors for microwave monolithic integrated circuits. However, planar structures require a DC block to isolate the radio frequency (RF) from the high DC voltage that is used to tune the ferroelectric permittivity [5].

3.1. Microstrip

The most common planar transmission line is microstrip. As shown in Fig. 1, both the bias and the dominant-mode microwave electric field are oriented primarily normal to the interface. It should be noted that although microstrip is the most widely used planar transmission line, when using thin-film ferroelectrics deposited on a substrate with the delineated metal layer on top as shown in the Fig. 1b, the high dielectric constant of the ferroelectric results in decreased tuning efficiency. This can be seen by considering the capacitance per unit length to be a series combination of the ferroelectric capacitor and the substrate capacitor. The capacitance contribution from the thin-film ferroelectric is much smaller than that from the substrate, and the tunability of the phase velocity and the characteristic impedance of the dominant mode are reduced accordingly.

Tunable filters employing parallel-coupled microstrip resonators do not suffer from this inefficiency since the

Figure 1. Microstrip planar transmission line cross section with (a) a homogeneous bulk substrate and (b) thin film on a bulk substrate. The electric field between the metal strip on the top surface and the metal ground plane is primarily normal to the surface.

coupled-line mode [6] possesses a significant electric field component parallel to the surface. This coupled-line mode is similar to the coplanar strip transmission line (discussed below) with a ground plane. Practical design equations for microstrip on layered dielectric substrates are based on a quasistatic analysis [7].

3.2. Coplanar Waveguide, Coplanar Strip, and Slotline

Other planar transmission lines such as coplanar waveguide, coplanar strip, and slotline have two or more conductors on the patterned surface. Hence the electric fields of both the dominant microwave mode and the bias are tangential to the substrate surface as shown in Fig. 2. The dominant mode of these planar transmission lines can be efficiently tuned with a bias field whether a bulk ferroelectric substrate or a thin-film ferroelectric on bulk dielectric substrate is employed. In the later case, good

Figure 2. Coplanar waveguide (CPW) transmission line cross section with (a) a homogeneous bulk substrate and (b) a thin film on a bulk substrate and coplanar strip (CPS) transmission-line cross section with (c) a homogeneous bulk substrate and (d) a thin film on a bulk substrate. The electric field between the metal strips on the top surface is primarily parallel to the surface.

tunability is retained since the thin-film capacitance and substrate capacitance are in parallel. Design equations for a coplanar waveguide on multilayered dielectric substrates are available [7]. Similar analyses using a partial-capacitance conformal-mapping approach can be applied to other geometries to account for the ferroelectric thin film.

For the coplanar waveguide, the narrower the gaps between the center conductor and the ground planes, the higher the electric field intensity (and tunability) for a given bias voltage. Although coplanar waveguide is one of the simplest transmission lines, the microwave current density is sharply peaked at the edges of the strips causing large conductor losses. The problem is enhanced by the high dielectric constant and small thickness of the ferroelectric [8].

3.3. Parallel-Plate and Rectangular Waveguides

A parallel-plate waveguide is a two-conductor guiding structure that supports transverse electromagnetic (TEM) waves. Thus, the electric and magnetic field are orthogonal to each other and to the direction of propagation. Figure 3 shows how this type of waveguide can be loaded with a ferroelectric medium to provide a variable phase velocity, which is given by

$$v_p = \frac{1}{\sqrt{\mu\epsilon}} \quad (4)$$

where μ and ϵ are the permeability and permittivity of the ferroelectric. Both the DC and the RF electric field are vertical. The ferroelectric is bifurcated with an electrode that is used to apply the DC bias with respect to the grounded waveguide walls.

Rectangular waveguides are popular in the microwave region. They are single-conductor guiding structures that confine the electromagnetic wave in the interior of the waveguide. Typically, the waveguide is operated in the dominant TE₁₀ mode. Figure 4 shows how a ferroelectric can be used in this type of waveguide to provide a variable phase velocity, which is given by

$$v_p = \frac{1}{\sqrt{\mu\epsilon} \sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}} \quad (5)$$

where λ_c is the cutoff wavelength. Again, both DC and RF electric field are vertical, and the ferroelectric is bifurcated by an electrode. Unlike the parallel-plate waveguide

Figure 3. Parallel-plate waveguide phase shifter (propagation into or out of paper).

Figure 4. Rectangular waveguide phase shifter (propagation into or out of paper).

(which has no sidewalls), rectangular waveguide has sidewalls. Therefore, a slot needs to be cut into a sidewall to connect the electrode to a DC power supply. The area of the slot opening must be small to prevent the microwave energy from leaking out of the slot.

4. APPLICATIONS

In this section, we will describe several applications of ferroelectrics at microwave frequencies. These include varactors, voltage-controlled oscillators (VCOs), tunable filters, and phase shifting devices.

4.1. Varactor

Varactors are variable-reactance circuit elements. They are used in switching or modulation of a microwave signal, for the generation of harmonics in an applied microwave signal, and in the mixing of two microwave signals of different frequencies. As a discrete tunable capacitor, ferroelectric-based capacitors are applicable in a number of microwave circuits including VCOs, tunable filters, and oscillators. Parallel-plate configurations have not been successfully implemented (due to high required processing temperatures) in producing a high-quality ferroelectric thin film on a low-surface-resistance metal. Interdigitated capacitors [9], where the metal electrodes are deposited on top of the ferroelectric (either thin-film or thick-film) or bulk substrate, have proven to be a more practical option. A typical interdigitated capacitor is shown in Fig. 5. Although strongly dependent on the ferroelectric material involved, Figs. 6 and 7 show the level of performance available from thin-film ferroelectric interdigitated capacitor technology. Losses in ferroelectric interdigitated capacitors arise from the losses in the ferroelectric material as denoted by the dielectric loss tangent and from resistive losses in the metal electrodes. Using a low-surface-resistance metal such as silver or (in some cases) superconductors minimizes the electrode loss component, and in most cases the unloaded quality factor of the ferroelectric varactor is given by

$$Q_U = \frac{1}{\tan \delta} \quad (6)$$

Design and modeling of layered interdigitated lumped element capacitors is based on a conformal mapping approach [10].

4.2. Voltage-Controlled Oscillator

Resonant circuits are used in oscillators and tunable filters. An oscillator provides a sinusoidal signal, and it is

Figure 5. Photograph of a typical interdigitated capacitor on a thin-film ferroelectric covered substrate. The gap between fingers in the metal electrodes is $6\ \mu\text{m}$. A microwave probe is shown contacting the device from the left.

used as a source of microwave energy. The oscillator output should be clean (noiseless) and stable (frequency and power should not change with time). A high- Q resonator is used in an oscillator circuit to obtain good frequency stability and low noise. The tunable capacitance of a ferroelectric-based capacitor is particularly applicable to a class of devices called a voltage-controlled oscillator (VCO). The bias-controlled change in reactance varies the oscillation frequency of an active element such as a transistor. Although there are many different oscillator topologies the designer can choose from, to first order the oscillation frequency can be varied in proportion to the square root of the bias-dependent capacitance. In principle, there is no difference in the design of a VCO using a ferroelectric capacitor and a semiconductor varactor diode [11]. A VCO employing a ferroelectric tunable ring resonator has demonstrated 3% frequency tunability at 17 GHz [12]. Phase noise is one of the primary limitations

Figure 6. Capacitance versus bias voltage of a $\text{Sr}_{0.5}\text{Ba}_{0.5}\text{TiO}_3$ thin-film interdigitated capacitor on an MgO substrate for frequency values of 1, 3, and 5 GHz. The data represents bias swept from $-40\ \text{V}$ to $40\ \text{V}$ and back to $-40\ \text{V}$.

Figure 7. Interdigitated capacitor quality factor as a function of frequency for a $\text{Sr}_{0.5}\text{Ba}_{0.5}\text{TiO}_3$ thin film on an MgO substrate with bias voltages of $0\ \text{V}$, $-10\ \text{V}$, $-20\ \text{V}$, $-30\ \text{V}$, and $-40\ \text{V}$.

of any VCO application. Although several mechanisms contribute to phase noise, in many cases the Q factor of the tunable element is the limiting factor. As can be seen from Leeson's formula, we have [11]

$$\mathcal{L}(f_m) = \frac{1}{2} \left[1 + \frac{1}{f_m^2} \left(\frac{f}{2Q_L} \right)^2 \right] \frac{FkT}{P_{\text{avs}}} \left(1 + \frac{f_c}{f_m} \right) \quad (\text{dBc/Hz}) \quad (7)$$

where f_m is the offset frequency, f is the oscillation frequency, P_{avs} is the power level, F is the noise figure, f_c is the $1/f$ noise corner frequency, and Q_L is the loaded quality factor, which is related to the unloaded device quality factor Q_U by

$$Q_U = \frac{1}{\frac{1}{Q_L} - \frac{1}{Q_{\text{ext}}}} \quad (8)$$

where Q_{EXT} is the external quality factor. As can be seen in Leeson's formula, the quality factor of the variable capacitor, which is, to first order, the reciprocal of the dielectric loss tangent, has a major impact on the phase noise of the VCO.

4.3. Tunable Filter

A filter is any device or circuit that exhibits frequency selectivity; that is, the amplitude and phase of the output signal are functions of frequency. A simple example is a bandpass filter where, ideally, all frequencies in a certain range are passed without change to the signal, whereas at any other frequency no signal appears at the output. There are many different ways to realize a microwave filter [13]. Many of these rely on resonators that are coupled together in a carefully controlled fashion to realize the desired filter transfer function. Tunability of the filter transfer function can be achieved with ferroelectrics [14,15]. It has been demonstrated that the center frequency of a microwave filter can be tuned by approximately 10% using ferroelectrics. In practice, there are many filter topologies that lend themselves to tuning with ferroelectrics. Conceptually the simplest to envision is tuning the

center frequency of a bandpass filter composed of coupled half-wavelength resonators by varying the phase velocity of the resonant elements and hence their resonant frequency. From Eq. (2) it can be seen that the phase velocity is inversely proportional to the square root of the capacitance. Since many filter topologies rely on capacitive coupling of resonators, utilizing tunable coupling between resonators allows the design of tunable bandwidth filters.

4.4. Phased-Array Antenna

Phased-array antennas can steer transmitted and received signals without mechanically rotating the antenna. Each radiating element of a phased array is normally connected to a phase shifter and a driver, which determines the phase of the signal at each element to form a beam at the desired angle. The most commonly used phase shifters are ferrite and diode phase shifters. Ferrite phase shifters are preferred at microwave frequencies, but they are expensive. The cost of a phased array depends mainly on the cost of phase shifters and drivers, and thus lower-cost phase shifting devices need to be developed to make the phased array antenna affordable for more applications. In this section, three different applications of ferroelectrics to phased array antennas will be described.

4.4.1. Ferroelectric Lens Antenna. The cost of a phased array depends mainly on the cost of phase shifters and drivers. A typical array may have several thousand elements as well as several thousand phase shifters and drivers; hence, it is very expensive. Therefore, reducing the cost and complexity of the phase shifters, drivers, and controls is an important consideration in the design of phased arrays. The ferroelectric lens phased array uniquely incorporates bulk phase shifting [2,3,16,17]; the array does not contain individual phase shifters but rather uses ferroelectric material. This will reduce the number of phase shifters from $(n \times m)$ to $(n + m)$, where n is the number of columns and m is the number of rows in a phased array. The number of phase shifter drivers and

phase shifter controls is also significantly reduced by using row-column beam steering. The ferroelectric lens has the advantages of small lens thickness, high power-handling capability, and simple beamsteering controls, and it uses very low power to control the phase shift. Thus, it leads to low-cost phased arrays. However, it should be noted that the use of row-column steering may limit the level of sidelobes that can be achieved.

4.4.1.1. Description of Ferroelectric Lens and Its Operation.

The ferroelectric lens is shown in Fig. 8; each column of the lens is a set of conducting parallel plates that are loaded with bulk ferroelectric material. The material is bifurcated by a center conducting plate that is used to apply the DC bias voltage to the ferroelectric. The separation between the parallel plates at the input and output end is $\lambda_0/2$, where λ_0 is the free-space wavelength. Since only the TEM mode is desired, the separation between the parallel conducting plates is reduced to avoid higher-order mode propagation in the dielectric-loaded section of the waveguide. Specifically, the separation between the center bias plate and either conducting plate is less than $\lambda/2$, where λ is the wavelength in the ferroelectric. Quarter-wave dielectric impedance transformers are used to match the empty waveguide to the ferroelectric-loaded waveguide.

For scanning applications, a phase shifting device must provide 360° differential phase shift. The amount of the ferroelectric material needed (in the direction of propagation) to obtain 360° differential phase shift is [16]

$$t = \frac{\lambda_0}{\sqrt{\epsilon_{r,max}} - \sqrt{\epsilon_{r,min}}} = \frac{\lambda_0}{\sqrt{\epsilon_{r,max}} [1 - \sqrt{1 - \text{tunability}}]} \quad (9)$$

where $\epsilon_{r,max}$ is the dielectric constant when no bias voltage is applied, and $\epsilon_{r,min}$ is the dielectric constant when maximum DC bias is applied. Tunability is the fractional change in the dielectric constant as defined earlier. Thus, the thickness of the ferroelectric material needed is a function of the dielectric constant and the tunability of

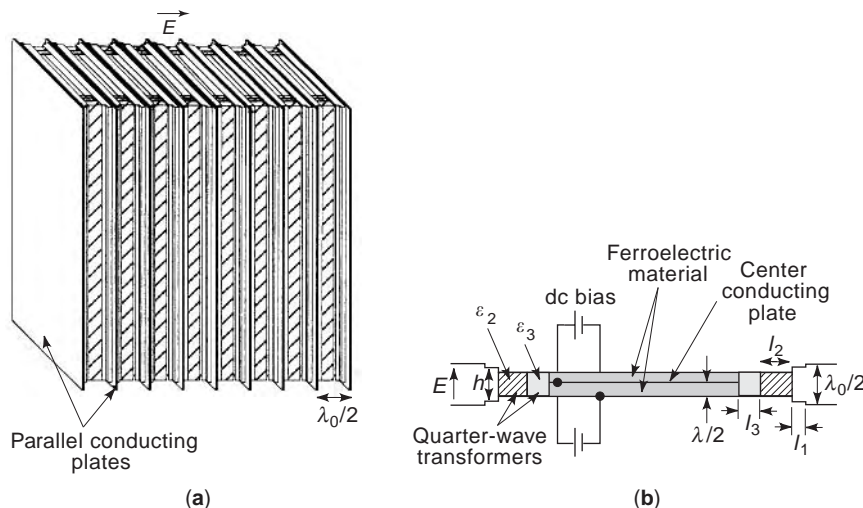

Figure 8. Ferroelectric lens.

the ferroelectric, and the wavelength. Also, it can be shown that in order to obtain 360° phase shift, the dielectric loss through the ferroelectric is [16]

$$\alpha(\text{dB}) = \frac{27.3 \tan \delta}{1 - \sqrt{1 - \text{tunability}}} \quad (10)$$

It may be noted that the lens loss is independent of the ferroelectric permittivity and depends only on its loss tangent and tunability.

In general, the ferroelectrics with higher dielectric constant offer higher tunability, which is desired to reduce the lens thickness. However, matching the lens to free space is easier for smaller ϵ_r . Therefore, a compromise is needed between reducing the lens thickness (to reduce overall lens size) and achieving reasonable impedance match to reduce reflections from the lens surface. For a typical value of $\epsilon_r \sim 100$, it is possible to obtain a tunability of 20%, which results in a reasonable lens thickness of $\sim \lambda_0$ (e.g., 3 cm at 10 GHz). From Eq. (10), it can be seen that the $\tan \delta$ must be less than 0.005 to limit the lens loss to less than 1 dB. The existing ferroelectric materials are a bit more lossy ($\tan \delta = 0.008$ at 10 GHz).

4.4.1.2. Phased-Array Configurations Using Ferroelectric Lens for Two-Dimensional Scanning. The ferroelectric lens offers electronic scanning in one plane. The lens proposed here can be fed by a non-scanning planar array, like a slotted waveguide array. A combination of slotted waveguide array with phase shifters and the lens proposed here can be used as a phased array that can scan in two planes. A space feed can be used with the combination of two lenses proposed here (with a polarization rotator in between) to scan the beam in two planes. The details of these alternatives are discussed elsewhere [16,17].

4.4.1.3. Theoretical and Experimental Results. For the theoretical analysis of the ferroelectric lens, an individual section between two conducting parallel plates of the lens can be considered as one column of a phased array.

The column can be analyzed as a two-dimensional (2D) parallel-plate waveguide with electric field of the TEM mode normal to the plates as shown in Fig. 8. A matching network was designed using mode matching technique assuming that the dielectric constant of the ferroelectric varies from 120 to 80 (33% tunability) over a frequency range of 8–12 GHz (40% bandwidth) and that $\lambda_0 = 0.8$ in. and $\lambda = 0.1$ in. The computed results are shown in Fig. 9. The matching network parameters are $l_1 = 0.2956$ in., $l_2 = 0.1860$ in., $l_3 = 0.0505$ in., $h = 0.2345$ in., $\epsilon_2 = 2.54$, and $\epsilon_3 = 35$ (see Fig. 8).

Experiments were performed with the ferroelectric composition $\text{Ba}_{0.55}\text{Sr}_{0.45}\text{TiO}_3$ with 60% oxide. This material offered a good compromise among ϵ_r , $\tan \delta$, and tunability. At 10 GHz, for this composition, $\epsilon_r = 100$ and $\tan \delta = 0.0079$. The ferroelectrics were 1 in. long (in the direction of propagation), 0.05 in. high and 5 in. ($\sim 4\lambda_0$ at 10 GHz) wide. Figure 10 shows the measured transmission and reflection coefficients at zero bias. The reflection coefficient is sufficiently small over a wide frequency band as the theory had predicted in Fig. 9. Figure 10 also shows that the loss increases with frequency; this is due to two reasons: (1) $\tan \delta$ increases with frequency, which is expected for ceramics; and (2) the electrical length (in terms of wavelengths) of the ferroelectric in the direction of propagation increases with frequency since the physical length is kept constant (1 in.).

Figure 11 shows the measured phase shift as a function of the bias voltage for various frequencies. As expected, the phase shift increases linearly with frequency because the electrical length of the material increases with frequency. Since ferroelectrics are good insulators, the DC current requirements are very low. For example, at 10 kV bias voltage, the DC current drawn was 0.05 mA, and thus the dc power dissipated is only 0.5 W. The bias voltage can be reduced by further bifurcating the ferroelectrics (using interdigital electrodes).

Figure 12 shows the reflection coefficients as a function of frequency for various bias voltages. The standing-wave ratio (SWR) is less than 2 for frequency range of 8–12 GHz as theoretically predicted earlier (see Fig. 9).

Figure 9. Theoretical reflection coefficient for ϵ_r to 80–120.

Figure 10. Measured reflection and transmission coefficient at zero bias voltage.

4.4.2. Traveling-Wave Antenna. Another type of phased-array antenna that also uses bulk phase shifting is a traveling-wave antenna, as shown in Fig. 13. The antenna is a slab of ferroelectric material with conducting strips on the topside of the slab and a ground plane on the bottom. This type of antenna is well suited for millimeter-wave applications when a low-loss dielectric (not a ferroelectric) is used as a substrate, and frequency variation is used to scan the antenna beam electronically. Instead of changing the frequency, the dielectric constant of the ferroelectric substrate can be changed to electronically scan the antenna beam in the E plane [17–19]. It can be shown [18] that the radiation angle of the antenna beam is given by

$$\theta = \sin^{-1} \lambda_0 \left(\frac{1}{\lambda_g} - \frac{1}{d} \right) \quad (11)$$

where λ_0 and λ_g are the free space and guide wavelength, respectively, and d is the spacing between the conducting

Figure 11. Measured differential phase shift.

strips. The guide wavelength and thus the scan angle change as the dielectric constant of the substrate changes. The main advantage of this type of antenna is that only a single DC power supply is needed to scan the beam, and it is a very simple structure. However, this antenna has a major disadvantage that makes it quite impractical. Since the physical size of most microwave antennas is at least a few wavelengths (if not a few tens of wavelengths), the loss that the electromagnetic wave would suffer as it travels down the antenna is enormous. Also, the instantaneous bandwidth of this antenna is very small because it is a frequency scan antenna; that is, the beam pointing direction changes as the frequency changes. Like the ferroelectric lens, the traveling-wave antenna offers electronic beam scanning in one plane. Electronic scanning in the other plane (azimuth plane in Fig. 13) can be achieved with phase shifters in the linear array feed for this antenna.

4.4.3. Discrete Phase Shifter. Ferroelectrics have also been proposed for discrete phase shifter applications at microwave frequencies. There are several advantages of using ferroelectrics over ferrites in phase shifters. First, since ferroelectrics are voltage-driven devices, the dc control power requirements are small. However, unlike latching ferrite phase shifters that only require current pulses, the bias voltage needs to be applied to the ferroelectrics during the entire transmit and/or receive cycle. Second, ferroelectrics provide reciprocal phase shift. Third, the high dielectric constant of the ferroelectric has the effect of decreasing the overall size of the phase shifter. At the present time, however, the dielectric loss in ferroelectrics is higher than that in ferrites at microwave frequencies.

The basic design equations for a discrete phase shifter are the same as those for the ferroelectric lens. For the same electric field applied in the lens, the discrete phase shifter should provide similar phase shift using the same ferroelectric. Phase shifters have been designed using ferroelectric-loaded rectangular waveguides as well as planar transmission lines, like microstrip and coplanar waveguide, on a ferroelectric substrate [5,20,21].

For the rectangular waveguide, impedance matching techniques similar to the ones used in the ferroelectric lens can be applied. For the microstrip line, several impedance-matching techniques have been tried [5] including quarterwave transformers, open-circuit stubs, and radial stubs. For the coplanar waveguide, usually the lines are tapered to provide a 50Ω impedance [21].

4.5. High-Temperature Superconductors and Ferroelectrics

The discovery of high-temperature superconductors (HTSs) has generated many tunable device designs [22] using both thin films and bulk ferroelectrics. One of the main incentives is the promise of the low conductor loss associated with HTS. In addition, both STO and BSTO are closely lattice matched with the HTS yttrium barium cuprate, $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (YBCO), meaning that the ferroelectric and YBCO can be epitaxially grown on top of each other to form multilayer thin film structures. This has been done with STO and YBCO. To take advantage of the

Figure 12. Measured reflection coefficient for various bias voltages (0–13.5 kV).

Figure 13. Ferroelectric traveling-wave antenna.

low microwave losses, operation must be below the critical temperature for YBCO. Most of the research has been done at 77 K, the liquid nitrogen boiling temperature. In BSTO, the barium to strontium ratio can be adjusted so that BSTO can be operated in the paraelectric phase at 77 K, and STO remains paraelectric down to the lowest temperatures.

1. INTRODUCTION

Microwave filters [1,2] are the basic building blocks with frequency-selective or filtering functionality in the development of various wireless systems that operate at frequency ranges above 300 MHz. Filter blocks play a key role in effectively transmitting the desired signals in certain passband regions while attenuating all the undesired signals in the remaining bandstop regions. The latter types are caused predominantly by the interference signals and unanticipated nonlinearity of many microwave active devices, and they have to be highly rejected by different types of filter blocks in order to transmit the desired signals, without receiving any distortion in amplitude and phase, which usually cover a certain frequency region. Basically, microwave filters can be classified into four distinct categories: lowpass, highpass, bandpass, and bandstop filter blocks [1]. The first two types of blocks realize effective transmission in the entire frequency region below or above a cutoff frequency while the third and fourth types transmit or attenuate signals within a certain frequency region that is terminated by the lower and upper cutoff frequencies.

At low frequencies, lumped-element capacitors and inductors can be reasonably constructed to make up all the filter blocks classified above on the basis of the efficient synthesis approach [1]. However, as the operating frequency increases to the microwave region of interest here, the reactance or susceptance of all the microwave circuit elements, including the so-called lumped elements, varies as a nonlinear function of frequency. Strictly speaking, the exact design of microwave filters should account for the distributed parameters of a variety of microwave circuit elements; thus it becomes very complicated in the design procedure to account for complex frequency behavior. But these elements can still be reasonably considered as

quasilumped elements in the low- or narrowband frequency region. As a result, the early developed synthesis procedure still can be effectively executed in the microwave range to efficiently design the microwave filters with acceptable accuracy in the frequency region of interest. In addition to the frequently cited classical handbook [1], many textbooks and reference books have been published so far so as to provide the beginners with a fundamental understanding of microwave filters as well as their relevant design approaches and practical implementation [3–6], or concentrate on the design of planar transmission-line filters [7,8] and waveguide filters [9]. In the following, we will start with the fundamental theorem for the microwave filters and then present a variety of practical microwave filters that have been widely used in the today's communication systems.

2. LOWPASS PROTOTYPE FILTERS

Figure 1 depicts the schematic of a generalized two-port filter block that is driven by a voltage source (V_s) with the internal impedance (Z_s) and terminated by the load impedance (Z_L). Under the assumption that the incident wave has the unity amplitude, the amplitudes of the reflected and transmitted waves are referred to as the *reflection* and *transmission coefficients*, namely, $R(\omega)$ and $T(\omega)$ (ω = angular frequency), which are frequency-dependent in a complex manner in conjunction with the varied passband–stopband characteristics. Figure 2 illustrates the frequency responses of the four categories of ideal filters with perfect transmission in the passband and infinite attenuation in the stopband, $T(\omega) = 1$ and $T(\omega) = 0$, respectively. As seen in Figs. 2a and 2b, lowpass filters transmit all signals below the cutoff frequency (ω_c) and reject those above ω_c , while the highpass filters attenuate all signals below ω_c and pass those above ω_c . On the other hand, the ideal bandpass and bandstop filters perfectly pass and attenuate all frequencies in the range of lower and upper cutoff frequencies, ω_{c1} and ω_{c2} , as designated in Figs. 2c and 2d, respectively. The frequency responses plotted there allow one to briefly grasp the basic frequency characteristics of various filter blocks via idealized frequency responses, but the actual microwave filters operate in a much more complex frequency-distributed function of frequency with finite-extent passband transmission and stopband attenuation, as will be discussed below.

Figure 1. Schematic of a two-port filter block that is characterized via frequency-dependent reflection and transmission coefficients: $R(\omega)$ and $T(\omega)$.

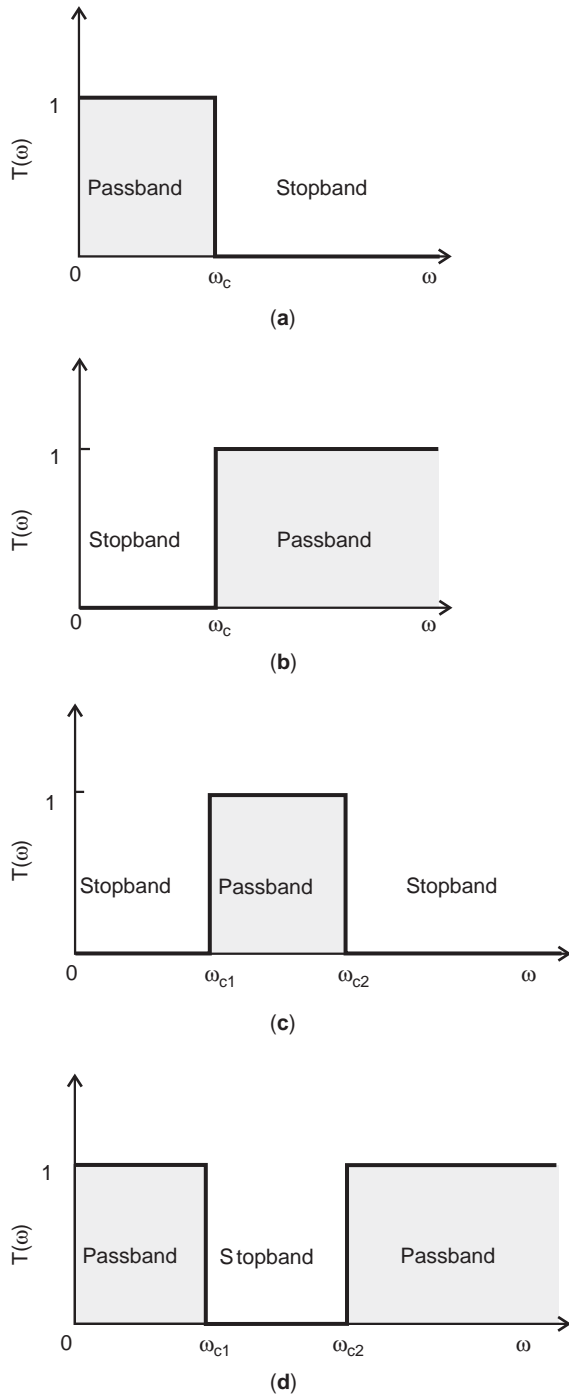

Figure 2. Graphical description of the four categories of idealized frequency-filtering/selective characteristics to be targeted in the filter design: (a) lowpass filter; (b) highpass filter; (c) bandpass filter; (d) bandstop filter.

Regardless of varied frequency responses described above, almost all microwave filters with lowpass, high-pass, bandpass, and bandstop performances can be realized and designed on a basis of the well-developed synthesis approach for a lowpass prototype filter network [1] via frequency transformation. This lowpass prototype filter is characterized in the normalized frequency $\Omega = \omega /$

ω_c , where ω_c is the cutoff frequency, and its frequency response is specified under the power insertion loss parameter: $L(\Omega) = 1/|T(\Omega)|^2$. Furthermore, $L(\Omega)$ is readily expressed in terms of a generalized polynomial function $F_N(\Omega)$, where N is the order of the lowpass filter, such that

$$L(\Omega) = 1 + k^2 F_N(\Omega) \tag{1}$$

where k is the constant related to the ripple or tolerance within the passband. Selection of $F_N(\Omega)$ should be based on the condition that the network topology can be physically constructed. In this context, two essential forms can be specified in the practical implementation: maximally flat or Butterworth filters and Chebyshev or equal-ripple filters. Equations (2) and (3) indicate their insertion loss parameters as a function of Ω , respectively, in which $T_N(\Omega)$ is the N th-order Chebyshev function.

$$L(\Omega) = 1 + k^2 \Omega^{2N} \tag{2a}$$

$$L(\Omega) = 1 + k^2 T_N^2(\Omega) \tag{2b}$$

Figures 3a and 3b depict the frequency responses of the decibel insertion losses L (dB) of the third-order lowpass prototype filters with $N = 3$. In order to quantitatively evaluate their lowpass characteristics, the insertion loss at the cutoff frequency ($\Omega_c = 1$) is readily specified as L_c . Meanwhile, an additional one (L_s) at a particular frequency (Ω_s) may be needed to characterize the upper stopband behavior beyond Ω_c . Looking at these two curves together, one can easily find that the Chebyshev filter increases much more rapidly beyond Ω_c in comparison to its Butterworth counterpart. In other words, the Chebyshev one has a much sharper cutoff frequency region separating the lower and higher stopbands, which is preferably desired to approach the ideal frequency response as shown in Fig. 2a.

Figures 4a and 4b depict the ladder networks of the two possible lowpass prototype filters, in which the element g_k is the k th normalized inductance or capacitance while g_0 and g_{N+1} are the normalized source and load resistance or conductance at the input and output ports, respectively. Their input impedances are first derived and then converted to their relevant insertion loss. As such, the values of each elements g_k ($k = 1, 2, \dots, N$) for the load $g_{N+1} = 1$ can be analytically calculated under the exact equality of the two sets of insertion loss, given in Eq. (2) and derived from the ladder networks in Fig. 4, respectively. For the Butterworth lowpass prototype filter with $L_c = 3$ dB at $\Omega_c = 1$ in which $k = 1$, the element values (g_k) may be calculated in the following closed-form equation and the values of each element are further listed in Table 1 up to $N = 8$:

$$g_0 = g_{N+1} = 1 \tag{3a}$$

$$g_k = 2 \sin\left(\frac{2k-1}{2N} \pi\right) \quad k = 1, 2, \dots, N \tag{3b}$$

For the Chebyshev prototype filter with the required insertion loss L_c at $\Omega_c = 1$, one can at first determine the constant k via Eq. (2b): $L_c = 10 \log_{10}(1 + k^2)$. For instance, if $L_c = 0.1$ dB, which is the equal ripple in the low

Figure 3. Frequency-dependent attenuation responses of the two types of the third-order lowpass prototype filters: (a) Butterworth type; (b) Chebyshev type.

passband, one can obtain $k=0.153$. Next, the values of each element g_k can be derived for the given N using Eq. (4). Table 2 lists the values of each element g_k for $L_c = 0.1$ dB. Considering the fact that the rising rate of insertion loss L (dB) beyond $\Omega_c = 1$ is gradually incremented with N for both prototype filters, selection of the integer number of N should be based on the required stopband performance that can be specified by the insertion loss (L_s) at the frequency Ω_s with reference to Figs. 3a and 3b

$$g_1 = \frac{2a_1}{\sinh(\beta/2N)} \quad (4a)$$

$$g_k = \frac{4a_{k-1}a_k}{b_{k-1}g_{k-1}} \quad k = 2, 3, \dots, N \quad (4b)$$

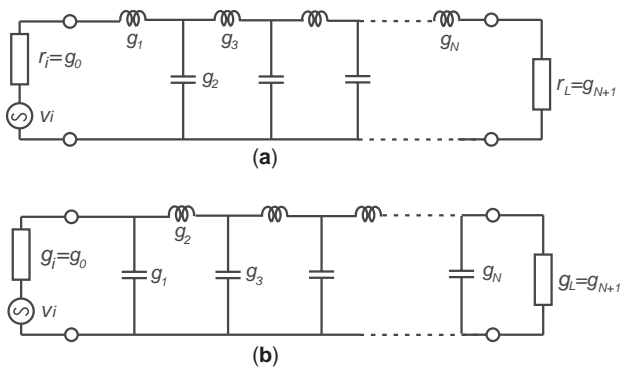

Figure 4. Lumped-element ladder networks of the two types of lowpass prototype filters: (a) inductive type; (b) capacitive type.

$$g_{N+1} = \begin{cases} 1 & N \text{ odd} \\ 2k^2 + 1 - 2k\sqrt{1+k^2} & N \text{ even} \end{cases} \quad (4c)$$

where

$$\beta = \ln\left(\frac{\sqrt{1+k^2}+1}{\sqrt{1+k^2}-1}\right), \quad a_k = \sin\left(\frac{2k-1}{2N}\pi\right),$$

$$b_k = \sinh^2\left(\frac{\beta}{2N}\right) + \sin^2\left(\frac{k\pi}{N}\right)$$

3. LUMPED-ELEMENT PRACTICAL FILTERS

The lowpass prototype filter is characterized above using the normalized source/load resistance or conductance (g_0 and g_{N+1}) as well as the normalized susceptance or reactance (g_k) of a N th-order ladder network in the normalized frequency domain ($\Omega = \omega/\omega_c$). In order to apply this approach to design of the lumped-element practical lowpass, highpass, bandpass, and bandstop filters that operate in the real frequency domain (ω), the so-called frequency transformation is required to map a frequency response in the Ω domain to that in the ω domain. Meanwhile, the impedance scaling procedure should be executed to guarantee the identical insertion loss responses of the lowpass prototype filter and its transformed practical filter. Under this restriction, the normalized prototype elements can be readily scaled to their relevant resistance/conductance elements at the source and load sides as well as the reactive/susceptive elements of various practical filter networks. In the following, the four typical frequency and element transformations are summarized with reference to the different network topologies in Figs. 5b–5e and different frequency responses in Figs. 6b–6e. Regardless of varied frequency transformations as denoted in Fig. 5, the source and load resistances can be commonly assumed ($g_0R_i = g_{N+1}R_L$) for simplification of theoretical description.

3.1. Lowpass-to-Lowpass Transformation

Figure 5b depicts the ladder network of a lumped-element lowpass filter with the source resistance (R_i), load resistance (R_L), as well as a number of series inductance (L_k) and shunt capacitance (C_k). In order to transform the Ω -domain frequency response of a lowpass prototype filter to its ω -domain counterpart (Figs. 6a and 6b), the frequency should be mapped to change the cutoff frequency from unity ($\Omega_c = 1$) to ω_c under the same insertion loss (L_c), and the normalized prototype elements also must be properly scaled to their corresponding lumped elements as expressed in Fig. 6b in such a way that

$$\Omega = \frac{\omega}{\omega_c} \quad (5a)$$

$$L_k = \frac{g_k R_L}{\omega_c} \quad (5b)$$

$$C_k = \frac{g_k}{\omega_c R_L} \quad (5c)$$

Table 1. Values of g_k for Butterworth Lowpass Prototype Filters ($g_0 = 1, L_c = 3.0$ dB)

N	g_1	g_2	g_3	g_4	g_5	g_6	g_7	g_8	g_9
1	2.0000	1.0000							
2	1.4142	1.4142	1.0000						
3	1.0000	2.0000	1.0000	1.0000					
4	0.7654	1.8478	1.8478	0.7654	1.0000				
5	0.6180	1.6180	2.0000	1.6180	0.6180	1.0000			
6	0.5176	1.4142	1.9318	1.9318	1.4142	0.5176	1.0000		
7	0.4450	1.2470	1.8019	2.0000	1.8019	1.2470	0.4450	1.0000	
8	0.3902	1.1111	1.6629	1.9616	1.9616	1.6629	1.1111	0.3902	1.0000

3.2. Lowpass-to-Highpass Transformation

For the highpass filter network in Fig. 5c, one needs to transform the prototype lowpass band to the highpass band covering from the cutoff frequency ω_c to infinity, as illustrated in Fig. 6c. As such, the frequency and element transformations should be inversely undergone so as to swap over the frequency stopband and passband, such that

$$\Omega = -\frac{\omega_c}{\omega} \tag{6a}$$

$$L_k = \frac{R_L}{g_k \omega_c} \tag{6b}$$

$$C_k = \frac{1}{g_k \omega_c R_L} \tag{6c}$$

3.3. Lowpass-to-Bandpass Transformation

To make up the bandpass filter in Fig. 5d, the frequency transformation should be selected to realize a bandpass response with the passband via Eq. (7a). Figure 5d also implies us that the inductive and capacitive prototype elements should be simultaneously transformed to the series and parallel LC resonators in the bandpass filters. Under the restriction that the insertion losses (L_c) at the lower/higher cutoff frequencies (i.e., ω_{c1} and ω_{c2} in Fig. 6d), must be equal to that (L_c) at $\Omega_c = 1$ of its related lowpass prototype filter, the inductance and capacitance, L_k and C_k , of each LC resonator are derived by

$$\Omega = \frac{\omega_0}{\omega_{c2} - \omega_{c1}} \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right) \text{ where } \omega_0 = \sqrt{\omega_1 \omega_2} \tag{7a}$$

$$L_k = \frac{g_k R_L}{\omega_{c2} - \omega_{c1}}, \quad C_k = \frac{\omega_{c2} - \omega_{c1}}{\omega_0^2 g_k R_L} \text{ for series } LC \tag{7b}$$

$$L_k = \frac{R_L(\omega_{c2} - \omega_{c1})}{\omega_0^2 g_k}, \quad C_k = \frac{g_k}{R_L(\omega_{c2} - \omega_{c1})} \tag{7c}$$

for parallel LC

3.4. Lowpass-to-Bandstop Transformation

The bandstop frequency response can be achieved via frequency transformation as indicated in Eq. (8a) so as to formulate the bandstop region between ω_{c1} and ω_{c2} as depicted in Fig. 6e. In this way, the elements of each LC resonator in the bandstop filter network in Fig. 5e can be derived in terms of the lowpass prototype elements by

$$\frac{1}{\Omega} = \frac{\omega_0}{\omega_{c2} - \omega_{c1}} \left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega} \right) \text{ where } \omega_0 = \sqrt{\omega_1 \omega_2} \tag{8a}$$

$$L_k = \frac{\omega_0^2 R_L}{g_k(\omega_{c2} - \omega_{c1})}, \quad C_k = \frac{g_k(\omega_{c2} - \omega_{c1})}{\omega_0^2 R_L} \tag{8b}$$

for series LC

$$L_k = \frac{g_k R_L(\omega_{c2} - \omega_{c1})}{\omega_0^2}, \quad C_k = \frac{1}{g_k R_L(\omega_{c2} - \omega_{c1})} \tag{8c}$$

for parallel LC

4. PRACTICAL FILTERS WITH IMMITTANCE INVERTERS

Looking at Figs. 5a–5e closely, one can see that all the filter ladder networks definitely require the occurrence of series and shunt elements that may be the inductance,

capacitance, or series/parallel LC resonators. In the practical implementation, it sometimes seems so difficult, especially in the microwave frequency range, to simultaneously make up both series and parallel LC resonators. As such, the immittance inverter, which is either an impedance or admittance inverter, is utilized to build up an alternative class of filter networks containing only series elements or only parallel elements. Figures 7a and 7b depict the two-port impedance and admittance inverters that invert the load impedance Z_b or admittance Y_b at one port to the input Z_a or Y_a at the other port with respect to the squared characteristic impedance and admittance, namely, K and J , respectively:

$$Z_a = \frac{K^2}{Z_b}, \quad Y_a = \frac{J^2}{Y_b} \quad (9)$$

Consider the parallel admittance element $Y_p(\omega)$ sandwiched by the two identical impedance inverters (K) at its two sides as shown in Fig. 8a. If the two output ports

are simultaneously terminated by the short circuits, the entire two-port network can be simplified as $Y_p(\omega)$ in parallel with the two open circuits at the two sides. Thus, the input impedance, looking into this network from both left and rightsides, can be derived as $K^2 Y_p(\omega)$, that is, the series impedance $Z_s(\omega)$. So, the shunt admittance $Z_p(\omega)$ can be inverted to the series impedance $Z_s(\omega)$. Similarly, the series impedance $Z_s(\omega)$ with the admittance inverters (J) at its two sides is the equivalence of a parallel admittance $Z_p(\omega)$ as denoted in Fig. 8b. The unique feature of these immittance inverters enables us to convert the practical filter blocks in Fig. 5 to those with either series or parallel elements. Most importantly, it provides us with much more convenience in the design of microwave bandpass filters with only series or parallel lumped/distributed resonators.

Figures 9a and 9b describe the two types of bandpass filter networks using the impedance and admittance inverters, respectively. In the former case, only series resonators with the reactance $X_k(\omega)$ are involved, and the two adjacent ones with $X_k(\omega)$ and $X_{k+1}(\omega)$ are cascaded across the impedance inverter, $K_{k,k+1}$, which is assumed frequency-independent. In the latter case, only parallel resonators with the susceptance $B_k(\omega)$ exist and the admittance inverter $J_{k,k+1}$ is utilized to link the two adjacent resonance susceptances $B_k(\omega)$ and $B_{k+1}(\omega)$. As will be discussed later on, the series or shunt resonators are usually the distributed circuits that are equivalently formulated by various transmission-line and waveguide cavity resonators. In order to factor in these distributed circuits in the synthesis approach, the two quantities, called *reactance slope* and *susceptance slope* parameters, x and b , respectively, are defined at the resonant frequency ω_0 , where $X(\omega_0) = 0$ or $B(\omega_0) = 0$, by

$$x = \frac{\omega_0}{2} \left. \frac{dX(\omega)}{d\omega} \right|_{\omega=\omega_0}, \quad b = \frac{\omega_0}{2} \left. \frac{dB(\omega)}{d\omega} \right|_{\omega=\omega_0} \quad (10)$$

which demonstrates that the slope parameter x becomes $\omega_0 L$ for the series lumped LC resonator, whereas b is equal to $\omega_0 C$ for a parallel lumped LC resonator. With the use of these two slope parameters, the bandpass filter with immittance inverters as shown in Fig. 9 can be transformed from their lumped-element counterparts. For the filter with impedance inverters in Fig. 9a, the source/load resistances are given as R_i and R_L , respectively. Thus, the characteristic impedances of all the impedance inverters can be derived in terms of the normalized prototype elements as denoted in Figs. 4a and 4b under the specified fractional bandwidth of $w = (\omega_{e2} - \omega_{e1})/\omega_0$:

$$K_{01} = \sqrt{\frac{R_i x_1 w}{g_0 g_1}} \quad (11a)$$

$$K_{k,k+1} = w \sqrt{\frac{x_k x_{k+1}}{g_k g_{k+1}}} \quad (k = 1, 2, \dots, N-1) \quad (11b)$$

$$K_{N,N+1} = \sqrt{\frac{R_L x_N w}{g_N g_{N+1}}} \quad (11c)$$

For the filter with admittance inverters terminated by the source/load conductances, G_i and G_L , as denoted in Fig. 9b,

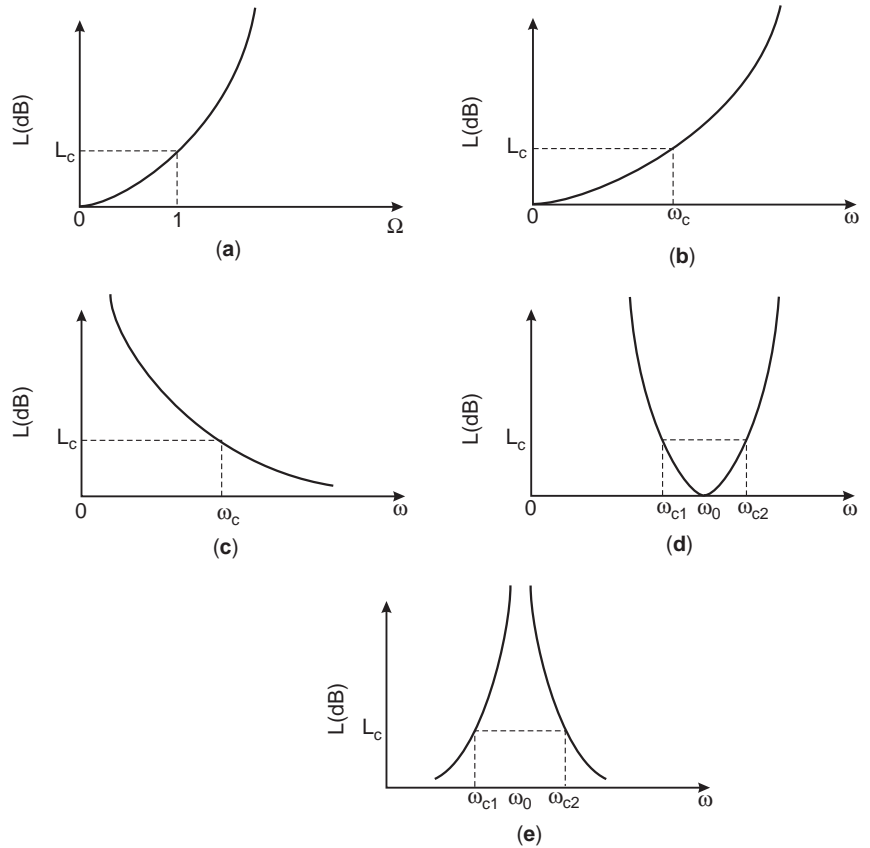

Figure 6. Frequency-dependent attenuation responses of the lowpass prototype filter and its relevant microwave filters: (a) lowpass prototype filter; (b) lowpass microwave filter; (c) highpass microwave filter; (d) bandpass microwave filter; (e) bandstop microwave filter.

the relevant expressions can be accordingly obtained by

$$J_{01} = \sqrt{\frac{G_i b_1 w}{g_0 g_1}} \quad (12a)$$

$$J_{k,k+1} = w \sqrt{\frac{b_k b_{k+1}}{g_k g_{k+1}}} \quad (k = 1, 2, \dots, N - 1) \quad (12b)$$

$$J_{N,N+1} = \sqrt{\frac{G_L b_N w}{g_N g_{N+1}}} \quad (12c)$$

Figure 7. Definition and block diagram of (a) impedance inverter and (b) admittance inverter.

In these filters, the impedance and admittance inverters are the two indispensable circuit elements that could be in practice constructed via quasilumped inductors/capacitors at low frequencies, distributed quarter-wavelength transmission lines with lower/higher characteristic impedances, and so on. As shown in Figs. 10a and 10b, the lumped T network with the positive inductance/capacitance, L or C , in shunt and two identical negative ones, $-L$ or $-C$, in series can make up a simple impedance inverter with the characteristic impedance $K = \omega L$ or $K = 1/\omega C$. Similarly, the admittance inverter can be formulated via the lumped π network and its characteristic admittance can be expressed as $J = 1/\omega L$ or $J = \omega C$, as also denoted in Figs. 10c and 10d. The negative L or C may be absorbed into adjacent series or parallel resonators so as to eliminate them from the overall filter network in practical design.

5. MICROWAVE LOWPASS FILTERS

As discussed in Section 3, the lumped-element lowpass filters consist of a number of series capacitances and shunt inductances in cascade as illustrated in Fig. 5b. These lumped elements are realized in the microwave range by an electrically short section of guided-wave structures, such as transmission line and waveguide, with high or low characteristic/wave impedance [1,3–8]. Figure 11a indicates a high-impedance transmission-line section with the length l_L much shorter than one

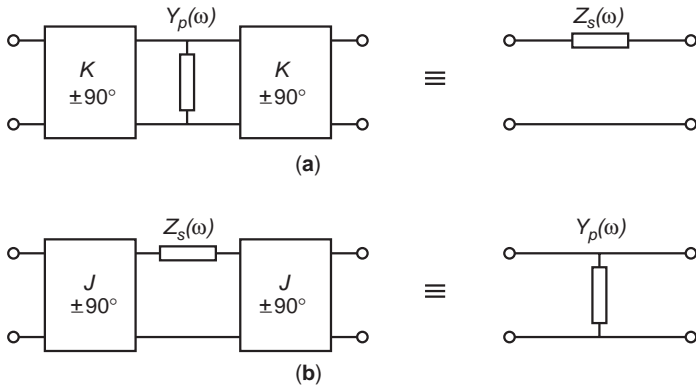

Figure 8. Illustration of equivalent transformation between the shunt susceptance and series reactance via inverter elements: (a) impedance inverter; (b) admittance inverter.

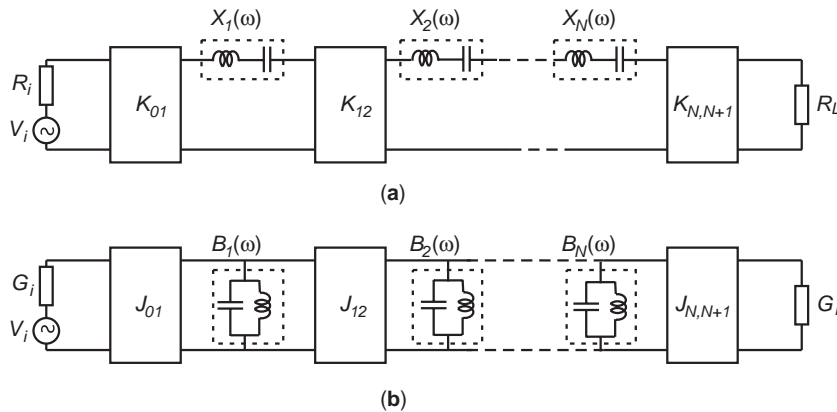

Figure 9. Equivalent networks of lumped-element microwave bandpass filters using (a) impedance inverter and (b) admittance inverter.

guided-wave length λ_g , in which Z_{0L} is much higher than Z_0 of the two feeding lines. This high-impedance line operates as a quasilumped series inductance, and its equivalent T network is depicted in Fig. 11b. Under the assumption that $Z_{0L} \gg Z_0$ and $l_L \ll \lambda_g$, series L and shunt

C can be obtained by [5]

$$L = \frac{Z_{0L}l_L}{c} \sqrt{\epsilon_{reL}} \tag{13a}$$

$$C = \frac{l_L}{2cZ_{0L}} \sqrt{\epsilon_{reL}} \tag{13b}$$

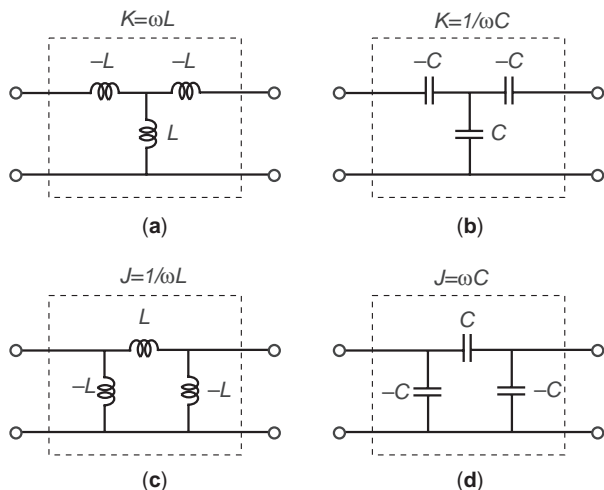

where c is the speed of light in free space and ϵ_{reL} is the effective dielectric constant of this transmission line in an inhomogeneous medium. For the microstrip line, the high impedance can be easily achieved by narrowing the strip conductor, as demonstrated in Fig. 11c. Similarly, the high-impedance coaxial line can be realized by reducing the diameter of its inner conductor with cylindrical configuration, and its cross-sectional view is shown in Fig. 11d.

On the other hand, the shunt quasilumped capacitance can be reasonably formed via an electrically short transmission line with the low impedance Z_{0C} , as depicted in Fig. 12a. As such, an equivalent π network with one major shunt capacitance (C) and the two minor series inductances (L) can be deduced as shown in Fig. 12b. The relevant equations are given as below to calculate these elements [5]

$$C = \frac{l_C}{cZ_{0C}} \sqrt{\epsilon_{reC}} \tag{14a}$$

$$L = \frac{Z_{0C}l_C}{2c} \sqrt{\epsilon_{reC}} \tag{14b}$$

where l_C and ϵ_{reC} are the physical length and the effective dielectric constant of this low-impedance transmission line. Figure 12c indicates the top view of a low-impedance microstrip line with increased strip width, whereas Fig. 12d is the cross-sectional view of a low-impedance coaxial line with enlarged diameter of the inner conductor. With these equivalent quas lumped elements in mind, various microwave lowpass filters can be accordingly designed on the basis of the synthesis approach discussed above.

Figure 13a describes a fifth-order microstrip lowpass filter, and its equivalent lumped ladder network is illustrated in Fig. 13b. At low frequencies in which each microstrip section is extremely shorter than λ_g , the wide- and narrow-stripline sections can be equivalently considered as quas lumped shunt capacitances (C_1, C_3, C_5) and series inductances (L_2, L_4). As usual, the source and load impedances are assumed as the standard 50Ω . The specifications for the microwave lowpass filter include the cutoff frequency (ω_c), passband ripple (L_c) at ω_c , and insertion loss (L_s) at the defined ω_s in the stopband. On the selection of Butterworth or Chebyshev lowpass prototype, the value of L_s is utilized to determine the order of this filter under the desired L_c ; thus the relevant normalized prototype elements are found from Table 1 or 2. Next, the lumped L_k and C_k in Fig. 13b are calculated via Eqs. (5b) and (5c), thereby

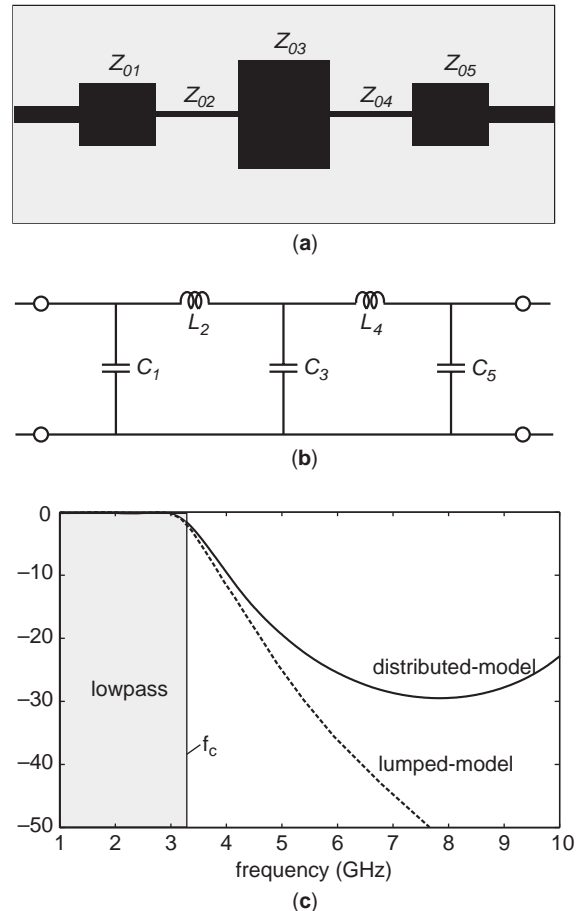

Figure 13. Front view and equivalent lumped-element representation of a fifth-order microstrip-line lowpass filter: (a) front view; (b) equivalent network; (c) attenuation response.

allowing us to obtain the width/length of each microstrip-line section using the closed-form formulas [10] under the selected dielectric substrate via Eqs. (13) and (14).

After filter layout is designed, the frequency response can be derived via a lumped network in Fig. 13b and full-wave simulation over its physical layout, as illustrated in Fig. 13c. Both results seem to closely match each other at low frequencies, but become increasingly different as the frequency rises. This is attributed to the approximation in the lumped model, which fully ignores the frequency distribution of each finitely extended microstrip line section. In fact, each line section is no longer electrically short at high frequencies, and it may operate as a distributed transmission-line section with the length comparable to or even exceeding one guided wavelength (λ_g).

6. MICROWAVE BANDPASS FILTERS

Two basic types of circuit elements are involved in the design of microwave bandpass filters: lumped resonators and immittance inverters. The resonator elements are equivalently made up by the uniform transmission-line sections or waveguide cavities with the length of one-quarter, half- or full wavelength at the center of the concerned passband. In addition to the uniformly shaped resonators, extensive work has been done so far to formulate a number of modified nonuniform resonator configurations toward realizing the compact size, harmonic suppression, and so on, as discussed widely in the literature [e.g., 8]. The inverter elements are basically constructed by various quasi-lumped and distributed capacitive and/or inductive coupling structures. In the following paragraphs, several typical inverter structures will be described in terms of their physical structures and equivalent-circuit networks.

Figure 14a depicts the front view of a microstrip gap element [10] that is formulated by closely spacing the two microstrip open ends via a gap or space of width (S). Its equivalent-circuit network is illustrated in Fig. 14b with a lumped T network, where the coupling effect between the two open ends is modeled as a mutual capacitance (C_g) and the two open ends themselves are perceived as the two identical shunt capacitances (C_p) due to the fringing field distribution. The relevant formulas are given in Ref. 11. This lumped network, driven by the two microstrip lines with the characteristic admittance of Y_0 , can be further converted to an alternative one with a distributed J inverter at the center and the two equivalent electrical lengths ($\phi/2$) at the two sides, as indicated in Fig. 14c. Under the exact equivalence of these two networks, we can obtain [1]

$$\frac{J}{Y_0} = \tan \left[\frac{\phi}{2} + \tan^{-1} \left(\frac{B_p}{Y_0} \right) \right] \quad (15a)$$

$$\phi = \tan^{-1} \left(\frac{2B_g}{Y_0} + \frac{B_p}{Y_0} \right) + \tan^{-1} \left(\frac{B_p}{Y_0} \right) \quad (15b)$$

where $B_p = \omega C_p$ and $B_g = \omega C_g$. To satisfy the requirement of widening the passband, various microstrip gap elements with unequal or offset microstrip feeding lines are

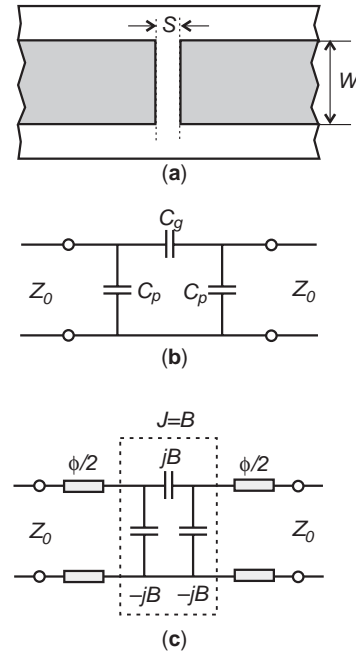

Figure 14. Microstrip series-capacitive coupling element for constructing an admittance inverter: (a) layout; (b) capacitance π network; (c) J -inverter network.

comprehensively discussed in Ref. 12 in terms of their equivalent lumped networks. To further raise the passband width, a microstrip interdigital capacitor with enhanced coupling degree is characterized as a more general J -inverter network with the two unequal electrical line lengths [13], allows the success in designing a compact wideband filter.

The parallel-coupled microstrip line [10] is realized by spacing the two open-end microstrip lines in parallel via longitudinal slot. Figure 15a illustrates such a coupled microstrip-line J -inverter element with the overlapped length of about one quarter-wavelength (i.e., $\phi = \pi/2$) for the filter design [14]. Here, the parameters of Z_{0e} and Z_{0o} are the characteristic impedances of the even and odd modes propagating along the coupled microstrip line. Because of its overlapped configuration and tightened coupling degree, this structure has gained wide application in the design of the compact and wideband microstrip bandpass filters. Figure 15b illustrates its related J -inverter network. Strictly speaking, the inverter admittance (J) appears to be frequency-dependent, but, it is usually considered as a constant value near the frequency in which $\phi = \pi/2$ if the relative narrow passband is considered. Under this restriction, J can be approximately derived by

$$Z_{0e} = Z_0 [1 + JZ_0 + (JZ_0)^2] \quad (16a)$$

$$Z_{0o} = Z_0 [1 - JZ_0 + (JZ_0)^2] \quad (16b)$$

Because of the essential difference between the phase constants of even and odd modes in the inhomogeneous coupled microstrip line, the first harmonic passband appears at the frequency twice that of the dominant passband. This problematic issue is addressed by loading the two

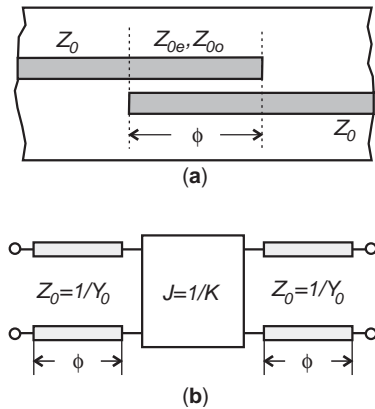

Figure 15. Parallel-coupled microstrip line with about one quarter-wavelength coupled length: (a) layout; (b) J -inverter network.

lumped capacitors at the two terminals [15]. In addition, a stepped-impedance resonator technique [16] has been developed to effectively suppress the concerned parasitic passbands in parallel-coupled line bandpass filters.

Coplanar waveguide (CPW) bandpass filters [17,18] with half- or quarter-wavelength resonators are constituted and explored in terms of CPW open-end gaps and/or short-end stubs, circuit models of which are described in Ref. 19. Similar to the microstrip gap, the CPW open-end structure operates as a series capacitive coupling element; thus its equivalent J -inverter network is the exactly same as those in Figs. 14b and 14c. Figure 16a indicates the CPW short-end stub, in which a pair of strip stubs with the width (S) electrically links the central conductor together and the two-side ground planes. In this way, such

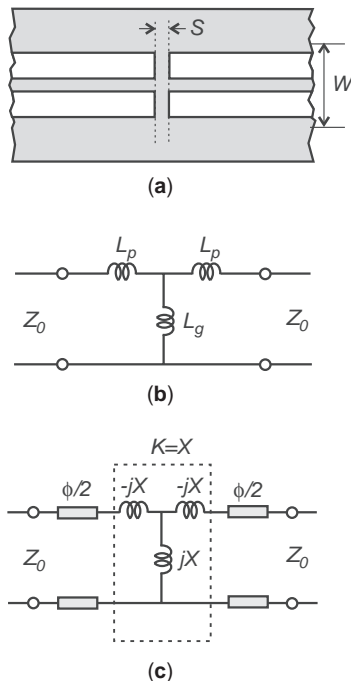

Figure 16. Coplanar waveguide shunt inductive coupling element for constructing an impedance inverter: (a) layout; (b) inductance T network; (c) K -inverter network.

the paired stubs can be equivalently considered as a shunt inductance (L_g) and the two-side CPW short ends are modeled as the two series inductances (L_p), thus forming a quasilumped T network as seen in Fig. 16b. Furthermore, such a lumped network can be converted into its corresponding K -inverter impedance (K) with the two equivalent electrical lengths ($\phi/2$) at the two sides. The complete network is depicted in Fig. 16c, and the relevant network parameters can be obtained by

$$\frac{K}{Z_0} = \tan \left[\frac{\phi}{2} + \tan^{-1} \left(\frac{X_p}{Z_0} \right) \right] \quad (17a)$$

$$\phi = \tan^{-1} \left(\frac{2Z_g}{Z_0} + \frac{X_p}{Z_0} \right) + \tan^{-1} \left(\frac{X_p}{Z_0} \right) \quad (17b)$$

where $X_p = \omega L_p$ and $X_g = \omega L_g$.

In parallel, various waveguide-based coupling structures [1,9] have also been widely investigated to design advanced waveguide bandpass filters with extremely small insertion loss and narrow bandwidth by making effective use of the very high quality factor (Q -factor) of an enclosed waveguide cavity. For instance, Figs. 17a and 17b illustrate the geometry of the two shunt inductive coupling waveguide structures, namely, inductive window/iris and inductive post. Their relevant equivalent-circuit networks can be commonly expressed as a π network, as shown in Fig. 17c, with the major shunt reactance (X_g) at the center, as investigated by Marcuvitz [20]. In the former, the metallic iris thickness is, as usual, extremely thin; thus the two series reactances (X_p) can be ignored and only shunt X_g remains. In the latter, the metallic post

Figure 17. Metallic waveguide shunt inductive coupling elements: (a) inductive window; (b) inductive post; (c) equivalent T network.

Figure 18. Examples of various planar transmission-line and waveguide bandpass filters (BPFs): (a) direct-coupled microstrip BPF; (b) parallel-coupled microstrip BPF; (c) coplanar waveguide BPF; (d) direct-coupled waveguide resonator BPF; (e) unified equivalent network.

has to be modeled in terms of the complete network in Fig. 17c because of its electrically finite diameter.

Using the above-described coupling structures together with transmission-line or waveguide resonators, various microwave bandpass filters can be constructed and then designed with the Butterworth or Chebyshev frequency response on a basis of the efficient synthesis approach discussed above. For instance, Figs. 18a and 18b demonstrate the layouts of the end-coupled and parallel-coupled microstrip-line bandpass filters [1,3,7], respectively, in which the two adjacent half-wavelength microstrip resonators are connected via equivalent J -inverter networks given in Figs. 14c and 15b. Figure 18c describes a CPW bandpass filter [18] via shunt inductive K -inverter network as shown in Fig. 16c. In addition, a waveguide bandpass filter [1] is demonstrated in Fig. 18d, in which the thin iris serves as the K inverter to link the metallic cavities together [20]. Regardless of different physical configurations as studied above, all these bandpass filters can be equivalently

expressed as a simple cascaded network with J or K inverters as well as several transmission-line resonators, whose lengths should be approximately equal to the half-wavelength (λ_{g0}) at the center of the frequency passband.

7. MICROWAVE HIGHPASS FILTERS

As the reciprocal structure of a lowpass filter, the highpass filter [1,21] can be constructed by cascading the series capacitances and shunt inductances in a ladder configuration as illustrated in Fig. 5c. It suffers from high insertion loss at low frequency because of very small series susceptances and shunt reactances. As the increases become sharper, these frequency-dependent parameters appear to be enhanced in a linear function, thus bringing out the almost perfect transmission beyond the cutoff frequency (ω_c). In order to achieve the specified small ripples in the highpass band, the values of each capacitance and inductance should be properly selected on the basis of lowpass-to-highpass transformations, as described in Section 3.

Figure 19a shows the ladder network of a fifth-order lumped-element highpass filter. The critical point here is how to produce the two types of lumped series capacitance and shunt inductances to a high degree, as usually requested in practical design. Figure 19b depicts the cross-sectional view of a coaxial-line filter [1]. Herein, the series capacitances are realized by closely spacing the two metallic disks of the two inner conductors, and the shunt inductances are formulated by the short-end stub line with small diameter and electrically short length. In addition, a microstrip highpass filter [8] is described in Fig. 19c that consists of microstrip interdigital capacitors and short-end

Figure 19. Equivalent-circuit diagram and implementation of highpass microwave filters: (a) lumped-element diagram; (b) coaxial-line configuration; (c) microstrip-line configuration.

Figure 20. Narrow- and wideband microstrip bandstop filters (BSFs): (a) layout of narrowband BSF; (b) equivalent network of a narrowband BSF; (c) layout of a wideband BSF.

microstrip stubs. These two elements operate as enhanced quasilumped series capacitances and shunt inductances at low frequencies, where their electrical lengths are negligibly short. At high frequencies, however, they no longer behave as lumped elements because their lengths become comparable with the wavelength, thereby degrading the desired highpass behaviors and restricting the highpass bandwidth.

8. MICROWAVE BANDSTOP FILTERS

There exist two essential types of microwave bandstop filters [1] with narrow and wide stopbands. The narrowband filter can be produced in such a way that a uniform transmission line or waveguide is either electrically or magnetically coupled to multiple resonators in periodic intervals with the periodicity of one quarter-wavelength or its odd integer numbers [1,8]. For instance, Fig. 20a shows the layout of such a fifth-order microstrip bandstop filter with a bandwidth of $<20\%$. In this case, a main microstrip line is periodically coupled to the five half-wavelength ($\lambda_{g0}/2$) microstrip-line resonators at the space of a quarter-wavelength ($\lambda_{g0}/4$) near the resonance. Figure 20b indicates its equivalent-circuit network, in which the line resonator and capacitive coupling gap are combined so as to constitute a shunt-series LC resonator. The reactance slope of each LC resonator needs to be properly adjusted by slightly differentiating the coupling gap and/or line resonator dimensions so as to achieve the requested values of each normalized element in the lowpass prototype filter. Furthermore, each $\lambda_{g0}/4$ -length line operates as an immit-

tance inverter in order to utilize the only shunt-series LC resonators. Its impedance may be equal to the source/load impedance (i.e., $Z_1 = Z_0$) for the Butterworth filter, but should be selected as below for the Chebyshev bandstop filter with the N th order:

$$\frac{Z_1}{Z_0} = \frac{1}{\sqrt{g_0 g_{N+1}}} \quad (18)$$

Figure 20c depicts an alternative microstrip bandstop filter [22] in which the main microstrip line is directly connected with the five quarter-wavelength open-end stubs at the space of a quarter-wavelength. This type of bandstop filter may be designed with any stopband width. However, for the narrow-stopband case, the characteristic impedances of these microstrip-line stubs, especially those located close to the input/output feeding lines, must achieve an impractically large width. Thus, this type of filter is found more suitable for design of wideband bandstop filters.

9. CONCLUSIONS

This article systematically describes the fundamental theorem, design approach, and practical implementation of various microwave filters. In the synthesis design of these filters, a lowpass prototype filter is first modeled as a ladder network and its frequency response is specified by preselected polynomial functions, thus determining the order and elements involved in this network per the specifications of concern. With the use of frequency transformation, the frequency response and ladder network of this prototype filter can be easily converted to those of microwave filters with lowpass, bandpass, highpass, and stopband frequency-selective characteristics. Moreover, a variety of representative planar transmission line and waveguide filters are investigated and discussed, allowing the reader to understand the practical implementation of microwave filters.

MICROWAVE HEATING

JOHN M. OSEPCHUK
Full Spectrum Consulting

Microwave heating is only part of the noncommunications applications of electromagnetic energy and only part of the range of electromagnetic heating [1,2]. The *microwave* range of the spectrum is variously defined. One prefers to think it is characterized by the fact that the dimension of the object to be heated is of the order of the wavelength. In practical terms this means heating at either 915 or 2450 MHz, two of the industrial, scientific, and medical (ISM) frequency assignments (in the United States) for

power or noncommunication applications. There are some medical heating applications (hyperthermia) at non-ISM frequencies where the expense of reducing leakage radiation to meet FCC (Federal Communications Commission) or CISPR (Special International Committee on Radio Interference) limits can be tolerated.

Industrial heating applications of microwaves exist at both 915 and 2450 MHz, but the higher power applications tend to use 915 MHz for meat tempering, bacon cooking, curing of rubber tires, and many other applications. Power levels of such systems range from 5 to 500 kW. At 915 MHz the dominant source of power is the magnetron, providing power from 25 to 75 kW protected by a circulator. By far the most dominant heating application is the microwave oven, which today operates at only 2450 MHz. There are roughly 200 million ovens in the world and roughly 20–25 million ovens are manufactured each year. Most of these are for the consumer market, although a small but significant number are produced for commercial and professional use. The widespread microwave oven market is made possible only because of the unique properties of the *cooker magnetron*. These include high efficiency (~70%) at power on the order of 1 kW, compatibility with simple unfiltered power supplies and arbitrary loads, and above all, low cost (~\$10 per tube in large quantities). An unavoidable (so far) concomitant to efficiency is high noise and other anomalous phenomena. A basic text on the microwave oven [3] and a broader treatment of industrial heating [4] have been published.

Most applications, whether for the microwave oven or industrial machine, correspond to the simple schematic depicted in Fig. 1. The basic objective is to deliver microwave power efficiently to the load. Thus, the system must be designed to minimize the reflected power. A practical microwave oven will not have a circulator or directional coupler, but in the design stage these tools or their equivalents will be present.

The absorption of microwave power depends on the dielectric properties of the load, which are temperature-dependent, its size and shape. Given these parameters, the extensive literature on dosimetry permits one to calculate or estimate the power absorbed by the load when it is exposed to a plane wave of given flux density. A convenient reference is the *Radiofrequency Radiation Dosimetry Handbook* [5] published by the U.S. Air Force. Most non-medical applications must be carried out in an enclosure. Thus, the modal and quasioptical properties of that enclosure will influence the equivalent plane waves that irradiate the object. The task of efficiently coupling energy from the power source waveguide to the enclosure is the function of the *feed*, which may be an antenna, aperture, or other coupling device. To achieve reasonable uniformity of heating, there must be some randomizing element in the system, for example, a rotating stirrer or scatterer or rotating feed antenna. Alternatively, there could be a rotating turntable on which the load is placed or a load-bearing belt that moves through a conveyerized oven of one or more cavities.

Because the magnetron is a key component of practical systems, knowledge of its properties is necessary. Frequency pushing, as the tube anode current varies, as well

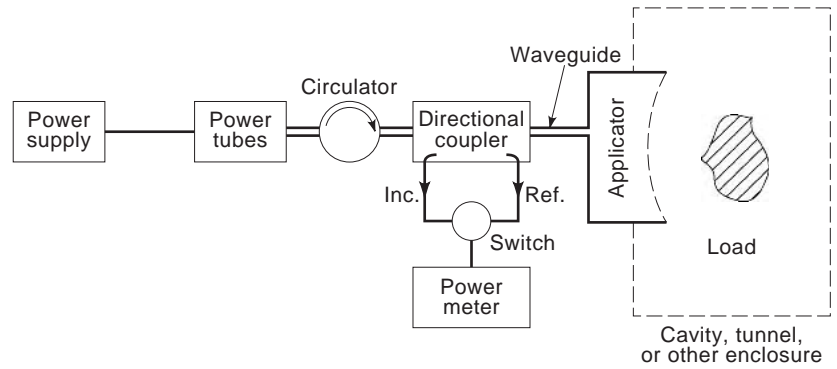

Figure 1. Basic elements of a microwave power system for processing of materials.

as frequency pulling as the load varies per stirrer rotation and load temperature increase, both spread out the power spectrum and average out or smear modal properties of the field pattern around the load. These variations also produce a complex pattern of electromagnetic noise both at microwave frequencies and at baseband frequencies. This information influences the design of the door seal and other parts of a practical system to meet limits imposed by the FCC or CISPR as well as the Food and Drug Administration (Center for Devices and Radiological Health).

At present, design procedures are basically empirical, in view of the complex dependence of the heating pattern on many variables, making prediction, and even experimental replication, impractical if accuracy (a few percent) is required. There are some pilot studies on computer codes for microwave heating, but they are useful only for the simplest systems, for example, a uniform rod in a waveguide. In the future, as tube sources are improved in noise, efficiency, and available frequencies coupled with improvements in applicators (e.g., multiple feeds), one can expect significant advances in microwave heating. Still further ahead are more exotic heating applications where the pulse or modulation characteristics of the source are important (e.g., in the stimulation of chemical catalysts).

1. BASIC PRINCIPLES OF MICROWAVE HEATING

The principles of microwave heating are well-established [1-5]. It is generally assumed that the material to be heated is adequately specified in terms of the macroscopic complex dielectric permittivity ϵ defined by

$$\epsilon = \epsilon_0(\epsilon_r + j\epsilon_i) = \epsilon_0 \left(\epsilon_r + \frac{j\sigma}{\omega\epsilon_0} \right) \quad (1)$$

where $\epsilon_0 = 8.86 \times 10^{-12}$ F/m, the permittivity of free space, ϵ_r is the real part of the relative dielectric constant, and σ is the conductivity in S/m (mho/m) which is equivalent to the following

$$\epsilon_i = \frac{\sigma}{\omega\epsilon_0} \quad (2)$$

where ω is the assumed radian frequency of the fields. It is convenient to define auxiliary terms like the loss

tangent, $\tan \delta$:

$$\tan \delta = \frac{\epsilon_i}{\epsilon_r} = \frac{\sigma}{\omega\epsilon_r\epsilon_0} \quad (3)$$

The rate of internal density of absorbed energy, or power P , is derived from the real part of the product of current density, from Maxwell's equations, and the internal electric field E_i , yielding

$$P = \sigma |E_i|^2 = \omega\epsilon_r\epsilon_0 \tan \delta |E_i|^2 \quad (4)$$

where P is in terms of watts per cubic meter. Equation (4) is the practical formula for computing power dissipation in materials and objects of uniform composition when adequately described by the simple dielectric parameters.

Given the values of the dielectric parameters, one can then calculate the penetration depth D , at which, for plane-wave irradiation of a material, the fields are reduced by a factor of $1/e$. The result is

$$D = \frac{0.225\lambda}{\epsilon_r^{1/2}} \cdot [(1 + \tan^2 \delta)^{1/2} - 1]^{1/2} \quad (5)$$

or for low-loss materials where $\tan \delta < 1$

$$D \cong \frac{0.318\lambda}{\epsilon_r^{1/2}(\tan \delta)} \quad (6)$$

where λ is the free-space wavelength of the microwave radiation.

For low frequencies or small objects, the components of electrical fields normal to a material boundary are related by the following equation

$$\left| \frac{E_i}{E_o} \right| \cong \frac{\omega\epsilon_0}{\sigma} \quad (7)$$

where E_i and E_o are the internal and external fields, respectively. The material is characterized by σ , and the outside volume is free space. If the applied field E_o is parallel to the surface, then the internal field is equal to E_o . Thus, if the applied field is parallel to the long axis of a body, the internal field is approximately equal to the external field. Otherwise, if the applied field is perpendicular

Table 1. Dielectric Properties of Foods and Other Materials at 2450 MHz and 20°C

Material	ϵ	$\tan \delta$
Distilled water	78	0.16
Raw beef	49	0.33
Paper	2–3	0.05–0.1
Wood	1.2–5	0.01–0.1

Liquid crystal polymer	3.9	0.007

to the long axis, the internal field, according to Eq. (7), is much less than the external field even for moderate conductivity of the order of 1 S/m.

The principal task in microwave heating problems is the determination of internal fields in an object that permit through Eq. (4) the determination of the heating distribution over time. The dielectric parameters are key data for such a calculation, particularly the dependence on temperature. Standard methods for measurement of these parameters are readily available [6]. The simplest technique, and often the preferred method, is that in which rods or long slender samples of the material of interest are placed in the central vertical plane of a rectangular waveguide through small access holes centrally located on top and bottom walls [7]. This is also a method for uniform heating of such a small sample, except for small volumes near the top and bottom access holes. Classical perturbation theory [7] permits the determination of ϵ and $\tan \delta$. Considerable data for a wide range of materials at room temperature and at various microwave frequencies are found in the literature [8].

Table 1 lists such data for a few important materials at 2450 MHz, the most commonly used frequency for microwave heating. Values of $\tan \delta$ well below 0.01 signify negligible absorption and heating, whereas values above

0.1 are considered good absorbers. Data on temperature dependence of dielectric parameters are not widely available in the literature. The classic data from Bengtsson and Risman [9] on temperature dependence for foods are reproduced in Fig. 2. They illustrate some general properties for heating of foods. The high value of ϵ , in the range of 40–80, signifies substantial reflection at the boundary of large food volumes of the order of 50%. For most foods, the value of $\tan \delta$ decreases with temperature, following that of water. This dependence is the basis for stabilization of heating, which aids a trend to uniformity of heating. On the other hand, a few foods such as ham that have significant salt content (ionic conductivity) show an increase in $\tan \delta$ with temperature. This tends to trigger thermal runaway at hot spots and nonuniform heating. When this happens in a glass or even ceramic tray in an empty oven, this can lead to dramatic melting at one spot. Although data for foods are generally limited to below 100°C, the temperatures of interest are much higher for oils and nonfood objects. Interest in ferrite materials as browning aids at a stable Curie temperature has been replaced by the development of the *susceptor* [10], in which a very thin (less than 100 Å) film of aluminum that is deposited on suitable insulating dielectrics highly absorbs impinging microwave radiation.

The calculation of absorption distributions in simple geometries (e.g., spheroids) is amply described in the literature [5]. Only for very small spheres is heating uniform and approximately uniform in long thin rods aligned with the E field. At very high frequencies penetration and heating is superficial. In general, heating is nonuniform. For frequencies in the resonance range and for some materials and certain frequencies, dramatic hot spots are possible in the center of objects. Figure 3 shows the visualization of such a hotspot in a sphere of glue with a cloud point near 50°C. This can lead to superheating and explosive phenomena associated with such spherical objects. This is an example where the geometry of the sample is the prime factor determining temperature distribution in an object rather than external field patterns or modal properties of the applicators. Another such factor is the concentration of field and heating at corners and cusps of objects to be heated.

2. MICROWAVE APPLICATORS

Figure 1 depicts an *applicator* acting as a transducer or coupling agent between the feed waveguide and the load object. The simplest applicator may be a rectangular guide with access holes on top and bottom walls [7] allowing thin rods or tubes of flowing liquid to be heated. More specialized applicators include helices and slow-wave applicators. These have been described by Metaxas and Meredith [4]. Antennas and other applicators for heating limited parts of the human body for diathermy or hyperthermia are reviewed by Guy [11], who restricts the reader’s attention to the multi-mode cavity because it is the basis of most ovens and industrial machines that must handle large quantities of material or a large variety of objects. The engineering literature on waveguides is dominated by papers on properties at low frequencies where one or only a few modes can propagate. Considerable literature also exists for the high-frequency limit where optical

properties come into the forefront. Little exists on the properties of waveguides that influence the performance of microwave heating systems.

A series of tests were conducted by the author on a machined aluminum cavity of dimensions 7 ft long by 2 ft². The cavity was excited by various antennas at one end and the transmitted signal was received at the other end with the same or a different antenna. Measurements were made of the incident, reflected, and transmitted signals over a broad range of frequencies from 0 to 8 GHz. The upper frequency limit corresponds to a factor of over 32 times the lowest cutoff frequency of the 2 × 2-ft waveguide or a transverse dimension of 16 free-space wavelengths. It may be noted that the transverse dimension of most microwave ovens and industrial machines is approximately three wavelengths.

Figure 4 shows transmission data when a 4-in. axially aligned monopole is used at both ends of the 7-ft-long wave-guide, over the frequency range of 0–1.8 GHz.

Figure 4. Transmission of microwaves through a 7-ft-long section of waveguide (2 × 2 ft), 0.0–1.8 GHz with axially aligned 4-in. monopole antennas at each end. This antenna preferably excites TM modes.

Although the maximum transmission peaks reflect an insertion loss of only 2–3 dB, there are occasional severe dips in transmission. It can be shown that these occur at or near the cutoff frequencies of transverse magnetic (TM) modes, which tend to be excited by an axial monopole. Reflection measurements show that the low transmission is associated not only with dissipative losses at cutoff resonances, but also severe reflection losses just below cutoff. One can see that according to the relation above for $D \sim 3\lambda$, the typical microwave oven might correspond to about 1.5 GHz. One can see a large dip near that frequency that can be related to mode indices of three and five. In fact, in practical microwave oven work, it has been found that when an antenna exciting TM modes is used in an oven with transverse dimensions near such a cutoff relation, an input impedance match cannot be achieved with ordinary tuning elements. Quine [12] has shown that properties near such TM mode cutoff resonances are related to the blindspot phenomenon found in the radiation properties of phased-array antennas. He shows that the application of the image theorem for an antenna near a ground plane clarifies the connection between a waveguide and a phased array.

If a shielded loop antenna is substituted at the ends of the cavity in place of the monopoles, the transmission data shown in Fig. 5 are obtained. Absent are the severe transmission dips at cutoff frequencies. The effects at cutoff frequencies are greatly diminished when present. Data taken above 2 GHz with this waveguide show the diminishing effect of cutoff resonances as frequency increases, and the increasing density of modes as a cavity with three mode indices. Furthermore, although absorption by an object in the guide is affected by its size-dependent cross section, there is some suggestion that higher frequencies yield more consistent absorption. One might speculate that this results from the lesser prevalence of sizable *coldspots* in field patterns at higher frequencies.

One can see that studies of such a waveguide can yield valuable insights for understanding practical microwave heating cavities. Location of the load object is an

important parameter. One can intuitively judge that the location of objects near a conducting wall is not desirable. In this case, if the space between the object and the wall is less than a freespace wavelength, it can be shown [13] that the only modal propagation in that interspace is of the slow-wave or bound-wave variety that exhibits a large propagation attenuation constant, α .

It is of interest to review the mode density of such cavities as a function of frequency. A review of such mode-counting exercises by Voss [14] shows that although the increase of density with frequency will on the average follow simple formulas, there are discrete regions where the mode density is quite low and other regions where it is much greater, for example, a factor of ≥ 5 when considering a bandwidth of 50 MHz or more at 2.45 GHz. A typical microwave oven cavity may be expected to show an average mode separation of approximately 4 MHz. Therefore, in the ISM band of 2.4–2.5 GHz, one could conceivably benefit from the mixing of up to 25 modes. In practice, any such benefit is not exploited because a much smaller frequency variation of the practical magnetrons is used. There is enough frequency variation, however, to prevent simple single frequency calculations to be of any direct relevance to practical performance.

3. PRACTICAL MICROWAVE HEATING SYSTEMS

Most practical microwave heating systems employ a heating space confined by metal walls, that is, a cavity or waveguide. The basic reason is related to efficiency, although limitation of radiated leakage and out-of-band noise is also a determining factor. Today all microwave ovens operate at 2450 MHz.

Figure 6 shows an exploded view of a typical microwave oven. Shown are the main features or components that relate to power and efficiency. Not shown are the electronic timer and control circuitry or the door interlock system. The basic elements are the microwave power generator, the magnetron, driven by an AC high-voltage power

Figure 5. Transmission of microwaves through a 7-ft-long section of waveguide (2×2 ft), 0–18 GHz with shielded-loop antennas at each end. This antenna preferably excites TE modes.

Figure 6. Exploded view of a microwave oven showing power components, microwave components, and cooling system; electronic control circuits are not shown.

supply connected to the electricity source. The magnetron is connected to a short section of low waveguide, which, in turn, couples energy into the oven cavity either through an antenna similar to a monopole, strip, or patch antenna or through a simple waveguide aperture. Most ovens employ a randomizing element such as the rotation of an antenna or a rotating *stirrer* (a scatterer) in the case of an aperture coupling. Contemporary oven designs also include a rotating turntable for the load placement in addition to (or in a few cases the substitution for) the stirrer. Moving conveyor belts also help smooth out heating patterns, but they are employed almost exclusively in industrial systems.

Practical microwave ovens dispense with a circulator and means of monitoring reflection (Fig. 1). These elements, however, are almost mandatory in high-power industrial systems, which operate at powers of many tens of kilowatts. Because the magnetron is not isolated from the variable load by a circulator, it will exhibit significant pulling, on the order of 10–20 MHz. The effect of the changing load on the power and frequency of the magnetron is shown in the Rieke diagram supplied by the tube manufacturer. For maximum efficiency, this diagram points the oven designer to the selection of a load impedance of a matched load or somewhat into the sink region of the diagram.

Because of the complexity of the situation, including the need for accommodating any food load, the feed design is optimized by empirical techniques. With water loads or even actual food loads, the input impedance is determined with a suitable reflectometer circuit [3,4]. Data obtained are a Smith chart representation similar to that shown in Fig. 7, where at a fixed frequency (e.g., 2450 MHz) the recurring path of the impedance locus is shown as the oven stirrer goes through its cycle. Figure 7a shows the impedance pattern for a large load of 2000 mL. It is desirable that the pattern be located close to the center match point or slightly into the sink phase of the magnetron (determined by appropriate techniques, [3,4]). This is done by

(a)

(b)

Figure 7. Input impedance contour of a microwave oven at a constant frequency as the variable element (stirrer) goes through its cycle: (a) for 2000 mL water load; (b) for an empty cavity.

appropriate tuning techniques, for example, by adjusting the length of the waveguide or adding a tuning post. Of course, all of this was done at a single frequency, hopefully to approximate the dominant frequency emitted by the magnetron at full power. But the oven impedance is a rapid function of frequency as well. For example, Fig. 8 shows a typical recorded impedance at a fixed position of an antenna (or stirrer) over the frequency range of 2.4–2.5 GHz. Thus, the designer must examine a two-dimensional array of datasets or plots such as those of either Fig. 7 or Fig. 8 and adjust for an optimum feed match over the anticipated range of frequency and stirrer position. Figure 7b shows the impedance plot at one frequency for an empty oven as the stirrer rotates. The wildly gyrating pattern is not susceptible to matching, of course; but its importance lies in signifying that when an oven operates with no load or light load (like popcorn), it will subject the magnetron to an extreme of impedance variations. This in turn leads to a wider range of frequency and noise emissions, including frequency skips.

Figure 8. Input impedance contour of a microwave oven at a constant position of the variable element (stirrer) as frequency is swept from 2.4 to 2.5 GHz.

Current magnetrons at 2.45 GHz may exhibit an efficiency of 70%. Because of losses in the power supply and losses in the feed and cavity, the net efficiency for a large load may be of the order of only 50%. For smaller loads down to 50 mL, there will be a further significant reduction of efficiency as shown in Table 2 taken from a typical set of data for several current ovens. The dominant causes for low efficiency at small loads are reduced magnetron efficiency at unfavorable load phases and reduced microwave circuit efficiency with significant heating of metal walls and dielectric parts, such as a tray.

Heating patterns, especially at 2.45 GHz, are notoriously difficult to replicate and optimize. An acceptable variation in array tests is a 10–20% variation in temper-

ature rise values. The prediction of an even measurement of heating patterns is a complex problem and no ideal solution has been found. For very thin sheets, frequency diversity as provided by a traveling-wave tube (TWT) (e.g., 2–4 GHz) yields dramatically improved uniformity [15]. For most applications however, TWTs remain unacceptably high in cost.

Conveyor systems, by virtue of varying load position, measurably and usually acceptably improve heating uniformity. Most high-power systems at 915 MHz utilize conveyors. On the other hand, circulators are used so that the magnetron frequency is not pulled. There remains only a few megahertz of frequency pushing, which is not a large contribution to frequency diversity as an element in improving uniformity.

Table 2. Effective Power Levels for Various-Size Water Loads in a Typical Microwave Oven (Three Different Models): 1–2 Min Operation

Water Load (mL)	Measured Power Relative to Power at 1000 mL		
	Oven A ^a	Oven B ^b	Oven C ^c
100	0.61	0.52	0.59
250	0.44	0.88	0.74
500	0.83	0.96	0.80
1000	1.00	1.00	1.00

^aOven A power at 1000 mL: 673 W.
^bOven B power at 1000 mL: 705 W.
^cOven C power at 1000 mL: 754 W.

4. POWER SOURCE PROPERTIES

Because the magnetron is almost exclusively the microwave generator of choice for microwave heating systems, it is important to focus on the properties of that tube and its associated power supplies. These determine the operating power spectrum from pushing and pulling characteristics. Furthermore, the noise and moding characteristics of the magnetron impacts on interference phenomena and the ability to meet increasingly stringent radiated and conducted noise limits imposed by regulatory authorities. Figure 9 is a schematic depicting the main electronic circuits and elements in a microwave oven. A half-wave high-voltage power supply is indicated with both filament and high-voltage secondary on the same transformer. This reflects the fact that most microwave ovens are cold-start. Thus, the magnetron current is a rectified pulse of roughly half-sinusoidal shape with a repetition frequency of 60 Hz and a pulsewidth of roughly 8 ms. The peak current is about 1 A for an average current of 0.3 A for a 700–800-W oven.

The magnetron is known to exhibit high noise at currents below 0.3 A, occasional discrete spurious sideband signals for currents between 0.3 and 0.6 A, and is typically quiet above 0.6 A [16]. The result is that the typical magnetron radiates spurious noise and signals in 1 ms pulses during the rise and fall of each pulse. Figure 10 depicts a full-wave power supply that yields a current waveform of two rectified half-waves per 60 Hz period and, therefore, lower peak current for the same average current. This does little to reduce magnetron noise. Note that in this supply there is a separate filament transformer. This supply may be used in commercial ovens. Figure 11 is a photo of several modern magnetrons. Note the small size (approximately 4 in. maximum dimension) and the *filter box* that reduces baseband radiation and emissions conducted to the powerline.

Figure 12 is an example of the radiated noise (peak signals) a few feet from a microwave oven when operating with a light load. Peak levels approaching 100 dB/pW effective radiated power are not uncommon in the range between 2.3 and 2.4 GHz. Because of the potential interference with various wireless communications systems, there is activity within CISPR (Special International Committee on Radio Interference) to apply more stringent limits on noise radiated from magnetron-powered systems [17].

Magnetrons can mode and produce spurious signals in the 4–5 GHz range that have interfered with satellite

communication links. This can occur when there is insufficient cathode emission (as at the end of life) or even when there is too much emission. This occurs because high emission may strengthen spurious sideband oscillations that can also cause moding. Figure 13 shows an example of a recorded magnetron voltage-current trace during such a moding event. Magnetrons in microwave ovens will exhibit as much as 4–5 MHz pushing and up to 20 MHz of frequency pulling.

In the higher power systems at 915 MHz for industrial use, the magnetrons are always protected by a circulator. Therefore, there is no pulling by load variations.

Figure 13. Voltage–current trace of a magnetron depicting moding at a spurious oscillation discontinuity; vertical—250 V/div; horizontal—0.1 A/div.

is that more emphasis should be placed on food standards without relying on the heating of foodstuffs for food safety.

6. FUTURE ADVANCES IN MICROWAVE HEATING

Microwave heating is in its infancy as pointed out by Kapitza [21]. Future expansion in large part awaits the development of efficient and low-cost power sources at various frequencies and power levels beyond what is now available. Thus, in the future one expects such power sources at 5.8 GHz, 24.125 GHz, and the millimeter-wave ISM frequencies. In addition, the availability at power levels down to 100 W, as well as high powers of many kilowatts, will spur many new applications. At present, many such applications are being explored [22] in the fields of chemistry, ceramics, and materials processing. In addition, there are applications to agriculture, pharmaceuticals, and various medical procedures.

In parallel with heating applications are important nonheating power applications, such as microwave-powered lighting [23]. The list of research needs includes: (1) a resolution of the efficiency versus noise tradeoff inherent in magnetrons, (2) the achievement of successful computer models [24] for characterizing real-life microwave heating systems, (3) improved applicators of various types, (4) improved door seals and suppression tunnels to meet noise limits, and (5) the exploitation of pulse modulation techniques for special interactions as in chemistry [25].

MICROWAVE INTEGRATED CIRCUITS

NIROD K. DAS
DONALD M. BOLLE
Polytechnic University

In this article a general overview and basic principles of operation of a class of highly integrated analog devices and circuits, used for applications in the microwave and millimeter-wave frequency range, are presented. Although there are subgroups of sister technologies that evolved over the years, having different acronyms such as MIC (microwave integrated circuits in hybrid form), MMIC (monolithic microwave integrated circuits), and MCMs (multichip modules), their basic principles of operation are similar, with their objectives and scopes rapidly overlapping. The discussions in this article may be directed to a broad class of such integrated circuits, referred to in general as microwave and millimeter-wave integrated circuits, with "MMIC" as a generic acronym. Essential building blocks of MMICs, such as the substrate material and parameters, transmission line geometries, passive and active devices, integrated antennas, integration architectures, and packaging concepts, are explained at a fundamental level for readers new to the subject. Fundamental design considerations and modern analytical and computer-aided design tools for the design of MMICs are introduced. Current trends and future directions of the technology are also discussed. More knowledgeable readers are referred to a selection of significant technical articles for further reading.

As indicated, *microwave and millimeter-wave integrated circuits* refer to a special group of highly integrated analog circuits, operating in the microwave and millimeter-wave frequency range. In this frequency range the various circuit functions that were usually implemented in the past using bulky metal waveguides and coaxial lines, can now be implemented using printed microstrip lines or other forms of planar transmission lines. These planar circuits can also be fabricated together with semiconductor active devices on a single chip, employing a technology similar to that used in microelectronic circuits. As a result, quite complex microwave and millimeter-wave circuits and systems have been realized in a compact, reliable, and cost-effective manner. In many ways, this class of modern integrated circuits has opened the promise and potential for microwave and millimeter-wave communication, much like what silicon digital integrated circuit technology has done for computers.

From a historical perspective, after the experimental demonstration of electromagnetic waves by Heinrich Hertz in 1888, and then the successful achievement of transatlantic communication by Guglielmo Marconi in 1901, signal distribution and circuit components in the microwave frequency range were implemented using rectangular metal waveguides. These waveguides were essentially hollow rectangular metal pipes capable of guiding microwave signals, and are sometimes referred to as "uniconductor waveguides." They are so named because the rectangular hollow waveguides use only one conductor,

which is fundamentally different from conventional signal transmission in the very-low-frequency range using two conductor transmission lines. Although the uniconductor waveguides had the advantages of low-loss propagation compared to two-conductor lines, due to their limited bandwidth of operation, dispersion and, above all, their bulky physical size, interest later shifted to "two-conductor lines," such as coaxial lines, for microwave circuits. However, due to the inconvenience of fabricating circuit components in coaxial form, flattened versions of coaxial lines were then introduced. Soon after, attempts were made to implement two-conductor lines by laminating metal strips on a hard dielectric surface in order to greatly simplify the fabrication process. The stripline and the microstrip line were the candidates of choice. The geometries of various waveguiding media used for microwave applications leading up to the printed microstrip line are shown in Fig. 1. A good discussion of the historical developments leading to MMICs is presented in Ref. 1.

Sometime in the 1960s, the concept of microwave integrated circuits was introduced. Instead of building individual microwave components separately and then connecting them on a piece-by-piece basis, it was thought cost effective to laminate or print an entire circuit on a single dielectric substrate with individual components (filter, coupler, etc.), connected to each other in a continuous

Figure 1. Evolution of waveguide geometries (cross sections) used for microwave circuits, from (a) hollow (uniconductor) metal waveguide, to (b) coaxial line, to (c) flattened coaxial line, to (d) stripline, and currently to (e) microstrip line. Microstrip line is now the most commonly used transmission line for MMICs. Interest in other forms of transmission lines, such as slotline and coplanar waveguides, came later in order to meet specialized needs.

integrated fashion. Miniaturization of the circuit was possible by meandering the connecting microstrip lines. Also by using high dielectric-constant substrates, the same electrical size could be achieved while maintaining smaller physical dimensions. The transmission-line components were printed on a hard dielectric substrate by photolithographic processes, and they constituted a major portion of the circuit. Other passive components, such as chip capacitors or chip resistors, and any active components, such as diodes or transistors, were discretely mounted on the circuit board. In this sense the MICs are really “hybrid” integrated circuits. The substrate materials commonly used include alumina, sapphire, low-loss plastics (fiber-reinforced), and ceramics. Although such MICs are much more cost-effective and compact, compared with bulky waveguide circuits, the density of circuits that can be implemented is strictly limited by the precision required in the manual placement of discrete components. Small to moderately complex circuits are implemented in this manner. Complexities could be increased, however, by using double-sided or multilayered circuit boards.

It was natural, then, to try direct integration of microwave semiconductor devices together with the printed transmission line components on the same substrate (i.e., in a “monolithic fashion”), in order to implement active as well as passive circuit functions. This generation of integrated circuits was called MMIC (monolithic microwave integrated circuits) [2]. The result was a dramatic reduction in size, allowed increased circuit complexity, and reduced cost. The substrate material needed for MMICs must be a semiconducting material, such as GaAs or Si, on which both active and passive components can be printed. As a result, the fabrication cost is increased, while allowing batch processing of significantly more complex and compact circuits, compared to the hybrid MIC. A comprehensive discussion of monolithic microwave integrated circuits, specifically those based on GaAs material, is available in Refs. 3 and 4.

As the acronyms suggest, the MIC and MMIC are meant for applications in the microwave range. The basic concepts of the technology are similar for applications in the millimeter-wave range, except for the need to maintain tighter dimensional tolerance in the fabrication process due to smaller wavelengths at these frequencies. A more specialized category of monolithic integrated circuits was then developed specifically for applications in a broader frequency band covering the millimeter-wave range. Though MMICs may generically refer to the microwave as well as the millimeter-wave range, a different acronym, MIMIC (microwave and millimeter wave monolithic integrated circuits) is sometimes used to cover millimeter-wave applications.

MICs, MMICs, and MIMICs are now rapidly taking on new meanings and employing new materials, 3D integration, integration of antennas, optical and optoelectronic components, high-speed digital circuits, and other specialized functions. Circuits and systems of greater complexity may be implemented on a single chip or module, consisting of multiple MMIC or MIMIC chips interconnected and packaged together in a hybrid MIC form [called a *multi-chip module* (MCM)] [1]. The entire circuit or system may

also be integrated through a batch process using multi-level processing technology. With the objective merging of these sister technologies, all related technologies for large-scale integration of circuits and systems operating in the microwave to millimeter-wave range are generally referred to as “microwave and millimeter-wave integrated circuits”—generically called by the common acronym MMIC. The applications may even cover the lower radio frequency (RF) range.

In the following sections the essential building blocks of MMIC, such as the substrate material and parameters, transmission-line geometries, passive and active components, integrated antennas, integration architectures, and packaging concepts are discussed.

1. THE SUBSTRATE

The choice of a proper substrate for MMICs is conditioned by several factors, including dielectric constant, resistivity, thermal characteristics, mechanical strength, and fabrication tolerance. For hybrid MICs the required characteristics are low-loss, low-cost, and mechanically rigid insulating materials, such as alumina or soft-plastic substrates. Alumina is a ceramic-type material with relative dielectric constant, $\epsilon_r = 9.7$. Teflon and similar types of soft-plastic materials can provide ϵ_r values ranging from 2 to 11. Usually the higher dielectric-constant substrates are preferred because they reduce the wavelength of propagation, which results in smaller-size circuits. However, for higher-frequency applications (20 GHz or higher), where the wavelength is already small and fabrication of very small-sized circuit components is a problem, a high-dielectric-constant substrate may not be desirable. Substrates of lower dielectric constant may be more useful in this high-frequency range. This results in increased wavelength allowing the design of larger-size circuit components, so that inaccuracies in dimensions during the fabrication process can be better tolerated.

For monolithic microwave circuits, where active devices have to be fabricated together with passive components, the substrate will have to be a semiconductor. Si and GaAs are the most common types of substrate materials in use. Two factors become important in the selection of a semiconductor substrate for MMICs: (1) higher substrate resistivity, in order to achieve low propagation loss and (2) higher carrier mobility, in order for the active devices to operate at higher frequencies. Si and GaAs, in their semiconducting states, cannot maintain high resistivity. Therefore, the base substrate must be in an insulating (or semiinsulating) state with higher resistivity levels, on which the passive microwave circuits can be printed. Then active devices are grown on the same base substrate in isolated regions, using ion implantation or epitaxial techniques. Table 1 lists the material parameters of various substrates pertinent to MMICs. It is seen that the electron mobility of GaAs is more than 5 times that of Si, and that the semiinsulating GaAs has a much higher (100 times or more) resistivity compared with that of Si, thus making GaAs a better choice for MMICs [3,4]. However, compared with GaAs, Si fabrication technology is much more ma-

Table 1. Properties of Semiconductors and Insulators Used in Microwave and Millimeter-Wave Integrated Circuits

Type of Substrate	Relative Dielectric Constant (ϵ_r)	Resistivity (ρ , Ω cm)	Electron Mobility μ_n , cm^2/V	Thermal Conductivity k , $\text{W/cm } ^\circ\text{K}$
Semiconductor

ture, owing to its extensive use in digital electronics. Also, as discussed earlier, in modern MMICs it is desirable to fabricate digital circuits for peripheral processing and control functions together with microwave circuits. The above situation makes it more compelling to try to use Si for MMICs. In this pursuit, the higher propagation loss due to lower values of resistivity of semiinsulating Si is a major hurdle. This problem is overcome by using silicon-on-sapphire (SoS) technology, where the base substrate is made out of low-loss sapphire, instead of the lossy semiinsulating Si. Even then, the SoS technology, due to lower carrier mobility of Si, usually finds application at lower frequencies (several gigahertz), leaving GaAs as the principal choice for the millimeter-wave range.

Assuming a printed microstrip line as the transmission line-of-choice for signal distribution in a MMIC, Fig. 2 shows the signal attenuation constant α for different

substrates as a function of frequency. A set of parameters of practical interest to MMICs were chosen for these data, assuming copper to be the conducting medium. As seen in Fig. 2, the semiinsulating Si is the most lossy, SOS and GaAs are comparable in their loss performance, whereas alumina substrate provides the lowest loss. It turns out that for SOS, GaAs, and alumina substrates, the loss is dominated by the metal loss, not by loss in the substrate material. For semiinsulating Si, however, the loss in the substrate material contributes significantly to the total loss.

Besides material loss in the substrate, the substrate parameters influence the power lost to radiation in the form of “surface waves” generated at various transmission-line junctions and circuits. The substrate thickness and the dielectric constant are the governing parameters. Figure 3 shows the effective dielectric constant, $\epsilon_e = (\lambda_0/\lambda)^2$, of the fundamental and the first higher-order surface-wave modes, where λ_0 is the wavelength in free space, and λ is the wavelength of the surface-wave mode [5]. The fundamental mode propagates for all frequencies, whereas the higher-order mode has a cutoff frequency. In order to avoid excessive surface-wave loss, the cutoff thickness ($d = d_c$) of the substrate at which the second higher-order mode is excited is often used as a reference value for design of the substrate thickness. As a general rule, up to one-third of the critical value d_c can be safely used and will yield reasonable levels of surface-wave loss. This amounts to maximum practical thicknesses of about $725 \mu\text{m}$ at 10 GHz, and $244 \mu\text{m}$ at 30 GHz, for GaAs, and somewhat higher thicknesses for Si and alumina. These thicknesses do not usually pose a manufacturing problem for monolithic circuits, but can be an important consideration for mechanical strength in hybrid MICs.

Figure 2. Attenuation (α) in a microstrip line with different substrate materials [semiinsulating Si and GaAs, indicated simply as Si and GaAs, SOS (silicon-on-sapphire), and alumina] as a function of frequency. All lines have approximately 50Ω characteristic impedance. Alumina substrate thickness $H = 500 \mu$ (for hybrid circuits), and for all other substrates $H = 100 \mu$. Resistivity of SOS = $10^{14} \Omega$ cm; for semiinsulating GaAs = $10^7 \Omega$ cm; for semiinsulating Si = $10^3 \Omega$ cm; and for alumina = $10^{11} \Omega$ cm. Line width W : SOS and semiinsulating Si, 80μ ; semiinsulating GaAs, 70μ ; alumina, 500μ . Conducting medium is assumed to be copper.

2. CHIP SIZE AND CIRCUIT COMPLEXITY

An estimate for the circuit complexity that one can achieve in a MMIC of a certain size, at two selected frequencies—3 GHz for lower-frequency and 30 GHz for higher-frequency applications—is presented here. A Si substrate is assumed for calculations, but the estimates should be close for GaAs and alumina, since these materials have similar dielectric constants. At 3 GHz, a

Figure 3. Dispersion characteristics for the fundamental (TM) and the first higher-order (TE) mode of a GaAs substrate with a metallized ground plane on one side, used in MMICs. The cutoff value of $\sqrt{\epsilon_r}d/\lambda_0$ for the first higher-order TE mode is 0.26. The dispersion characteristics for Si and alumina substrates are very similar to that of GaAs, with the corresponding cut-off numbers for the first TE modes equal to 0.261 and 0.264, respectively.

microstrip transmission line on Si has a guide wavelength $\lambda \simeq 4$ cm. The distributed “subcircuits” are assumed to be $\lambda/4 \times \lambda/4 \simeq 1 \text{ cm} \times 1 \text{ cm}$ in size (these are typical dimensions for distributed circuits) and therefore occupy most of the substrate area. If a mixture of 20% distributed functions and 80% lumped-circuit functions (of size $1 \times 1 \text{ mm}$) are used, a 2×2 -in. substrate can accommodate about 120 circuits or, equivalently, about 60 circuit functions if a factor of 2 is used to account for additional space required between components, to avoid intercomponent coupling. At 30 GHz, on the other hand, the distributed and lumped circuits are comparable in size: $\lambda/4 \times \lambda/4 \simeq 1 \text{ mm} \times 1 \text{ mm}$. This will yield about 1300 circuit functions on a 2×2 -in. substrate, taking into account a factor of 2 for additional intercomponent spacing. These figures are indicative of a low level of integration density in MMICs, compared with that achievable in digital integrated circuits. This fact strongly motivates the use of multilevel integration by stacking circuit layers with proper electrical isolation between layers. Although this stacked integration leads to other constraints, it can potentially increase the effective circuit density several times, while also allowing convenient integration as well of other functions (digital, optical, antennas, etc.) on independent layers.

Figure 4. Different configurations of printed transmission lines (cross sections) currently used in MMICs. The slotline and coplanar waveguides may sometimes use a conductor backing under the dielectric substrate for added mechanical support, but require careful design [8,9,30]. Other variations of these transmission lines with multilayer substrates are also useful.

3. TRANSMISSION MEDIA

Figure 4 shows various configurations of printed transmission lines that are used in MMICs [6,7]. Other variations of these transmission lines with different arrangements of the dielectric substrates or metal planes are also useful. For example, the slotline or coplanar waveguide may be used with a conductor backplane for added mechanical support and increased signal isolation [8,9]. Among the geometries in Fig. 4, the microstrip line is the most commonly used transmission line for MMICs. However, under certain situations other geometries may be more suitable. Table 2 compares the practical features of various transmission lines. Specific technical details of the transmission lines can be obtained for microstrip [10,11], coplanar waveguide [12,13], and slotline [14].

In the following, basic design data are provided, and important design considerations for MMICs are discussed, based on requirements for the transmission line used. Microstrip line is assumed as the transmission line of choice. Figures 5a–e present data for various useful transmission-line characteristics for GaAs, Si, and alumina substrates.

Figure 5a shows variation of the characteristic impedance Z_c of a microstrip line as a function of W/H , while keeping the substrate thickness H fixed, for different substrate materials. Data are plotted for values of W/H around 1, where the characteristic impedance is nominally 50 Ω . The characteristic impedance reduces for larger values of W/H , owing to an increase in the effective capacitance between the line and the ground plane. Figure 5b shows the attenuation constant owing to material loss for

Table 2. Characteristic Features of Common Printed Transmission Lines

Type of Line	Z_c (Ω)	Loss	Dispersion	Connect Series Element	Connect Shunt Element	Discontinuity Radiation
Microstrip line	10–100	Low	Low	Easy	Difficult	Low
Coplanar waveguide (CPW)	20–150	Medium	Medium	Easy	Easy	Low
Coplanar stripline (CPS)	40–250	Medium	Medium	Easy	Easy	High
Slotline	60–250	High	High	Difficult	Easy	High

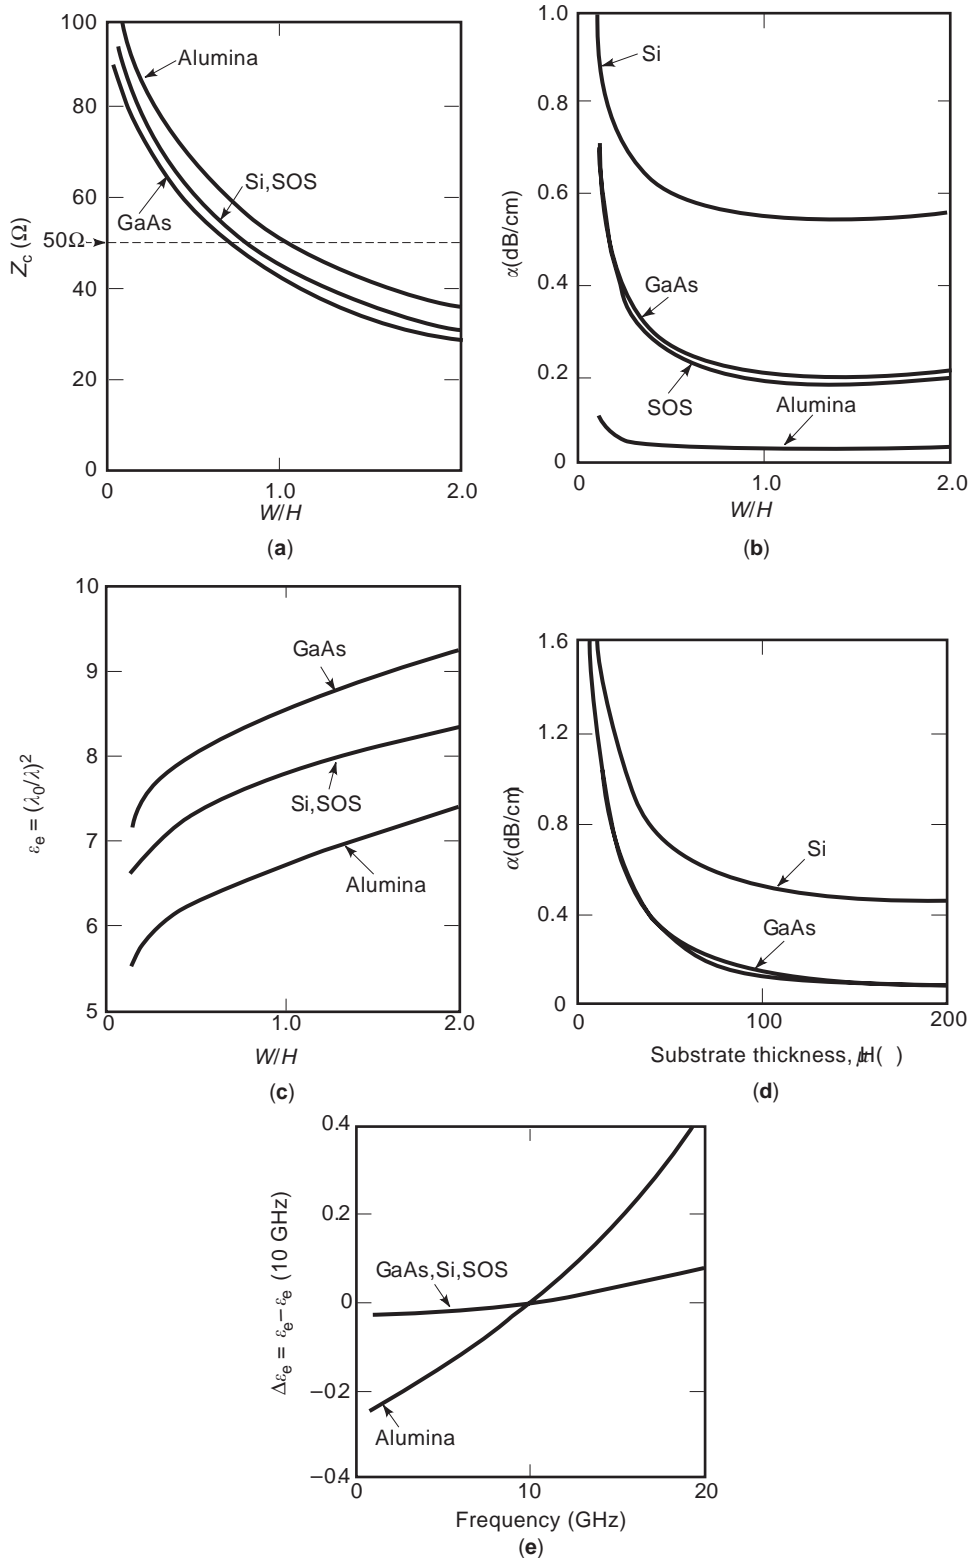

Figure 5. Variation of (a) characteristic impedance Z_c ; (b) attenuation constant α ; and (c) effective dielectric constant $\epsilon_e = (\lambda_0/\lambda)^2$, as a function of W/H for the substrates of Fig. 2, but with frequency = 10 GHz. Variation of α for semiinsulating Si and GaAs substrates (characteristics for SOS and alumina are close to that of GaAs) as a function of substrate thickness H (with W selected for different H to have $Z_c = 50 \Omega$) at 10 GHz is plotted in (d). Frequency variation for the ϵ_e of (c) is plotted in (e), in order to show dispersion behavior.

the same parameters of Fig. 5a. As can be seen from Fig. 5b, the loss increases sharply for smaller values of W/H , making small values of W/H undesirable. In order to maintain compactness of integration the upper limit of W/H is restricted—a reasonable upper limit for W/H is 4. The aforementioned constraints in W/H limit the range of Z_c values that can be practically attained to about 10–100 Ω .

Figure 5d shows the variation of attenuation constant for different values of substrate thickness H , while maintaining a 50- Ω line (with properly adjusted linewidth W). These data show that material loss sharply increases as the substrate thickness is reduced. Therefore, the choice of substrate thickness H below a certain limit is not desirable. It may be recalled that the upper limit for H is restricted, in order to minimize excitation of substrate modes.

The microstrip line, like other printed transmission lines used in MMICs, does not support the TEM (transverse electromagnetic) mode. This is so because the material medium around the transmission line is not uniform—it is partly air and partly the substrate material. As a result, the transmission line is dispersive. The effective dielectric constants ϵ_e of microstrip lines on different MMIC substrates are shown in Fig. 5c. As should be expected, the effective dielectric constant lies between 1.0 and ϵ_r of the substrate material. The actual value depends on the electrical “filling factor” of the substrate. This filling factor increases with increased W/H . This is because as W/H increases, the fraction of the total electric field confined in the dielectric material increases, allowing only a small fraction to fringe out into the air medium. Figure 5e shows the dispersion behavior of ϵ_e for the same parameters of Fig. 5c, but keeping the linewidth W fixed. Notice that the dispersion is stronger for the line on an alumina substrate. This is because the alumina substrate chosen for the data in Fig. 5e is much thicker than is the case for Si or GaAs. Dispersion worsens for thicker substrates. This is also a consideration that limits the substrate thickness to smaller values.

Besides the restriction on the linewidth and substrate thickness, it is important to consider the constraint on the spacing between two adjacent lines. The lower limit of the line-to-line separation determines the minimum level of isolation that can be maintained between nearby circuits. This consequently restricts the compactness of integration. Figure 6a plots the electric field of a 50- Ω transmission line on a GaAs substrate as a function of distance Δ (normalized with respect to the linewidth W) from the center of the transmission line in the transverse direction. The field rapidly drops beyond the region below the line. At a distance 4 times the linewidth W the field strength drops to about 3% of its peak value. In order to achieve this high level of isolation, one must, therefore, maintain a center-to-center separation S between two lines of about 8 times the linewidth W ($7W$ for edge-to-edge separation). For a 10% field isolation the corresponding value for center-to-center separation is about $4W$. Figure 6b illustrates how this field coupling translates to coupling of signal power, as a function of edge-to-edge separation S between lines. For $S/W=3$ one can achieve better than about 25 dB isolation, which can be increased to about 30 dB

Figure 6. (a) Variation of the field strength of normal (to the substrate) component of electric field of a 50- Ω microstrip line on a 100- μ -thick GaAs substrate, sampled at the bottom ground plane, plotted as a function of the distance Δ from the center of the line. Width W of the line is 70 μ , and frequency = 10 GHz. (b) Level of power that can be coupled from a signal line to a nearby line as a function of edge-to-edge separation S between the lines. It is assumed here that the signal line is matched to the source and terminated by the characteristic impedance of the line. The coupled line is also match terminated at both ends. Here the maximum level of power that can be coupled between the lines, which occurs when the line lengths are odd multiples of $\lambda/4$, is plotted. Such characteristics also generally apply to other substrates and frequency, and are useful to determine the minimum separation one must maintain between lines in an MMIC in order to maintain a minimum level of isolation.

for $S/W=4$. In most practical applications an S/W ratio greater than 3 provides reasonable isolation.

4. PASSIVE COMPONENTS

Some of the passive components commonly used in MMICs include (1) resistors, (2) capacitors, and (3) inductors. These components can be implemented in lumped form if their physical size can be maintained sufficiently small ($< \lambda/10$) compared to the operating wavelength λ . Otherwise, “distributed” behavior becomes more pronounced, and therefore the components no longer operate as normally expected. The lumped condition is more easily

satisfied at lower microwave frequencies (where λ is larger), making the use of such lumped components more practical in this range. Except for resistances, the inductive and capacitive elements can also be realized in distributed form, using a transmission-line stub of a certain length. As a basic principle, however, the lengths of such distributed components are proportional to the operating λ . At a low operating frequency, where the operating wavelength may be too large, the required large length of the distributed components can make it difficult to implement in an MMIC. Therefore, the use of the distributed elements in MMICs is limited only to the higher-frequency range (where the wavelength is sufficiently small). In the intermediate frequency range (around 10–20 GHz) a mixture of lumped and distributed components may prove useful.

Besides implementing simply inductances and capacitances in distributed form, a variety of other circuit functions, such as delay lines, couplers, resonators, and filters can be implemented only in distributed form. Transmission-line segments are interconnected in a variety of ar-

rangements to achieve circuit functions that are useful in many microwave applications. However, all such distributed-circuit elements are essentially transmission-line metallizations, which can be fabricated in a MMIC similar to other metal interconnections. The various lengths and widths of transmission-line segments required can be designed using distributed-circuit theory [15,16].

In the following only lumped-circuit elements as used in MMICs will be discussed. Figure 7 shows various configurations of MMIC lumped components, some of which may be relevant to hybrid-type integration, and others to monolithic integration.

4.1. Capacitors

Figure 7a shows useful configurations of capacitance components used in MMICs: (1) edge-coupled, (2) end-coupled, (3) interdigitated, (4) end-coupled overlay, (5) overlay, and (6) chip capacitor. Of these, (4) and (5) are relevant only to monolithic integration, (6) only to hybrid MIC configuration, and the others can be implemented in either

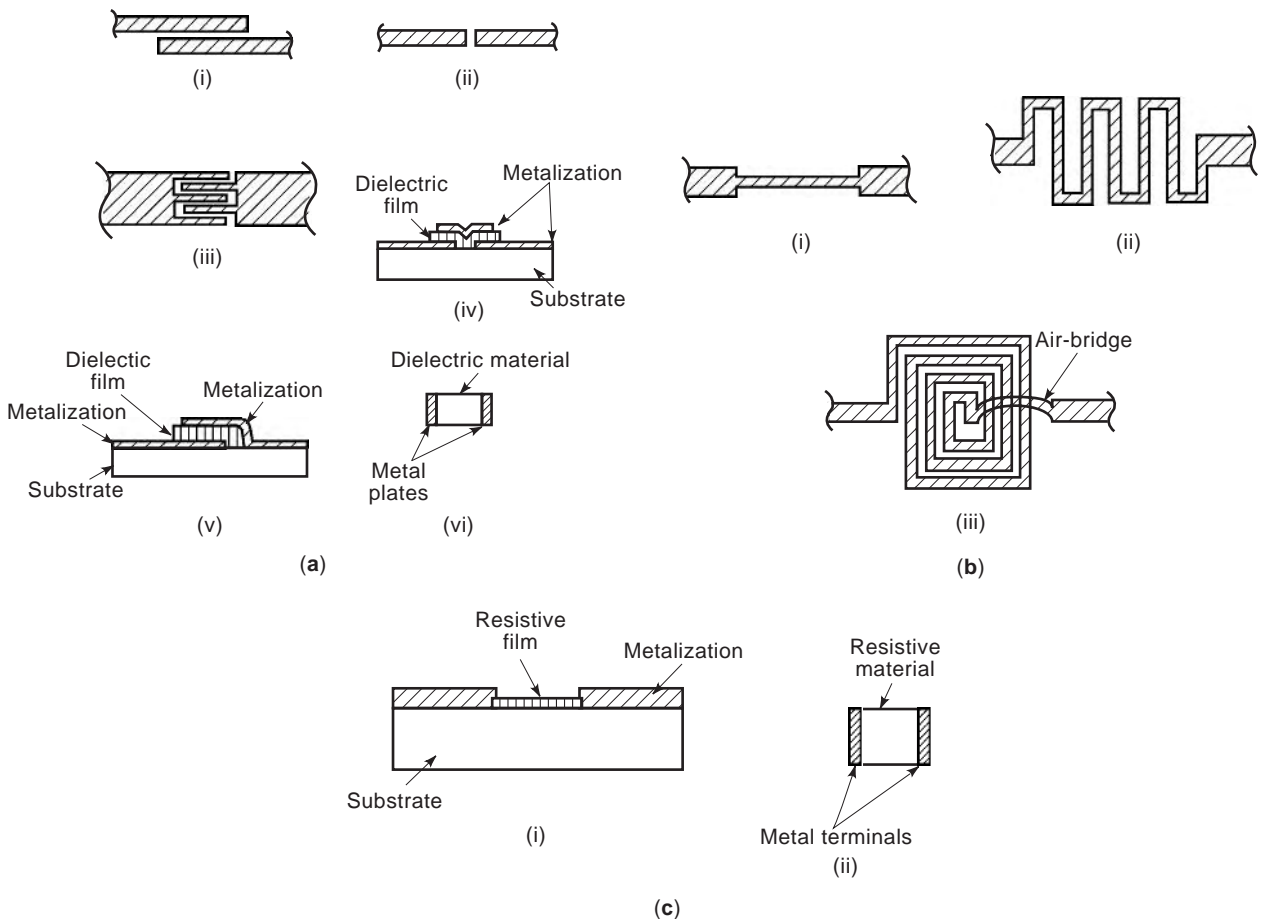

Figure 7. Various configurations of lumped passive components used in MMICs. (a) Capacitors in different forms: (i) edge-coupled, (ii) end-coupled, (iii) interdigitated, (iv) end overlay, (v) overlay, and (vi) chip capacitor. (i)–(iii) are planar forms showing the top view of the metallizations, whereas (iv)–(vi) are nonplanar components showing their side views. (b) Planar inductors in different forms: (i) using a straight section of a high-impedance transmission line, (ii) meander-type line, and (iii) spiral inductor with an overbridge connection. (c) Resistances in two forms: (i) film resistance and (ii) chip resistance.

monolithic or hybrid form. All capacitances shown in Fig. 7a are essentially series-type circuit elements, but a shunt-type capacitance can be realized by connecting a via hole to one of the terminals. Up to about 1 pF capacitance can be achieved using an edge-coupled or end-coupled design, with some higher values possible from an interdigitated configuration. Capacitance values in the range of 10–30 pF can be realized by overlay-type designs, which are useful for RF-bypass or dc-blocking applications. Much higher values can be implemented only in discrete chip form, which can be used in hybrid MICs, but not in monolithic form.

The edge-coupled, end-coupled, and interdigitated capacitors are implemented in MMICs as two metallized lines with a suitable gap(s) maintained between them. No additional dielectric film is required. In all other designs in Fig. 7a an additional dielectric film is needed. In a monolithic fabrication process such film capacitances are realized by controlled deposition of dielectric films of required thickness. Some important considerations for the dielectric films to be used include (1) dielectric constant of the material (and hence the capacitance values that can be achieved per unit area), (2) compatibility with monolithic fabrication process, (3) microwave losses, and (4) breakdown field. The capacitance would exhibit some resistive behavior in the microwave frequencies, due to (1) losses in metal and dielectric film, and (2) radiation into the free-space and/or substrate medium. Q factors of the order of 50–100 can be achievable in the X band (10 GHz). Distributed effects are always present, to some extent, resulting in deviations from lumped behavior of the device. These effects may be taken into account through the use of computer-aided modeling and design.

4.2. Inductors

Figure 7b shows different configurations of MMIC inductors: (1) using a high-impedance line, (2) a meanderline type, and (3) a spiral type, among which the spiral type allows a higher range of inductance that can be achieved. All such inductors are implemented in a planar metallized form, and, thus, can be used in hybrid or monolithic integration. In the spiral-type inductor one would need an airbridge to connect to the center of the spiral. This would require an additional fabrication step in monolithic form, or could be manually established in a hybrid MIC. The operation of all inductance elements is based on the production of strong magnetic stored energy in the vicinity of the device (equivalent to the operation of a coil in audio or RF circuits). The goal here is to achieve high inductance within a small physical space.

Unavoidable capacitive effects are also present in the planar inductor design, due to edge coupling between lines and the presence of the ground plane under the metal lines. This is in addition to resistive effects owing to material loss (metal and dielectric), as well as radiation. Therefore, the planar inductor does not behave like an ideal inductance, but needs to be treated as an $R-L-C$ resonant circuit, with a dominant inductive effect in the operating frequency range. All the nonideal factors must be carefully accounted for, requiring the use of accurate

computer-aided modeling tools. Inductance values on the order of 10 nH can be achieved using planar spiral inductors, with Q factors on the order of 50 in the X band. These values are useful for RF isolation/bypass purposes. The use of inductors requiring higher inductance values should be avoided in MMICs.

4.3. Resistors

Figure 7c shows two general classes of MMIC resistors: (1) the resistive film element and (2) the chip resistor. Chip resistors find application only in hybrid circuits, while the film resistors are convenient to implement in monolithic circuits. The resistors are useful in resistive loading and match termination elements. Resistances requiring high power dissipation (e.g., in DC biasing) should be avoided in MMICs.

The resistive film used in a film-type resistor can be realized by the deposition of a lossy metal film or a semiconductor film. A lossy metal film of an appropriate material can be deposited in the MMIC fabrication process, in a manner similar to the fabrication of a film capacitance. Important considerations for the choice of the lossy metal film are: (1) sheet resistivity (which determines the resistance per unit length), (2) thermal variation of resistivity, and (3) compatibility with MMIC fabrication. The resistive film may also be realized in an MMIC using a semiconductor process, similar to that used for active devices. The doping level in the semiconductor controls the resistance value, which can be realized using an epitaxial or implantation technique. The use of metal films for resistors is usually preferred over semiconductor films, owing to nonlinearity behavior of the latter at high current values and poor thermal stability. Nonideal effects common to both types of film resistors include additional capacitive effects between the film and the ground plane, inductive effects of the metal connection, and some radiative effects. This results in frequency dependence of the performance, which must be properly accounted for in the design process.

4.4. Other Passive Elements

Besides the aforementioned passive circuit components, other passive circuit configurations such as (1) junctions between transmission lines, (2) transmission line bends, (3) vias, and (4) open ends, which are frequently used in MMICs, need to be considered. These are generally called “discontinuity” elements, whose presence is not desirable but inevitable in MMICs. The discontinuity elements can be modeled as $R-L-C$ equivalent circuits, using a computer simulation or some approximate theoretical approach. Whenever possible, their unwanted effects should be minimized by proper design of the discontinuity itself, or through compensation within the design of the rest of the circuit.

It is desirable to integrate antenna elements together with other microwave circuits in an MMIC. This approach is particularly attractive in large integrated phased-array radars, in order to avoid the complexity of fabricating the circuits and antenna elements separately and then manually connecting them. Although current applications of

MMICs in the wireless communication industry are growing, large phased-array radars are still the major driving force behind MMIC technology. The microstrip antenna [17] is the most suitable candidate for such integration. This is mainly because of the planar nature of microstrip antennas, which can be fabricated with an MMIC process in a manner similar to other metallizations. The basic geometry of the metallization structure of a microstrip antenna, which can be connected to the rest of the MMIC by a microstrip line, is shown in Fig. 8a. The radiation from this microstrip antenna is along the broadside direction (outward, perpendicular to the substrate). Sometimes it may be preferable to have the antenna element radiate

along the endfire direction (along the substrate plane). Figure 8b shows one such printed antenna configuration, called a tapered-slot antenna [18]. The tapered-slot antenna shown in Fig. 8b is fed by a slotline, and radiates to the right along the plane of the substrate.

One of the drawbacks of integrating antennas with MMICs is that it often occupies significant space on the valuable semiconductor substrate. Another problem is that since the MMIC substrate is normally optimized for circuit functions in order to minimize radiation from the circuit components, the same substrate cannot at the same time be optimal for antenna radiation. Certain techniques may sometimes be used to provide a compromise between

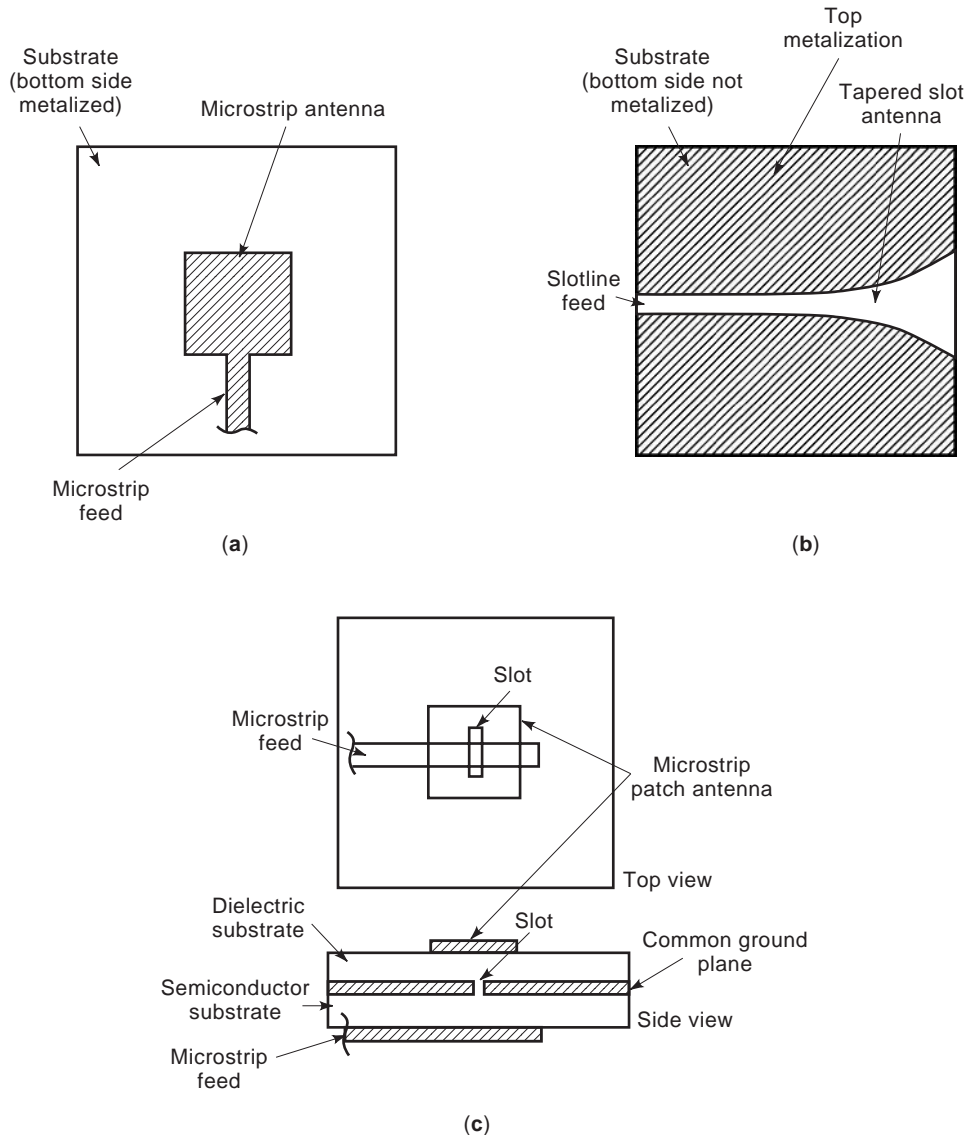

Figure 8. Geometries of printed antennas that can be integrated together with MMICs: (a) a microstrip-line-fed printed antenna (shows top surface) for radiation normal to the substrate; (b) a coplanar stripline-fed printed tapered-slot antenna (shows top surface), which radiates along endfire direction, (toward the right side along the substrate plane). In (a) and (b) the antenna and microwave circuitry are printed on the same substrate, whereas (c) shows an aperture-coupled microstrip antenna, where the antenna is printed on a different substrate layer, coupled to the microwave circuit layer through an aperture on a common ground plane.

both functions. In such a situation, a multilevel integration, as shown in Fig. 8c is desirable, where the antenna is fabricated on a cheaper dielectric substrate, independently optimized for antenna radiation, retaining the valuable semiconductor substrate only for circuit integration. The common metal plane between the antenna and circuit layers serves as the ground plane for both. It may be noticed in Fig 8c that the antenna and circuit layers are electrically isolated from each other by the common ground plane, while they are “electromagnetically” connected between each other only through a small slot etched on the ground plane [19]. This idea can be naturally extended to more layers, with possibly more than one antenna layer, or an additional dielectric layer for distributed feeding circuitry, thus reserving the bottom semiconductor layer mostly for active functions.

5. ACTIVE DEVICES AND PROCESSING

For hybrid-type integration there is flexibility gained in using heterogeneous active components such as bipolar or field-effect devices, and two- or three-terminal devices. However, uniformity must be maintained in the type of active device one might use in monolithic integration. In the following the active device and fabrication process used in monolithic MMICs will be discussed. Some early forms of MMICs used two-terminal active devices, such as Schottky and Gunn diodes. Modern MMICs use MESFETs (metal semiconductor field-effect transistor) as a versatile active component (20). MESFETs are convenient to fabricate in an MMIC process, and are known to provide good performance in implementing a large class of active circuits, including specialized amplifiers with low-noise, high-gain, and broadband features, as well as mixers, switches, oscillators, and phase shifters. The power levels that can be achieved from a single MESFET amplifier or oscillator are low to moderate. Power may be increased by use of on-chip power combiners. However, operation of MMICs should be limited to moderate power levels, to avoid problems associated with heat dissipation. Power outputs on the order of 10 W can be realized from a single chip using power-combining techniques. For a detailed theory of MESFETs one may refer to texts on semiconductor devices [20–22]. Theoretical work and practical techniques for the design of microwave active circuits can be found elsewhere [15,23–25].

The MMIC fabrication process starts with a good-quality substrate wafer, followed by more than 30–40 individual processing steps. For GaAs MMIC, the substrate material is semiinsulating GaAs, whereas in SoS (silicon-on-sapphire) MMIC the base material is sapphire. The specific processing steps for the two cases are different, though they more or less share a major set of common processing techniques. Only the major processing techniques will be briefly discussed. First, an active semiconducting layer, which is needed for active device fabrication, is formed on the substrate. There are two techniques commonly used in forming the active layer: (1) epitaxy and (2) ion implantation, which may be used independently or in combination. In the epitaxial technique,

a doped single-crystal semiconducting layer can be deposited on top of a crystalline base substrate. An intermediate high-resistivity buffer layer is used in the epitaxy process, in order to screen out any diffusion of impurity atoms from the substrate into the active layer. There are different types of epitaxial growth processes: VPE (vapor-phase epitaxy), MBE (molecular-beam epitaxy), and LPE (liquid-phase epitaxy), each having different basic advantages and drawbacks. In the ion implantation technique, on the other hand, the dopant atoms can be implanted directly onto a semiinsulating semiconductor substrate, using high-energy impurity ions. This process is quite versatile, and even selective doping profiles at different locations on the substrate may be possible. However, this process requires a base semiconductor substrate with a high state of purity. Therefore, if direct implantation is not practical, an epitaxially grown “buffer” layer on top of the primary substrate may be used as the implantation medium.

Once the active layers are formed using one or a combination of the above techniques, the active device areas are isolated from the surrounding regions, leaving “mesas.” This is important for microwave circuits, in order to reduce parasitic coupling to the active components. Mesa isolation may be achieved by deep etching of the substrate around the active area. The mesa-etching process may be substituted by implantation of oxygen onto the epitaxial layer surrounding the active device region. The oxygen implantation creates the required high-resistivity barriers. This process is called isolation implant, which essentially uses the epitaxial deposition in combination with selective ion implantation.

Next, ohmic contacts to the active areas are made to provide source and drain contacts for the MESFET. The standard approach involves alloying of Au (gold) or AuGe (gold–germanium) onto the substrate. This results in a heavily doped region under the contact, which facilitates establishing the ohmic junction. The gate regions of the MESFET are then processed. The gates are Schottky-type contacts, which are formed by depositing Ti-Pt-Au (titanium–platinum–gold compound). Because the gate regions are usually small ($\leq 1 \mu\text{m}$), this calls for high alignment accuracy in the lithographic patterning process. Some form of lithography (optical or electron-beam) is needed here, as well as in other fabrication steps, for accurate definition of devices and the interconnection layout.

At this stage the active device processing is essentially completed. The active devices are now subjected to on-wafer DC and microwave tests. Wafers that do not meet process control specifications are rejected, in order to avoid any subsequent processing costs. Following this, the first layer of metallization is deposited for external contacts, transmission line interconnections, spiral inductors, and distributed circuits. Then, thin films of appropriate resistive or dielectric materials are deposited to form thin-film resistors and capacitors. Resistors may also be realized using semiconductor material in the initial epitaxial or implantation process. Then a second layer of metallization is deposited to connect thin-film capacitors, and to form crossovers or other miscellaneous connections. The two-level metallization process allows topological flexibility in

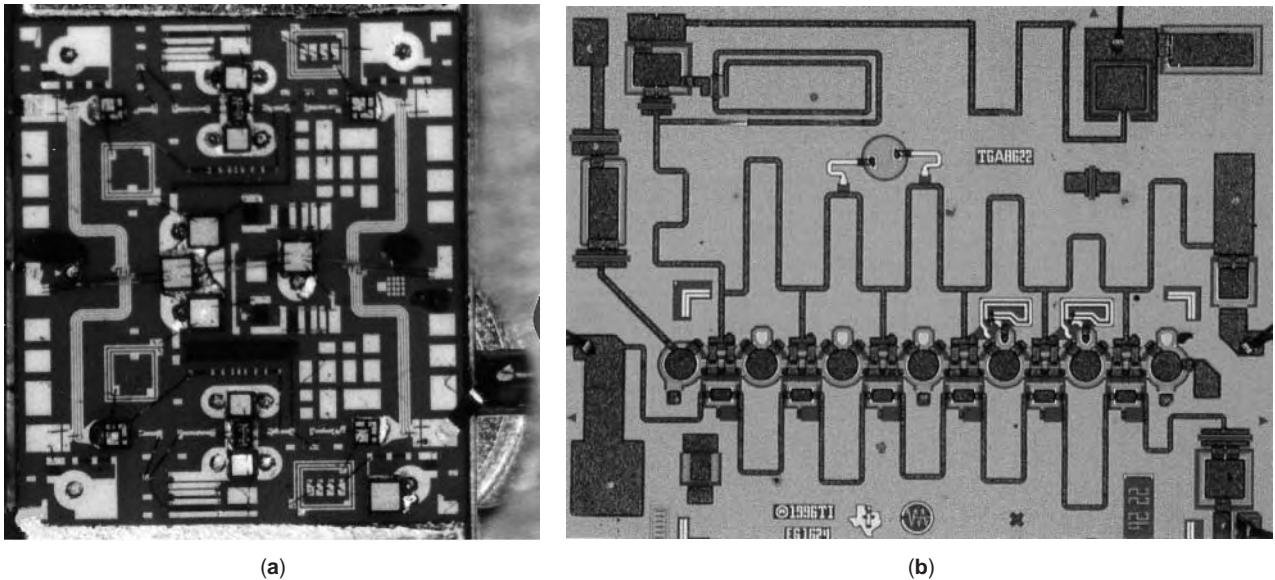

Figure 9. Photographs of commercially used hybrid and monolithic microwave/millimeter wave integrated circuits: (a) A balanced amplifier operating in the 2–8 GHz frequency range, consisting of printed Lange coupler, FETs and associated power supply and biasing circuits (film/chip resistance, chip capacitance, and printed inductance) integrated in a hybrid MIC form. Actual size is $\frac{3}{8}$ in. \times $\frac{1}{8}$ in. (Picture courtesy of Mini-Circuits, Brooklyn, NY.) (b) A GaAs traveling-wave MMIC amplifier (7 dB gain, 18 dBm output power level) operating over a broad bandwidth of 2 GHz to 18 GHz, consisting of six stages of GaAs FETs, printed transmission lines, biasing film resistance, capacitance and printed inductance, integrated in a monolithic MMIC form. Actual size 0.11 in. \times 0.086 in. (Picture courtesy of MITEQ Inc., Hauppauge, NY.)

the circuit layout. Some of the functionalities of the first- and second-level metallizations may be interchanged as needed.

The final steps in the MMIC fabrication involve backplating of the substrate, in order to provide the ground plane for the circuit. The thickness of the substrate is critical for maintaining correct values of characteristic impedance of the transmission-line components. Therefore, the back side of the wafer must be “thinned” in a controlled manner. The entire backside is then metallized. Ground connections from the bottom metal plane to the circuits on the top surface are provided through “via holes.” This is possible by the etching of through-holes at required locations and then metallizing the inner surface of the hole. Wet-chemical etching, reactive-ion etching (RIE), or combinations thereof are used.

It may be mentioned that much of the technologies used for MMIC fabrication have been adapted from well-established techniques used in the silicon digital IC industry. Each processing step needs to be optimized for MMIC application, however—particularly for GaAs MMIC [4]. Figure 9 shows photographs of two integrated circuits fabricated in hybrid and monolithic processes.

6. COMPUTER-AIDED DESIGN

It is virtually impossible to design complex MMICs through an experimental trial-and-error procedure. Except for a few simple MMIC components, analytical

formulas are not available for accurate design. This is owing to the complexity of electromagnetic interactions in and between different MMIC components. Because of the nature of MMIC fabrication, any “tuning” after fabrication would also be quite difficult or impossible. From the above considerations, computer-aided simulation and design [26] play a critical role in the successful design of MMICs.

The computer-aided simulation tools for MMICs that are currently available may be classified into four broad categories: (1) purely circuit-based tools, (2) circuit 2D tools, (3) circuit 2.5D tools, and (4) full EM-based tools or 3D EM tools. Purely circuit-based tools perform simulations employing simple circuit theory, which requires the user to provide an equivalent-circuit model for individual components, valid for the microwave frequency range of operation. As a result of the relative simplicity of the circuit theory used in simulation, such tools are computationally fast (particularly for linear circuits), but electromagnetic interactions cannot be properly modeled. This approach has only limited use, because accurate equivalent-circuit models for MMIC components are often not available. On the other hand, purely EM-based tools can rigorously model all electromagnetic interactions in an MMIC, and can handle arbitrary geometries of components, package structures, and microstrip antennas. This is accomplished by treating the entire chip as a 3D (three-dimensional) electromagnetic system and, therefore, such tools may be called “3D EM” tools. However, compared with purely circuit-based tools, the 3D EM tools are often computationally quite time-consuming. A suitable

compromise between the purely circuit-based and purely EM-based (or 3D EM) tools is provided by the circuit 2D and circuit 2.5D tools, which are based on hybrid circuit EM models. Compromise between speed and rigor is also achieved, having subgroups among the 3D EM tools, depending on the level of rigor, type, and size of geometries the software tools can handle.

In the circuit 2D tools the parameters of the transmission lines are calculated by treating them as infinite-length lines, which simplifies the problem to a 2D structure. An approximate "quasistatic" or a more accurate "full wave" approach may be used to this effect [6,15]. Coupling between nearby transmission lines can also be incorporated via coupled-line analysis. However, electromagnetic effects of transmission line discontinuities, such as junctions, bends, and open/short circuits, coupling among lumped/distributed components, and the effect of

the surrounding package structure, are ignored. The circuit 2.5D tools, on the other hand, model the electromagnetic effects of the discontinuities, in addition to the transmission line parameters, but still fail to model the electromagnetic interactions among components and package. The term "2.5D" in circuit 2.5D tools appropriately suggests that the rigor of EM modeling used here lies somewhere between the circuit 2D and 3D EM tools.

The various commercial CAD tools that are currently available mainly provide simulation capability, where the operator needs to manually iterate the simulation procedure to arrive at a final design. In addition to the simulation, limited design capability may also be available in some cases, where a final design with user-defined parameters can be reached, starting with an approximate design specified by the user. However, owing to the excessive computation needed in design algorithms, such design-oriented tools are mostly circuit-based, with very limited EM-modeling.

The EM-modeling required for different types of MMIC CAD tools can be performed using a variety of numerical techniques. The major techniques include (1) moment method (MM), (2) finite-element method (FEM), (3) transmission line matrix method (TLM), and (4) finite-difference method (FDM). The individual techniques have their own advantages and drawbacks, and have specific strength in being able to handle specific classes of problems. For example, the moment method may be suitable for planar geometries, whereas FEM can be useful for nonplanar components, such as film capacitors, via holes, and so on. A comprehensive review of commercial EM simulation tools currently available, their modeling techniques, and scope of application, is presented in Ref. 27. Major suppliers of product lines for MMIC CAD include Hewlett-Packard Co. (HP-EESOF), Westlake Village, CA; Ansoft Corporation, Pittsburg, PA; and Sonnet Software Inc., Liverpool, NY.

Figure 10. Conceptual sketch of a multifunctional MMIC configuration with microwave/millimeter wave active and passive circuits integrated together with printed antennas, optoelectronics, digital circuits, and possibly other specialized functions, in multiple levels. The next generations of MMICs may take such forms in order to realize high-density, reliable, and multifunctional integration on a single package.

Figure 11. Geometry of a packaged microstrip line, in contrast to a conventional microstrip line, which can be useful for avoiding parasitic coupling between nearby components. Similar packaged configurations for other types of printed lines are also possible.

7. CURRENT TRENDS AND FUTURE DIRECTIONS

In current MMIC technology there is greater emphasis on advanced interconnects and packaging of MMICs in the form of multichip modules (MCM). In addition to compact, highly integrated chips, future system applications will require greater packaging density and increased functionality at the MCM level. The effect of the packaging structure is recognized to have a critical role in the overall performance of MMICs. Packaging of multichip modules in a “tile” architecture, interconnected in multiple levels using layer-to-layer transitions, and between chip to substrate or chip to chip using “solderless” connections, is an attractive approach to achieve the high-density, low-cost, and multifunctionality demands of the future. A sketch of one such architecture is shown in Fig. 10. The multichip modules may be fabricated similarly to the chip itself on a larger substrate, using a common semiconductor processing technique. The functional and fabrication concepts of chips and MCM will therefore merge, expanding the scope of MMICs to also include digital, optoelectronic, and other functionalities. A review of current trends and future directions of MMIC research and technology can be found in Ref. 1.

In a multilevel architecture, particularly for applications in higher frequencies, there may be fundamental problems owing to a nonconventional “power leakage” phenomenon. Under certain conditions power can leak or couple from the printed transmission lines to the surrounding substrate structure [28]. This can cause attenuation of the signal along the transmission line, and also result in undesired coupling to the surrounding structure. Such problems should be carefully considered in advanced MMIC designs. The undesired effects can be minimized or eliminated by using shorting pins, properly designed multilayer substrate arrangement, or new types of transmission media [8].

Besides the nonconventional leakage problem, conventional parasitic coupling between various planar trans-

Figure 12. The geometry of a dielectric guide that exhibits low-loss characteristics, compared with metal lines for millimeter and submillimeter applications. The guide is not truly a dielectric guide, because it has metal planes on top and bottom (sometimes called NRD guide [31], H-guide [32], or PPDW [33], operating in different preferred modes). The metal planes are useful for isolation from top and bottom, permitting integration of circuits in multiple levels on top of one another. Most of the signal is contained in the dielectric medium between the metal planes, resulting in lower attenuation, compared with commonly used metal lines (e.g., microstrip line or coplanar waveguide).

PPDW layer	Passive devices, power distribution, interconnects
Low-loss	
Bottom layer	Active devices and/or passive devices
Heat dissipation	

Figure 13. Schematic of a hybrid-integration architecture in multiple levels, with parallel-plate dielectric waveguide (PPDW) in the middle level(s) for signal distribution, and printed metal lines in the top and bottom levels for connection to active components. Such architectures will be attractive for millimeter and submillimeter ranges for low-loss signal distribution. Conventional circuits with metal lines (e.g., microstrip line) will prove to be too lossy at high frequencies.

mission line discontinuities may also be prohibitive at higher millimeter and submillimeter frequencies, requiring new techniques to achieve greater isolation between components. Approaches to minimizing the parasitic coupling, by placing components physically farther apart, will not be desirable due to space limitations. Lines fabricated in a “boxed” manner, with metal walls surrounding the central line (see Fig. 11) may be useful. This can be achieved in semiconductor processing using “micromachining” technology [29]. Ironically, this concept is equivalent to a “flattened coaxial line,” which in the past was rejected for use in MMICs because of perceived inconvenience in fabrication.

Another concern is the metallic loss experienced by printed lines at higher frequencies. This loss can be significantly reduced by using dielectric-type guides (see Fig. 12), where a significant fraction of the field is confined to a dielectric medium (which will have lower loss than metals). However, the dielectric waveguides will not be suitable for connecting to active devices that require metal connections for their operation. A hybrid architecture with combinations of metal lines and dielectric guides, as schematically shown in Fig. 13, can solve this problem. Designs combining the dielectric waveguide concept, together with other ideas discussed above, may allow us to meet diverse and fundamental challenges.

MICROWAVE ISOLATORS

VERNON E. DUNN
Space Systems/Loral

Isolators are used extensively in microwave equipment to prevent interaction between other components of the system. This article describes the principles of operation of the most common types of microwave isolators and typical operating characteristics of these isolators. In addition, references are provided for further information on the theory of operation and design details.

An isolator is a two-port device that has low insertion loss from port 1 to port 2 and high insertion loss from port 2 to port 1, as shown schematically in Fig. 1. An ideal isolator is represented by the following scattering matrix, which indicates that ideally the device is also perfectly matched at the input and output ports:

$$S = \begin{bmatrix} 0 & 0 \\ S_{21} & 0 \end{bmatrix} \text{ where } |S_{21}| = 1 \quad (1)$$

Isolators find wide application in microwave systems eliminating interactions between components, for instance, as in Fig. 2a, between a transmitter's power amplifier and an antenna. The output from the amplifier is transmitted with low loss to the antenna, but energy reflected from the antenna is absorbed by the isolator. Other typical applications are to reduce interaction between stages of amplification (Fig. 2b) or between a local oscillator and a mixer (Fig. 2c).

An ideal isolator would have no insertion loss in the forward direction, infinite loss in the reverse direction, and a perfect match at the input and output. It would maintain these characteristics over a wide frequency range and would be able to handle high-power signals in both the forward and reverse directions without limiting or distorting the signal by generating nonlinear intermodulation products. Practical, commercially available isolators typically are expected to have less than 0.5 dB

Figure 1. Schematic representation of an isolator.

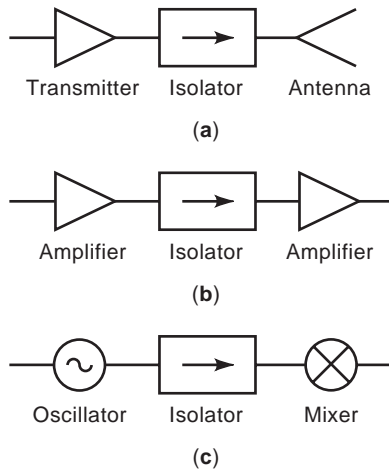

Figure 2. Typical isolator applications: (a) isolating transmitter from antenna; (b) isolating two stages of an amplifier; (c) isolating local oscillator from mixer.

insertion loss in the forward direction, greater than 20 dB loss in the reverse direction, and return loss of the input and output ports greater than 20 dB over frequency bandwidths up to an octave. If the isolator must operate over a wider frequency range, some sacrifice in insertion loss and isolation performance must be expected. Conversely, better performance may be required for some applications and is obtainable over narrow bands.

In a typical application illustrated in Fig. 3, the effect of the less-than-ideal characteristics of the actual isolator would be analyzed by considering the reflection at port *b* resulting from the mismatch between the load and the output impedance of the isolator. This reflected signal is then attenuated by the isolation of the isolator, and the resulting signal at port *a* is added vectorily to the reflection resulting from the mismatch between the source impedance and the input impedance of the perfectly terminated isolator. For example, if the isolator has an insertion loss of 0.5 dB, isolation of 20 dB, and an input and output return loss of 20 dB and the signal at port *b* is totally reflected back to the isolator, the reflected signal returning to the input port will be 20.5 dB below the incident signal and will be added vectorily to the reflection resulting from the input port mismatch, which is 20 dB down from the incident signal. The resulting total return loss will be between 14.2 and 45 dB depending on the relative phases.

Microwave isolators make use of the nonreciprocal microwave properties of a ferrite material biased by an applied direct-current (DC) magnetic field. Of the many different approaches that have been devised to use these

Figure 3. The total reflected signal at *a* is the vectorial sum of the reflection resulting from the mismatch of port *a* plus the signal reflected at *b* reduced by the isolation of the isolator.

properties to form practical devices, most are included in the following general categories:

1. Terminated circulators
2. Faraday rotation isolators
3. Resonance isolators
4. Field displacement isolators

All these isolators differ from the ideal. In evaluating these different types of isolators, important characteristics that must be considered are forward and reverse insertion loss and the frequency bandwidth over which those values are obtained as well as the power handling capability. Some approaches are more applicable to some frequency ranges than others, and they differ in their applicability to different transmission media such as waveguide, coaxial line, or microstrip.

The following discussions describe the operation of these different types of isolators and compare their characteristics.

1. TERMINATED CIRCULATORS

Microwave circulators are described in detail in another article of this encyclopedia and are devices with three or more ports with low loss, for example, from ports 1 to 2, 2 to 3, and 3 to 1 as illustrated in Fig. 4a. Ideally they are lossless and are described by

$$S = \begin{bmatrix} 0 & 0 & S_{13} \\ S_{21} & 0 & 0 \\ 0 & S_{32} & 0 \end{bmatrix} \text{ where } |S_{13}| = |S_{21}| = |S_{32}| = 1 \quad (2)$$

Terminating port 3 of a three-port circulator (Fig. 4b) in a matched load results in an isolator between ports 1 and 2.

Figure 4. Connecting a matched load to port 3 of a three-port circulator forms a two-port isolator.

The isolation depends on the match between the termination and port 3 of the circulator.

The circulator may be constructed in any of the many forms described elsewhere, such as waveguide, stripline, microstrip, or lumped constant, and at frequencies from UHF to millimeter wavelengths. In addition to being compatible with the wide variety of transmission media, the terminated circulator approach has a significant advantage over other types of isolators in that the nonreciprocal function performed by the circulator is entirely separated from the problem of dissipating the energy of the signal propagating in the reverse direction. Thus, in applications where a large amount of reverse power must be dissipated, a high-power load, with external cooling if necessary, can be provided; or in low-power applications, a miniature termination such as a chip resistor can be integrated with the circulator to form a compact device.

The successful development of junction circulators in many forms and over a wide frequency range has resulted in the terminated circulator being the most common type of ferrite isolator.

2. FARADAY ROTATION ISOLATOR

The Faraday rotation isolator (1) was one of the first types of microwave ferrite devices. Its operation can be described with reference to Fig. 5. The Faraday rotator section consists of a ferrite rod at the center of a circular waveguide with its axis parallel to that of the waveguide. A DC magnetic bias field is applied along the axis of the ferrite rod. It is a property of the Faraday rotator that, if the input to the rotator section is a signal in the TE_{11} mode of circular waveguide, the orientation of the E field will rotate as the signal propagates through the rotator as shown. This Faraday rotation can be demonstrated theoretically by considering the linearly polarized field in the circular waveguide section to be composed of two counterrotating circularly polarized modes. The magnetized ferrite can be shown to present a different microwave permeability to the two counterrotating modes, which therefore propagate with different velocities, resulting in the rotation of the total field pattern [2].

Figure 5. A Faraday rotation isolator.

To make an isolator from this Faraday rotator, rectangular-to-circular waveguide transitions are placed at the input and output with matching provided to the ferrite-loaded section. Resistive cards are placed across the circular sections of the guide at both the input and output. An incoming signal from port a will go through the rectangular-to-circular waveguide transition transforming to the TE_{11} mode in the circular guide with the E field perpendicular to the resistive absorber. Thus the signal is transformed with low loss to the ferrite-loaded section. The ferrite-loaded portion of the guide is terminated at the point where the E field has been rotated by 45° , where it passes another resistive absorber oriented perpendicular to the E field and enters the transition back to the rectangular guide. Thus, the signal passes with low loss to the output port b .

On the other hand, if a signal is applied to port b , it again passes with low loss to the ferrite-loaded section, where it is rotated so that at port a it is oriented with the E field parallel to the resistive absorber. The signal is then attenuated by the absorber.

The Faraday rotation isolator was one of the first microwave ferrite devices to be introduced, but it suffers from several performance limitations. The rotation in the basic device of Fig. 5 is frequency-dependent, so the isolator is narrowband. In addition, the rotator is inherently a low-power device because of its geometry. The ferrite and the absorber are thermally isolated so that the power that can be handled, especially in the reverse direction, is limited. Techniques have been developed to increase the bandwidth over that of the basic device [2,3]. For example, dielectric loading, ridged waveguide, and cascading of stagger-tuned sections have been used to produce acceptable performance over bandwidths of several gigahertz at X band, but because of its limitations the Faraday rotator has largely been superseded by the other isolator approaches discussed here.

One version of the Faraday rotation isolator that still finds application was described by Barnes [4]. In this approach, instead of using a circular waveguide loaded by a ferrite rod, the conducting waveguide walls are eliminated, and the ferrite rod is increased in diameter so that the ferrite becomes a dielectric waveguide. The high dielectric constant (typically between 12 and 15) of the relatively large ferrite rod confines most of the energy to the ferrite.

The details of this type of isolator are described in detail by Barnes [4]. The rotator consists of a short length of ferrite rod suspended in a nonconducting housing by plastic supports and is coupled to the input and output rectangular waveguides by dielectric tapers that protrude into the waveguides. The attenuator films that provide the reverse loss are deposited metal films sandwiched into the tapered dielectric waveguides.

Barnes shows that, because the dielectric rod guide with approximately 95% of the energy confined to the ferrite behaves much like an infinite ferrite medium, the Faraday rotation is less dependent on frequency than in a ferrite-loaded metal waveguide. Figure 6 shows the performance reported by Barnes for a 50–60-GHz isolator, along with the performance of a “conventional” Faraday rotation isolator. Because of its broadband performance

Figure 6. Performance of the broadband isolator of Barnes (solid curves) compared with a “conventional” Faraday rotation isolator (dashed curves) [4]. (Copyright © 1961 IEEE.)

and low magnetic bias field requirement, this approach has proved to be useful for broadband millimeter wavelength isolators.

3. RESONANCE ISOLATORS

The resonance isolator makes direct use of the phenomenon of ferromagnetic resonance, characterized by the precession of the magnetization vector in a ferrite about the direction of an applied DC bias field [2]. In an unperturbed state, the direction of the magnetization vector of the ferrite is aligned with an applied bias field. Any disturbance, such as a momentary magnetic field applied perpendicular to the bias field, will cause the magnetization to precess about the direction of the bias field, as illustrated in Fig. 7. After the perturbation is removed, the precession will decay at a rate that depends on the magnetic losses of the material, until the magnetization is again aligned with the DC field.

The frequency of the precession, the ferromagnetic resonance frequency, is proportional to the DC field. In an

Figure 7. When perturbed from the steady state, the magnetization M will precess about the bias field H_b at the ferromagnetic resonant frequency.

infinite ferrite medium

$$f_0 = \gamma H_{dc} \tag{3}$$

where, in the commonly used units, γ is 2.8 MHz/oersted. In the case of a finite ferrite element such as a plate or rod, the demagnetizing factor of the sample must be taken into account to relate the applied bias field to the internal field that determines the resonant frequency. For readily achievable magnetic fields, this resonant frequency is in the microwave region. Microwave signals near the resonant frequency with magnetic fields perpendicular to the bias field will interact strongly with the ferrite magnetization. In particular, circularly polarized fields in the plane perpendicular to the bias field will interact strongly if the sense of polarization corresponds to the direction of the resonant precession but only weakly if the sense of circular polarization is opposite to the direction of the precession.

Now consider a rectangular waveguide operating in the fundamental TE_{10} mode. Figure 8 shows the magnetic field of this mode, looking down on the broad face of the guide. At point A in the guide, the magnetic field will be circularly polarized in the counterclockwise direction for a signal traveling from left to right and in a clockwise direction for a signal traveling from right to left. If a ferrite is placed in the waveguide at this point and biased by a DC field, as shown in Fig. 9, the ferrite will interact strongly with a signal in the waveguide with a frequency near the ferromagnetic resonant frequency when the direction of propagation is such that the sense of circular polarization corresponds to direction of the ferromagnetic precession. The interaction will be weak for a signal traveling in the opposite direction. By proper design, the parameters such as the dimension and location of the ferrite, ferrite material properties, and bias field can be chosen so that, at frequencies near the ferromagnetic resonance frequency, excellent isolator performance can be achieved.

In principal resonance isolators can be constructed in any transmission line where circularly polarized radiofrequency (RF) magnetic fields exist. For example, they have been built with various degrees of success in dielectric-loaded coaxial line, finline, dielectric waveguide, and image line; however, by far the largest application of the resonance isolator approach is in rectangular and ridged waveguide where extensive analysis and optimization has resulted in devices with very attractive properties.

Figure 8. At point A the RF magnetic field for a signal traveling from left to right in the fundamental mode of the rectangular waveguide will be circularly polarized in the counterclockwise direction.

Figure 9. In this basic resonance isolator, the ferrite will interact strongly with a signal in one direction but not with one in the opposite direction.

Of the possible geometries illustrated in Fig. 10, Fig. 10b has demonstrated advantages over Fig. 10a. Placing the ferrite in a thin strip along the broad waveguide wall allows efficient dissipation of the heat produced in high-power operation. In addition, the magnetic fields are more nearly circularly polarized in the configuration of Fig. 10b than in Fig. 10a, and experiments of Weiss [5] have shown Fig. 10b to have a superior ratio of isolation to forward insertion loss. This ratio of isolation to forward insertion loss is a figure of merit used to compare different isolator configurations. The figure of merit for Fig. 10b was determined by Weiss to be 75 compared with 14 for Fig. 10a. Further improvement can be achieved with dielectric loading as illustrated in Fig. 10c. The dielectric concentrates the energy in the vicinity of the ferrite and increases the figure of merit to 150.

Resonance isolators in rectangular waveguide have been developed to give good performance over a full waveguide bandwidth (e.g., 30 dB isolation, 1 dB forward loss, and 1.15 VSWR over 8.2–12.4 GHz, or 12.4–18 GHz).

Such resonance isolators are large and heavy because of the permanent magnets required to bias the ferrite to ferromagnetic resonance at microwave frequencies (approximately 1.5 kg in the case of the previously mentioned 8.2–12.4-GHz and 12.4–18-GHz isolators). This becomes a serious problem at higher frequencies. Because the DC field required to bias the ferrite to resonance is proportional to frequency, at millimeter wavelengths this field becomes quite large, on the order of 1.5–3.5 T or more. In order to minimize the size and weight of millimeter

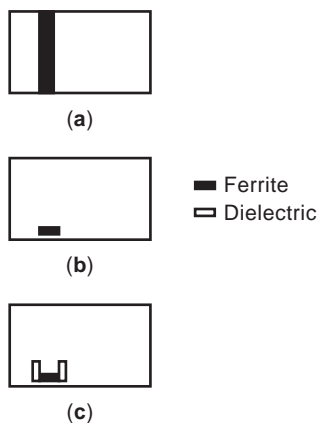

Figure 10. Three different configurations for a resonance isolator in rectangular waveguide.

Figure 11. A resonance isolator using hexagonal ferrites.

wavelength resonance isolators, devices have been developed making use of magnetoplumbites, often called *hexagonal ferrites* [6]. Such materials have a strong anisotropy field. All ferrite materials exhibit a certain amount of magnetic anisotropy because, in the individual crystallites that make up the material, the crystalline structure produces a preferred direction for the orientation of the magnetic moment vector. In a typical polycrystalline ferrite, however, these microscopic crystallites are randomly oriented with respect to each other, so that in the bulk material the effect of the anisotropy of the individual crystallites averages out, resulting in an isotropic material.

The materials most useful for resonance isolators are the so-called uniaxial compounds that possess a large anisotropy field along the *C* axis of the hexagonal crystals. By special processing used to produce the ferrite material, for instance by pressing the slurry of the appropriate material in the presence of a large magnetic field before firing, it is possible to produce a material in which the individual crystallites are oriented in a particular direction. This results in a large anisotropy field that in some ways is indistinguishable from an externally applied bias field. In this way, it is possible to make self-biased materials, or materials that require very little applied field to bias them to resonance at millimeter wavelengths.

Such an isolator is illustrated in Fig. 11. Thin slices of the hexagonal ferrite material are bonded to the dielectric slab, which serves to concentrate circularly polarized magnetic fields in the ferrite. In order to achieve wide bandwidth, the isolator may consist of a cascade of several sections of ferrite materials with different anisotropy fields and dielectric characteristics. Additional small permanent magnets can be used to achieve the correct resonant frequencies for the different sections. Figure 12 shows the performance of an isolator of this type weighing only 160 g. Materials have been developed enabling such isolators to be built at frequencies to 110 GHz.

4. FIELD DISPLACEMENT ISOLATORS

Field displacement isolators can be of many types but are all based on the fact that, in a transmission line loaded by a magnetically biased ferrite, the field pattern may exhibit nonreciprocal behavior by being distinctly different for the two directions of propagation. An isolator can then be built by judiciously locating dissipative material in an area where the fields are intense for one direction of propagation but weak for the other.

Figure 12. Performance of a 33–50 GHz isolator using hexagonal ferrites [6]. (Copyright © 1963 IEEE.)

Figure 13 illustrates an early type of isolator based on this principle [7]. As in the resonance isolator, a ferrite slab is introduced into the rectangular waveguide, and a DC magnetic field is applied across the narrow dimension of the waveguide; however, in this case the bias field is less than that required for ferromagnetic resonance. With an appropriate choice of dimensions, ferrite properties, and magnetic bias, the resulting field pattern for the two directions of propagation can be as shown with a concentration of electric fields at one surface of the ferrite in one direction and minimal electric field at that surface for the other direction of propagation. If a sheet of resistive material is placed at this surface of the ferrite, it will dissipate energy for one direction and have very little effect on the other. An isolator of this type can produce, for example, isolation of greater than 30 dB over the 5.9–6.4 GHz band with a forward loss of less than 0.25 dB [8]. The isolator of Fig. 13 was one of the earliest types of microwave ferrite devices, but it has largely been supplanted by the other types of isolators.

One more recent type of field displacement isolator that has significant unique advantages, particularly in regard to broadband operation, is the peripheral mode, or edge-guided, isolator. This device uses the edge-guided mode analyzed by Hines [9]. Circulators and isolators using this mode of propagation were patented by Anderson [10].

The analysis by Hines revealed that in a stripline, or microstrip transmission line, with a wide center conductor and ferrite as the dielectric medium, and with a magnetic bias field perpendicular to the ground plane(s), a mode of

Figure 13. A field displacement isolator in a rectangular waveguide.

Figure 14. Fields in a ferrite-filled stripline as analyzed by Hines [9]. (Copyright © 1971 IEEE.)

propagation exists in which the energy concentrates toward one edge of the center conductor. The fields of this mode in stripline are illustrated in Fig. 14. The fields are similar to transverse electromagnetic (TEM) modes except for their displacement to one side or the other of the center conductor, depending on the direction of the bias field with respect to the direction of propagation. Hines has shown that for a very wide center conductor in comparison to the ground-plane spacing, with a weak bias field, sufficient only to saturate the ferrite, this mode of propagation is free of dispersion and has a constant characteristic impedance over all frequencies.

Because the energy is concentrated at one edge of the center conductor, an isolator can be constructed by placing lossy material along one edge of this conductor. One direction of propagation will be unperturbed by this material, while a signal in the opposite direction can be strongly absorbed. Such an isolator is illustrated in Fig. 15. In the idealized case, this isolator would have infinite bandwidth. In practice, the bandwidth is limited by low field losses at low frequencies, by higher-order modes at high frequencies, and by the difficulties in matching at the input and output to or from a conventional stripline or coaxial line. Nevertheless, very broadband isolators can be achieved using this approach. Hines reported the results shown in Fig. 16 for a basic microstrip configuration and in Fig. 17 for the case of added capacitive loading along the low-loss edge. Thus the approach yields performance acceptable for some applications over a multioctave band.

The isolators described in this article are those that have found significant application in microwave systems.

In recent years development of microwave isolators has continued with most effort being devoted toward development of isolators compatible with newer types of transmission lines, particularly for application at millimeter wavelengths. For example isolators have been developed for use with finlines [11,12], image lines [13], and quasi-optical transmission lines [14]. These isolators will become important as these transmission media find application.

MICROWAVE LIMITERS

ROGER KAUL
U.S. Army Research Laboratory

A microwave limiter is designed to allow low-power signals to pass through it, while attenuating high-power signals. Stated another way, microwave limiters are power-dependent attenuators that prevent intense microwave energy from interfering with susceptible microwave components in the latter stages of a cascade.

Most limiters operate by reducing the impedance of a transmission line when the incident power is above the threshold power level, reflecting or absorbing the incident power. Although, in most cases, a limiter reflects the majority of the intense incident power back toward the power source on the transmission line, where a circulator, an isolator, or a hybrid coupler may divert or absorb it, a microwave limiter may also be designed to absorb the incident power in the same manner as a microwave switch.

In most applications, microwave limiters (sometimes referred to as *receiver protectors* and *terminal protection devices*) are located near the antenna port. However, limiters have also been used in intermediate-frequency channels, where signals from a number of channels are combined to create an intense signal (e.g., the intermediate frequency circuit of a phased-array radar). In radar applications, the term "duplexer" is sometimes used to refer to the front-end receiver protection circuitry.

Table 1. Common Microwave Limiter Technologies

Technology	Common Implementations
Solid-state	p-i-n diode MESFET
Gaseous	Waveguide Stripline
Ferrite	Filter Stripline

Many microwave limiter technologies have been investigated since the midtwentieth century. The common technologies are identified in Table 1. The solid-state limiter, which was first designed using the varactor diode, today employs the Si p-i-n (or PIN) diode, because of the p-i-n's lower capacitance per unit area resulting in better thermal characteristics, in addition to the fact that it requires no external power supply. Also shown in the table is the fact that a MESFET-based, MMIC-compatible microwave limiter is being developed for integration with the low-noise amplifiers common in MMIC designs. Furthermore, although gaseous limiters are widely used in high-power radars as receiver protectors, ferrite limiters have not found the same wide use.

1. SOLID-STATE LIMITERS

At radiofrequencies, it is common to place back-to-back signal diodes (e.g., 1N914) shunted to ground across the input transmission line of a radio receiver, as shown in Fig. 1a. When the peak voltage on the line exceeds the forward conduction voltage (typically, 0.7 V) the transmission line voltage is clipped. Below the threshold voltage, the diodes appear as shunt capacitors across the line. The high capacitance of the 1N914 prevents the extension of this design to microwave frequencies, where the capacitive reactance becomes very low, yielding an undesirable impedance discontinuity, shunting the transmission line that must be tuned out to retain a small voltage standing-wave ratio (VSWR) at low line voltages. The additional reactance narrows the bandwidth of the transmission line, which may be unacceptable.

1.1. p-i-n Diode Limiter

The p-i-n diode has a lower capacitance for a given cross-sectional area than other diode designs, because the distance between the p⁺ and n⁺ regions is separated with the i (intrinsic) region, whereas in other signal diodes, only the depletion region separates the two highly doped regions. The i-region thickness of a p-i-n diode is typically in the 1–200 μm range, whereas other diode depletion regions are typically less than 2 μm. A good measure of the i-region thickness (h) is the reverse breakdown voltage (V_b) at a few microamperes. Several relations are used, including $V_b = 36h^{0.81}$ [1] and the simpler rule of thumb $V_b = 20h$ for $h \geq 5$, where V_b is in volts and h is in micrometers.

Since the capacitance of a parallel-plate capacitor is inversely proportional to the separation distance of the charged plates (represented by p⁺ and n⁺ charge

regions), the p-i-n diode has significantly lower capacitance per unit area at zero bias than a signal diode. This feature allows the p-i-n diode to be a high reactance connected in shunt across a transmission line even at microwave frequencies, yielding low insertion loss. The feature also provides more volume than a signal diode for dissipating heat from intense incident pulses.

The i region changes the terminal current-voltage relationship, as compared to other minority-carrier (e.g., signal) or majority-carrier (Schottky) diodes. Varactor diodes have carrier distributions similar to thin i-region p-i-n diodes. For this reason, varactor diodes were used as limiter diodes until the special doping profile of the p-i-n was developed. Leenov [2] studied the p-i-n diode configuration and determined that, at frequencies lower than the inverse transit time of the i region, the diode rectifies with a low series resistance. At very high frequencies, the charge distributions at the edges of the i region oscillate with the applied terminal voltage; however, since carriers do not have time to transit the i region, the current is primarily a displacement current and the diode impedance remains high. Leenov found that, when excited with a sine wave, the diode resistance is

$$R = \frac{10^{-4}kT}{q(D/2\pi f)^{1/2}} \left(\frac{Z_0}{P_i} \right) h \quad \Omega \quad (1)$$

where k is Boltzmann's constant ($1.38 \times 10^{-23} \text{ W} \cdot \text{s/K}$), T is the absolute temperature (K), q is the electron charge ($1.6 \times 10^{-19} \text{ C}$), D is the diffusion coefficient ($15.6 \text{ cm}^2/\text{s}$ for Si), Z_0 is the impedance of the transmission line in ohms, and P_i is the incident power in watts. Garver [3] uses Eq. (1) to show that the attenuation α provided by a single diode across a transmission line is

$$\alpha = 10 \times \log \frac{(q/kT)^2 D Z_0 P_i}{8 \times 10^{-8} \pi f h^2} \quad \text{dB}$$

The attenuation is proportional to the $\log(1/fh^2)$ for a given impedance and p-i-n device material. At higher frequencies, the h must be reduced, resulting in a higher shunt capacitance per unit area for the diode and increased low-power level attenuation or bandwidth limiting. To compensate for this effect, the cross-sectional area of the diode is reduced. Brown [4] showed that the device thickness should be less than about 25 μm at 0.1 GHz to 2.5 μm at 10 GHz in order to avoid high spike leakage, high power absorption during the transition from the high-impedance diode state to the low-impedance diode state, and low insertion loss at low signal levels. Spike leakage is the momentary power that passes through the limiter before the diode's impedance reduces, thus reflecting the incident power back toward the source. Fast-risetime, incident pulses will appear to have a "spike" of leakage power at the output of the limiter.

Since the performance of the p-i-n diode depends on the ability of carriers to transit the i region, transient effects occur that are dependent on frequency and other parameters (e.g., i-region doping density). For example, Fig. 2 shows the voltage-time waveform of a limiter consisting of

20- μm Si p-i-n diodes closely spaced in shunt with a 50- Ω transmission line as shown in Fig. 1a with $l \cong 0$ at four incident voltage amplitudes. Note that this circuit is shown only to present the concept; actual limiters might use thinner i-region diodes arranged in another configuration (see Figs. 1b-1f). All these circuits allow rectified current to flow through both diodes. Leenov [2] showed that a DC current is much more efficient in lowering the p-i-n diode's impedance than an RF current. Unless this

rectified current is allowed to flow in a low-impedance circuit (typically less than 5 Ω), the p-i-n diode resistance may not be reduced to a few ohms (typical). The voltage-time waveforms on the left in Fig. 2 are the incident voltage at 1.1 GHz, and the waveforms on the right are the voltage following the dual-diode limiter. The p-i-n diodes do not clip the incident wave as would a high-speed signal diode; rather, their impedance is reduced by injection of carriers into the i region. At the lowest incident voltage V_i ,

Figure 1. Diode limiter equivalent circuits.

Figure 2. Incident and output voltage-time waveforms for a p-i-n diode limiter.

the attenuation (insertion loss) of the limiter is $20 \log_{10}(V_o/V_i) \approx -1$ dB, where V_o is the output voltage. As the V_i is doubled, the V_o tends to show an initial transmission transient (termed “spike leakage”), followed by a relatively constant output voltage (termed “flat leakage”). It requires tens of nanoseconds for the two diodes to lower their impedance below the Z_o of the transmission line. However, the spike leakage period would be much more rapid if the *i* region were thinner or the 20- μm diodes were excited at a lower frequency. The amount of energy in this period (i.e., the integral of the power-time profile) is the spike energy that may destroy susceptible microwave devices in cascade with the limiter. As a rule of thumb, low-noise, microwave amplifiers will be destroyed if the spike energy exceeds 1 μJ , and destruction of microwave mixers will occur at the 10 μJ level. If the spike energy must be reduced, the second limiter diode with a thinner *i* region is located with a quarter-wavelength behind the first limiter diode as shown in Fig. 1a with $l = \frac{1}{4}$ wavelength.

A commercial limiter using three p-i-n diodes shunting a soft-substrate, 50- Ω transmission line is shown in Fig. 3. The thinnest p-i-n diode is located near the output receiver port, of the limiter and activates first, setting the threshold for limiting. The 10-turn coil allows the rectified

current to flow through the diode(s). The standing wave reflected from the thinnest diode excites the middle diode, and the thickest diode is activated at higher incident power levels. At signal levels below threshold, the bandwidth (defined by $\text{VSWR} \leq 1.6 : 1$) of this limiter design is 2–8 GHz, with an insertion loss less than 1.3 dB. The limiter is specified to sustain a 3 W continuous incident power, with 0.1 W output level. The input-output curve measured at 2 GHz for the commercial limiter (shown in Fig. 4) confirms the flat leakage level at 0.1 W, and the insertion loss at less than 1 dB at the low end of the operating band. The input 1 dB compression point was measured to be 11 dBm, and the input third-order intercept was 18 dBm at 3 GHz and was 15 dBm at 7 GHz. During pulsed operation, the unit will sustain a 1000 W pulsetrain, with a 1 μs length and a 1% duty cycle. The recovery time (defined as the time to return to low insertion loss after the high incident power is removed) is specified as less than 1 μs .

1.2. Spike Leakage

The data in Fig. 2 show that the peak spike leakage power increased and the duration of the spike decreased with increasing incident voltage. The measured spike energy

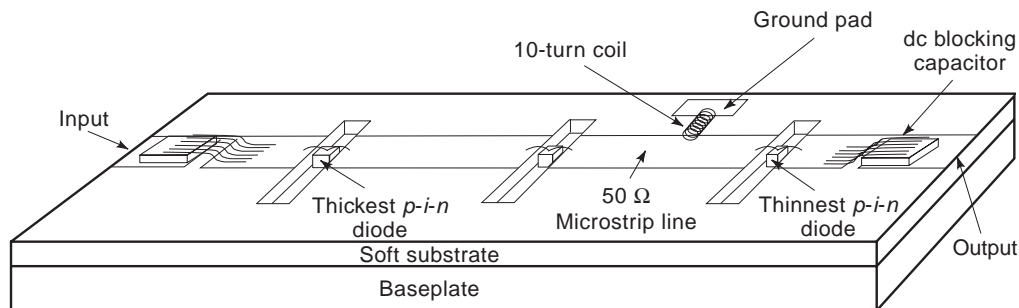

Figure 3. Sketch of a multistage p-i-n diode limiter.

for 1.5 and 5- μm i-region diodes is shown in Fig. 5. Calculations supporting these results (1) show that a slightly p-doped (10^{15} cm^{-3}) intrinsic region would exhibit less spike leakage than does the usual n-doped (10^{14} cm^{-3} or less) intrinsic region. This result arises because a higher density of the lower mobility holes yields a lower impedance i region than in the usual case with the n-doped i region

1.3. Diode Limiter Circuits

Figure 1 shows many configurations of diode limiter circuits. Figure 1a has been discussed previously. Figure 1b is a single-diode circuit in which the rectified current flows through the inductor. Note that since the diode's impedance is lowered at high signal levels throughout the cycle, the single diode does not rectify the positive or negative peak voltages on the transmission line; if that were the case, the maximum isolation would be only 3 dB. The inductor's reactance X_L should be high at the operating frequency, but have a low inductance at frequencies associated with buildup of the rectified current to allow the rectified current to build up rapidly, thereby reducing spike leakage.

In waveguides, the p-i-n diode is mounted parallel to the electric field lines in the lowest-order mode on an inductive post. The equivalent circuit in Fig. 1c shows the reactances of the post in shunt with the waveguide impedance Z_w . For self-activated limiter operation, the low-pass filter for inserting the DC bias is not needed. The

limiters shown in Figs. 1a-1c reflect most of the incident power back toward the source. If this reflected power is undesirable (e.g., an application in which a limiter is used for stealth purposes), a nonreflective limiter (i.e., a power-dependent attenuator, as shown in Fig. 1d) may be required. A nonreflective design developed by Glenn et al. [5] is self-activating but does not provide the same amount of isolation that reflective limiters provide. The nonreflective design is parallel-resonated by the L and C at high signal levels, for added isolation. Nonresonant, nonreflective circuits using resistors are possible; however, resistors provide only moderate levels (10-15 dB) of isolation.

Where spike leakage is a significant problem at high power levels, the delay-line limiter (Fig. 1e) rectifies a sample of the large signal and applies a DC bias to the p-i-n diode, lowering its impedance before the intense signal arrives. The delay line may be implemented in a low-loss coaxial cable yielding an approximate 3 ns delay per meter.

Figure 1f shows the duplexer application for a pulsed, monostatic radar receiver protector. At normal receive signal levels, the balanced duplexer design employs two 3 dB, 90° , hybrid couplers to split the input signal between two diode limiters. Since the limiters are in their high-impedance state, the signals are recombined at the output into the receiver input. If an intense receive signal is present, the p-i-n diodes conduct, and the signal is reflected back into the transmitter's circulator stage, where

Figure 4. Input-output power characteristic of a p-i-n diode limiter.

Figure 5. Spike energy for 1.5 and 5- μm -thick i-region p-i-n diodes.

it is absorbed in the matched load. During transmit, the p-i-n diodes are low impedance and reflect the power out of the antenna port. If the antenna VSWR is high, the transmitter power is rereflected by the diodes and is absorbed in the load of the three-port circulator. This duplexer circuit uses all passive components. If desired, the p-i-n diodes can be externally biased during the transmitter's pulse. If a DC path for the rectified p-i-n diode current is not available through the 3-dB hybrids, one must be provided via shunt inductors or other bias circuitry.

In Fig. 1, all diodes assume no package parasitics. These package parasitics (see Fig. 1g) can have a significant effect at microwave frequencies. The p-i-n diode is represented by the variables C_j and R_j , where C_j is small (typically less than 1 pF) and R_j is large at low signal levels. At high signal levels, R_j is small (typically 1–2 Ω), thereby shunting C_j . R_s represents the series contact resistance of the diode and the resistance of the inductive bondwire L_s to the diode chip. C_p is the package capacitance. Additional details of limiter design in microstrip and waveguide configurations are found in White [6] and Garver [3].

1.4. Unexpected Effects

Some limiters exhibit a hysteresis effect when operated CW, or with long pulses, as sketched in Fig. 4. The sudden increase in the isolation above an input power threshold is retained as the input power is reduced, until the input power equals the value marked A in Fig. 4. If the power is increased again, the original input-output curve is retraced and the threshold can be observed. However, if the input power is not reduced to point A, the lower input-output curve is followed, and a threshold cannot be observed. A plausible explanation, based on space-charge effects, is given in Ward et al. [1]; however, the hysteresis effect needs further experimental investigation.

When connected to high- Q circuits (e.g., filters), limiters may exhibit the nonlinear dynamic effects (chaos) of period doubling and noisy behavior. This behavior was first observed with a limiting filter that utilized a p-i-n diode as a capacitive reactance at the output of a microwave filter structure developed by Tan [7]. Unexpected signal generation by a limiter appears to be avoidable above 1 GHz by using i-region thickness exceeding 3 μm and a circuit Q less than 100. Further experiments and analyses are needed to fully understand and alleviate this device-circuit interaction.

1.5. Limiter Burnout Levels

The CW burnout level of a commercial p-i-n diode limiter is usually only a few watts. It is recommended that the CW power specification not be exceeded since the diode may be operating above its maximum junction temperature or the mounting solder could melt. The same power limitation applies to pulse lengths long compared to the thermal response time of the diode.

Most limiters are also specified for pulsed operation with 1 μs pulselength at 0.1% duty cycle (1000 pps). In general, these ratings are conservative and can usually be exceeded by 3 dB.

Table 2 shows the burnout level results of a limited number of experiments in 50- Ω coaxial circuits for p-i-n diode limiters with varied-thickness i regions. Damage was observed in three stages: (1) reverse current increases causing reduced reverse breakdown voltage, (2) as the diode impedance became lower the insertion loss increased, and (3) eventually fusing occurred and the diode became an open circuit, ceasing its limiting action.

GaAs p-i-n diode limiters have been fabricated and their performance has been measured. There appears to be little advantage to using GaAs, since its lower thermal conductivity cannot transfer the heat generated in the diode to the heatsink as effectively as Si can. However, for GaAs monolithic microwave integrated circuit (MMIC) devices, where high volumes make the specialized assembly of Si technology expensive, GaAs p-i-n devices may be a viable alternative. Fabrication of the GaAs i region is usually an additional process in manufacturing GaAs MMIC devices, incurring higher cost and possibly leading to lower MMIC yields. The reliability of GaAs p-i-n diode limiters have been questioned. GaAs limiters designed for high-power, high-duty-cycle, pulsed operation have degraded and become lossy after a few thousand hours of operation. However, majority-carrier GaAs devices (e.g., MESFETs) do not appear to exhibit this form of degradation.

1.6. MESFET Limiters

MMICs are finding increasing application in today's designs when uniform performance and high quantities can justify the relatively high nonrecurring design engineering costs. Use in applications such as phased-array radars and high-volume consumer products is typical. In these applications, low-noise devices with relatively small physical dimensions are used, resulting in a susceptibility to burnout due to incident short single- or multiple-pulse

Table 2. Single-Pulse Damage Levels for p-i-n Diode Limiters

i-Region Thickness	Pulselength	Frequency (GHz)	Damage Level (kW)	Damage Observed
0.5	10 ns	2.7	30	V_b reduced 1 V
1	1 μs	9.4	0.2	V_b reduced to 12 V
1	1 μs	3.3	1.1	V_b reduced to 25 V
2	10 ns	2.7	135	V_b reduced to 10.5 V
5	10 ns	2.7	> 330	No damage up to 300 kW
10	1 μs	9.4	10	V_b reduced to 9 V

Figure 6. Schematic of a simple MESFET limiter.

energies from 0.1 μJ to 10 μJ . (Most devices can sustain a CW incident power up to 0.1 W without degradation.) A MESFET limiter that operates as a switch has been built using standard MMIC technology, to allow its fabrication along with the circuit that it must protect. This cost-effective approach avoids the requirement for employing mixed technologies (e.g., using an Si limiter with a GaAs MMIC, or adding an i-region fabrication step to the GaAs fabrication process).

The GaAs MESFET limiter circuit in Fig. 6 shunts the transmission line to ground when the gate voltage allows current from drain to source. Note that the location of the drain and source change each half-cycle, based on the instantaneous polarity at the limiter's terminal connected to the transmission line. The MESFET is operated in a bidirectional mode, since no dc bias is required on the transmission line. The R - C voltage divider network that biases the gate is high impedance (typically, $40Z_0 \Omega$), thereby shunting the line. This bias port (V_g) may be used as a switch in applications for which the presence of the high-power incident pulse is known a priori (e.g., the transmitter's pulse in a phased-array radar). When V_g is grounded, a depletion-mode MESFET exhibits low impedance across the transmission line, protecting the front end when not in use. An enhancement-mode version of the MESFET limiter has been developed [8]. It operates in a similar fashion to the p-i-n diode limiter and requires no external bias in the low-loss state.

When the gate is backward-biased (backbiased) at small signal levels, the MESFET represents a small capacitance, consisting of the drain-to-gate and gate-to-source capacitances in series, in parallel with the drain-to-source capacitance. These capacitances are proportional to the gate width for a given MESFET technology. When the gate is not backbiased, the saturated drain-to-source current (I_{dss}) and the drain-to-source resistance are also proportional to the gate width. As a result, the designer performs a tradeoff of the amount of shunt MESFET capacitance allowed across the transmission line, to the peak current that the MESFET can pass (which, in turn, sets the power limit rating) in order to determine the gate width of the MESFET. A typical design (e.g., using a 1 mm gate width) will have an insertion loss less than 1 dB at 10 GHz and sink 0.2 A peak. The insertion loss decreases at lower frequencies because the MESFET's capacitive reactance shunting the transmission line increases. Larger

MESFET widths allow more current with increased insertion loss.

Simple limiter circuits have been refined for specific applications by Vasile [9] and Podell and Stoneham [10].

2. GASEOUS LIMITERS

Gaseous limiters are able to operate over a wide range of incident power levels from a few watts to megawatts. For this reason, gaseous limiters are the technology of choice for the highest-power applications throughout the microwave spectrum. Most gaseous limiter designs have a few percent bandwidth and are suitable for radar receiver protector applications. However, a new TEM design has low insertion loss over several octaves of bandwidth.

Gaseous limiters use the breakdown of a gas in a high electric field to change the impedance across a transmission line. The typical high-power waveguide design shown in Fig. 7 places a quartz tube filled with a noble gas (typically Ar) across the waveguide gap at the point of the highest electric field. The capacitance of the posts is canceled by the inductance of the iris in the waveguide. These two reactances limit the bandwidth to a few percent. Other designs use waveguide windows to contain the gas in the post region. The window design has a lower lifetime because of the increased absorption cross section of the gas (or gas cleanup) with the metal (typically Ni) walls, resulting in reduced gas pressure and performance. Because the quartz absorption cross sections are several orders of magnitude smaller than those made of metals, gaseous limiters using quartz gas reservoirs have useful lifetimes usually exceeding 20 years.

At electric field intensities below the arc threshold, the posts and iris appear to be a resonant circuit across the waveguide. The gaseous pressure, mixture, and electric field intensity in the presence of "seed" electrons set the threshold for the arc. When the arc occurs, the increased conductance across the posts presents a severe mismatch to the waveguide impedance, resulting in significant

Figure 7. Cross section of a gaseous limiter in waveguide.

reflected power. The arc absorbs about 7% (10%, worst case) of the incident power, resulting in heat that must be conducted through the quartz tube to the walls of the waveguide posts. Because quartz has a high melting point, pulsed operation with hundreds of kilowatts incident is possible. The gas pressure and mixture is adjusted according to the Paschen curve (see discussion of gas-discharge tubes) for the desired arc threshold. The seed electrons are provided by a radioactive source or a small microwave oscillator. The tritium source (typically 100 mCu) emits electrons with a half-life of 12.6 years. Since only a few electrons are needed to initiate the arc, the tritium is useful for three half-lives. The tritium is positioned to irradiate the gas between the posts. Goldie and Patel [11] used a small microwave oscillator that continually excite enough gas molecules to provide the “seed” electrons. When Ar is used for the gas the threshold is several watts, with a recovery time of several milliseconds. If the Ar recovery time is too long, a chlorine–oxygen mixture may be used in which the electrons and ions recombine faster (typically within 100 ns), and the arc loss is lower, but the arc threshold is higher (10 W to 20 W). If the flat leakage of the gaseous limiter is too great, p–i–n limiters may be cascaded to remove the spike leakage and lower the flat leakage to an acceptable level.

The wideband gaseous limiter operates on the same principle as the narrowband device. Patel et al. [12] configured a suspended, 50 Ω , stripline with the gas mixture surrounding the transmission line. Units with 6–8 W threshold and 50 W of average power have been built. The device operates over a 30% bandwidth primarily limited by coax-to-stripline transitions at the ports.

3. FERRITE LIMITERS

Ferrites [e.g., yttrium iron garnet (YIG)] are used for tunable filters and other applications. These filters are narrowband devices in which the magnetic spin vectors (magnetic dipoles) of the ferrite are oriented by an externally applied magnetic field (typically, 100 Oe) that can be varied to change the resonant frequency of the filter. The spins on the lattice sites are also coupled to the magnetic field of a microwave signal. If the strength of the signal’s magnetic field exceeds a threshold, energy from the signal’s magnetic field is coupled to the spin vectors of the fixed lattice ions, thereby creating spin waves. These spin waves are able to transfer energy to heat the lattice, removing energy from the incident microwave signal. The process is nonlinear, with respect to incident microwave magnetic field strength, and yields substantially different performance as a microwave limiter. Lax and Button [13] stated that limiting thresholds vary from –25 dBm to 50 dBm.

Carter and McGowan [14] developed a limiter consisting of a ferrite slab mounted against the narrow wall of a waveguide with a 1500 Oe externally applied magnetic field. This ferrite limiter was able to dissipate 10 kW incident pulses. The insertion loss over the 8.9–9.5 GHz range was less than 1 dB. The threshold power and flat leakage power levels were 28 W. At 10 kW incident power, the spike energy was 3 μ J with a spike power level of

Figure 8. Cross section of a frequency-selective limiter.

2.9 kW. The recovery time was less than 20 ns, which is much shorter than that of a gaseous limiter. The threshold and flat-leakage power levels were reduced to <30 mW with the addition of a varactor (thin i-region p–i–n diode) limiter behind the ferrite limiter.

Because of their tunability by varying the externally applied magnetic field by at least an octave, ferrite filters can be used as frequency-selective limiters. They have the ability to attenuate a signal at a frequency selected by the magnitude of the external field, while providing minimal attenuation at nearby frequencies. Adam and Stitzer [15] determined that the bandwidth of the limiting frequencies (typically 50 MHz) is related to the linewidth of the spin-wave coupling. A frequency-selective limiter will attenuate an intentional jamming signal, while an electronic warfare receiver is able to listen to signals on nearby frequencies.

A stripline configuration of the frequency-selective limiter was developed by Adam and Stitzer [15] using single-crystal YIG in place of the usual microwave dielectric material, as shown in Fig. 8. The limiting threshold was about 20 dBm. The ultimate limiting capability of this technique appears to be in the 15–20 dB range. By cascading limiter, amplifier, limiter, and so on, they demonstrated that an incident power range of 60 dB could be compressed to a dynamic range of less than 5 dB.

Ferrite limiters require a significant amount of peripheral support, since they require an external magnetizing field; their insertion losses are usually high (except in the waveguide configuration), necessitating an external amplifier; they are sensitive to temperature variations; and they are large and heavy, when compared to other technologies. For these reasons, they have been used only in applications that require tunability.

4. OTHER LIMITER TECHNOLOGIES

4.1. Multipactor

Experimentation has been taken place using numerous other technologies, with mixed success. A summary of some of the technologies appears in Table 3.

The multipactor takes advantage of secondary electron resonance (multipacting) to provide low impedance across a waveguide. The multipactor is usually configured as the first stage of a two-stage limiter, since it limits the power to only several watts. The second stage is a p–i–n diode limiter, with a flat leakage of less than 100 mW.

Table 3. Other Limiter Technologies

Technology	Performance	Status
Multipactor	Excellent, requires external biases	Implemented in waveguide configurations
Bulk Window switch array	Excellent millimeter wave switch	Limiter performance untested, difficulty making thin <i>i</i> region
Electrooptic	Fair, requires laser and optics	Relatively high insertion loss
Superconductor	Fair, 50 ns turnon	Demonstrated at 10 GHz
Field emitter array limiter	Unknown	Needs fabrication on low-loss substrate
Varistor paint	Unknown	Initial attempts failed
Temperature-dependent resistor	Fair	Only analyzed to date

Multipacting is an electron avalanche phenomenon operating in a vacuum. The multipacting region allows electrons in an alternating electric field to flow across a gap in less than a one-half cycle of the field. Both surfaces of the gap are coated, so that the secondary electron emission coefficient δ is greater than 1. The incident electric field accelerates the electrons toward one of the gap surfaces. As these initial electrons N_i strike the surface, the RF field changes sign, and the secondary electrons δN_i are accelerated toward the opposite surface. The speed at which the multipactor ignites is $N = N_i \delta^{2if}$, where t is the time and f is the frequency (in hertz) of the electric field. Electron multiplication continues until a space charge in the gap inhibits additional electrons from being emitted from the gap's surfaces. At 10 GHz, the saturated electron density of 3×10^{10} electrons/cm³ is achieved in 0.6 ns. The impinging RF field is reflected by the lower impedance in the gap region and is absorbed by conversion to heat in the electron cloud.

The multipactor gap consists of low- Q resonators in a combline filter configuration. An electron source emits enough electrons (N_i) into the gaps to cause the multiplication to begin on the first few cycles of RF. A supply of oxygen is leaked into the gap region so that the metal oxides continue to have a coefficient δ , since prolonged electron bombardment of the surface reduces the oxides to the metal with low δ . To counter this leak of oxygen, a small ion pump is required. The pump maintains a vacuum pressure suitable to enable the electrons to be accelerated across the gap without colliding with the oxygen molecules. Clearly, the multipactor is a more complex limiter than the others discussed here. Therefore, it has found only limited application where biases for the ion pump are already available. The multipactor operates within the bandpass of the combline filter, while the filter protects the receiver's front end from intense signals out of band. Measured performance of a 9.6-GHz multipactor had a 12% bandwidth (VSWR < 1.6:1), would attenuate a 50 kW pulse to a 50 mW flat leakage with a 2 μ J spike energy, and had a recovery time of less than 15 ns. Below threshold, the insertion loss was 1.5 dB, due to the combline filter [16].

4.2. Bulk Window Waveguide Switch Array

This switch array (or the monolithic diode array) was developed by M/A-COM Semiconductor Products, Burlington, MA, as a low-loss millimeter-wave switch for use in waveguide applications. The switch consists of a matrix of Si p-i-n diodes grown monolithically onto an insulating Si

substrate. The substrate acts as a carrier, which is attached to a waveguide flange with suitable contacts to apply bias to the switch. The few attempts to operate the switch array as a self-activated limiter have not been successful, apparently because the *i* region could not be designed thin enough at millimeter-wave frequencies to allow the microwave energy to lower the impedance of the p-i-n diodes. However, with external bias, the switch array has sustained operation at 1 kW pulse and 20 W levels at 94 GHz, with a low signal-level insertion loss of only 1 dB [17].

4.3. Electrooptic

The electrooptic limiter uses a coplanar waveguide transmission-line configuration on an electrooptically active, semiinsulating semiconductor as the switched medium. When illuminated with photons that have sufficient energy to excite electron-hole pairs, the coplanar transmission line becomes lossy and absorbs most of the incident power. This limiter design is complicated because it requires an intense light source (e. g., a laser) to create enough electron-hole pairs to provide the level of conductivity modulation of the substrate. The light source is activated above a threshold established by external circuitry coupled to the coplanar line, similar to the delay-line limiter shown in Fig. 1e. An implementation of this limiter design in semiinsulating Si yielded more than 30 dB isolation at 1.7 GHz, with over 100 mW of optical power. The isolation bandwidth was 25%. With no optical illumination, the same limiter had a high insertion loss of 6.5 dB, which was probably due to the high series resistance of the center conductor of the coplanar transmission line.

4.4. Superconductor

High- T_c superconductor (HTSC) films with a superconducting-to-normal transition at 86 K have been fabricated that show a surface resistivity change of 10^5 . Gaidukov et al. [18] fabricated a two-element filter in a 8.0–12.4-GHz rectangular waveguide. The filter used resonant irises spaced a quarter-wavelength apart, fabricated with HTSC film strips across the opening of each iris. In the superconducting state, the film strip appears as a resonant inductor across the iris, with an insertion loss of ≈ 1 dB. The 3 dB bandwidth is ≈ 1 GHz. In the normal state, the film strip is resistive, reducing both the Q and the resonant frequency of the iris, and yielding over 20 dB of isolation. When operated at 65 K with 0.8 μ s pulses, the limiting began at 50 mW, and the pulse shape was unaffected by the limiter up to 0.5 W. With increased power

levels, the pulse shape showed more attenuation later in the pulse, due to the heating of the HTSC film with a time constant ranging from 0.1 to 0.5 μ s. The insertion loss increased about 5 dB during a pulse. If the HTSC film strips are heated with an external current, the dual iris assembly can be used as a switch.

4.5. Field Emitter Array

Field emission from a cathode incorporating a matrix of TaSi₂ rods with final tip radii of curvature in the range of 1–10 nm has been measured at DC. Kirkpatrick et al. [19] showed that the parameters of the Fowler–Nordheim relation depend on the magnitude of the electric field at the tip. The emission is fast enough to be useful at microwave frequencies, when configured as a suspended 50- Ω microstrip (cathode) above a ground plane (anode). The TaSi₂ rods are mounted in an insulating Si substrate. For the limiter application, Glenn et al. [20] used a configuration similar to that shown in Fig. 8, with a vacuum replacing the YIG and a microstrip-to-ground plane spacing of 40 μ m. When the electric field at the tips exceeded a threshold, electrons were emitted that shunted the transmission line, thereby operating as a limiter. As expected, the device worked with a DC threshold voltage of \approx 200 V, providing limiting above 400 W on a 50- Ω transmission line. The device showed a high insertion loss at 1 GHz, which was attributed to losses in the Si substrate.

Two other limiter circuit technologies have been proposed, but have not been demonstrated to date: varistor paint and temperature-dependent resistor. The first technology uses the coplanar waveguide configuration with a varistor paint, shunting the center conductor to the coplanar ground planes. Initial attempts to build this device failed because the fringing electric field from the coplanar line was too low to activate the varistor paint.

The second technology is a highly temperature-dependent resistor (e.g., tungsten) with a small thermal mass, in series with a transmission line. The limiter could be used in series with, or in place of, the bondwire of a susceptible microwave component. However, experimental results indicated that the shunt capacitance of the temperature-dependent resistor was too high, reducing the current heating in the resistor.

5. FUTURE ACTIVITIES

While p–i–n diode limiter technology is rather well developed, several investigations still remain to be conducted. These investigations include: determining why input–output power hysteresis occurs for continuous and long-pulse operation; experiments to determine whether a slightly p-doped i-region diode will have lower spike leakage than do present designs; and determining why GaAs p–i–n devices appear to degrade with intense pulses.

MESFET limiters must be designed to carry higher pulsed currents to enable operation above 100 W, without the requirement for a large gate width. Also, limiters must be developed using the low-noise PHEMT technology, to make them compatible with the amplifiers they must protect.

Although self-activated, high-power, millimeter-wave limiters are not presently available, the monolithic diode array concept appears to be the most likely to have low insertion loss, if the thickness of the i region can be reduced. Furthermore, the monolithic diode array does not increase the loss at low signal levels, due to the distribution of the carriers at the p⁺–i and the n⁺–i transitions.

1. INTRODUCTION

During World War II, intense research and effort in the radar development program brought about the radiofrequency (RF) spectrum extension beyond the usual applications in radiocommunications. Shorter wavelengths induced specific design of reduced dimension laboratory equipment, in order to generate, convey, transmit, and detect higher-frequency signals. By convention, the RF/microwave region ranges between 30 MHz and 300 GHz, since shorter than 1 mm wavelengths require equipment too small to be easily realized.

Voltage, current, and impedance concepts lose their conventional meanings when operating wavelength is approximately equal to the dimensions of the structures under test, and the behavior of propagating electromagnetic waves must be analyzed in terms of electric and magnetic fields. However, as there is no simple and direct way to measure these quantities, it is necessary to resort to indirect methods.

Until the 1960s, microwave measurements were carried out by instruments such as

- *microwave cavities*, for wavelength measurements
- *power sensors*, for power measurements
- *standing-wave-ratio meters* (slotted lines) and waveguide bridges, for impedance measurement

All the techniques were based on scalar measurements combined with precision mechanical measurements (e.g., probe displacement in a slotted line). Vector quantity, such as impedance measurements, were indirectly carried out by making different scalar measurements along a slotted line.

In the 1960s, another type of microwave power measuring instrument was introduced, based on the principle of superheterodyne conversion: the *spectrum analyzer*. This instrument, which has evolved to have wider bands and dynamic ranges and to perform math and calibration, exploits the principle of converting each microwave signal frequency component to an intermediate frequency (IF), where the signal can be more easily detected.

At the same time, the first scattering parameter measurements were performed with the most popular microwave instrument: the *vector network analyzer* (VNA); this instrument is based on subsampling or mixing techniques, to downconvert the microwave signals to an IF frequency, where they can be detected in both magnitude and phase. From the first scalar versions, the instrument evolved into vector measurements, with faster acquisition times and higher (up to 130 dB) dynamic ranges. Up-to-date instrumentation can include a PC microprocessor plus operating

system and perform automatic measurements as well as the required calibrations.

In the following sections, power, spectral, and network analyzer measurements are described. A final section is dedicated to advanced microwave measurements.

2. POWER, SPECTRAL AND NOISE MEASUREMENTS

Since the beginning of the microwave years, the main techniques for microwave measurements were based on *power meters*. Those instruments evolved from traditional bolometer-based systems to diode-based power sensors for peak power measurements; furthermore, the dynamic range increased to 70 dB, from the initial 40–45 dB. Power measurements are also used as primary microwave standards with calorimeters, to correlate microwave power to basic standard units [4,17].

A power meter is typically based on a main unit and one or more power heads; the heads are generally specified with respect to the bandwidth and the power range, while the main unit contains the interface circuits, the head bias control, and, more recently, math and calibration functionalities.

The core of a power head can be a thermistor, placed on a low-frequency resistive bridge, as shown in Fig. 1. The system measures the RF power through a DC substitution technique by keeping constant the total dissipated power (RF + DC), on the thermistor. Since the value of the thermistor resistance changes with the temperature (i.e., the dissipated power), the bridge becomes unbalanced as more RF is injected. The feedback network acts on the bridge DC voltage supply arm to reduce the amount of DC dissipated power and to keep the bridge balanced. In this way, the change of DC voltage corresponds to the amount of RF power injected, and its measurement, usually done with a digital conversion system, provides an accurate measurement of the RF power. Since a change of external temperature may induce the same effect as an RF signal, an identical (and within the same environment) bridge is used, so that a temperature compensation is also applied.

Ordinary power heads are calibrated through a reference chain to the National Power Reference Standard, generally based on a microcalorimeter [61]. An alternative way to measure microwave power is given by the *spectrum analyzer*, which measures the power of each frequency component of an input signal and is based on a superheterodyne conversion.

A simplified scheme is shown in Fig. 2; the local voltage-controlled oscillator (VCO) sweeps over frequency, so that the portion of the input signal which has $f_{in} = f_{VCO} - f_{IF}$ is converted to the IF frequency, then detected and passed to elaboration or display. The sweep of the local oscillator is chosen to cover the desired spectrum of the input signal, while the band of the IF filter determines the frequency resolution of the spectral measurement and is thus called *resolution bandwidth* (RBW). If two adjacent frequency components of the input signal are within the RBW, they are combined together at the filter output and their measurement becomes misleading, as shown in Fig. 3. A large RBW may introduce unacceptable error

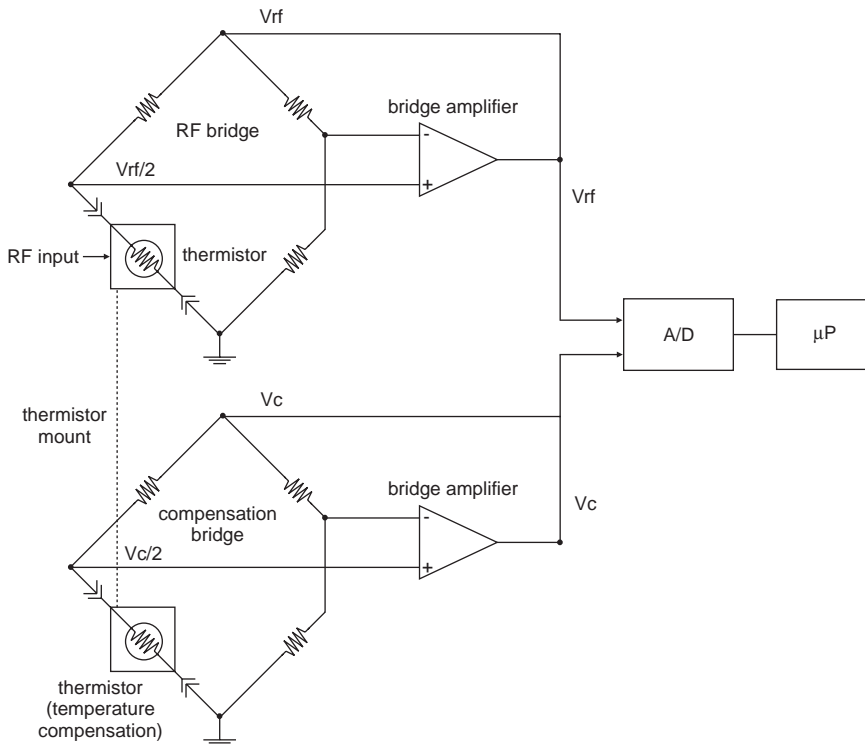

Figure 1. Simplified diagram of a power meter thermistor-based power head.

especially in measurements such as intermodulation distortion.

The RBW is also linked with the measurement speed, since the filter settling time fixes the minimum time required to have a stable output, and thus the maximum change rate of the mixer output. For this reason if a better resolution is required, specifically, a narrow IF band, a slower VCO speed is set.

Another effect of RBW is linked to noise floor. Thermal noise generally prevails over other noise sources, and its contribution is constant versus frequency (white noise). The revealed noise power is thus proportional to RBW. A reduction of a factor 10 on RBW implies a reduction of 10 dB in noise floor.

Unfortunately, noise floor cannot be reduced by rising the value of the input attenuator, since noise main contri-

butions are introduced right after the first converter. Furthermore the RF attenuator reduces the signal-to-noise ratio (SNR) of the measured signal. Thus, in order to maximize the SNR, it's preferable to work with the minimum RF attenuation that gives the minimum distortion of the mixers.

Spectrum analyzers are widely used for noise measurements. The measurement of network properties in terms of noise is especially felt in receiving systems, when noise becomes comparable to signal. To increase the SNR, a reduction of the noise introduced by the receiver components is required. For this purpose, reliable noise measurements are necessary, to characterize the receiver components.

The most popular quality factor for noise performance is the noise figure. It is defined for two port devices [34] as

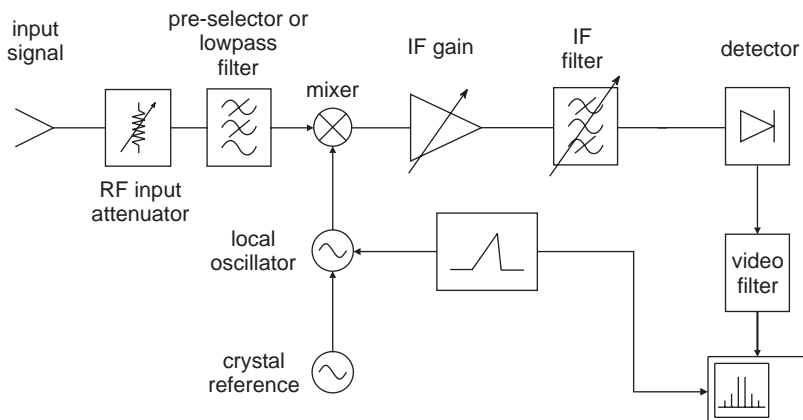

Figure 2. Simplified diagram of a spectrum analyzer with superheterodyne detection.

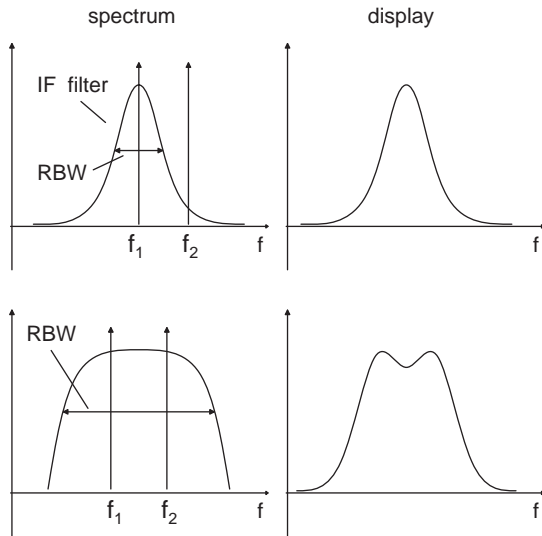

Figure 3. Errors introduced by large RBW in intermodulation distortion measurements. On the left side of the figure, the input signals f_1, f_2 and RBW filter spectra are sketched, while on the right side the corresponding spectrum analyzer displays are shown for a correct RBW configuration (top) and in an erroneous configuration (bottom).

the ratio of SNR input to SNR output

$$F = \frac{S_i/N_i}{S_o/N_o} \tag{1}$$

where S_i, N_i and S_o, N_o are the input and output signal and noise powers.

Any receiver component, such as an amplifier, adds its own noise to the output. Thus noise figure becomes

$$F = \frac{S_i/N_i}{S_o/N_o} = \frac{N_a + G_a N_i}{G_a N_i} \tag{2}$$

where G_a is the amplifier gain ($S_o = G_a S_i$) and N_a is the noise power added by the amplifier, and the overall output noise power becomes $N_o = N_a + G_a N_i$. If the noise can be represented as thermal noise, then the noise output power is:

$$N_o = N_a + G_a k_b B T_i \tag{3}$$

where k_b is Boltzmann's constant, B is the equivalent bandwidth, and T_i is the temperature of the noise source at the input of the amplifier. The noise figure is then

$$F = \frac{N_a + G_a k_b B T_i}{G_a k_b B T_i} \tag{4}$$

Noise figure meters determine the noise added by a DUT (device or design under test) by comparing it to the noise present at the input. Generally, they switch a solid-state noise source on and off to generate two equivalent noise temperature points (T_c and T_h) and measure the corresponding two noise power outputs with a tuned receiver with a fixed RBW. As shown in Fig. 4, N_a is

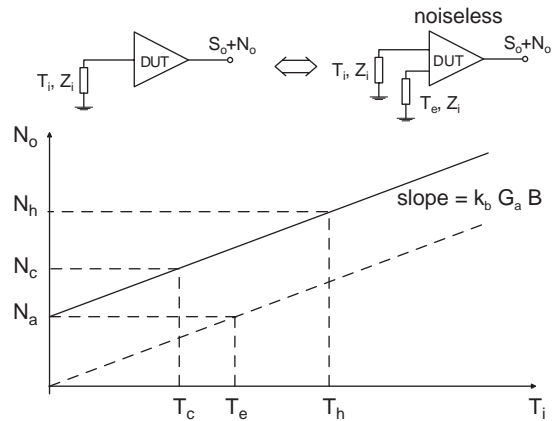

Figure 4. Noise introduced by an amplifier (N_a) is measured extrapolating two measurement points corresponding to T_c and T_h . The situation can be modeled with a noiseless amplifier plus an additional noise source, with equivalent temperature T_e .

computed by extrapolating the straight line to the $T_i = 0$ point. The added noise can be then transformed in an equivalent input noise temperature (see Fig. 4) T_e with $N_a = G_a k_b B T_e$. Finally, with Eq. (4) or

$$F = 1 + \frac{T_e}{T_i} \tag{5}$$

the noise figure F is presented to the user.

3. NETWORK ANALYZER MEASUREMENTS

In the 1960s, the basic principle for network analysis was introduced in an innovative instrument called a *vector voltmeter* [15], which is able to measure a microwave signal in both magnitude and phase.

The idea was the conversion to an intermediate frequency (IF), where the use of ordinary AC voltmeter and phasemeter is possible, of a test and a reference microwave signal, with a synchronous conversion. This is achieved through a subsampling process [7], where a strobe signal, formed by a series of very narrow pulses spaced by the sampling period t_s , samples an input signal, having period $T(t_s \gg T)$, as shown in Fig. 5a. In the frequency domain the strobe signal is again a series of pulses, spaced by $f_s = 1/t_s$, while the input signal is generally a sinusoidal one. The process is called *subsampling* since the sampling frequency is well below the Nyquist one, and the technique can be applied if the input is sinusoidal or with a periodic pattern; thus the microwave signal has an effective bandwidth well below the sampling frequency.

The microwave signal is acquired when the equation $f_{IF} = f_{in} - n f_s$ is satisfied for a certain n value, where $n f_s$ is the strobe signal n th harmonic. By a proper choice of f_s through a PLL (phase-locked loop) technique, the IF frequency can track any change of the input frequency.

By subsampling two microwave signals at the same frequency with two identical sampling pulses, the IF signals keep the same magnitude and phase relationships

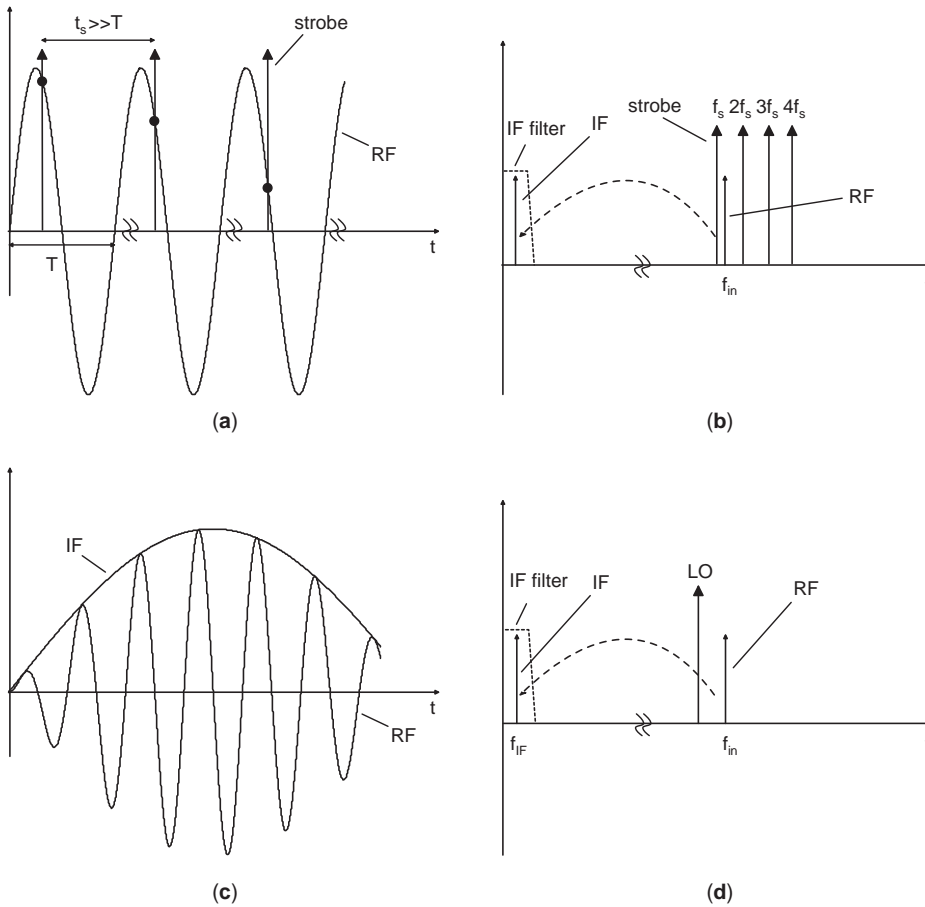

Figure 5. Comparison between sub-sampling process in time domain (a) and frequency domain (b) and mixing process in time domain (c) and frequency domain (d).

existing between the original waves, but at a much lower frequency, so that they can be easily measured in amplitude and phase with ordinary instrumentation [7].

The block scheme of the vector voltmeter is shown in Fig. 6. A PLL technique adjusts the frequency of a voltage-tuned local oscillator (VTLO) that triggers the samplers as explained above. The frequencies out of IF band are rejected by the narrowband IF filter. Therefore, the system becomes frequency-selective and reaches great perfor-

mance in terms of dynamic range, reduction of noise, and resolution. Finally, the two sampled signals are measured with low-frequency A.C. voltmeter and phasemeter, or digitally acquired through S/H (sample-and-hold) and A/D (analog-to-digital) converting circuits.

The phase-locked sampling process is equivalent to a heterodyne conversion with mixers, but with a basic advantage—it does not require a microwave frequency local oscillator to downconvert the input signal, but it only

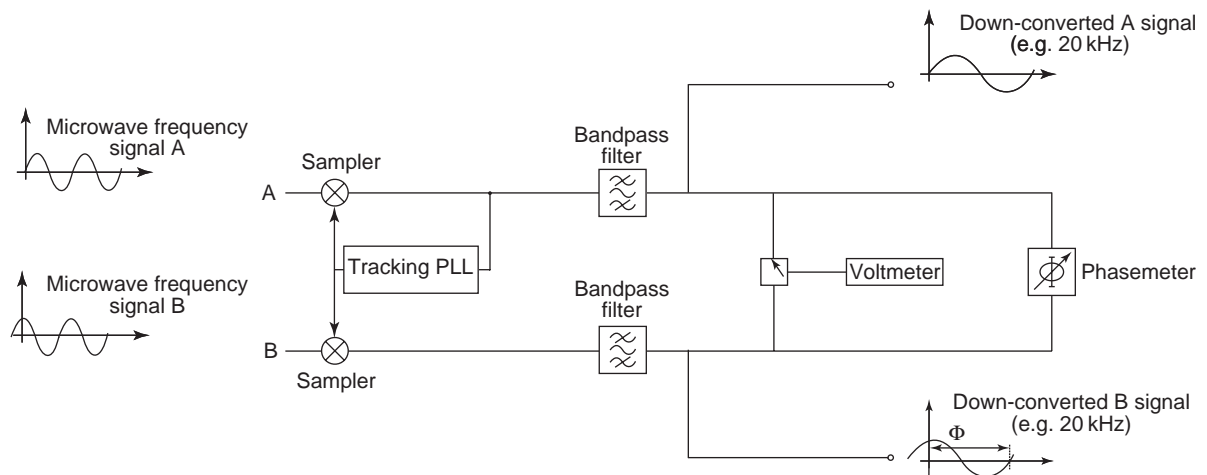

Figure 6. Block scheme of a vector voltmeter based on sub-sampling techniques.

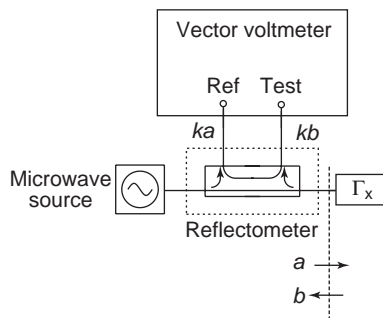

Figure 7. Reflectometer system.

needs a low-frequency pulsed VTLO. As a drawback, the sampler philosophy requires a PLL to tune the VTLO; thus the phase lock is reached after a finite amount of time and it requires a stable reference signal, or it can be lost.

This measurement principle, joined with the introduction of high-directivity, low-loss broadband directional couplers, which separate the forward and reverse traveling waves along a transmission line, formed an alternative system to a direct measurement of reflection coefficients (in amplitude and phase) rather than the classic slotted-line standing-wave ratio meter. As shown in Fig. 7, a directional coupler is used to pick up the forward and reverse traveling waves from the mainline through its coupled arm where the reference and test inputs of a vector receiver are connected. In this way a direct reading of the reflection coefficient is easily obtained.

From the basic reflectometer, an extension of the *S*-parameter measurement system, termed a *vector network analyzer* (VNA), follows immediately.

The VNAs were introduced in the late 1960's [5,38,53] for one-port and two-port device characterization in coaxial environment and since the mid-1970s they became a fundamental testset for all microwave laboratories. While the lower frequency ranges span from 30 kHz to 100 MHz, the upper frequency of commercial systems extended, at the beginning, up to 12 GHz, afterward to 18 GHz, and today it reaches 110 GHz.

A complete VNA is a very complex system, which usually includes

- A microwave synthesized source
- Dual reflectometer testset based on directional couplers or directional bridges and switches to separate and select incident and reflected waves at the device ports
- A multichannel microwave receiver where the separated signals are downconverted
- A central unit for intermediate frequency (IF) detection, A/D conversion, data processing, and presentation [18].

A simplified block scheme of a two-port network analyzer is shown in Fig. 8.

This system allows very broadband measurements with hundreds of frequency points or limited measurement bands with extremely high-frequency resolution (useful for testing high selectivity devices).

Normally, VNAs have coaxial (for very broadband applications) or waveguide measurement ports while DUTs can have leads on microstrip, on-chip contacts, on-wafer ports, and so on. Such mechanical and/or electrical

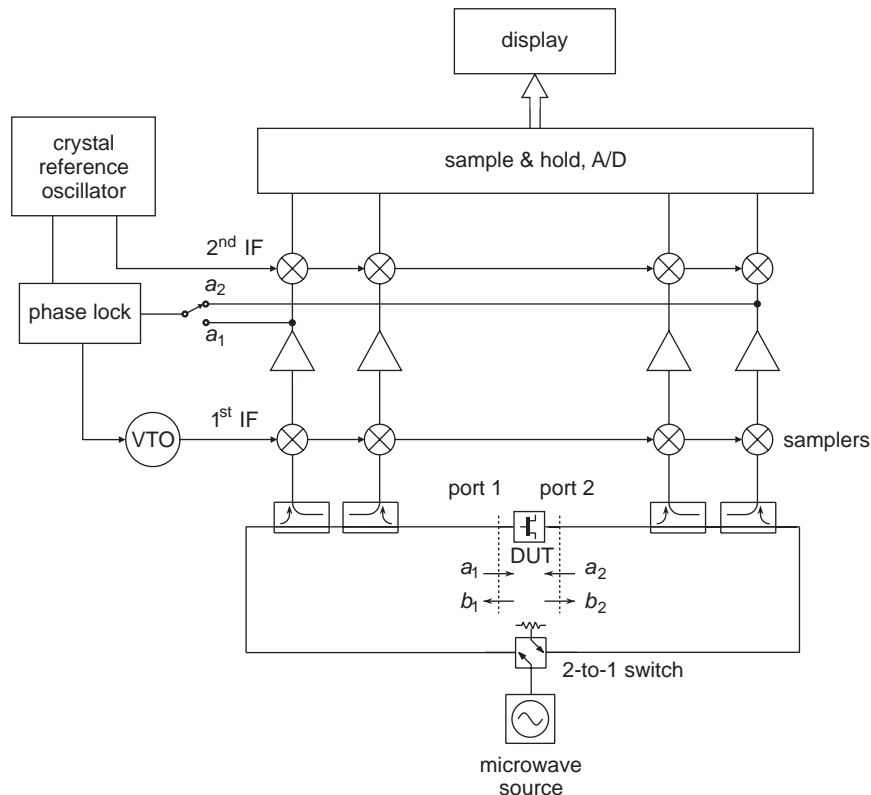

Figure 8. Block scheme of two-port network analyzer [18].

discontinuities from one transmission line to the other require accurate studies of the interface between the measurement equipment and the device to reduce the measurement errors, since they can be only partially corrected by a calibration procedure.

3.1. Calibration of Network-Analyzer-Based Systems

Network analyzer measurements are affected by different kinds of errors and uncertainties, generally classified as

- Random uncertainties
- Drifts
- Systematic errors

Random uncertainties are due mainly to noise and connector repeatability effects, while drifts are typically due to temperature, but the effects of systematic errors overwhelm all the others by at least an order of magnitude. For such reasons the use of an appropriate calibration technique is mandatory for useful VNA based measurements. Typical causes of systematic errors are

- Directional couplers imperfections (directivity, port mismatch, frequency variation of the coupling coefficient)
- Mismatch errors due to adapters and cables
- Coaxial configuration switches losses and mismatch
- Crosstalk

The traditional way to handle such errors was to develop different models based on flowgraph representation of each error effect. The first studies in this field began right after the introduction of vector network analyzers in the 1960s [5,15,63], but it was only with the introduction of microprocessor controlled VNA, like the HP8510, that the so-called *calibration procedures* became common and widely used. Here, a brief overview of how an error removal procedure is organized and the limitations of the today available techniques will be given.

Modern calibration procedures are based on a systematic model of errors that overcomes the traditional approach. The actual VNA is viewed as an ideal system without systematic error followed by a linear network, called *error box*, which models the influence of the systematic errors altogether, as shown in Fig. 9.

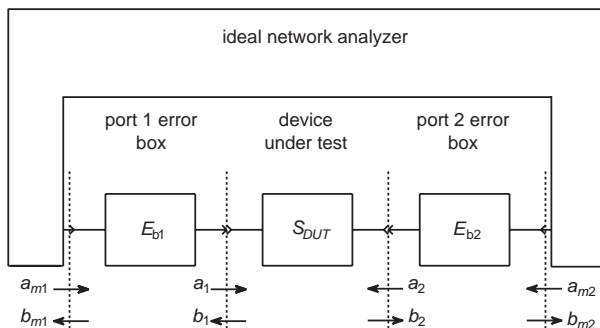

Figure 9. Error box model of VNA systematic errors.

Figure 10. Typical model of coaxial open standards. The nonlinear capacitance depends on frequency. The line parameters (length l_{off} , characteristic impedance Z_{off} , and losses α_{off}) are evidenced in the scheme.

This error model is the basis of all calibration techniques available today, where the various solutions vary according to how they handle identification of the error box parameter. However, the whole approach works if, and only if, the actual VNA can be seen as a perfect linear receiver; otherwise the entire process of error coefficient computation and correction fails, since the error box is everywhere assumed as a linear network (i.e., the relationships between raw and corrected parameters are linear equations). This is a typical case for the current systems with >100 dB of dynamic range, but for accurate measurements of a highly isolated device, it is mandatory to check for proper power levels at each port, in order to quantify the amount of nonlinearity errors [50].

To compute the error box parameters, calibration techniques use a set of precise components called *standards*. Each standard is modeled through electromagnetic simulation or through low-frequency measurement of scaled devices. A typical model for an open standard is given in Fig. 10.

The model parameters are stored inside the VNA and their electrical responses computed during the calibration procedure. The error box parameters are obtained from comparison of the modeled responses and the actual standard measurements.

Different calibrations are normally classified respect to the degree of the standard knowledge they require:

- Calibrations based on well-known standards such as
 - Short (circuit)/open (circuit) load thru (through) (SOLT)
 - Offset shorts (short circuits)
- Self-calibrations such as
 - Thru reflect line (TRL)
 - Line reflect match (LRM)
 - Short (circuit)/open (circuit) load reciprocal (SOLR)

These techniques are only few of the various calibration algorithms available today; furthermore, although originally obtained separately, [2,26–28,31,32,39–41,45,52,64], they are all special cases of a more general theory derived for one- and two-port VNAs [56]. Description of the algorithm is beyond the scope of this section; instead, the focus will be on the differences in terms of accuracy, required standards, and applicability.

The most widely adopted calibration for the two-port VNA is the SOLT, an acronym obtained from the required standards: a short (circuit), an open (circuit), a load, and a

direct port connection, called a “thru.” This technique has been applied since the early years of automatic VNAs, and the corresponding standards are available in almost every environment (e.g., waveguide, coaxial, on-wafer). All VNA manufacturers as well as other independent companies have these standards in their catalogs; this procedure is also available in every VNA firmware. The main drawbacks of SOLT are

- Perfect knowledge of all standards is required.
- A large number of standard connection and measurements are needed.
- A direct port connection (i.e., the thru) is mandatory.

The degree of measurement accuracy following the calibration procedure is strongly contingent on the

- Number of standards implied during the calibration,
- Degree of their knowledge,
- Quality of the interconnections.

The SOLT ideally requires a perfect knowledge of all the standards used, and this condition obviously cannot be achieved.

Other calibration techniques, as TRL or LRM, do not require a complete set of fully known calibration standards, and for this reason they are called “self-calibrations.” In particular, the TRL technique is based on the use of one direct connection (i.e., the *thru*), one reference transmission line of unknown length (i.e., the *line*), and an unknown *reflection*, measured at both VNA ports. Since the direct port connection cannot be considered standard and the reflection is unknown, this technique requires only the knowledge of the line reference impedance.

Furthermore, it has been proved [44] that TRL allows an accurate definition of the scattering parameters in terms of traveling waves referred to the line reference impedance, which is easy to correlate to the line mechanical properties. For this reason, TRL is commonly used as a reference calibration technique at metrology laboratories.

The only significant drawback of TRL is the working bandwidth, which is limited below the resonant frequency of the line. At this frequency, the line does not introduce any phase shift and is undistinguishable from the thru connection (zero length, for definition), thus invalidating the calibration. To overcome this problem, a set of lines of varying lengths is normally used, and their measurements combine to achieve a broad frequency coverage [45].

Another very popular self-calibration method is the line reflect match (LRM) technique. It uses a fully known one-port matched load to substitute the line of the TRL algorithm and is particularly useful for on wafer applications, where probe movement is difficult. Very high-precision laser trimmed resistors are normally used as match standards, offering constant resistance and low parasitic effects up to 50 GHz.

To close this brief overview on the most recent calibration techniques, it’s worth noting the short/open load reciprocal (SOLR) [31], which requires three fully known one-port standards and an unknown, but reciprocal, two-port device. This technique avoids the use of a fully known

two-port device, such as the thru, which is compulsory in all other calibrations. Thus SOLR is very useful in many situations where the direct port connection cannot be achieved or substituted with an accurate two-port device, such as when the DUT ports have the same gender or when they are too far apart.

More recently, rather than describing the standards through electrical models, a precharacterization technique has been used. The standards are measured in a certified laboratory with TRL-calibrated VNAs, and data files substitute the standard electrical models.

This approach is widely used for the so called *electronic calibrator* module, generally a pin (positive–intrinsic–negative) diode network that presents a precharacterized series of electrical states that simulate the different standard insertions. The user connects only the electronic calibrator to the VNA, while a computer changes the impedance shown by the module at its ports and measures them through the VNA, as they would be different standard connections. The error boxes are computed using a SOLT-adapted algorithm [25,60,66], where the standard parameters are substituted by the previously measured data files.

3.2. Time-Domain Reflectometry

The technique of time-domain reflectometry (TDR) was introduced in the early 1960s as a simple way to characterize the position and type of a reflection along a line, using an oscilloscope. In particular, using a step generator and sampling the reflected waveform with an oscilloscope, the impedance of simple discontinuities could be calculated [58].

While the traditional TDR was useful as a qualitative tool, it has some limitations affecting its accuracy and utility:

- Limited risetime
- Sampling scope jitter
- Poor dynamic range
- DC path needed

Common TDR systems based on sampling scope and step or pulse generator, such as the one sketched in Fig. 11, are still commonly used, especially for digital bus characterization. After the introduction of VNA and digital signal processing, it was clear that the reflection coefficient as a function of time could be easily obtained by the inverse Fourier transform of the network reflection coefficient as a function of frequency, which is normally measured by the VNA. This technique, called *synthetic TDR*, is now widely adopted in every VNA and is used in many fields, from cable discontinuity detection to parasitic interconnection modeling.

The use of frequency-domain data, followed by data processing, has several advantages over the traditional TDR, in particular

- Exact knowledge of the step or pulseshape and equivalent bandwidth

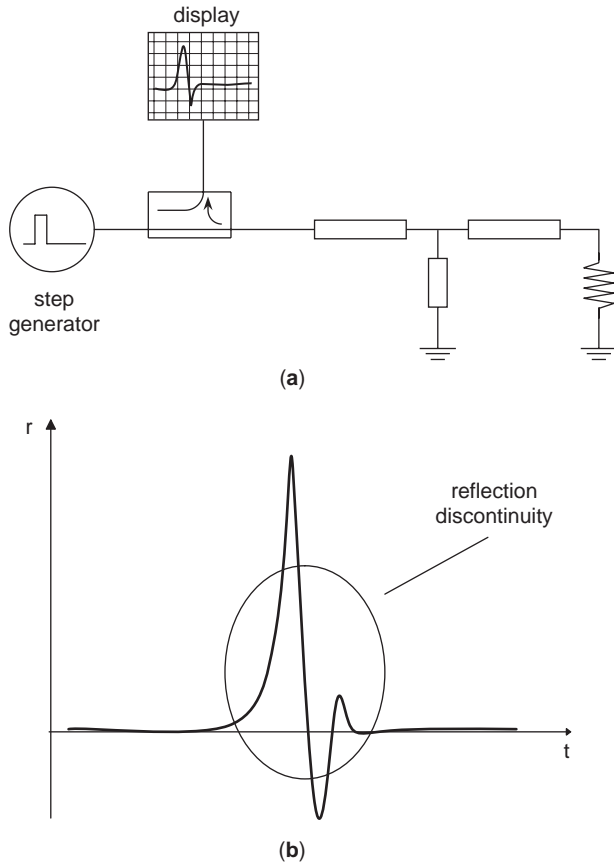

Figure 11. TDR system based on sampling scope and pulse generator (a) and typical time-domain pulse response (b).

- Vectorial error corrected data that avoid spurious reflections from cables and interconnections
- High dynamic range

Different types of excitation can be easily computed, and the time-domain network response is normally shown on the VNA screen; furthermore, the use of sophisticated signal processing tools, such as time-domain gate function and frequency-domain windows, allow one to greatly increase the technique capabilities. For example, by gating the time-domain response of a particular discontinuity and retransforming the data into the frequency domain, accurate modeling of interconnections and launchers can be obtained [11,12,58].

3.3. Multiport and Differential Measurements

The VNA is currently evolving from the basic two-port instrument toward a more sophisticated multiport system. Typical currently available multiport VNA has 4 ports, while 8 or even 12 ports are available at low-frequency bands. Applications of such VNAs span from the television distribution systems up to bus characterization of differential digital circuits.

In this latter case the traditional definition of scattering parameters has been extended to the *differential S parameters* [14], which are obtained as the difference between the traditional single-ended lines and allow one

to better highlight the behavior of microwave systems where the signal flows on coupled lines rather than on a single-ended ones. This technique is very promising in the digital marketplace, where the bus speed is reaching the microwave field and the crosstalk effects need to be precisely controlled and simulated.

4. ADVANCED MICROWAVE MEASUREMENTS

The more recent technological advances require the evolution of microwave measurements to very complex setups that can perform different types of characterization simultaneously and can extract more and more information for the new modeling and designing needs. Nonlinear techniques for active devices will be briefly described in the following text.

4.1. Nonlinear and Load-Pull Measurements

When the devices work under a strong nonlinear state, the models and best operating conditions cannot be often predicted by linear analysis or measurements, since input and output matching networks (as well as bias point) influence the performance of any transistor or power amplifier. Therefore, a traditional way to characterize a transistor for power amplifier applications consists in effectively trimming the load (Γ_L) and the source (Γ_S) reflection coefficients seen by the device under nonlinear conditions, to meet the required amplifier specifications [21]. In this case of power amplifiers, transistor nonlinearities play a fundamental role and the optimum loading conditions may be significantly different from the linear case, where *S* parameters are used to compute the best loading conditions.

Measurement setups that allow one to change the loading conditions are often referred as *load-* and *source-pull systems* [21,24]. Load-pull application examples are high power amplifier, mixer [43], and oscillator design [36], while source-pull systems have important applications in low-noise amplifier design, where the best noise figure and, in general, the transistor noise parameters are found by applying different source impedance values [3,16,22,42].

A simplified scheme of a generic real-time load source-pull system is shown in Fig. 12. To obtain a variable load, passive networks with manual or automatic variable elements can be used (slug tuners, solid state tuners, etc.)

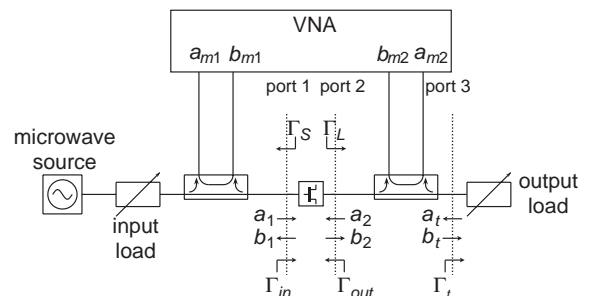

Figure 12. Real-time load/source-pull setup.

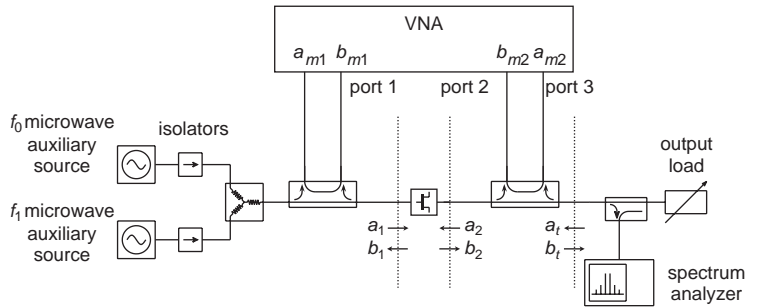

Figure 13. Load-pull system for intermodulation measurements [23].

[1,46,55,62]. The alternatives are active loads, which electronically synthesize the required reflection coefficients by properly amplifying, phase shifting, and combining microwave signals [10,59].

In the simplest load-pull implementation, the device is driven by the microwave source at a single frequency, and its performance is measured while physically changing Γ_L or Γ_S . Vector measurement techniques with VNA allow real-time determination of the load and source reflection coefficients, as well as input and output power, through the dual directional couplers, shown in Fig. 12.

A very popular and less expensive technique exploits power meters, connected to the system through directional couplers, at the input and output of the DUT. Since no vectorial real-time correction is possible in this case, the measurements rely on the accuracy of directional coupler and tuner precalibration. For this reason, VNA-based systems are faster and have lower uncertainties than do power-meter-based systems, as has been demonstrated in Ref. 33.

4.1.1. Harmonic Measurements. Load-pull measurements are inherently for single-frequency or small-bandwidth applications; nevertheless, nonlinear devices produce harmonics, and the loading conditions at harmonic frequencies may significantly affect device performance, as proved by theory [57] and experiments [30]. Harmonic source- and load-pull systems allow one to change Γ_S and Γ_L values at a discrete set of frequencies (typically two or three), while measuring device performance over the entire spectrum of interest. A typical application is the design of high-efficiency solid-state amplifiers and transceiver output stages [6,54]. The introduction of harmonic tuners [47,48] has provided a compact and economic solution for harmonic source load-pull testsets. However, like any other passive tuner, harmonic tuners cannot offer highly reflective terminations at higher frequencies, due

to losses; a good solution is, again, the active load, realized by combining, with power splitters and combiners, more single-frequency active loads [37,48,51].

4.1.2. Intermodulation Set-ups. By driving the device with two tones or with digitally modulated signals, intermodulation or adjacent-channel power ratio (ACPR) are traditionally measured to evaluate the linearity characteristics of the transistor. A typical application is the power amplifier design for CDMA- and WCDMA-based telecommunication systems, where the phone and base station performance is more sensitive by amplitude distortion than in previous access technologies based on constant-envelope modulation schemes.

Like all the other device characteristics, intermodulation distortion depends on the loading conditions; therefore, load-pull systems have evolved to integrated load-pull and intermodulation measurement capabilities, as shown in Fig. 13 [23].

4.2. Time-Domain Waveform Measurements

The growth of strongly nonlinear devices for wireless applications (mobile units and base stations), has compelled the development of another measurement philosophy: time-domain waveform measurements. This technique can provide important information for both device modeling [35,49] and design [9,13]. For example, if the waveforms at the input and output of the device are directly accessible, the effects of the harmonic terminations [8] or of the envelope impedance [65] can be studied directly in the time domain.

Time-domain waveforms are commonly measured by *sampling oscilloscopes*, which are based on microwave signal subsampling, as sketched in Fig. 5. The IF filter is not a narrow-, bandpass filter one as in the VNA, but a low-pass filter, and IF signal spectra become exact copies of the microwave signals. The magnitude and phase

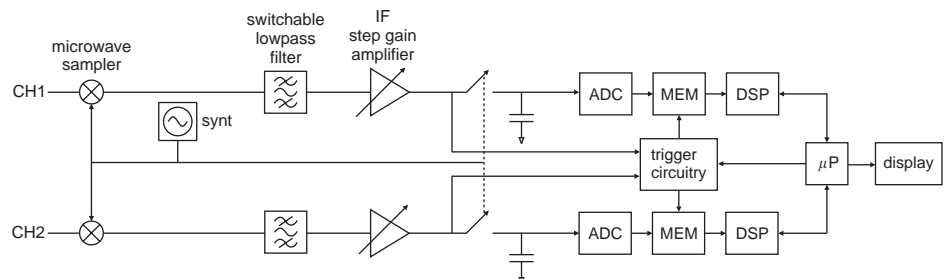

Figure 14. Simplified block scheme of a time-domain waveform receiver.

relationships between the spectral components are maintained and are measured by A/D conversion and FFT of the IF signals, as shown in Fig. 14 [19,20].

Calibrations can be performed in the frequency domain, after fast Fourier transform (FFT); then, corrected measurements are displayed again in the time domain, after an inverse fast Fourier transform (IFFT) [29]. The main drawbacks of waveform measurements is the low dynamic range and speed.

MICROWAVE MIXERS

R. S. TAHIM
RST Scientific Research, Inc.
New York

1. INTRODUCTION

Mixer as a component is found in almost all kinds of microwave and millimeter-wave systems that include various communication systems, interferometer systems, phased arrays, sensors, and radar systems. Microwave mixers form a highly mature technology [1]. However, there are still interesting and new circuits that continue to be developed in order to make the microwave/millimeter-wave systems more efficient. A number of microwave systems are extremely vital to the defense applications involving the collection and distribution of information

both to and from the forward-deployed troops and between the command centers and the troops in the field. Wideband radar systems that incorporate wideband mixers are needed in large-scale surveillance, tracking targets, identification, and reconnaissance applications. Therefore, the U.S. military has placed significant emphasis on the development of wideband microwave and millimeter-wave transceiver systems for both radar and data transmission systems at high frequencies. Such wideband systems are needed for transferring high-value data such as videos, high-resolution images, and radar, optical, and computer data that military personnel need to carry out the military operations more efficiently and effectively.

Radar and the wireless telecommunications industry have also established itself as one of the strongest growth areas in the commercial sector side. Although vigorous expansion is expected to continue in the established wireless applications, the next major growth areas in the wireless revolution have already begun to emerge. As a result, variety of new applications are envisioned in such areas as homeland security, intelligent highway systems, autonomous landing systems, mobile satellite communications, intersatellite links, tracking and data relay, direct conversion receivers, ultra-wide-band (UWB) systems, advanced security systems, and local multipoint distribution systems. In most of these applications, low-noise receivers that include high-performance microwave mixers are desirable.

In all RF, microwave, and millimeter-wave systems there are two major parts: the transmitter and the receiver. In a microwave communication system, the transmitter and receiver systems are installed at different locations. The message is sent from the transmitter to the receiver using the antennas. In a radar system, the transmitter and the receiver are located very close together. The transmitted signal is reflected by a target or the targets to the receiver; thus the information about the target (range and velocity) is obtained by the radar. Along with the development of communication and radar systems for military applications, another highly interesting area called *electronic warfare* (EW) has also emerged over the years. In EW applications, the receivers are used to intercept signals of limited information from a hostile transmitter, while a jamming transmitter is used to generate false information or noise to mask the true signal received by the possible hostile radar receiver.

2. MIXER OPERATION

In the microwave systems for both radar and communications, the incoming signal at microwave frequency (f_s) is downconverted in a mixer to generate a low intermediate frequency (f_{IF}), which is further processed to generate the baseband signal in order to retrieve the required information or data. Frequency down-conversion is accomplished by utilizing the properties of a nonlinear impedance element of the mixer, which is simultaneously interacting with the receive signal (f_s) and a usually a much stronger signal at f_{LO} generated by a local oscillator. In the mixer conversion process, information about the frequency,

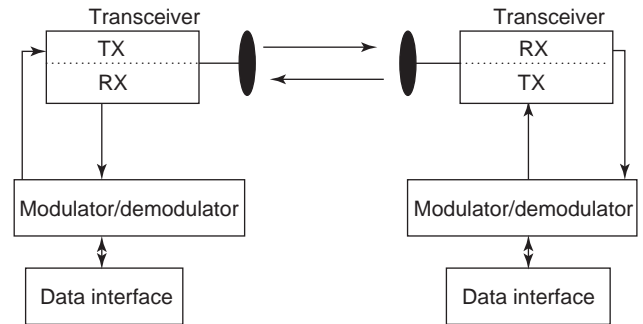

Figure 1. Schematic of a microwave communication system.

amplitude, and phase of the original signal is preserved. Therefore, we find the mixer as a component in almost all kinds of microwave systems that include various communication systems, interferometer systems, phased arrays, radars, and all kinds of instruments such as frequency upconverters, modulators, frequency synthesizers, spectrum analyzers, and network analyzers.

3. MIXERS IN MICROWAVE/MM-WAVE SYSTEMS

Microwave mixers in a communication receiver and radar system play a critical role in the data transfer and the identification of the targets. Figure 1 is a basic block diagram of a wireless communication system, which generally consists of two transceivers, each transmitting and receiving the microwave signals. In the modern telecommunication systems, a receiver consists of a low-noise-amplifier (LNA) followed by a mixer circuit.

A monopulse receiver topology consisting of low-noise amplifier and microwave/millimeter-wave mixers is shown in Fig. 2 [2]. In the receiver system, the signal f_s from the antennas is first amplified in the low-noise amplifier before being downconverted using a balanced

Figure 2. A monopulse receiver topology with four slot-ring antennas.

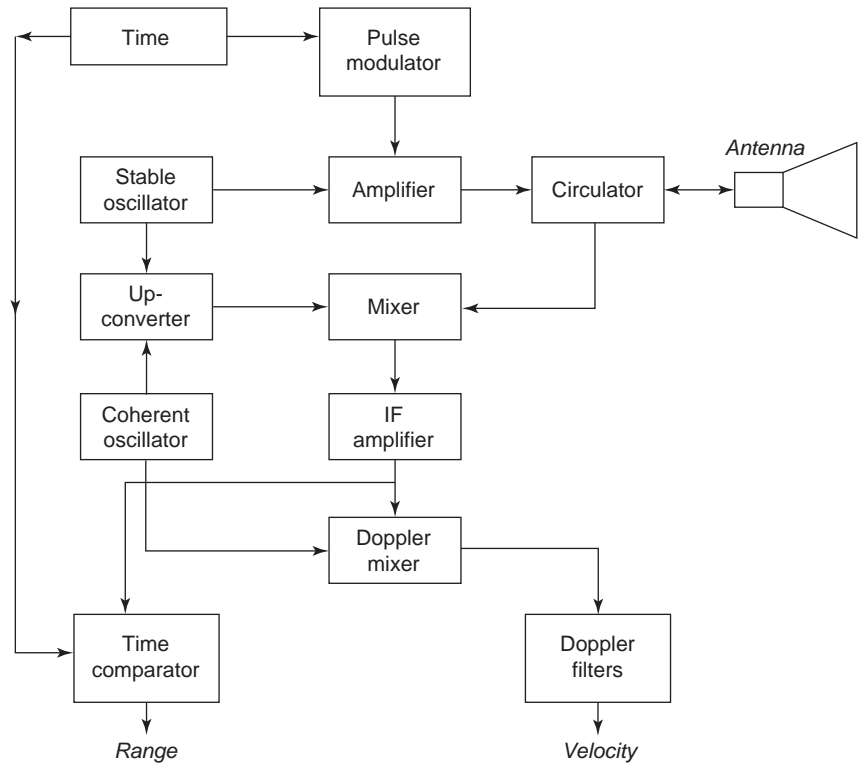

Figure 3. Microwave mixer in Doppler radar system.

mixer to the IF frequency band. A low noise and a highly stable local oscillator source or a dielectric resonator oscillator (DRO) is generally used as the local-oscillator (LO) source to drive the mixer (frequency downconverter).

A system block diagram of a typical radar system illustrating the use of a microwave mixer in the system is shown in Fig. 3. In the radar receiver, the returned echo is mixed with the stable oscillator frequency to obtain the Doppler shift frequency [3]. The Doppler frequency is passed through a set of Doppler filters to determine the target velocity. The return signal is also compared with the reference time in a time comparator to determine the target range. In the system, the exciter provides the local oscillator power to the downconverter (mixer) to generate the desired intermediate frequency (IF).

In the receiver, as long as the amplifier gain before the mixer is sufficiently high to mask the contribution of the mixer noise figure, the overall noise figure of the receiver is determined mainly by the amplifier noise figure. However, at millimeter-wave range, the way to obtain high gain for the amplifier is to cascade several amplifiers. In such a case, either the cost or the complexity of the circuit is increased. In order to achieve a low receiver noise figure in the system, it is more desirable to use the mixer in the receiver front end as a first element and to minimize the mixer conversion loss to achieve the low receiver noise figure.

The receiver and mixer parameters in the microwave communication system, are related as [4]

$$S/N = (G_T P_T)(G_R/T_S)(\epsilon_p/k\Delta f)(\lambda^2/[4\pi R]^2) \quad (1)$$

where

- G_T = transmit antenna gain
- P_T = input power to antenna
- G_R = receive antenna gain
- T_S = effective noise temperature at receiver input
- k = Boltzmann constant = $1.379 \times 10^{-23} = -228.6$ dB (W/Hz · K)
- $\Delta f = B$ = bandwidth of receiver

The receiver noise figure in the system in which mixer is used in the front end is given by [5]

$$F = L_c(N_r + F_{IF} - 1) \quad (2)$$

where L_c is the total conversion loss (including frequency conversion loss, diode series resistance loss, and the mismatch losses) in the mixer, then F_{IF} is the noise figure of the IF amplifier followed by the mixer and N_r is the diode noise ratio.

4. MIXER CONFIGURATIONS

Seven basic types of mixers have been developed for various applications:

1. Single-ended mixers
2. Single-balanced mixers
3. Double-balanced mixers
4. Subharmonically pumped mixers

5. Image-rejection mixers
6. Image-enhanced mixers
7. Quadrature mixers

The single-ended mixer is the simplest mixer configuration using one mixer diode. However, microwave mixer configurations using two or more Schottky diodes are quite common and have proved to provide substantial advantages in terms of operating bandwidth, intermodulation, spurs, LO noise cancellation, high dynamic range, low intermodulation, and so on [6,7]. At high microwave and millimeter-wave frequency bands, subharmonically pumped mixer designs are preferred because the LO frequency requirement in subharmonic mixers is roughly half that required in the fundamental mixer design. The two-diode mixer also provides substantial AM local oscillator noise suppression [7]. The noise associated with the LO sources (used in the frequency downconverter), when translated at the IF frequency band during the conversion process, can be a source of problems in the receiver. Another important property of subharmonically pumped mixer is the strong attenuation of downconverted local oscillator noise available at the IF output.

5. MIXER PARAMETERS

High-performance mixers in the microwave and millimeter-wave receivers form an important part in the current telecommunications, meteorology, and electronic warfare systems. Important mixer parameters that determine its usefulness in such microwave and millimeter-wave systems are

- Conversion loss
- Operating bandwidth
- Local-oscillator power requirements
- Isolation between the RF, LO, and IF ports
- RF and IF impedance match
- Intermodulation
- LO noise cancellation
- Dynamic range

The *conversion loss* of a microwave mixer is defined as the ratio of the IF output power to the signal input power. Conversion loss measures the efficiency with which mixer converts RF energy to the IF energy and is one of the most important mixer parameters. Conversion loss L_c is expressed in the form

$$L_c = L_o L_p \quad (3)$$

where L_o includes the intrinsic conversion loss arising from the conversion process within the nonlinear resistance of the diode plus the signal loss associated with the impedance mismatch losses at the RF and IF ports. L_p is the parasitic loss associated with the parasitic elements of the diode, such as junction capacitance C_j , the spreading resistance R_s , and series inductance L_s .

Figure 4. Equivalent circuit of a mixer diode.

The junction capacitance C_j , series resistance R_s , and other parasitic reactance L_s are shown in Fig. 4 for the diode equivalent circuit, and they are frequency-dependent. Their effect on controlling the mixer performance such as operating bandwidth and the conversion efficiency becomes much stronger at high microwave and millimeter-wave frequencies [8].

Since $C_j \propto d^2$ and $R_s \propto d^{-1}$, where d is the diameter of the junction, d should be reduced as the operating frequency is increased. Reducing the size of the junction area of the diode increases the current density through the diode and consequently may increase the intrinsic conversion loss of the mixer [9].

In addition to the parasitic losses, the conversion loss depends on the losses in the RF circuitry surrounding the mixer, the quality of the nonlinear device, the mismatch between the RF circuit and the diodes and the bias level to the diodes. When no energy is dissipated at the idler frequencies, the fundamental limit on the conversion loss of a mixer is 3 dB [10]. The discrepancy between the measured mixer loss and the predicted loss is shown to have three main causes and is generally divided into the following three parts:

L_1 mismatch loss due to impedance mismatch at RF and IF ports

L_2 diode parasitic losses due to junction capacitance and series resistance

L_3 intrinsic junction loss of the diode

The overall conversion loss L is the sum of three losses:

$$L = L_1 + L_2 + L_3 \quad (\text{all in dB}) \quad (4)$$

The conversion loss is a very important mixer parameter, especially in the receivers without RF amplifier in front of the mixer, since the first component at the input of a receiver has the most influence on the noise figure of the receiver. In a mixer circuit, in which the $2f_{LO} - f_s$ frequency product lies close to the RF signal, the conversion loss can be further improved by extracting the power associated with $2f_{LO} - f_s$ signal [11] by remixing this signal with LO to generate more IF power.

When the signal power approaches the same power level as the local oscillator, the mixer becomes saturated; specifically, the output IF power no longer increases linearly with the input power. Since the mixer is a three-port device, isolation between RF and LO ports, isolation between RF and IF ports, and isolation between LO and IF ports is very important. Isolation is the measure of circuit balance within the mixer. Poor isolation between the RF and LO means that a LO signal can reach the RF port and power can radiate through the receiving antenna [12]. In receivers, where LNA forms the front end, the poor isolation between the LO and RF can result in signal distortion because the FET devices in the amplifier also exhibit nonlinear characteristics. Isolation between the mixer ports becomes a problem in a multichannel receiver in which a single LO is used to feed a number of mixers [13].

In the resistive mixer operation, the signal level in a mixer is significantly lower than that of LO power and does not therefore perturb the LO-pumped conductance waveform. Under such conditions, no harmonics of signal are generated. However, if the RF and LO signal powers are at sufficiently high level, the harmonics and inter-modulation products are generated according to $\pm mf_{\text{RF}} \pm nf_{\text{LO}}$, where $m = 0, 1, 2, \dots$ and $n = 0, 1, 2, \dots$, although a filter is used at the mixer output to allow only f_{IF} to pass. In case the intermodulation frequency product falls within the IF frequency range, it must be -40 dBc below the actual IF signal level.

In a wireless system, which must operate in severe interference environments, microwave receivers are especially susceptible to intermodulation frequency products generated in mixers. Spurious signals or distortion in mixers continue to be problems in virtually all microwave systems. Mixers are frequently the dominant components in establishing the system's distortion performance. Inter-modulation (IM) products are undesirable mixer generated output products exiting the mixer from any port. Any RF frequency that satisfies the following equation can generate spurious responses, spurs, in a mixer

$$mf_{\text{RF}} - nf_{\text{LO}} = \pm f_{\text{IF}} \quad (5)$$

where f_{IF} is the desired IF frequency.

6. MIXER DESIGN TOPOLOGIES

Although single-ended mixers occasionally are used, most practical mixers are balanced mixers incorporating more than one Schottky mixer diode. Balanced mixers require baluns or hybrids, which largely determine the bandwidth and overall performance of the mixer. Thus, they have been the subject of considerable research interest. As a result, a number of balanced mixer configurations have been developed for various applications. A few of these design configurations are:

- Planar balanced mixer
- Crossbar balanced mixer
- Inline balanced mixer
- Subharmonically pumped mixer

In spite of the maturity of FET circuits, diode mixers are still widely used in microwave circuits, because diode mixers have an important advantage over FETs and bipolar devices. The Schottky barrier diode is inherently a resistive device and as such has very wide bandwidth. The bandwidths of diode mixers are generally limited primarily by the bandwidths of baluns, not the diodes [14]. FETs have high- Q gate input impedance, causing difficulties in achieving flat wide bandwidth as compared to the mixer designs using Schottky mixer diodes. Diode mixers usually have 5–8 dB conversion loss, while active mixers usually can achieve at least a few decibels of gain. More recently, a number of design topologies for the balanced mixers have been developed for various applications. Many of these design topologies provide state-of-the-art performance in terms of bandwidth, conversion loss, and other parameters.

Marchand baluns have been found to be quite useful for planar mixer designs and can achieve a 10–1 bandwidth. Figure 5 shows the mixer design topology using Marchand balun [14]. Planar mixers using microstrip transmission-line couplers operating up to W-band frequency ranges have also been developed [15].

Figure 6 shows the configuration of broadband microwave integrated circuit crossbar mixer. In the crossbar mixer RF and LO signals are coupled (using waveguides) to two Schottky mixer diodes orthogonally. Such configuration provides the necessary isolation between the RF and LO ports. Such design configurations also provide very broadband performance. Crossbar mixers have been developed in high-microwave and millimeter-wave frequency spectra [16,17].

The two-diode subharmonically pumped mixer design topology on suspended substrate strip transmission line is shown in Fig. 7. Two Schottky mixer diodes are shunt-mounted with opposite polarities. Two lowpass filters are used to separate the signal frequency at $\omega_s = 2\omega_p \pm \omega_{\text{IF}}$, the LO frequency ω_p , and the IF frequency ω_{IF} .

Quadrature mixers are important in many communication systems and in direct-conversion receivers. A quadrature mixer typically consists of a pair of balanced mixers with the input signal split into in phase and quadrature

Figure 5. Planar mixer using Marchand balun.

Figure 7. Millimeter-wave subharmonically pumped mixer.

Figure 8. Microstrip layout of subharmonically pumped mixer.

parts, resulting in the in-phase and quadrature signals translated to the intermediate frequency.

A planar microstrip subharmonically pumped mixer circuit layout is shown in Fig. 8 [18]. In this design, the short-circuited stub (SC) I does not impede the pump signal but shorts the RF signal to the ground. The open stub (OC) II, on the other hand, short circuits the pump signal without affecting the RF signal. The SC stub and OC stubs are $\lambda/4$ in length at LO frequency. Two antiparallel pair of Schottky mixer diodes are connected between the LO and RF ports as shown in Fig. 8. The conversion loss of harmonic mixers is about 0.5–1 dB higher than that of a conventional balanced mixer [18].

7. CONCLUSIONS

Although mixer design is often viewed as a mature technology, there seems to be no end to the supply of new ideas for mixer circuits. Mixer parameters are generally determined by the system designers who are constantly researching for high performance, low-cost, manufacturability and integratable designs. This is particularly true of mixers for wireless and other modern communication systems and radar systems where distortion is a major concern. As a result, there are continual developments in mixer technology. These include new circuits, new devices and device technologies.

MICROWAVE OSCILLATORS

JONGHOON CHOI
AMIR MORTAZAWI
University of Michigan
Ann Arbor, Michigan

Oscillators are an integral part of receiving and transmitting systems used for communication, radar, and other applications. Any oscillator circuit consists of an active device and a resonant circuit that determines the frequency of oscillation. The active device can be either a two-terminal negative-resistance device such as Gunn diode, IMPATT (impact avalanche transit time) diode, resonant tunneling diode (RTD), and so on, or a transistor with appropriate feedback to cause instability. In general, an oscillator can operate at a fixed frequency, or its frequency of operation can be tunable. The frequency tuning can be achieved either mechanically or electronically. An oscillator is usually characterized by its frequency of operation, output power, noise, long-term frequency stability, and DC-to-RF efficiency.

1. MODELING OF MICROWAVE OSCILLATORS

An oscillator consists of linear circuits and active devices, and its operation relies on the nonlinear behavior of the active devices. In order to accurately characterize an oscillator, it has to be analyzed using linear and nonlinear circuit analysis techniques. An oscillator can be analyzed using either the feedback model or the negative-resistance model. These two analysis models are identical; however, the negative-resistance model is the most commonly used approach in the design of microwave oscillators. The popularity of the negative-resistance model is due to its simplicity and the fact that it can be related to device and

circuit reflection coefficients since they can be measured accurately at microwave frequencies. In the negative-resistance model, the oscillator is divided into two parts, the active device and the embedding passive circuit. In a simplified oscillator analysis, the active device is assumed to operate under small-signal conditions. This type of analysis can provide some information about startup conditions for oscillation and predict the approximate frequency of oscillation. In order to accurately determine the oscillation frequency, output power, stability, and spectral purity of an oscillator, large-signal analysis of the oscillator circuit must be performed. Usually simplified large-signal models for active devices can provide valuable insight into the operation of oscillators.

1.1. Oscillator Design Using One-Port Negative-Resistance Devices

Figure 1 shows the simplified block diagram of an one port oscillator circuit. The small-signal impedance of the negative-resistance device and the embedding circuit impedance can be denoted as $Z_d = -R_d + jX_d$ and $Z_c = R_c + jX_c$. For a series-resonant circuit, assuming that current I is flowing through the circuit, we obtain

$$I[Z_d + Z_c] = 0 \quad (1)$$

which results in

$$Z_d + Z_c = 0 \quad (2)$$

The startup conditions for oscillation for a series resonant circuit are given as follows:

$$-R_d + R_c < 0 \quad (3)$$

$$X_d + X_c = 0 \quad (4)$$

This means that the magnitude of the device negative resistance must be larger than the overall circuit losses in order for oscillation to build up. The startup of oscillation is initiated either from noise present in the circuit or from

Figure 1. Simplified block diagram of a one-port oscillator.

transient introduced during power turnon. As the oscillation amplitude builds up, the device enters into its non-linear region, where the device negative resistance drops and eventually becomes equal to the overall circuit losses. At this point the oscillation amplitude reaches its steady state.

For a parallel-resonant circuit, the steady-state oscillation condition is given in terms of active device and circuit admittances Y_d and Y_c , respectively as

$$Y_d + Y_c = 0 \quad (5)$$

The startup conditions for a parallel-resonant circuit are given by

$$-G_d + G_c < 0 \quad (6)$$

$$B_d + B_c = 0 \quad (7)$$

where $Y_d = -G_d + jB_d$ and $Y_c = G_c + jB_c$.

The steady-state oscillation condition can be written in terms of device and circuit reflection coefficients Γ_d and Γ_c as

$$\Gamma_d \cdot \Gamma_c = 1 \quad (8)$$

Voltage-controlled devices such as the Gunn diode should be connected to a parallel-resonant circuit, and the appropriate startup conditions for oscillation should be satisfied. Current-controlled devices such as IMPATT diode are placed in a series-resonant circuit for proper operation. In this case startup conditions for oscillation for a series-resonant circuit should be met. The startup oscillation frequency can be different than the steady-state oscillation frequency. This is because the large-signal device impedance is a function of the voltage (or current) amplitude across (through) the device. As the oscillation amplitude builds up, the device impedance varies until it reaches its final value. However, for high- Q circuits, the steady-state oscillation frequencies are very close to the startup frequency of oscillation. It should also be mentioned that the startup condition for oscillation is a necessary but not sufficient condition for having an unstable circuit [1–3]. (Nyquist or root locus analysis can always be used to determine the circuit instability.)

1.2. Oscillator Design Using Two-Port Devices

The block diagram of a two-port oscillator circuit is shown in Fig. 2. Most microwave transistors are conditionally stable within a limited range of frequencies. By plotting the input and output stability circles on a Smith chart, one can graphically determine the range of impedances for unstable operation. When designing microwave oscillators, the input port of the two-terminal device can be terminated with a purely reactive load that lies in the unstable region of the Smith chart. This is shown in Fig. 2 as Z_T . This will result in the output impedance (Z_{out}) looking into the device to render negative real parts ($|\Gamma_{out}| > 1$). The load impedance Z_L must be chosen to satisfy the startup conditions for oscillation. In practice,

Figure 2. Block diagram of a transistor oscillator.

the load impedance is determined by Eqs. (9) and (10) in order to achieve maximum power

$$X_L(\omega_o) = -X_{out}(\omega_o) \tag{9}$$

$$R_L(\omega_o) = \frac{|R_{out}(A, \omega_o)|_{A=0}}{3} \tag{10}$$

where A is the amplitude of $i(t)$, ω_o is the oscillation frequency, R_L and X_L are the real and imaginary parts of the load impedance (Z_L), and R_{out} and X_{out} are the real and imaginary parts of the output impedance (Z_{out}).

When a microwave oscillator is designed according to this procedure, the measured oscillation frequency will usually deviate from the design frequency by several percentages. This is because the design procedure is based on the small-signal, linear S parameters that do not consider the fact that R_{out} and X_{out} are functions of the oscillation amplitude.

The steady-state oscillation condition for a two-port oscillator in terms of the transistor's S -parameter load and

source reflection coefficients is given by

$$\frac{1}{\Gamma_T} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} \tag{11}$$

$$\frac{1}{\Gamma_L} = S_{22} + \frac{S_{12}S_{21}\Gamma_T}{1 - S_{11}\Gamma_T} \tag{12}$$

If the oscillation conditions are satisfied at one port, they are satisfied at all other ports [4,5]. If the oscillator is stable at the desired frequency of operation, it can be made unstable by using series (Z_F in Fig. 2) or shunt feedback. There are a total of six configurations: three for series feedback and three for shunt feedback as shown in Fig. 3 [6].

1.3. Oscillator Design Using Large-Signal Analysis

The large-signal design approach, called *device-line measurement*, can be applied to one-port oscillator design in order to achieve better accuracy compared to the oscillator design using small-signal S parameter [7]. For the large-signal oscillator design, a nonlinear model for the active device and a nonlinear simulation technique such as the harmonic balance are needed to predict the large-signal S parameters and the output power.

Starting with a two-port network (Fig. 2), one first terminates one of the ports with a proper impedance (Z_T) such that the impedance of the resulting one-port network (Z_{out}) has a negative real part, or equivalently, the magnitude of its reflection coefficient (Γ_{out}) is larger than unity. A test source is then connected to the aforementioned one-port negative-resistance network, as shown in Fig. 4, to determine its large-signal reflection coefficient. It should be mentioned that the device-line measurement system requires the internal impedance (Z_s) to prevent the measurement circuit from oscillating. Therefore, R_s , which has a larger value than the magnitude of the real

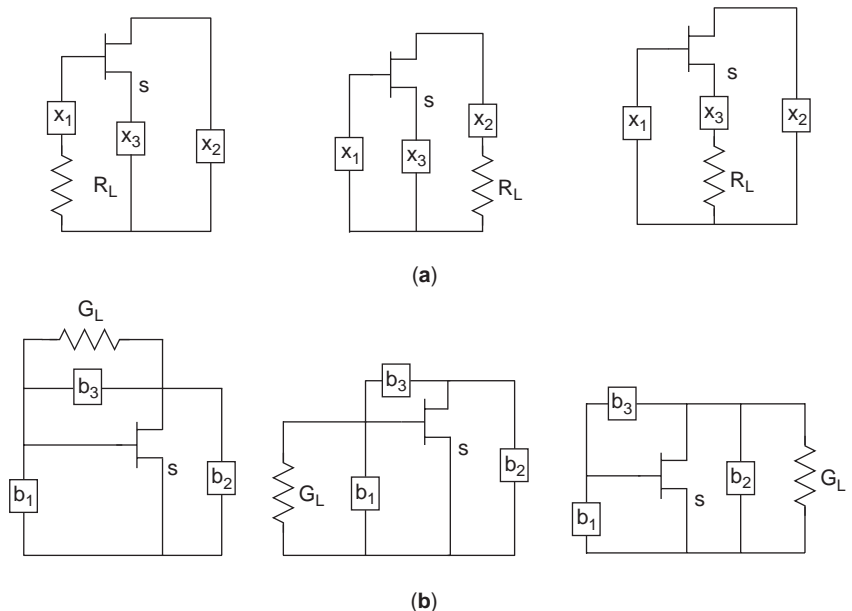

Figure 3. Circuit configurations for (a) series feedback oscillators and (b) shunt feedback oscillators.

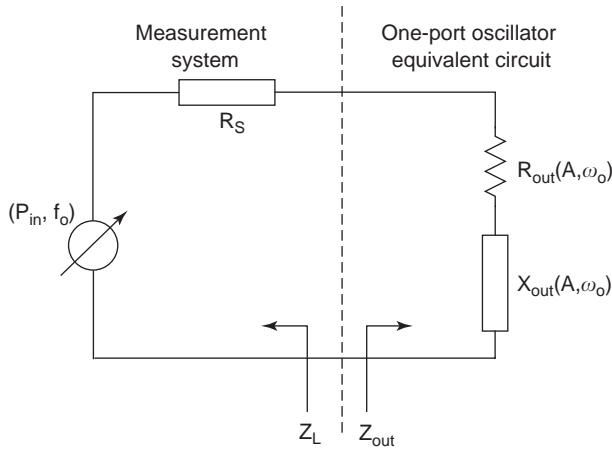

Figure 4. Device-line measurement setup.

part of the output impedance ($|R_{out}|$), should be inserted next to the test source. By varying the amplitude of the RF signal at the design frequency, the large-signal dependence of Γ_{out} can be measured. Since $|\Gamma_{out}|$ is larger than unity, due to the negative resistance $R_{out}(A, \omega_o)$, the added power (P_{add}), as given in the following equation, is therefore positive

$$P_{add} = P_{av}(|\Gamma_{out}|^2 - 1) \quad (13)$$

where P_{av} is the available power of the source.

When the load impedance (Z_L) is selected to satisfy the steady-state oscillation condition, specifically, $\Gamma_{out}\Gamma_L = 1$, the designed oscillator can generate the same power as the added power (P_{add}) that the one-port negative resistance device generated as determined by Eq. (13). On the basis of the large-signal output reflection coefficient, the load impedance Z_L is determined as follows:

$$X_L(\omega_o) = -X_{out}(A_o, \omega_o) \quad (14)$$

$$R_L(\omega_o) = -R_{out}(A_o, \omega_o) \quad (15)$$

The device-line measurement technique can be used to maximize the output power of an oscillator. By varying RF source power at the design frequency, the point where the added power is maximized can be found. At this power level, one can measure the large-signal output reflection coefficient and design the load impedance on the basis of Eqs. (14) and (15). Furthermore, a more accurate estimate of oscillator frequency is obtained using this technique.

1.4. Injection Locking of Microwave Oscillators

Injection locking of a microwave oscillator is accomplished by applying a small signal to the free-running microwave oscillator, provided the frequency of the small signal is close enough to the free-running frequency of the oscillator. Through injection-locking a free-running microwave oscillator to a low-noise low-power source, the free-running frequency is locked to the injection signal frequency, thereby improving its frequency stability and phase noise. It has been shown that the phase noise of the

injection-locked oscillator is reduced to that of the external locking source near the carrier frequency; however, it approaches that of the free-running oscillator far from the carrier frequency [12].

The effect of the injection signal can be studied by adding a small current source in parallel with the equivalent circuit for a free-running microwave oscillator as shown in Fig. 5. Suppose that the injected and the free-running oscillator signals are represented by $i_i(t) = I_i(t) \exp j[\omega_i t + \phi_i(t)]$ and $v(t) = V(t) \exp j[\omega_o t + \phi(t)]$, respectively.

The circuit equation for this injection-locked oscillator is given by

$$C \frac{dv(t)}{dt} + [G - G_d]v(t) + \frac{1}{L} \int v(t) dt = i_i(t) \quad (16)$$

where $-G_d$ is the negative conductance of a nonlinear active device. Using the assumption that the amplitudes of $v(t)$ and $i_i(t)$ are very slowly time-varying signals, and dividing the real and imaginary parts of Eq. (16), the amplitude and phase equations for the injection-locked oscillator can be obtained by

$$\frac{dV(t)}{dt} + \frac{G - G_d}{2C} V(t) = \frac{1}{2C} I_i(t) \cos[\phi(t) - \phi_i(t)] \quad (17)$$

$$\frac{d\phi(t)}{dt} + \omega_i - \omega_o = -\frac{1}{2C} \frac{I_i(t)}{V(t)} \sin[\phi(t) - \phi_i(t)] \quad (18)$$

When this system reaches the steady state, the first term in Eq. (17) with the time derivative goes to zero and can be further simplified:

$$G - G_d = \frac{I_i(t)}{V(t)} \cos[\phi(t) - \phi_i(t)] \quad (19)$$

Assuming that the device negative conductance is not a function of frequency, the left side of Eq. (19) goes to zero because $G - G_d \approx 0$. Also, the right side of Eq. (19) is close to zero because the amplitude of the injected signal is negligibly small compared to the amplitude of the free-running oscillator ($|I_i(t)| \ll |V(t)|$). Ultimately, the left and right sides of the amplitude equation [Eq. (17)] become balanced in the steady state. On the other hand, the phase equation [Eq. (18)] has a more significant meaning in the injection-locking process. In the steady-state

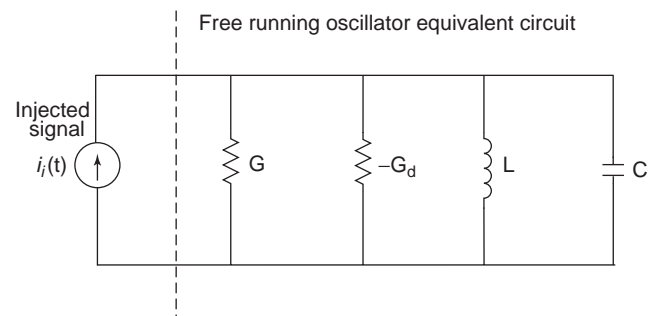

Figure 5. Equivalent circuit of an injection-locked oscillator.

condition, Eq. (18) can be simplified to

$$\omega_i - \omega_o = \frac{\omega_o I_i(t)}{2Q I(t)} \sin[\phi(t) - \phi_i(t)] = -\omega_m \sin \phi \quad (20)$$

where Q is the external quality factor ($Q = \omega_o C/G$).

The following condition must be satisfied for the phase difference ϕ in Eq. (20) to be real:

$$-\omega_m \leq \omega_i - \omega_o \leq \omega_m \quad (21)$$

This condition indicates that when the injection signal frequency remains within the locking range, the steady-state solution for the phase equation can be obtained and the injection-locking behavior is realized.

The locking bandwidth can be expressed as

$$\Delta\omega_{\text{lock}} = 2\omega_m = \frac{\omega_o}{2Q} \sqrt{\frac{P_i}{P_o}} \quad (22)$$

where P_i and P_o are the injection signal power and the free-running oscillator output power, respectively. Equation (22) shows that one can decrease the oscillator circuit Q and increase the injection signal power in order to increase the locking bandwidth.

Through injection locking, the oscillator's free-running frequency is locked to the injection frequency and the phase difference between the free-running signal and the injection signal is determined by Eq. (20).

2. NOISE IN OSCILLATORS

The spectral purity of an oscillator is degraded by the random fluctuations of its amplitude, frequency, and phase. Noise generated in the active device and passive components modulates the signal produced by the oscillator. The sources of random sideband noise in an oscillator include thermal noise, shot noise, and flicker ($1/f$) noise. These noise sources result in amplitude and phase noise in oscillators. In general, the output of a noisy oscillator can be represented by

$$v(t) = (A + a(t)) \cdot \cos(\omega_o t + \phi(t)) \quad (23)$$

where A and ω_o are deterministic amplitude and frequency and $a(t)$ and $\phi(t)$ are random amplitude and phase noise, respectively. In practice, amplitude noise can be dramatically attenuated by an amplitude-limiting mechanism of oscillators. In case an oscillator has large amplitude noise, amplitude noise can be easily eliminated by placing a limiter at the output of the oscillator. Therefore phase noise plays a dominant role in the spectral purity performance of oscillators. As shown in Fig. 6b, the existence of phase noise broadens the frequency spectrum of a noisy oscillator output around the carrier frequency, whereas the frequency spectrum of an ideal oscillator output is represented by a delta function (Fig. 6a).

Phase noise of the oscillators in radio receivers and transmitters limits the performance of the communication system. Phase noise of the local oscillator in a radio receiver downconverts the adjacent channels into intermediate frequency (IF), thereby limiting the receiver's immunity to nearby interference. In a radio transmitter phase noise can overwhelm the nearby weak channels.

Normally, phase noise is measured as the ratio of noise power (P_n) in one sideband contained in a specified bandwidth (B) at an offset frequency ($\Delta\omega$) compared to the carrier output power, referred to here as P_s . Such a power ratio is usually expressed as decibels below carrier per hertz (dBc/Hz).

To explain the behavior of phase noise, several models for phase noise can be considered. The most general model for phase noise in oscillators was described by Leeson [13]. This model is constructed using an oscillator consisting of a feedback amplifier and a resonator, under the assumption that the oscillator is a linear and time-invariant (LTI) system. When we consider only white noises such as thermal and shot noise, the noises decrease with frequency offset as a result of the filtering effect of the resonator in the oscillator. Therefore, phase noise is given by

$$L(\Delta\omega) = 10 \log \left[\frac{2kT}{P_s} \left(\frac{\omega_o}{2Q_L \Delta\omega} \right)^2 \right] \quad (24)$$

where k is Boltzmann's constant, T is the absolute temperature, and Q_L is the loaded quality factor of the resonator. However, since flicker ($1/f$) noise in active devices is upconverted to the oscillation frequency by means of

Figure 6. Output spectrum in (a) noiseless and (b) noisy oscillators.

nonlinear modulation mechanism in practical oscillators, Eq. (24) is modified into the final form of Leeson's formula as

$$L(\Delta\omega) = 10 \log \left[\frac{2kTF}{P_s} \left\{ 1 + \left(\frac{\omega_o}{2Q_L\Delta\omega} \right)^2 \right\} \left(1 + \frac{\Delta\omega_{1/f^3}}{|\Delta\omega|} \right) \right] \quad (25)$$

where F is the excess noise measure (empirical constant) and $\Delta\omega_{1/f^3}$ is the corner frequency between $1/f^2$ and $1/f^3$ regions. Leeson's formula [Eq. (25)] can be graphically depicted as seen in Fig. 7. The effect of flicker noise is dominant near the carrier frequency, leading to the decrease of phase noise with offset frequency at 9 dB/octave up to the $1/f^3$ corner frequency. From the $1/f^3$ corner frequency to $\omega_o/2Q_L$, phase noise shows a decreasing slope of 6 dB/octave. Also, Leeson's model suggests the following methods to reduce phase noise of an oscillator:

1. Use a high- Q resonator because phase noise is inversely proportional to Q^2 .
2. Increase the signal output power.
3. Select an active device with low flicker noise and low noise figure.

Even though Leeson's LTI model provides valuable insights into microwave oscillator designs in an engineering perspective, it cannot explain several phase noise phenomena such as flicker noise upconversion. To overcome this limitation, many approaches based on linear time-varying (LTV) models have been investigated. More recently a LTV model in conjunction with the concept of impulse-sensitive function based on the fact that phase fluctuation varies according to where the impulse noise is injected into a free-running oscillator has been introduced [14]. For microwave oscillators with distributed components, a perturbation theory for phase noise behavior was proposed, based on the solution of the Langevin equations describing the stochastic behavior [15]. A unifying theory for phase noise derived an exact nonlinear equation for oscillators in the presence of deterministic and random perturbations, which led to a general mathematical solution for phase noise representation [16].

Figure 7. Phase noise spectrum of Leeson's model.

3. OSCILLATOR TYPES

3.1. Gunn Oscillators

The Gunn diode [17] is a negative-resistance device that operates on the basis of transfer of electrons between two valleys in the conduction band of a semiconductor material. For this reason it is also referred to as a *transferred-electron device* (TED). A Gunn device may be described as a bulk of GaAs that exhibits negative resistance when DC bias is applied. In this respect the Gunn diode is not precisely a diode since it does not contain any junctions. Gunn diodes are capable of producing from a few milliwatts to a few watts with efficiencies up to 15–20%. The operation frequency of Gunn diodes reaches 100 GHz. Gunn diodes have a good phase noise performance. The equivalent of the Gunn diode chip can be described by a parallel RC circuit where the value of R is negative. Gunn diodes exhibit a negative resistance at low frequencies as well as RF frequencies. Precautions must be taken in order to avoid parasitic oscillations due to resonances introduced by the bias circuit. This can be achieved by rendering the bias circuit lossy at low frequencies in order to stabilize it.

The Gunn diode oscillator can be made in waveguide, coaxial, and microstrip lines. The most widely used Gunn oscillator circuit is an iris-coupled waveguide cavity oscillator. This circuit has high stability and low phase noise because of its high Q . Furthermore one can mechanically or electronically tune the oscillation frequency. Figure 8 shows the iris-coupled waveguide cavity Gunn oscillator. The resonance frequency of the waveguide cavity is determined by the distance between the iris to the effective back wall and should be a half-wavelength. The effective back wall is in between the diode's post and the physical back wall. If the diode's post is near the cavity's sidewall, then the effective back wall is very close to the physical back wall. By adjusting the diameter and the position of the diode's post with respect to sidewalls, optimum impedance match to the cavity resonator can be achieved. In order to mechanically tune the frequency of the cavity, a dielectric rod can be inserted into the cavity resonator. The electronic tuning of oscillation frequency can be accomplished by mounting a varactor diode inside the cavity using another post. By adjusting the varactor bias, the

Figure 8. An iris-coupled waveguide cavity Gunn diode oscillator.

oscillation frequency is tuned. This is a simple method for frequency-modulating such an oscillator.

3.2. IMPATT Oscillators

The term *IMPATT* is an acronym for *impact avalanche transit time*. IMPATT diode is used in the design of solid-state microwave and millimeter-wave oscillators with an operating range of frequencies from several gigahertz to >200 GHz. The IMPATT diode exhibits negative resistance due to 180° phase delay of the current with respect to the voltage. This phase delay is due to (1) the finite delay between the applied RF voltage and the current due to avalanche breakdown and (2) the subsequent transit of carriers through a drift region. One version of IMPATT operation was first proposed by Read in 1958 [18]. The first demonstration of an IMPATT oscillator was reported by DeLoach [19]. The two most commonly used versions of IMPATT diodes are the single-drift region and double-drift region. IMPATT diodes produce from 0.5–4 W with efficiencies usually greater than 10% (≤ 30 GHz) and 4% (≤ 100 GHz). IMPATT diodes differ from Gunn diodes in several respects: (1) the output powers of IMPATTs are up to 10 times higher than Gunn diodes, (2) IMPATT diodes are more efficient than Gunn diodes, (3) the operating voltage for the IMPATT is higher than that of the Gunn diode (20–100 V for an X-band IMPATT as compared to ≤ 10 V for an X-band Gunn), (4) IMPATT diodes are noisier than Gunn diodes, and (5) the circuit design using IMPATT diodes is more difficult because their negative resistance is about one order of magnitude lower than that of Gunn diodes.

The IMPATT diode is a current-controlled device and therefore requires a current source for bias. The IMPATT diode equivalent circuit consists of a series *RC* circuit, where *R* is a negative number. Since IMPATT diode is a current-controlled device, it is usually placed in a series-resonant circuit for stable oscillations. Usually a radial line (Fig. 9a) or a coaxial line (Fig. 9b) quarter-wave transformer is used to match the low negative resistance of the IMPATT to a waveguide cavity.

3.3. Dielectric Resonator Oscillators

Microstrip resonators have a limited *Q* on the order of 100. In order to reduce the phase noise of oscillators, it is necessary to increase the resonant circuit's *Q*. A low-cost technique to increase the resonator's *Q* is to couple a dielectric resonator to a microstrip circuit. Typical dielectric resonators have a cylindrical geometry with a dielectric constant between 10 and 100. The $TE_{01\delta}$ of the cylindrical dielectric resonator can be coupled to a microstrip line by placing it on top of the substrate close to the microstrip line. The distance between the resonator and the microstrip line determines the coupling factor. The *Q* of dielectric resonators is on the order of several thousand. The resonance frequency of a dielectric resonator can be adjusted by placing a movable metal plate on top of the dielectric resonator. Figure 10 shows different configurations of dielectric resonator oscillators.

Figure 9. IMPATT diode oscillators in waveguide using (a) a radial-line transformer and (b) a coaxial-line transformer.

3.4. Electronically Tunable Oscillators

In order to construct electronically tunable oscillators, either a varactor diode is connected to the resonator, or an yttrium iron garnet (YIG) sphere is used to construct the

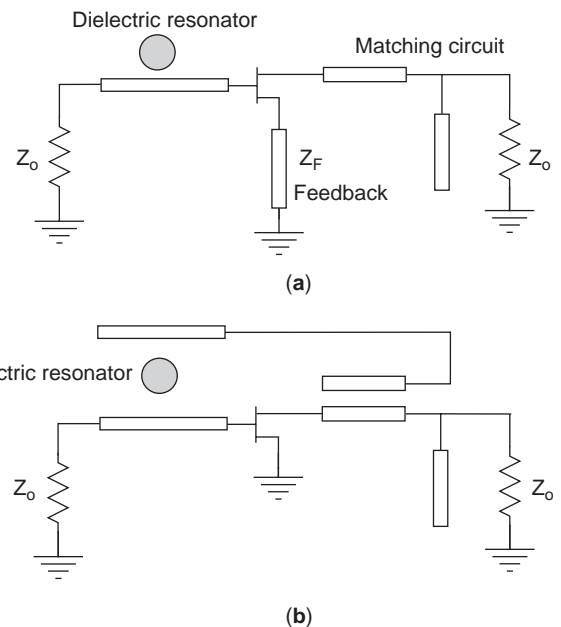

Figure 10. Dielectric resonator oscillator circuits using (a) series feedback and (b) shunt feedback.

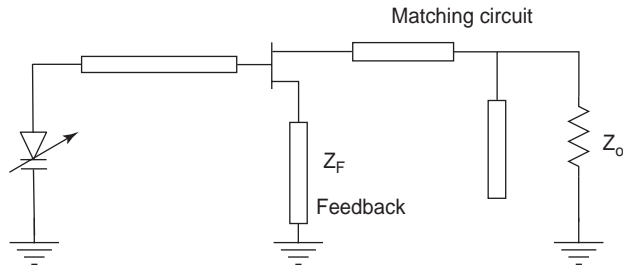

Figure 11. A varactor-tuned oscillator.

Figure 12. Diagram of a YIG-tuned oscillator.

resonator. In varactor-tuned oscillators, by changing the reverse bias voltage across the varactor, the varactor capacitance and thereby the resonance frequency can be tuned. The tuning range is dependent on the varactor's capacitance ratio C_{\max}/C_{\min} . This ratio is largest for hyperabrupt varactor diodes. The frequency tuning limit of a varactor tuned oscillator is determined by [4].

$$\frac{\omega_{\max}}{\omega_{\min}} = \sqrt{\frac{C_{\max}}{C_{\min}}} \quad (26)$$

A typical varactor-tuned oscillator circuit is shown in Fig. 11.

Another technique for construction of an electronically tunable oscillator is to make the resonator by using a magnetic material. Single-crystal yttrium iron garnet is a magnetic material that resonates at microwave frequencies when subjected to a DC magnetic field. The resonance frequency is directly proportional to the applied magnetic field; hence a linear frequency tuning over wideband can be achieved by adjusting its biasing DC magnetic field. The YIG resonator consists of a RF coupling loop, an electromagnet, and a YIG sphere. YIG is a low-loss material, and YIG resonators can provide Q factors as high as several thousand. YIG tuned oscillators are commonly used in sweep generators. The frequency tuning range of the YIG oscillators is determined by the bandwidth over which the active device provides negative resistance. Figure 12 shows a diagram of a YIG tuned oscillator. YIG tuned oscillators with oscillation frequencies as high as 60 GHz have been reported [20].

3.5. MMIC Oscillators

Because of their low cost, improved reproducibility, and small size, many oscillators have been implemented using

monolithic microwave integrated circuit (MMIC) technique. Table 1 compares the different types of RF/microwave oscillators reported in more recently published scientific papers in terms of active device, resonator type, operation frequency, output power, and phase noise. In the design of MMIC oscillators, important figures of merit are phase noise, DC-to-RF efficiency, and the tuning range for phase-locked loop applications. To satisfy these goals, the choice of active devices is crucial. Each device has different characteristics such as the $1/f$ corner frequency, forward gain, and cutoff frequency (f_T), which can produce oscillators with varying degrees of performance.

In most cases, practical MMIC oscillators have been implemented with GaAs MESFET or silicon bipolar transistor. The GaAs MESFET can operate at high frequencies (up to millimeter-wave frequency) because of its high cutoff frequency. In addition, it has higher gain and higher output power than does the silicon bipolar transistor. However, the high $1/f$ noise corner frequency of the GaAs MESFET (around 10–100 MHz) degrades the noise performance of oscillators significantly. Therefore, many designs for low-noise oscillators are based on the silicon bipolar transistor because of its low $1/f$ noise corner.

Since the high-electron-mobility transistor (HEMT) has the advantages of high electron mobility and high f_T , it presents high power capability at high frequencies and low-noise characteristics. Therefore, HEMT MMIC oscillators show good performance at extremely high frequencies of 70–200 GHz.

The heterojunction bipolar transistor (HBT) is a bipolar transistor with a structure similar to that of a silicon bipolar transistor; however, HBT consists of different semiconductor materials, while the BJT contains only silicon. The heterojunction structure enables the HBT to operate at higher frequencies than the silicon BJT. In addition, the

Table 1. Recently Reported Integrated Microwave Oscillators

Year [Ref.]	Active Device	Resonator Type	Frequency (GHz)	Output Power (dBm)	Phase Noise (dBc/Hz)
2000 32	SiGe HBT	LC	4.63–4.90	–13	–100 at 100 kHz
2000 32	Si BJT	LC	5.59–5.94	–9	–90 at 100 kHz
2000 33	GaAs MESFET	LC	11.25–11.8	11.5	–91 at 100 kHz
2000 34	CMOS	LC	1.1–1.45	4	–119 at 600 kHz
2002 35	SiGe HBT	Sapphire resonator	4.85	–	–133 at 1 kHz
2002 36	SiGe BJT	LC	43.6–47.3	5.6	–108 at 1 MHz
2003 37	CMOS	LC	5.86–6.02	–4	–110 at 1 MHz
2004 38	InGaP-GaAs HBT	LC	12.71–13.54	0	–113.8 at 1 MHz

HBT presents intrinsic characteristics of low $1/f$ noise corner, which makes it a good candidate for low-noise oscillators at microwave frequencies. Additionally, the capability of generating high negative resistances over a wide frequency range makes this device suitable for the VCO design. Currently, SiGe HBTs have been actively researched because of reduced fabrication costs, higher integration levels, and the compatibility with lower frequency circuits on the same chip.

The advances in CMOS processing technology begin to challenge GaAs devices and bipolar transistors in commercial circuits with the benefit of cost-effective mass production. Reducing the minimum channel length leads to the increase in f_T , which makes CMOS an attractive candidate for microwave oscillators. However, the major challenges in the oscillator design using silicon technology including silicon BJT, SiGe HBTs, and CMOS, lie in the difficulty in implementing good passive elements, such as on-chip inductors and high- Q resonators. This is due to the fact that silicon substrates exhibit frequency-dependent losses. Therefore, the development of high- Q on-chip inductors is one of the active research topics in the oscillator design. Many topologies such as the optimized one-layer inductor, the series-parallel stacked inductor, the differential inductor, and the 3D micromachined solenoid inductor have been proposed in order to increase circuit Q .

MICROWAVE PARAMETRIC AMPLIFIERS

MAREK T. FABER
Warsaw University of
Technology
Warsaw, Poland

1. INTRODUCTION

It has been known since nineteenth century that a mechanical system or an electric circuit in which there is a parameter that varies periodically with time may oscillate under certain conditions. The first use of this periodic variation to amplification, frequency changing, or harmonic generation was investigated in the 1940s, but real progress in the parametric amplification dated from the development in the mid-1950s of semiconductor diodes in which the barrier capacitance could be modulated at microwave frequencies. Since then, there has been a continual and tremendous increase in the amount of theoretical and experimental work devoted to parametric amplifiers [1–11]. This is because of their ability to maintain a low level of noise that is inevitably introduced at each stage of analog signal processing. A typical microwave receiver of the early 1960s consisted of a silicon point-contact diode mixer followed by a vacuum-tube amplifier. The addition of a parametric amplifier (or *paramp*, as it was popularly called) ahead of the mixer gave an order of magnitude improvement in sensitivity of the receiver.

The question arose at that time as to why the parametric amplification allows noise levels lower than with the usual type of amplifier. To answer this fundamental question, it should be remembered that an amplifier consists of both passive elements and active energy sources and that the whole is terminated by two ports, one receiving the signal to be amplified and the other delivering the amplified signal. In the ordinary type of amplifier, the energy sources consist of DC sources that are incorporated into a network of passive elements that may be linear or nonlinear. The essential condition for such a system to act efficiently as an amplifier is the inclusion of a nonlinear and/or electrically controlled resistive element to provide an energy transfer from the source to the signal [11].

Unfortunately, its operation is accompanied by a background noise that is an inevitable result of its dissipative character. In order to obtain an amplifier with a low noise level, the energy must no longer be supplied to the network directly from DC sources, and so other methods of energy transfer must be envisioned. One of these methods is to employ AC sources. It has been shown [1,4,6,8] that if a nonlinear reactance is incorporated in the network, a system of this kind may be used efficiently as an amplifier. In such a parametric amplifier a nonlinear reactance does not generate any noise, provided it is free from loss.

The first practical realization of the principle of transferring energy from a “pump” source at a high frequency to a signal at a lower frequency was based on a nonlinear inductance [2,3,7], with the nonlinearity depending on the properties of ferrite materials. Unfortunately, large levels of pump power were required to provide the necessary nonlinearity. With pump levels in the kilowatt region and relatively high loss in the reactance, this type of amplifiers had only very limited applications.

Capacitive parametric amplifiers depend on the nonlinear capacitance–voltage characteristic of semiconductor diodes. The diodes, which are specially made for the purpose, are called *varactor diodes* or more simply *varactors*. When used in a parametric amplifier, the varactor junction is biased in the reverse direction to prevent current flow across the junction and thus suppress “shot” noise associated with the current, leaving only thermal noise present in series resistance of a real diode. The effective noise level of the amplifier depends on both the signal and pump frequencies as well as on the properties of the diode, and, as it is thermal in origin, the noise level also depends on the temperature of the diode. Thus, it can be lowered by cooling the amplifier.

Varactor parametric amplifiers could be operated at convenient temperatures from room temperature, through liquid nitrogen temperature, down to liquid helium temperature, and offered versatility of system design. These amplifiers gained popularity because the improvement in sensitivity they offered outweighed the complications they introduced (the requirement for a low-loss ferrite circulator and a high-power, high-frequency pump oscillator—coupled with a reputation for being touchy to operate) [12]. Among uncooled amplifiers, the parametric amplifier was the most sensitive amplifier in existence in the 1960s. The noise level of a cooled paramp was not as low as that of a maser, but the paramp was much smaller and much less costly and did not require a liquid helium cryostat to operate. The wideband ultra-low-noise paramps [5,6,9] had been the key devices that had brought commercial and military communication satellite systems into existence. They also dominated in radio astronomy receivers throughout the world, opening new horizons in exploration of our universe. The growth in technology of the wideband paramps in the late 1960s had been exceptionally rapid. The microwave parametric amplifier evolved from a relatively high noise temperature device (250–300 K) with narrow bandwidth of 25–50 MHz to one capable of operational noise temperature as low as 12 K in cryogenically cooled mode and as low as 50–120 K in an uncooled mode and 1 dB bandwidth in excess of 500 MHz. In the early

1970s, Peltier cooled paramps were the configuration of the day.

In the early 1980s parametric amplifiers were challenged by gallium arsenide field-effect transistor (MESFET) amplifiers. With their simplicity and cost advantages, the MESFETs were encroaching on the previously exclusive property of the paramps, eroding their monopoly. Rapid improvement in GaAs MESFET technology and development of the high-electron-mobility transistor (HEMT) resulted in lower intrinsic noise, and thus less noisy amplifiers, leaving paramps behind in the race for the highest sensitivity [13] and finally displacing them at microwave frequencies. But the elegance and refinement of the parametric amplification are still fascinating, and the technique might emerge in its classical form at the terahertz region of the electromagnetic spectrum where there are no active semiconductor devices but there are many powerful far-infrared lasers to pump contemporary submillimeter-wave varactors [14]. More recently optical control in optoelectronic devices and nonlinear interaction between optical and microwave signals in semiconductor devices have gained much interest because of potential application in signal switching, mixing, and frequency modulation. Parametric amplification plays an important role in increasing sensitivity of such devices employing semiconductor photodetectors [15,16].

2. PRINCIPLE OF OPERATION

In a parametric amplifier, the energy at one (signal) frequency is increased by supplying energy at a second (pump) frequency. The basic idea is illustrated in Fig. 1. Considering the simple resonant circuit of Fig. 1, it is assumed for the purpose of illustration that the plates of the capacitor can be separated mechanically [2,17]. Let us assume that prior to a time $t=0$, the circuit has been induced to oscillate at its resonant frequency. Suppose that when the charge in the capacitor is reaching its first maximum after $t=0$, separation of the plates is suddenly increased, thereby decreasing the capacitance. Because of the electric field, this separation requires mechanical work to be supplied. The relation between charge q , capacitance c , and voltage v on a capacitor is, of course, $q=cv$. Thus, if the plate separation is increased and the capacitance thereby decreased, in a time short enough for q to be considered essentially constant, the voltage and also the stored energy $qv/2$ must both be suddenly increased. If, at the next zero of voltage across the plates, the original separation is suddenly restored, this does not change the stored energy of the circuit since the field is then zero. If the whole sequence is then repeated every half-cycle, the voltage and energy may also be increased every half-cycle, giving a buildup of the voltage across the capacitor and the energy stored in the circuit (thus also the charge in the capacitor). This buildup will continue until the energy added by separation of the plates exactly equals the energy dissipated in the circuit. It should be noted that the plates are moved (or "pumped") at twice the resonant frequency and that the phase of the pumping is important. A variable-capacitance amplifier operating

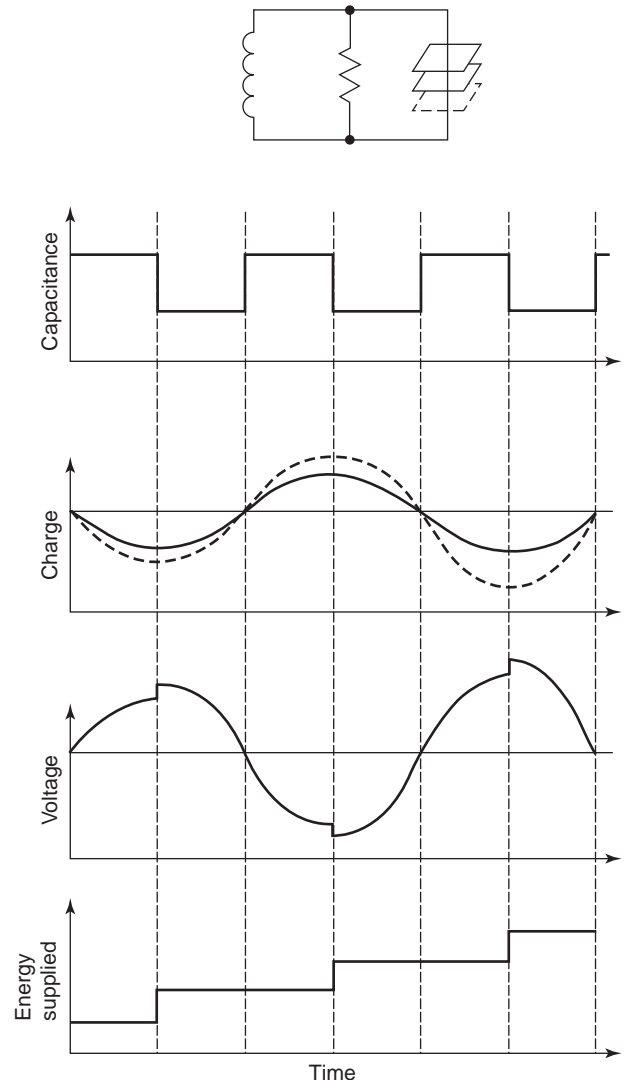

Figure 1. Illustration of basic parametric amplifier principle. The separation of the plates forming the capacitor is increased (thus the capacitance is decreased) so fast that the charge q remains constant, giving buildup in voltage $v=q/c$ and stored energy $qv/2$. Original separation is then restored at the moment when $q=0$. The whole sequence is repeated every half-cycle.

exactly on this principle, in which a signal is supplied at the resonant frequency f_s with the pump frequency $f_p = 2f_s$, is called a *degenerate amplifier*.

Nondegenerate parametric amplifiers, which do not impose this restriction on pump frequency or phase, can be constructed by connecting a second tuned circuit across the variable capacitance. This circuit is known as the *idler*, and its frequency f_i is tuned to $f_p - f_s$. Operation of such an amplifier can be explained in much the same way as above for the single resonant circuit; interested readers may refer to Ref. 17.

In practical circuits a semiconductor junction is used as an electronically variable capacitance instead of a mechanically controlled parallel-plate capacitor. The waveform changing such a capacitance is sinusoidal (rather than rectangular) and is produced by a special generator

(called a *pump*) pumping energy to the nonlinear capacitance. The theoretical power flow into and out of an idealized lossless nonlinear reactance is described in terms of two generalized equations known as the Manley–Rowe relations, which can be written as

$$\begin{aligned} \sum_{m=0}^{\infty} \sum_{n=-\infty}^{\infty} \frac{mP_{mn}}{mf_1 + nf_2} &= 0 \\ \sum_{n=0}^{\infty} \sum_{m=-\infty}^{\infty} \frac{nP_{mn}}{mf_1 + nf_2} &= 0 \end{aligned} \quad (1)$$

where P_{mn} represents, algebraically, the power flow into the nonlinear reactance at the frequencies $mf_1 + nf_2$. These equations are a result of only the nonlinear variation of the reactance and are independent of the shape of its characteristic and of the driving power levels. The spectrum of signals at the nonlinear reactance is illustrated at Fig. 2. If we consider a typical case of three-frequency amplifiers (however, more frequencies may be used in some specific applications)— f_1 , f_2 , f_3 , where $f_3 = f_1 + f_2$ —then, provided $f_1 \ll f_1 + f_2$, the general Manley–Rowe equations can be simplified to

$$\frac{P_1}{f_1} + \frac{P_3}{f_3} = \frac{P_2}{f_2} + \frac{P_3}{f_3} = 0 \quad (2)$$

This equation and Fig. 2 can be used to understand the operation of some of the different types of parametric amplifiers (nonlinear capacitance is assumed here to be lossless).

Let $f_1 = f_s$ be the signal frequency and power be supplied from an external source at frequency $f_2 = f_p$. Since pump power $P_2 = P_p$ is supplied to the capacitor ($P_p > 0$), then $P_3 < 0$ represents power leaving the reactance at the frequency $f_3 = f_p + f_s$; hence $P_1 = P_s > 0$. It follows that the device is absolutely stable and has the maximum power gain equal to $f_3/f_1 = 1 + f_p/f_s$. This type of amplifier is called an *upper-sideband (noninverting) upconverter*.

Now, let $f_1 = f_s$ be the signal frequency but let power be supplied from the pump at the frequency $f_3 = f_p$. Hence, $P_3 = P_p > 0$ and both $P_1 = P_s < 0$ and $P_2 < 0$; so the reactance can deliver energy at frequencies $f_1 = f_s$ and $f_2 = f_p - f_s$. If the power is extracted at the frequency f_2 , the device is called a *lower-sideband (inverting) upconverter*. The term *inverting* is used because the input signal spectrum is inverted at the output in this mode of operation.

If, as stated, the nonlinear capacitance is pumped at the frequency $f_3 = f_p$, that is, $P_3 = P_p > 0$ and $P_1 = P_s < 0$

Figure 2. Spectrum of signals at a nonlinear reactance. Input signal spectrum (f_s and its vicinity) appears at both sides of the harmonics nf_p of the pumping signal.

and $P_2 < 0$, but the output is at the frequency $f_1 = f_s$, then the negative sign of P_1 indicates that the capacitor emits more power than that fed from the generator at $f_1 = f_s$. It should be noted that the power supplied from the varactor to the signal source is independent of that supplied by the source itself; thus infinite gain is possible and the device is able to oscillate. It indicates that the pumped varactor presents a negative resistance to the signal source. Hence, with this frequency arrangement the signal power can be amplified at the same frequency, in contrast to the previous cases. The powers P_1 and P_2 are strongly dependent on the pump power and the external impedances. When the input and output frequencies are the same at $f_1 = f_s$, power at $f_2 = f_p - f_s$ is simply dissipated in the circuit and is unused. It justifies the name *idler* used traditionally for this frequency. The idler signal is an inevitable byproduct of this type of amplification, and suppressing it would also suppress the desired amplification of the signal. The separation of the idler and signal frequency is an important factor determining design and properties of this single-port (or *reflection* type) amplifier—the closer the idler to the signal, the more difficult it is to separate them by filtering. If the signal and idler frequencies are separated far enough so that the signal circuit does not pass the idler, the amplifier is called a *nondegenerate* amplifier. In the opposite case, if the signal circuit passes both the signal and idler bands and the input termination is common to both, that is, $f_i = f_p - f_s \approx f_s$, the amplifier is said to be *degenerate*.

3. VARACTOR DIODES

The most convenient nonlinear reactance element is a semiconductor diode specially designed to provide large variation of diode junction capacitance as a function of the applied (reverse) pumping voltage. Varactors may be classified into two broad groups, depending on the method of fabrication: the junction varactors, widely used at microwave frequencies, and the Schottky barrier varactors, generally used at millimeter waves and in high-performance amplifiers. Both groups are extensively discussed elsewhere in this encyclopedia, so only brief descriptions are given here and only problems specific for parametric amplifiers applications are discussed.

A typical junction varactor is made on an n-type silicon or gallium arsenide wafer, with a highly doped conducting substrate on which is grown a lower doped epitaxial layer. A suitable p-type dopant is then diffused into the epilayer to the obtain p^+ region and to form the p^+ -n junction. Ohmic contacts are made to a small circular area on the top of the wafer for the anode and to the bottom of the wafer for the cathode. Most of the epitaxial layer is then etched away, except the portion that is under the top contact. In this way a mesa of the desired diameter is formed. Diodes fabricated in this manner are called *diffused epitaxial varactors*.

A Schottky barrier varactor diode consists of a circular metallic contact pad (usually platinum) deposited on a lightly doped n-type layer epitaxially grown on a heavily doped GaAs substrate. The epitaxial layer is conductive

except in the vicinity of the metal–semiconductor interface, where an insulating depletion zone is formed. Depletion-layer thickness, and thus the capacitance, varies with the biasing voltage applied to the metal–semiconductor junction.

Simple, but justified by relatively low operating frequencies, varactor models are used in the analysis and design of parametric amplifiers; the reader is referred to Ref. 14 for advanced modeling of varactor diodes. A typical equivalent circuit of a microwave varactor is shown in Fig. 3. The reverse-bias junction is modeled in this simple circuit by a voltage dependent capacitor $C_j(v)$ and series resistance R_s . The terms L_p , C_p , and C_s are linear parasitic inductance, capacitance, and stray capacitance, respectively. The dependence of the junction capacitance on the applied reverse voltage v is given by

$$C_j(v) = C_{j0} \left(1 - \frac{v}{\phi} \right)^{-\vartheta} \quad (3)$$

where ϕ is the barrier potential and C_{j0} is the zero-bias capacitance. The exponent ϑ depends on the doping profile of the epitaxial layer of the varactor. For Schottky diode varactors with uniform epitaxial layer doping, it is close to $\frac{1}{2}$. For p^+ - n -junction varactors the ϑ factor varies from $\frac{1}{3}$ for a linearly graded diffused junction up to $\frac{1}{2}$ for an ideal abrupt junction. Other doping profiles (e.g., hyperbolic) have also been used in *hyperabrupt varactors* to obtain larger capacitance variation and thus higher values of the ϑ factor (ϑ in excess of 1 have been reported). However, the performance of the parametric amplifier depends not only on the capacitance change ΔC_j but also on the series resistance R_s of the varactor. Unfortunately, hyperabrupt varactors have high series resistance ($\Delta C_j/R_s$ is lower than for other varactors), which excludes their use in high-performance amplifiers.

In Schottky barrier varactors the series resistance is dominated by the contribution from the undepleted epitaxial layer. For parametric amplifiers, a breakdown voltage of a few volts is sufficient and this allows relatively high doping and a thin epitaxial layer, thereby reducing the series resistance. In diffused epitaxial varactors there are additional sources of parasitic resistance, namely, the resistance of the diffused p^+ -region and the resistance of the ohmic top contact. The p^+ -region resistance becomes large at cryogenic temperatures, causing serious degradation of diode performance. Similarly, silicon diodes cannot be used in cooled amplifiers because of series resistance

Figure 3. Equivalent circuit of a varactor. The reversed-bias junction is represented by a voltage-dependent capacitor $C_j(v)$ and a series resistance R_s . L_p , C_p , and C_s are parasitic inductance, capacitance, and stray capacitance, respectively.

increase and carrier freezeout below 40 K [14]. Hence gallium arsenide Schottky varactors have been the best choice for cooled parametric amplifier applications because of their low, relatively temperature-insensitive resistance.

3.1. Varactor Figures of Merit

Efficient varactor operations require the reactance of the junction capacitance to be much larger than the diode series resistance. It places an upper frequency limit on the usefulness of a given varactor, and figures of merit quantify this limit.

The static *cutoff frequency* f_c gives an indication of loss and is defined as that frequency at which the capacitive reactance of the junction at zero bias becomes equal to the series resistance:

$$f_c = \frac{1}{2\pi R_s C_{j0}} \quad (4)$$

For varactor applications the diode is characterized by the *dynamic cutoff frequency* defined as

$$f_{cd} = \frac{1}{2\pi R_s} \left(\frac{1}{C_{j,\min}} - \frac{1}{C_{j,\max}} \right) \quad (5)$$

where $C_{j,\min}$ and $C_{j,\max}$ are the values of C_j at the reverse breakdown voltage and at the zero bias voltage (or at $1 \mu\text{A}$ forward current), respectively.

Correspondingly, the quality factors at a specified frequency f_0 are given as $Q = f_c/f_0$ and for a pumped abrupt junction as $Q_d = 0.25 f_{cd}/f_0$.

In an amplifier, the capacitance is modulated by the application of microwave power at the pump frequency f_p and thus varies periodically in time. Hence $C_j(t)$ can be expanded into Fourier series

$$C_j(t) = C_0 \left(1 + \sum_{n=1}^{\infty} 2\gamma_n \cos 2\pi n f_p t \right) \quad (6)$$

where C_0 and γ_n are the Fourier coefficients. The values of γ_n , in particular that of γ_1 , determine parametric amplifier performance. In most practical cases higher terms may be ignored and only C_0 (the average value of the pumped capacitance) and γ_1 need to be considered. The diode capacitance *modulation coefficient* γ_1 is, of course, a function of the voltage developed across the diode at pump frequency, but will have a maximum attainable value, termed *nonlinearity factor*, given by

$$\gamma = \frac{C_{j,\max} - C_{j,\min}}{2(C_{j,\max} + C_{j,\min})} \quad (7)$$

When γ is referred to, it is usually this maximum value that is intended.

For parametric amplifier applications the most useful quantity to characterize the diode is the *pumped figure of merit*, defined as

$$M = \gamma f_{c0} \quad (8)$$

where

$$f_{c0} = \frac{1}{2\pi R_s C_0} \tag{9}$$

is the *pumped cutoff frequency*. A high pumped figure of merit indicates a low attainable noise of the amplifier.

4. NONDEGENERATE PARAMETRIC AMPLIFIER

As mentioned above, several three-frequency amplifier configurations are feasible. Of these, the negative-resistance nondegenerate parametric amplifier with a varactor diode providing a suitable nonlinear capacitance has achieved the most success as a practical low-noise paramp. A lumped-circuit analog of the microwave amplifier is used to obtain some insight into the operation of this type of amplifier. The model, shown in Fig. 4, consists of three resonant circuits coupled by a varactor that may be represented by the equivalent circuit of Fig. 3. So that the properties of the nonlinear element, rather than these of the resonant circuits, can be emphasized, it is assumed that the resonant circuits are ideal, and this is taken to mean that at certain frequencies they are pure resistances, while at all other frequencies they are very high impedances and, therefore, virtually open circuits.

With these assumptions, the behavior of the amplifier at the frequency $f_1 = f_s$ can be described in terms of a negative resistance \Re (voltage developed across \Re is out of phase of the current flowing through it), which appears in the equivalent circuit of the amplifier at this frequency. Its value is given by [1,8]

$$\Re = -\frac{\gamma^2}{\omega_s \omega_i R_{Ti} C_0^2} \tag{10}$$

where $R_{Ti} = R_s + R_2$ is the total series resistance at the idler frequency $f_i = f_2$.

The transducer power gain is taken as the ratio of power dissipated in the load resistance R_L to the available power from the signal source (internal resistance R_g) and

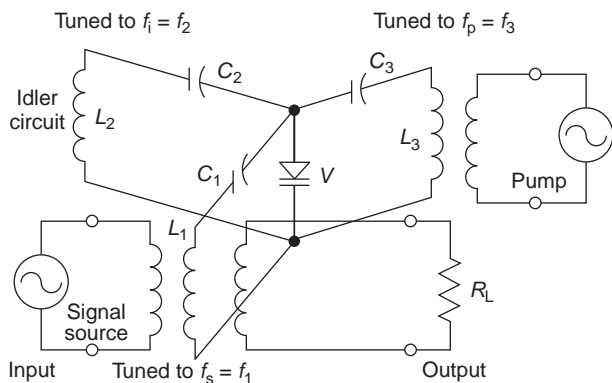

Figure 4. Lumped-element model of a microwave nondegenerate parametric amplifier. Three ideal resonant circuits tuned to signal, $f_s = f_1$, idler, $f_i = f_2$, and pump, $f_p = f_3$, frequencies are coupled by a varactor represented by the equivalent circuit of Fig. 3.

is given by

$$G_p = \frac{4R_g R_L}{(R_g + R_L + R_s + \Re)^2} \tag{11}$$

clearly, for high gain $R_g + R_L + R_s \approx |\Re|$.

In common with all other negative-resistance amplifiers, the negative-resistance parametric amplifier is extremely sensitive to small changes in the value of \Re and changes in source and/or load resistance when it is operated under high-gain conditions. In practice \Re may change as a result of fluctuations in the pump power and frequency, and control circuits have often been employed in conjunction with klystron pump sources in an effort to minimize such fluctuations. The popular approach was to control the attenuator in the pump line to maintain a constant varactor bias. Frequency fluctuations were handled in critical applications by locking the pump to a stable reference. The introduction of Gunn oscillators as pump sources resulted in a considerable improvement in stability, making stabilization schemes unnecessary in most cases [12].

4.1. Operation with a Circulator

Nonreciprocal devices such as circulators are used to separate the amplified output from the input and to protect the amplifier against changes in impedance at the input or at the following stage of the receiver. An ideal circulator is a circuit element that directs energy from one port to the next port without loss and prevents transmission in the opposite direction. This passive component obtains its nonreciprocity from the presence of a central ferrite structure placed in a DC magnetic field.

Early paramps used three-port circulators, but most recent designs incorporated five-port circulators to increase immunity from the effect of source impedance variation and to provide greater isolation between adjacent stages in multistage amplifiers. (For stability, the gain was usually limited to 20–25 dB for a single-stage device. If higher gain was required, a number of 10–15-dB stages were connected in cascade.)

Knowing that the variation of the varactor’s junction capacitance is completely controlled by the pump, it is then possible to concentrate entirely on that variation, and omit details of the source that produced it. The circuit of Fig. 4 can therefore be redrawn as in Fig. 5, leaving out the pump circuit; the capacitance is then specified as $C_j(t)$, emphasizing in this way the time variation. The signal source and the load are connected to the amplifier via a three-port circulator.

4.1.1. Power Gain. The power gain of the amplifier-circulator combination can be seen to depend on the ratio of the powers entering and leaving the amplifier. Since the circulator has a characteristic impedance Z_0 to which it should be matched, source and load resistances will have the same value, and the circuit available gain will equal the transducer gain. The required power gain is therefore equal to the square of the magnitude of the voltage reflection coefficient Γ and, since $R_g = R_L = Z_0$, is

Figure 5. Equivalent circuit of the nondegenerate parametric amplifier employing a circulator to separate the amplified output from the input. The pumped varactor is represented by a capacitance $C_j(t)$ periodically varying in time and series resistance R_s .

given by

$$G_p = \Gamma\Gamma^* = \left| \frac{R_s + R_L - \Re}{R_s + R_L + \Re} \right|^2 \quad (12)$$

With the use of a circulator, the input loop of the amplifier effectively contains only one of two resistors, R_g or R_L . For high gain, that is, $R_L + R_s \approx |\Re|$, Eq. (12) can be rewritten as

$$G_p = \frac{4R_L^2}{(R_L + R_s + \Re)^2} \quad (13)$$

Comparing the expressions for power gain with and without the circulator (setting $R_g = R_L$ and remembering that $R_s \ll R_L$), it can be seen that the use of a circulator has increased the power gain 4 times for the same gain stability, where instability of gain results from changes in \Re .

4.1.2. Noise Temperature. In low-noise amplifiers, it is more convenient to express noise performance in terms of *effective noise temperature* (or, in short, *noise temperature*), which is related to the noise figure F by the equation

$$T_e = T_0(F - 1) \quad (14)$$

where $T_0 = 290$ K is a standard temperature.

The effective noise temperature of the parametric amplifier depends on the thermal noise contributions from all the resistances in the circuit (shot noise is not present in the reverse-biased junction). Neglecting contributions other than that from the varactor itself, the noise temperature of a negative-resistance reflection-type parametric amplifier can be calculated in this limiting case from the following equation [5,7,8]

$$T_{ea} = T \left(1 - \frac{1}{G_p} \right) \frac{\left(\frac{f_{c0}}{f_i} \right)^2 \gamma^2 + 1}{\frac{f_{c0}^2}{f_s f_i} \gamma^2 - 1} \quad (15)$$

where T is the diode physical temperature and G_p is the amplifier power gain. It is possible to calculate the pump frequency $f_{p,opt}$ at which the parametric amplifier noise temperature has its minimum value. This is given by

$$f_{p,opt} = f_s \left[1 + \left(\frac{f_{c0}}{f_s} \right)^2 \gamma^2 \right]^{1/2} \approx \gamma f_{c0} = M \quad (16)$$

and the optimum noise temperature for large gain becomes

$$T_{ea,opt} = T \frac{2f_s}{\gamma f_{c0}} = \frac{2f_s T}{M} \quad (17)$$

Thus, it is apparent that for good amplifier performance a diode should combine high cutoff frequency with a marked capacitance variation, even at low temperatures, in order to achieve low noise temperature.

If we now add contributions from losses in the signal and idler circuits, the circuit behavior of the circulator-type amplifier (where $R_L = R_g$), is then described by the noise temperature

$$T_{ea} = \frac{T_1 R_1}{R_g} + \frac{T_d R_s}{R_g} + \frac{f_s |\Re|}{f_i R_g} \left[\frac{T_d R_s + T_2 R_2}{R_2 + R_s} \right] \quad (18)$$

where \Re is the negative resistance given by Eq. (10), R_g is the generator resistance in the signal circuit and R_1 and R_2 represent losses (other than R_s) in signal, $f_1 = f_s$, and idler, $f_i = f_2$, circuits. T_1 , T_2 , and T_d are the temperatures of R_1 , R_2 , and R_s , respectively. In practical amplifiers temperatures are usually equal, that is, $T_1 = T_2 = T_d = T$ and the amplifier is designed to have, as far as possible, R_1 and R_2 negligibly small in comparison with R_s . Then, at high gain, that is, $|\Re| \approx R_g + R_s$, the noise temperature is given by

$$T_{ea} = T \left(\frac{R_g + R_s}{R_g} \frac{f_p}{f_i} - 1 \right) \quad (19)$$

For many applications cooling is not necessary. Adequate low-noise performance can be achieved using simple circuits with diode of moderate cutoff frequency. If lower noise temperatures are required, it is necessary to use higher idler frequencies, and this is possible only if a diode of sufficiently high cutoff frequency is used. When cooling is necessary to lower the noise temperature, it must be remembered that any loss in the path between the signal source, such as an antenna, and the parametric amplifier may considerably degrade the overall noise temperature. If the loss of the circulator is $A = 10 \log(L)$, then the noise temperature of the circulator-amplifier cascade is calculated from

$$T_{e,c-a} = T_{e1} + \frac{T_{e2}}{G_1} = (L - 1)T + LT_{ea} \quad (20)$$

If, for example, a circulator with $A = 0.41$ dB transmission loss is ahead of a low-noise, $T_e = 100$ -K amplifier, then at room temperature, $T = 290$ K, the receiver has noise

temperature $T_{e,c-a} = 0.1T + 1.1T_{ea} = 139$ K. When the amplifier is cooled down to temperature 20 K, its noise temperature lowers to, say, $T_{ea} = 10$ K. Leaving the circulator uncooled will increase the overall noise temperature 4 times to $T_{e,c-a} = 40$ K. It is thus obvious that both the circulator and the amplifier must be cooled down to obtain low-noise performance of the receiver ($T_{e,c-a} = 13$ K in this illustrative example).

4.1.3. Bandwidth. Much effort has been spent in devising ways of obtaining the broad bandwidth essential in some applications—see Ref. 9 for a thorough review of advanced techniques used for the purpose. Because the bandwidth of an amplifier depends on its gain (decreases with increase of gain), the gain–bandwidth product is used to characterize the amplifier performance. It can be shown [8] that for a negative-resistance amplifier operated in conjunction with a circulator, the gain–bandwidth product may be derived as

$$G_p^{1/2}B = 2 \left(\frac{1}{B_s} + \frac{1}{B_i} \right)^{-1} \quad (21)$$

where B_s and B_i are the unpumped signal and idler circuit bandwidths, respectively. Both signal and idler circuits should therefore be as broadband as possible to give the amplifier a good gain–bandwidth product.

Since the signal circuit is loaded externally by the source resistance, whereas the idler has no external loading, the latter will tend to be a high- Q circuit limiting the bandwidth. The resistance present in the idler has already been fixed at the diode resistance R_s , and any increase in this will degrade the amplifier performance. Therefore, in order to optimize the bandwidth of the idler circuit, it is necessary to keep the reactance of the idler circuit as low as possible. (The bandwidth of a series-tuned circuit is given by the R/L ratio.) This can be achieved by confining the idler power to the varactor encapsulation. From Fig. 3 it can be seen that there is the possibility of a series resonance, associated with L_p , C_0 (the average value of the pumped junction's capacitance), C_s , and R_s at the frequency given by

$$\omega_{si}^2 \approx \frac{1}{L_p(C_0 + C_s)} \quad (22)$$

neglecting the effect of R_s . The resonant frequency f_{si} can be arranged to be the idler frequency of the amplifier, but in order to use the series resonance in this way, a return path for the current must be provided (e.g., by a lumped circuit or a length of transmission line). An elegant solution to this problem uses two antiparallel connected diodes. When sufficiently excited, the idler current will circulate around this structure and will not propagate to any other part of the amplifier. A further development of this idea has seen the production of suitable diodes in one encapsulation. Another approach is to mount the diodes back to back across the pump waveguide with signal line entering through the sidewall and contacting the junction between them (crossbar configuration).

For parametric amplifiers with a high idler frequency it is more convenient to use the parallel resonance of the encapsulated diode (which is actually a series resonance for the idler currents) to form the idler circuit. Such an amplifier uses a single diode and can be further refined by modifying the series resonance to support the signal frequency.

Careful attention to the design of the idler circuit leaves the bandwidth of the signal circuit as the main limitation on the overall bandwidth of the parametric amplifier. An estimate of the maximum attainable bandwidth under these conditions may be made putting $B_i \ll B_s$ in Eq. (21) to yield

$$G_p^{1/2}B \simeq 2B_s \quad (23)$$

If the signal circuit is now designed for the minimum possible Q -factor associated with the source resistance, then the added inductance must just resonate the diode capacitance at the signal frequency (i.e., single-tuned circuit). Then under the high-gain condition, it is found that

$$G_p^{1/2}B \simeq 2\gamma f_s \left(\frac{\gamma f_{c0}}{f_p - f_s} \right) = 2\gamma^2 f_{c0} \frac{f_s}{f_i} \quad (24)$$

The result suggests that high-quality diodes are important in securing large gain–bandwidth products, and that there must be a tradeoff between effective noise temperature and bandwidth in selecting the pump and, therefore, the idler frequency.

Considerable improvement in the overall gain–bandwidth product can be achieved by introducing a filter structure in place of a simple single resonant circuit. Improvements of over 5 times have been reported with little increase of noise temperature. For a maximally flat design, the limiting bandwidth should be given by $B \log(G_p) = \text{const}$, but in practice the use of more than two or three compensating elements leads to practical difficulties in tuning the device.

5. OTHER PARAMETRIC AMPLIFIER CONFIGURATIONS

5.1. Degenerate Parametric Amplifiers

In the degenerate parametric amplifier, the pump frequency is approximately twice the signal frequency. The signal and idler passbands overlap, and instead of idler circuit being terminated inside the amplifier, it is effectively terminated in the input of the amplifier. The absence of a separate idler circuit makes construction of such an amplifier much simpler than the corresponding non-degenerate version. The additional advantages are a low pump frequency and a wider bandwidth. Therefore, degenerate amplifiers were finding applications in some early broadband radiometers and more recently in millimeter-wave paramps.

The phase-coherent degenerate amplifier in which the pump frequency is exactly twice the signal frequency is by its nature a single-frequency device since no departure from coherence with the pump is allowed [1,4,8]. To

achieve the required frequency relationship, in practice it would be necessary to synchronize the pump frequency to the second harmonic of the signal frequency with special phase-locked loop (PLL) circuitry. It can be shown [1] that the gain of the amplifier changes with changes in phase of the pump signal, rendering the use of this amplifier impracticable in the majority of potential applications.

Even if phase relations are loosened and the signal frequency is only approximately equal to the idler frequency, care must be taken in using the amplifier. It should be noted that the degenerate amplifier is not suitable for direct use with frequency-modulated signals, since when f_s increases in frequency, then $f_i = f_p - f_s$, which is present at the same terminals, decreases in frequency. The signal fed into a degenerate amplifier may be amplitude-modulated, although if the amplifier has the idler frequency only approximately equal to the signal frequency, beats between the two waveforms can cause interference. A cascade of the degenerate paramp followed by a parametric converter pumped synchronously at $0.5f_p$ was used to overcome both difficulties (1).

The major disadvantage of degenerate amplifiers becomes apparent when we consider that a signal entering receiver appears in both idler and signal responses of the amplifier and the output contains both the signal and its image (also noise from both responses adds at the amplifier output). When coherent communication signals are involved, this double response is unacceptable. In radiometer applications, where the signal takes the form of broadband noise, this type of amplifier has good sensitivity, since the signal is received equally in both the signal and idler bands. In general, the use of degenerate amplifier must be judged carefully considering the nature of the signal, single- or double-sideband operation at the input and the output of the amplifier, and the nature of the detector employed in the receiver. A detailed discussion of this subject can be found in Refs. 4, 10, and 11.

5.2. Multiple-Idler Parametric Amplifiers

To circumvent some of the disadvantages of the three-frequency paramps, many other frequency combinations had been proposed for parametric amplifiers in the hope that an improved performance would outweigh the disadvantages of (usually) increased complexity. If more than one idler frequency is used, it is possible to use a pump frequency lower than the signal frequency. In the 2-idler case (the so called four-frequency paramp), the usual restriction

$$f_i = f_p - f_s > 0 \quad (25)$$

is replaced by

$$f_{i1} = f_s - f_p > 0 \quad (26)$$

for the first idler, and

$$f_{i2} = (f_p - f_{i1}) = 2f_p - f_s > 0 \quad (27)$$

for the second idler. Therefore $\frac{1}{2}f_s < f_p < f_s$ is required for efficient operation (negative resistance at signal frequencies $f_p < f_s < 2f_p$). Note that if f_p is chosen as $\frac{2}{3}f_s$,

then the two idler frequencies will both be equal to $\frac{1}{3}f_s$. The lack of adequate pump generators was the main reason to use four-frequency paramps at millimeter waves. However, more complex microwave construction usually resulted in higher losses and hence poor noise performance and, therefore, multiple-idler paramps found only limited applications [9].

5.3. Traveling-Wave Parametric Amplifier

Up to now parametric devices utilizing essentially resonant structures have been considered. Such circuits suffer from previously discussed drawbacks; some of them can be minimized by resorting to nonresonant propagating circuits. A variety of configurations are possible, each with its own characteristics. Perhaps the simplest is the case where all the three traveling waves—signal, idler, and pump—have positive phase and group velocities. This was exploited in amplifiers taking the form of a transmission line periodically loaded with varactor diodes. It was difficult in practice to satisfy phase requirements for all the signals, and some experimental amplifiers provided separate pump feeds for each diode [10]. For frequencies below 1.5 GHz, experimental amplifiers had usually the form of stripline with diodes between the central and outer conductors [1,7]. For higher frequencies, the diodes were mounted across rectangular waveguide or a series of coupled cavities [10].

In practice, because of the difficulties of providing a considerable number of identical diodes and the experimental difficulties of providing the correct phase characteristics at the three frequencies, the performance of traveling-wave amplifiers was worse than that achieved with much more simple and requiring much less pump power single-diode devices. Therefore, traveling-wave parametric amplifiers have never been developed beyond the experimental stage and have never left the laboratory. A distributed varactor was needed for success in this field. However, it appeared at the end of the 1970s in a form of nonlinear transmission line employing distributed Schottky barrier varactors [14]. It was too late—parametric amplifiers were just giving way to new technology of GaAs field-effect transistor amplifiers.

6. ILLUSTRATIVE EXAMPLE

There were many species of microwave parametric amplifiers, and a wide range of amplifiers design were available (see Refs. 4–6, and 9–11 for detailed and complete design theories and practical considerations). The choice was dependent on the particular application. In many applications, the lower limit of background noise in the system was determined by thermal noise entering the antenna from the terrestrial surroundings, and for such applications relatively simple uncooled parametric amplifiers were commercially available. For reception of the weak signals from communication satellites or interplanetary probes, however, extremely low system noise temperature was essential and a whole range of specialized cooled amplifiers was developed offering noise temperatures as low as 12–15 K (comparable with masers).

Figure 6. Representative example of the microwave construction of a parametric amplifier: section diagram of a 3.25-GHz nondegenerate parametric amplifier. (Source: J. W. Archer and R. Batchelor, Multipliers and parametric devices, in K. Chang, ed., *Handbook of Microwave and Optical Components*, Vol. 2, p. 187. ©1990 John Wiley & Sons. Reprinted by permission of John Wiley & Sons, Inc.)

Bandwidth and operating frequency requirements were widely diversified. Paramps were made to amplify signals up to the millimeter-wave frequencies (60-GHz paramps are reported in Ref. 9). For some terrestrial communication and radar requirements, with several MHz bandwidth were routinely manufactured. Satellite communication systems required 500 MHz bandwidth, and specially designed paramps were developed for such systems.

A 3.25-MHz nondegenerate parametric amplifier [12] has been selected as a representative example to illustrate the elegant design and refinement of microwave construction. The amplifier designed for spectral line radio astronomy covers the frequency range 3.1–3.4 GHz with an instantaneous bandwidth of 40 MHz. A section drawing of the amplifier is shown in Fig. 6. Description of the amplifier is rewritten here with permission of John Wiley & Sons, Inc.:

The varactor diode is mounted in the E -plane of a reduced-height waveguide which couples pump power from a 22 GHz reflex klystron to the varactor. A short length of high-impedance coaxial line series resonates the diode mean capacitance at the signal frequency. A three-element low-pass filter isolates the pump and idler from the input line while the pump waveguide is cut off at the idler frequency, confining the idler to the vicinity of the varactor and the idler cavity. The idler circuit contains a tunable cavity coupled to the varactor by an iris. The position of this iris was chosen to optimize the pump coupling to the varactor. The idler frequency is determined by the combination of the package parasitic reactances, the coupling, and the tunable cavity, which consists of a micrometer-adjustable noncontacting short circuit in a cylindrical tube. The pump and idler blocking filter forms part of a quarter-

wave transformer in the input coaxial line, which is used to transform the characteristic impedance of an external cir-

culator to the value required to obtain a desired gain [R_L in Eq. (13)].

No external bias is provided, the varactor being pumped until self-bias is developed.

The amplifier gain was set to 20 dB and, from noise measurements of uncooled receiver, its effective noise temperature was estimated to be 60 K.

MICROWAVE PHASE SHIFTERS

JOSEPH F. WHITE
JFW Technology, Inc.

1. SCANNING ARRAY ANTENNA APPLICATIONS

Mechanical motion necessary for antenna scanning was perceived to be slow and unreliable. For this reason the microwave industry developed an intense interest in phased-array antennas, primarily for military but also

for commercial applications. The antenna's radiated wavefront would be steered by thousands of individual radiators, roughly one for each half-wavelength square area of the radiating aperture. Each radiator would be controlled by a solid-state (either semiconductor or ferrite) phase shifter, having low insertion loss and 0–360° of phase shift. For computer control the phase shift would be accomplished in binary bits. Thus a 3-bit phase shifter would have a 180°, a 90°, and a 45° section and these could be used to provide 0–315° control in 45° steps (the last step to 360° is not needed, being equivalent to 0° in the steady state). The antennas would be more expensive, both because of their need for numerous control elements (a circular aperture 30 wavelengths in diameter requires about 2500 elements) and the fact that, since a phased array provides only about $\pm 45^\circ$ of steering, four separate apertures are needed for 360° azimuthal coverage. But they would be fast and nearly failsafe, since a failure of a few elements would result in but “graceful degradation” of the system.

Ideally time delay (Fig. 1) is used to steer an array of antenna elements, and a two-dimensional array uses total time delay equal to that required for both azimuth and elevation steering. When time delay is used, the steering is frequency-independent, very desirable for a broadband antenna. However, the time delay required, equivalent to 70% of the antenna width for 45° beam steering along either of the antenna's steering axes, can amount to thousands of degrees of control. Instead, phase control is used. The requisite time delay is first calculated by the beam-steering computer and then all integer wavelengths dropped. The residue in degrees is then provided (to within one-half of the least significant bit) as a command to the binary bit phase shifter. In some cases, groups of adjacent phase shifters (subarrays) may employ time-delay steering to enhance antenna bandwidth performance.

Over the last four decades there has been a keen competition between the rival technologies, semiconductor and ferrite, to achieve the phase control. The semiconductor devices and their circuitry are generally faster switching and inherently reciprocal (having the same phase shift on transmit as receive), a useful antenna property. Being switches, their phase control is essentially temperature invariant, and the circuits more easily reproduced. Driver circuits, which interface the microwave control circuit to the array antenna beam steering computer, are very simple for the semiconductor phase shifter. However, semiconductors are discrete and small switching elements, and thereby limited in their peak power-handling

Figure 1. A linear phased array steered with time delay.

capacity. Furthermore, their insertion losses increase with frequency.

Ferrites are a controllable propagation medium for microwaves and thus have more volume and a higher power-handling capacity. Properly designed, they have low losses at higher microwave frequencies and, for certain circuit configurations, can be made reciprocal, even though propagation through the medium itself is nonreciprocal. Considerable attention must be given to the ferrite's flux driver circuitry to achieve reproducible binary phase control from unit to unit and over temperature and bias supply voltage changes. In fact, taking its driver circuit into account, a ferrite phase shifter typically includes more semiconductors than does a semiconductor phase shifter.

This section treats the semiconductor phase shifter. While they could be built using a variety of semiconductors, diodes, and bipolar and field-effect transistors, the principal development was with silicon pin diodes because of their relatively low cost, high microwave Q , and inherent inertia to changes in characteristics with applied microwave (RF) excitation. To appreciate this requires some description of the pin diode.

2. THE PIN DIODE

Generally, semiconductor pn junctions have rapid response to an applied voltage and even can be used to rectify an RF signal for detection purposes. However the pin has a high resistivity (intrinsic), undoped region between its p and n zones. The result is that holes and electrons which are injected from the p and n zones under forward bias move by diffusion into the i region, where they serve as mobile charge not unlike electrons in copper, rendering the i region conductive to an applied RF signal. Electrons and holes can combine with one another, resulting in carrier death, but to do so they must give up energy equal to the energy difference between the valence and conduction bands (the bandgap). For silicon this is 1.1 electronvolts, and such a drop in energy requires an energy emission, if performed in one step, of a photon of visible light. We do not observe silicon to be glowing with such light emission, because such a transition is very unlikely. Put another way, the lifetime of an electron-hole pair is long, tens of microseconds for the resistivities obtained in practical diodes. The "staircase" of energy steps resulting from impurities and stresses in an otherwise ideal silicon crystal produce a far more likely energy transition between bands, consequently lower carrier lifetime.

The charge storage in a pin's i region is equal to the product of the lifetime and the forward bias (Fig. 2). Thus, for example, a 1000 V breakdown pin diode might have a $5 \mu\text{s}$ lifetime and be biased with a current of 100 mA, resulting in a stored charge of $0.5 \mu\text{C}$. When a 1 GHz sinusoid having a peak current of 50 A is applied to the diode, it causes a peak-to-peak charge movement of less than $0.025 \mu\text{C}$, less than 5% of the charge stored by the bias. The result is that the diode appears to be a low value of resistance throughout the entire RF sinusoid.

The same diode, when operated at a reverse bias of -100 V , is able to sustain, without conduction, an applied

Figure 2. Example comparing charge stored in a pin diode by the bias to the charge movement due to a high-level RF signal.

RF sinusoid of 1000 V peak. This is because the diode requires a microsecond or more to establish a conducting state in the i region, much longer than the 0.5 ns forward-going voltage duration of a 1 GHz sinusoid.

Well-made pin diodes enjoy a bulk breakdown voltage of about $10 \text{ V}/\mu\text{m}$ ($250 \text{ V}/\text{mil}$) of i-region width. It is this bulk breakdown that determines the pin's ability to sustain RF voltage. Conduction due to impact ionization in the i region can occur rapidly, even within an RF half-cycle.

Ryder [1] has likened the bias on a pin diode to the "large signal" and the RF as the "small ac component," the truth of which is evident from the relative magnitudes of the charges related to each. The result of this remarkable behavior is that the pin can control tens of kilowatts of RF power, using only fractions of a watt of bias power.

Using the charge control approach for determining the RF properties the RF resistance, R_i , of the pin under forward bias is found to be [2, p. 62]

$$R_i = W^2 / (2\mu_{AP}\tau i_0) \quad (1)$$

where, in the pin diode's i region, W = the i region thickness; μ_{AP} = the ambipolar mobility (the effective average velocity per unit applied electric field of the holes and electrons); τ = the average lifetime of holes and electrons; and i_0 = the forward bias current.

For the pin used in the example of Fig. 1, $W = 100 \mu\text{m}$ (4 mils), $\mu_{AP} = 610 \text{ cm}^2/\text{V}$ (in silicon), $\tau = 5 \mu\text{s}$, and a suitable bias current is 0.1 A, resulting in an RF resistance of only 0.16Ω . To R_i must be added the ohmic contributions of the p and n regions of the diode, as well as the contact resistances of the diode package. Even so, the total forward-biased resistance R_F is usually 0.5Ω or less. Interestingly, R_i is not dependent on i-region diameter D , directly. However, indirectly it is, since smaller diameter diodes have lower τ , because carriers, on average, are

Figure 3. pin-diode chip equivalent circuit.

closer to the i-region boundaries at which recombination can more readily take place.

PIN diode area A does relate to the junction capacitance, C_J , which follows the parallel plate formula fairly closely.

$$C_J = \epsilon_R \epsilon_0 A / W \tag{2}$$

At low frequencies, say, 1 MHz, a C change between zero and reverse bias voltage is observable; however, at RF, it is the minimum capacitance that is experienced due to the dielectric relaxation of the i region [2]. With the high dielectric constant of silicon ($\epsilon_R = 11.8$), there is little fringing of the electric field.

In series with this capacitance is a resistance R_R (not necessarily equal to R_F), which is determined by measurement. An RF figure of merit for the pin is the switching cutoff frequency F_{CS} , given by

$$F_{CS} = 1 / (2\pi C_J \sqrt{R_F R_R}) \tag{3}$$

As will be described later, the F_{CS} value permits a prediction of the minimum insertion loss to be obtained in a phase shifter, switch, or duplexer circuit, even before the circuit configuration has been specified [2, Chap. 5]. The RF equivalent circuit of the pin chip in its two bias states is shown in Fig. 3. Package capacitance and inductance must be added for a complete packaged diode. For our sample diode, having a junction diameter of 0.49 mm (19 mils), $C_J = 0.2$ pF.

When suitably soldered either into a package or onto a good heat sink, it is found that the junction temperature rise of our sample diode is about 15°C per watt of power dissipated in the junction. Equivalently stated, its thermal resistance, $\theta = 15^\circ\text{C}/\text{W}$. In pulsed RF power applications there may be insufficient time during the pulse for thermal equilibrium to be reached. The junction temperature may rise linearly and the diode i region, small as it may seem, must sink the heat dissipated until it can flow out through the thermal resistance path (Fig. 4). The heat capacity HC of the i region is given by

$$\text{HC} = (\text{specific heat}) \times (\text{density}) \times (\text{volume}) \tag{4}$$

which, for a silicon $pin = (0.74 \text{ J/g}\cdot^\circ\text{C}) \times (2.43 \text{ g/cm}^3) \times (\pi D^2 W / 4)$.

For our sample diode, having $D = 49 \mu\text{m}$ (19 mils) and $W = 100 \mu\text{m}$ (100 mils), $\text{HC} = 34 \mu\text{J}/^\circ\text{C}$. This is indeed a small heat capacity, yet it implies that, for a given

Figure 4. pin model used for heatsinking calculation.

temperature rise, the pin could dissipate nearly 7 times as much power for 1 μs as it could sustain with continuous dissipation. Furthermore, this HC calculation is conservative, because it ignores the heatsinking capacity of the bondwires and the p and n portions of the diode that are in intimate contact with the i region. The product of HC and θ gives the thermal time constant, τ_T , from which the temperature rise, ΔT_J of the i region can be estimated for any pulse length, t , of power dissipation, P_D . Thus

$$\tau_T = (\text{HC})(\theta) \tag{5}$$

$$\Delta T_J = P_D \theta (1 - e^{-t/\tau_T}) \tag{6}$$

The temperature rise is shown graphically in Fig. 5. For the sample diode the minimum τ_T is 500 μs . If a safe temperature rise is considered to be 100°C, then the diode could dissipate 6.6 W continuously, 16 W for 500 μs , 66 W for 50 μs , and so forth. Following the pulse, the diode cools during the interpulse periods with the same thermal time constant (Fig. 6).

This same reasoning could be applied to develop a more complete thermal model of the diode, which includes its thermal surroundings. Figure 7 shows a more representative model of the diode, with its thermal elements and

Figure 5. General pulsed temperature-rise profile of a pin diode, using the minimum-time-constant model.

Figure 6. Sample estimate of pin junction temperature during a train of power dissipating pulses.

that of the packaging materials. Generally, however, the simple conservative model is sufficient to estimate the maximum temperature rise to be expected from a given pulsed power dissipation.

A representative listing of a wide range of pin diodes is shown in Table 1. Given these parameters, it is possible to estimate most of the performance of a variety of RF phase shifter, switch, and duplexer circuits, even before the circuits themselves are specified.

3. LOADED LINE PHASE SHIFTER

A diode phase shifter is a device whose primary function is to change, by means of a control bias, the propagation

Figure 7. Construction pin detail and its thermal model.

phase of a microwave signal. Most switches, attenuators, limiters, and duplexers introduce phase shift, although seldom by design. Moreover, since any reactance placed in series or shunt with a transmission line introduces phase shift, the possibilities for phase shift networks are unlimited. However, adding the requirement that the device has minimum insertion and reflective losses reduces the selection of practical circuits.

Most think of switching between circuit paths as a direct means of phase shift (Fig. 8). Actually this is a switched time-delay circuit, producing phase shift that is linearly proportional to frequency. This might seem all the more desirable, since it could lead to broadband array antenna steering. However, in practice, the switching between paths is accomplished with limited isolation of the nonselected path. Figure 9 shows how the loss can increase dramatically when the OFF arm resonates.

While time delay circuits have a place, they are not efficient. All the RF power must be switched between paths and four diodes minimally are required to do this. The insertion loss is the same for all bits, whereas in a phase shifter circuit, only two diodes are required per bit and the diode loss is much less for small phase shift bits. Accordingly, we shall omit further discussion of time-delay circuits and proceed to phase shifters (which, generally, do not have linearly increasing phase change with frequency).

Initially it was thought that very high power phase shifters would be required. In fact, the author conducted a Navy-sponsored project, whose objective was a 100 kW peak power phase shifter—an objective that was met and applied to a high power array! The key to the development was the recognition that, since numerous diodes would be required for very high power, each contributing a small amount of the total phase shift required, a circuit lightly coupling the diodes to the propagating wave was needed.

The solution was the transmission phase shifter (Fig. 10), in which pairs of diode-switched susceptances load the transmission line. The spacing of the susceptances, about 90°, is selected to cause mutual cancellation of their reflections. The magnitude of the susceptances is made small (less than 0.4 Y₀), and so the diodes are subjected to relatively small RF currents and voltages, producing low dissipation in each diode. This enhances both power-handling and insertion-loss performance.

This loaded line section has an equivalent circuit [2, p. 410] consisting of a uniform line section of new characteristic admittance Y_E and electrical length θ_E, related to the loaded line's admittance Y₀ and electrical length θ by

$$\cos \theta_E = \cos \theta - (B/Y_0) \sin \theta \tag{7}$$

$$Y_E = Y_0 [1 - (B/Y_0)^2 + 2(B/Y_0) \cot \theta]^{1/2} \tag{8}$$

Consider Eq. (7) first. If the line loading susceptance is somehow switched by the pin diode between equal-magnitude and opposite-sign susceptors, B₁ and B₂, then the electrical length of the loaded line is described by the vector diagram in Fig. 11.

Notice from Fig. 11 that when θ = 90° the sine of the phase shift Δφ/2, produced by each of the equal susceptances B_i, is equal to the normalized susceptance term

Offered by the M/A-COM Division of AMP Inc. in Burlington, MA.

Figure 8. Schematic for switched delay line phase shifter.

$BZ_0 (Z_0 = 1/Y_0)$. Then, approximating the sine by its angle, the total phase shift in radians obtained by switching between B_1 and B_2 is given by

$$\Delta\phi \cong (B_2 - B_1)Z_0 \tag{9}$$

For example, if the normalized susceptances switch between plus and minus 0.2, then the phase shift is 0.4 radians, near 22.5° , a 16th of a wavelength. The respective 4 bits of a phase shifter can be made up of one, two, four, and eight such sections in cascade.

But, the reader may ask, suppose that the individual reflections from each section, although small in themselves, combine when 15 such sections are cascaded to produce very large reflection and with it high mismatch loss.

Such is not the case. Referring to Eq. (8) and applying the values $\theta = 90^\circ$ and $|B_i Z_0| = 0.2$, gives $Y_E = 0.98Y_0$. This is true for either positive (capacitive) or negative (inductive) line loading. Thus, even as the phase length of

Figure 9. Switched path circuit example demonstrating loss resonances.

Figure 10. Switched transmission phase shifter section, also called the loaded line phase shifter.

the section changes, its characteristic admittance does not. Nor is its value very different from Y_0 . Accordingly, an arbitrarily long cascade combinations of such sections would not result in a VSWR larger than 1.04, provided that there are no line sections intervening between the phase shift sections. Even this small mismatch could be further compensated by installing a quarter-wave line of admittance $1.02Y_0$ at each end of the phase shifter cascade. This inherent match of the loaded line phase shifter is one of its most useful attributes.

It now remains to design the line loading circuits, such that a two-state diode can yield the ± 0.2 normalized susceptance switching. The first circuit approach used shunt stubs, whose length was varied by pin-diode switches (Fig. 12). The diodes were similar to the 0.2-pF, 4-mil I region model described in Table 1. The line lengths α_1 and α_2 were adjustable. The phase shift was proportional to α_1 while the average of the two lengths was adjusted to control the transmission match. With 5° of phase shift per stub pair, a level of 140 kW peak power was sustained with 0.001 duty cycle, 5- μ -sec-long pulses at 1300 MHz. There were eight sections in the experimental model and the results are shown in Fig. 13.

The maximum powers listed are those that cause or nearly cause burnout, usually occasioned by voltage breakdown of the pin diodes in the reverse biased state. For pins, as well as all semiconductors, reliable operation requires a rating that impose only 50% of this maximum voltage stress on the semiconductor. Since power is related

Figure 11. Graphical representation of the loaded line phase shifter's change in electrical length caused by switching the loading susceptances.

Figure 12. Equivalent circuit for one section of the switched stub, loaded line phase shifter tested at 1300 MHz under high peak power.

to the square of voltage, this means devices need be rated at one-fourth the power level, which would cause immediate failure.

For microwave phase shifters this is especially useful in the event of a short-circuited output, which could nearly double the voltage stress on its diodes. Such a short can result from an arc over or damaged radiating element, even a disconnected output. Indeed, a customary acceptance test for a high-power-control device is operation into a short-circuited load, which is varied through all phases. Given this derating, very high reliability of pin phase shifters is experienced, as is necessary in an array antenna.

While it is true that no practical phased array could radiate such levels (a 2500-element array using 35 kW

phase shifters would radiate 87 MW peak power), this result is significant, because single-pole double-throw switches can be constructed by installing such phase shifters between 3 dB hybrid couplers, allowing, for example, the full output power of a radar to be switched between alternate antennas.

The loaded line approach was extended to 3 GHz in a circuit in which the diode's own capacitance terminates the quarterwave shunt stub. Switching between forward and reverse bias changed between $-j50 \Omega$ (the diode has about 3 pF capacitance) and its forward resistance of 0.5Ω . Adjusting the shunt stub impedance produced as much as 45° phase shift per pair and a maximum RF peak power of 70 kW [2, p. 429]. This phaser was used in the U.S. Safeguard system, of which only a prototype system was built.

Figure 13. L-band measurements of phase shift, insertion loss, and ultimate peak power capability of the switched stub, loaded line phase shifter. Varying switched stub lengths (a_2 and a_1) produced the different phase shift values and adjusted transmission match.

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix}_{1,2} = \begin{bmatrix} 1 & 0 \\ jb & 1 \end{bmatrix} \cdot \begin{bmatrix} 1 & jx \\ 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} 1 & 0 \\ jb & 1 \end{bmatrix}$$

$$= \begin{bmatrix} (1 - bx) & jx \\ jb(2 - bx) & (1 - bx) \end{bmatrix}$$

For a match, $|A + B|^2 = 1$
 $x = \frac{2b}{1 + b^2}$

and under this condition,
 $\phi = \arg(V_2/V_0) = -\arg(A + B)$

$$\phi = \tan^{-1}\left(\frac{2b}{b^2 - 1}\right)$$

Figure 14. The lumped-element π -configuration phase shifter.

Figure 15. The reflection phase shifter circuit employing a coupler to achieve matched two-port transmission.

4. LUMPED-ELEMENT PHASE SHIFTERS

If the quarterwave section of line in the loaded line section is replaced with a diode switchable reactance (Fig. 14), the lumped-element, *highpass-lowpass* π circuit is obtained, which can yield up to 180° of phase shift. A similar tee configuration [2] is also practical. These circuits are advantageous in integrated circuit applications, because they employ a minimum of switching elements and no space-consuming distributed elements.

For modest power levels, the most common diode phase shifter configuration is the reflection circuit, employing a 3-dB, 90° coupler (Fig. 15). The coupler can be realized in numerous ways, three of which are shown in Fig. 16. The operation of the coupler is to convert the pair of variable phase reflection circuits containing pin diodes into a matched two-port network, having the reflection angle change of the terminations.

This operation can be explained based on the coupler's operation. Consider the backward-wave (hybrid coupler) circuit at the bottom of Fig. 16. Power enters the coupler at port 1 and divides evenly to exit at ports 2 and 4. The wave exiting port 4 has an additional 90° . On encountering the reflective circuits at ports 2 and 4, all energy reenters the

Figure 17. VSWR performance with frequency for a coupled-line hybrid coupler terminated in symmetric reflections for various coupling values. Note that the -2.4 -dB coupler would operate with a maximum VSWR of 1.35 over a band of 0.5 – $1.5 f_0$, a 3–1 frequency range (f_0 is the frequency at which the coupling section is 90° long).

coupler, but due to the second 90° phase difference in the signals on this second pass, they cancel at the input (port 1), but add perfectly at the normally decoupled port 3.

This operation requires perfectly even power split and 90° phase difference. The backward coupler (but not the other types shown) has the remarkable property that the 90° phase difference prevails at all frequencies [2, p. 194]. Of course, the power split varies with frequency, being equal at only one frequency (or two frequencies if the design is overcoupled at the center frequency). Nevertheless, more than octave bandwidth (Fig. 17) with modest VSWR

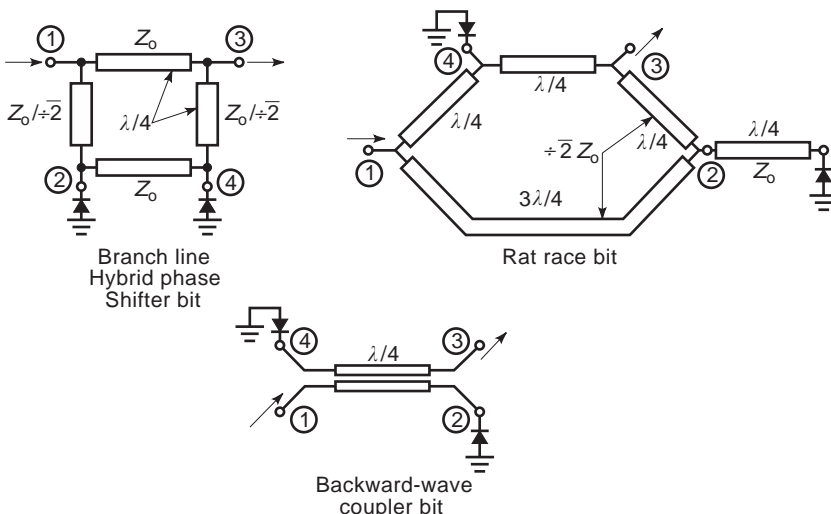

Figure 16. Methods of realizing 3-dB, 90° couplers.

Figure 18. The loss-equalized phase shifter termination with series inductor and quarter-wave transformer to adjust phase shift value.

can be obtained with a single coupled line section, even more bandwidth with multistage couplers.

As was true of the loaded line circuit, there are numerous ways to configure the pin in a reflection circuit to yield any desired phase shift. However, regardless of what configuration is used, if the circuit is designed to present to the pin its maximum sustainable RF voltage V_M in the reverse biased state and the maximum sustainable RF current I_M in the forward-biased state, Hines [3] showed that the maximum power P_M sustainable when the circuit yields a phase shift $\Delta\phi$ is as shown in Table 2. Similarly, if the circuit is designed such that the fraction of incident power dissipated (P_D/P_A) is the same in both forward bias and reverse bias, then the minimum for this ratio is that shown in Table 2.

Generally, the choice of circuit that would provide the maximum power stresses to the diode is not the same

choice that would produce equal power dissipation in its two states, but the two limits are very useful for estimating what performance limits a practical circuit might incur. Furthermore, since phase shifter bits are usually designed for low loss, the average of the losses in the two bias states is about equal to the minimum value specified in Table 2. The loss so calculated is for pin dissipation only. Circuit losses add to this value; but, as will be shown, a practical 3-bit, L-band phase shifter can be made with less than 1 dB of total insertion loss.

If the series resistance of the pin is about the same in both bias states ($R_F = R_R$), an equal loss phase shifter can be made by installing the pin at the 3 dB outputs of the coupler with a series inductance whose reactance magnitude is half that of the pin's capacitive reactance. By installing a quarterwave transformer between coupler and diode termination (Fig. 18), the phase shift can be adjusted to any desired value, allowing use of the same pin and series inductance for all bits (Fig. 19).

The method for constructing the backward-wave coupler [2] reflection phase shifter is shown in Figs. 20 and 21. A three-layer dielectric stripline sandwich is employed, wherein the center dielectric is used for the coupled lines. Using this approach, a 3-bit phase shifter was designed for use in the Cobra Dane radar built for the U.S. Air Force by the Raytheon Company on Shemya Island, near the western tip of the Aleutian Island chain. To minimize losses, the outer dielectrics were removed, resulting in air stripline in the transformer and diode regions. The operating bandwidth was approximately 1200–1400 MHz,

Figure 19. The reflection coefficients seen at the coupler for loss-equalized 180°, 90°, and 45° phase shift bits.

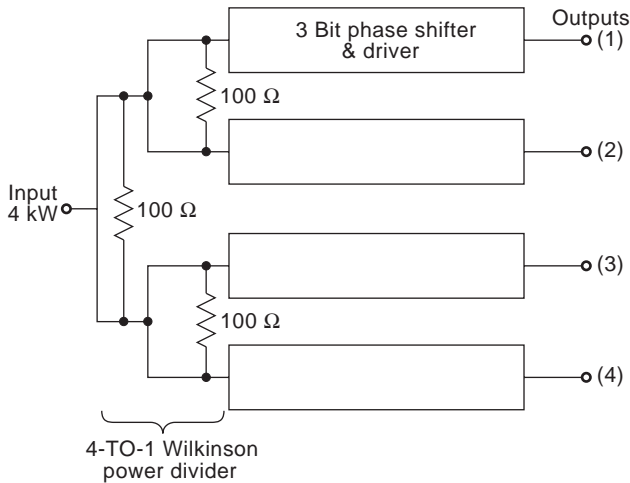

Figure 20. The 4-to-1 power divider and phaser assembly.

and the required power-handling capacity was to be 1 kW peak, with evenly spaced pulses of up to 2000 μs and 0.05 duty cycle.

The schematic diagram for the unit is shown in Fig. 20. Four separate phase shifters and a Wilkinson equal-phase power divider were housed in a single assembly to reduce costs and interface connections. Figure 21 shows the diode mount detail, and measured performance is shown in Fig. 22. A photograph of the completed assembly is shown in Fig. 23.

The diode used for all bits was the 3-pF, 1800-V bulk breakdown pin listed in the first column of Table 1. The individual phase shifter section, tested with -200 V bias on all diodes, sustained 4.1–4.8 kW peak power before burnout, and therefore could be rated for 1 kW operating level. The insertion loss of each phase shifter, including both pin diode and circuit losses, was 0.7 dB. About 16,000 phase shifters were installed in the Cobra Dane antenna array, which radiates approximately 16 MW peak and 1 MW of average power. At the time of installation the array was operated 20 h per day, resulting in nearly 2 million device hours daily.

In separate projects, pin phase shifters of 3- and 4-bit designs were implemented at S, C, and X bands [2, Chap. 6]. C-band phasers find use in the scanning-beam microwave landing system (MLS), for which a worldwide standard exists. Generally, higher-frequency diode phasers have progressively higher insertion loss and lower peak

Table 2. Limits of Power Handling and Insertion Loss (P_D/P_A) for Transmission and Reflection Phase Shifters

	Power	Loss
Reflection circuit	$P_M = \frac{V_M I_M}{4 \sin(\Delta\phi/2)}$	$\frac{P_D}{P_A} \approx f \left(\frac{f}{f_{cs}} \right) \sin \left(\frac{\Delta\phi}{2} \right)$
Transmission circuit	$P_M = \frac{V_M I_M}{2 \tan(\Delta\phi)}$	$\frac{P_D}{P_A} \approx 2 \left(\frac{f}{f_{cs}} \right) \tan(\Delta\phi)$

power capacity. At X band, the 4-bit design had 2 dB of insertion loss and a burnout power of about 1000 W with 1 μs pulselengths and 0.001 duty cycle.

5. CONSTANT PHASE SHIFT WITH FREQUENCY

Frequently there is a need for a phaser whose phase shift is constant over a considerable bandwidth. Schiffman [2,4] observed that when the backward wave coupler has ports 2 and 4 connected to each other (Fig. 24), an allpass network results, having a dispersion characteristic (an electrical length that does not increase linearly with frequency) that can be adjusted with the coupling coefficient (Fig. 25).

Figure 22. Measured performance for the L-band, 3-bit stripline phase shifter.

variable over a 5–1 or wider range with the application of a reverse bias. Such a variable reactance can be used in place of the pin in the reflection phase shifter circuit, to provide phase control that varies continuously with applied bias voltage. Of necessity, the continuous phase

Figure 24. Schiffman phase shift section.

A switched-path phase shifter (Fig. 26), which alternates between a Schiffman section and a uniform transmission line of appropriate length, can be made to have a nearly constant phase shift over an octave bandwidth (Fig. 27).

6. VARACTOR DIODE, CONTINUOUS PHASE SHIFTER

The varactor diode, lacking a wide I region, consists only of a pn junction, whose capacitance at RF frequencies is

Figure 25. Dispersion characteristic of the Schiffman section.

Figure 27. The octave bandwidth Schiffman phase shifter formed by a $\rho = 3.01$ [2] coupled line pair θ long a uniform line path 3θ long. Phase shift is $90^\circ \pm 4.8^\circ$ for $55^\circ \leq \theta \leq 125^\circ$, a 2.24:1 frequency ratio.

Figure 28. Representative varactor diode capacitance and circuit termination for a varactor continuous phase shifter.

shifter is limited to low power, below 1 W, since the varactor capacitance can change at the RF rate. In fact, varactors are used as the nonlinear element in frequency multipliers.

For varactor phase shifters, a figure of merit F applies [2, p. 486], relating the number of degrees of phase shift per decibel of loss to the cutoff frequency of the varactor, $f_c = 1/2\pi RC_{MIN}$, where C_{MIN} is the minimum capacitance obtained at a reverse bias just before the breakdown voltage, V_B ; M is the ratio of the capacitance at zero volts to

that at V_B ; and f is the frequency of operation.

$$F = (fc/f)(1 - 1/M)(6.6^\circ/\text{dB}) \tag{10}$$

This equation applies when the loss is small, below 1 dB. Thus a varactor having a junction capacitance which varies from 10 to 2 pF in series with a 2.6 Ω resistance (Fig. 28) has a cutoff frequency of 159 GHz and could yield 323°/dB at 1 GHz. Circuit losses must be added to this value.

Generally, higher loss is obtained as a result of the tuning effect of the varactor’s series inductance and the circuit reactance employed to transform the reflection coefficient into a range which covers both the upper (inductive) and lower (capacitive) halves of the Smith chart (Figs. 29 and 30).

The varactor phase shifter experiences little variation with temperature, typically only a 1% change in total phase shift over a 50°C temperature change. Even this small change may be attributable to circuit changes and possibly could be reduced further. However, variations in RF power beyond one watt produce significant changes, particularly near zero bias, at which the applied RF voltage swings into the forward conducting region (Fig. 31).

7. THE FET AS A SWITCHING DEVICE

Actually, any electronically switched device can be used as the control element in a phase shifter as long as it has sufficient Q to provide acceptably low insertion loss. The considerable strides made in the development of field effect

Figure 29. Phase shift (change in reflection coefficient angle) and loss (departure from unity reflection coefficient magnitude) of varactor circuit in Fig. 28.

Figure 30. Calculated and measured phase shift and insertion loss at 1 GHz for the varactor termination of Fig. 27.

transistors (FETs) both for microwave power generation and switching [12–18] have two important implications for semi-conductor phase shifting.

First, phase shifting for array antennas can be performed at low power levels with subsequent amplification by FETs and other solid-state devices to the required output level at the array antenna radiating element. With this approach the achievement of lowest insertion loss is less critical. Of course, the amplification generally will be nonreciprocal, requiring that switching be performed between transmission and reception modes.

Second, the phase shifter can be realized using FET elements for switching instead of pin diodes. FET switches have an inherent advantage when compared to pin diodes in that the FET has a third (gate) terminal to which bias is applied, simplifying the design of the microwave circuitry in which bias blocking otherwise is needed for two terminal control elements.

FETs can be modeled as a lossy capacitor in the non-conducting state and a resistor in the conducting state,

essentially the same equivalent circuit format used for the PIN diode. As a result, most of the formation developed for the pin can be used directly with FETs. The FET switched phase shifter can be reciprocal, as is the pin phase shifter.

MICROWAVE PHOTONICS: TECHNOLOGICAL EVOLUTION AND ITS APPLICATIONS

AFSHIN S. DARYOUSH
Drexel University
Philadelphia, Pennsylvania

1. INTRODUCTION

The last two decades of the twentieth century witnessed significant advances in IC technologies and proliferation of commercial fiberoptic communication techniques, and microwave photonics has emerged as a new discipline. It is envisioned that microwave photonics systems will be employed in many civilian and military systems. Although optical control of microwave devices and circuits was initially considered as one of the most promising applications of microwave photonics, now its most widely used applications are for optical distribution and processing of information in telecommunication systems, such as radio-over-fiber, as shown for a wireless local-area network in an office environment. In this figure, personal computers (PCs) are networked together through this hybrid wireless–fiberoptic networks in applications such as radio-over-fiber (ROF). The digital data from the PC is upconverted by a millimeter-wave (MMW) stable carrier and are then radiated by an omnidirectional antenna. The modulated received RF signal is then downconverted to the coded digital signals using the same stabilized MMW local oscillator (LO). The coded digital signal is then networked to other users through a high-speed fiberoptic network at data rates well above 100 Mbps (megabits per second).

An important component of a personal communication services (PCS) for the portable PC or PDA is the use of the low-power-consuming frequency translation circuits, which up- and downconverts the information without any degradation in its spectral purity. Frequency stability of the local oscillators used in the MMW wireless communication, and the clock recovery circuits used in the decision circuits, are critical in accurate data retrieval Fig. 1.

This evolution could not be realized without technological advances in optical sources/amplifiers, passive components, modulators, and detectors. The presentation in this article follows the assumption that the reader has a general understanding of these technologies (please review for fundamentals of optics and device physics aspects of photonics the books by Saleh and Tiejch [1] and Bhattacharya [2] respectively) and discussions in here are primarily on subsystem-level implementations of analog fiberoptic links for distribution of data and local oscillator, RF signal processing, analog-to-digital conversion, and medical imaging.

2. LIGHT INTERACTION WITH DEVICES AND CIRCUITS

From the early beginning of optical control of TRAPPAT (trapped plasma avalanche triggered transit) and IMPATT (impact avalanche transit time) in 1970, optical control of semiconductor devices has provided the promise of remote control along with isolation of optical source other electrical sources. Over time a number of techniques have been developed to control performance of a number of devices and circuits using optical interactions. Various optically controlled microwave subsystems have been demonstrated

HEMT	Large (log)	Slow	Large (log)	Very slow	Small	Fast	—	—	—	—

since the early 1980s, such as optically tuned antennas [3], phase shifters [4], oscillators and filters [5], switches [6], and amplifiers [7]. Although these techniques are intriguing, they have not yet found significant applications. More recently, spurred by rapid developments in fiberoptic-based networks (MAN and LAN), the chip-level integration of photonic and microwave components for high-performance optical receivers have attracted attention. PIN-amplifier configurations, such as PIN-HEMT [8], have been reported, and more recently high-performance PIN-HBT combinations have been realized by Gutierrez-Aitken et al. [9]. The three-terminal microwave devices are preferred to perform photodetection and control functions in the receiver front end [10,11]. This configuration enhances receiver performance by reducing parasitics, requires less pre-amplification due to intrinsic gain of transistors, and has lower power consumption and less costly fabrication.

Key to these developments and related applications in communications and control of microwave systems is understanding of the optical properties of microwave devices [12] in transistors. In particular, photoresponse of HBT, MESFET, and HEMT could be unified and a comparison is made in terms of inherent photodetection mechanism, gain, sensitivity, and bandwidth.

2.1. Static Analysis

Table 1 summarizes various effects that contribute to the photoresponse of the HBT, MESFET, HEMT, and comparison of these devices to the PIN photodiode. (The performance of the PIN photodiode is considered as the baseline.) For the PIN photodiode, the photoresponse current is determined by the photogenerated electron-hole pairs in the intrinsic region and no current gain is experienced. The light level directly controls the photocurrent in a linear fashion. On the other hand, in HBT, in addition to photogenerated electrons at the collector depletion region, there is an increase in the effective base current due to the drift of photogenerated holes from the collector depletion region to the base. This source of this term is a change in the current injection rate due to change in base voltage and hence it is termed the *internal photoconductive effect*; since this increase occurs under constant bias current, it results in current gain. The photoresponse of the HBT is linear with optical power. On the other hand, the photoresponse in both field-effect transistors (MESFET and HEMT) is attributed to three mechanisms [13]. The photogenerated carries collected at the gate yield a photovoltage V_{phx} , when passing through an external resistor. Thus the *external photovoltaic* increases in gate

bias, which opens the channel and results in a photocurrent of $I_{pvx} = g_m V_{phx}$. The *internal photovoltaic effect* results in $I_{pvi} = g_m V_{ph}$, where for MESFET [14] V_{ph} is a light-induced modulation of the channel height and in the case of the HEMT, V_{ph} represents a shift in the quasi-Fermi level [15]. The *photoconductive effects* I_{pc} are very small and are neglected. The optical responsivity of microwave semiconductor transistors is compared in Fig. 2. At low illumination the logarithmic response of FET devices provides large gain. However, photoresponse saturates rapidly, which limits their dynamic range. The HBT, which has relatively large dark current but low noise [16], performs best at moderate and high illuminations.

2.2. Dynamic Response

The frequency response of a PIN is limited by the carrier transit time, where a shorter intrinsic region yields a faster response, but this behavior is at the expense of quantum efficiency for vertical devices. (Traveling-wave photodiodes are designed to simultaneously meet high power-handling, speed, and efficiency requirements.) The speed of the HBT is governed by sum of different time constants associated with the charging time of the base-emitter junction, the base transit time, the charging time of the base-collector junction, and the transit time across the collector depletion region. The optical response of the HBT is fast since these time constants are the same as those that determine the HBT ultra-high-speed response, whereas for FET devices the external photovoltaic effect is very slow because of the long charging time of the gate external circuit. The MESFET's dynamic response is dominated by the

Figure 2. Comparison of the static light responsivity for microwave transistors and performance comparison to PIN photodiode as a baseline.

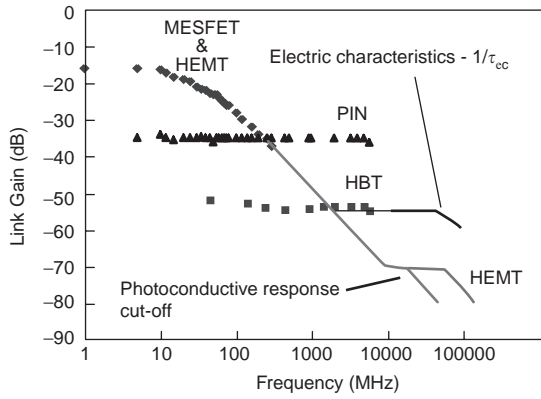

Figure 3. Frequency response of microwave devices. Measured data are represented by discrete points and theory by solid lines. The optical coupling efficiencies were calculated to be less than 1% for the HBT, 4% for the MESFET and HEMT, and 60% for the PIN diode.

dynamics of the internal photovoltaic effect, which is defined by the RC time constant of substrate resistance and the epitaxial layer–substrate junction capacitance [16]. For the HEMT, on the other hand, the RC time constant, determined by the buffer resistance and the change in electron concentration in the 2DEG (two-dimensional electron gas) channel [14], defines the speed. It is important to note that the speed of the photoresponse of the FETs is independent of their microwave speed.

The measured and calculated frequency response for these devices is depicted in Fig. 3. At low frequencies FETs perform well, but the intrinsically slow photovoltaic effect yields a small gain–bandwidth product. The speeds of the HBT and the PIN are comparable. Note that increasing the coupling efficiency of the HBT from 1% to 10%, which is a feasible task, will reduce the link insertion loss by 20 dB, thus superseding that of the PIN. Using devices with larger β (e.g., 250 instead of 25) will also give additional advantage to the HBT.

A publication by Madjedi et al. on the nonlinear behavior of high-temperature superconducting film as photomixer has provided an opportunity to generate terahertz signals using the kinetic inductive photoresponse [17]. These new applications maintain interest in interactions between light and microwave circuits.

3. FIBEROPTIC LINK DEVELOPMENT

Fiberoptic (FO) links are employed for distribution of frequency reference as well as data communications in dis-

tributed systems, where these links need to provide RF signals with high dynamic range and low phase noise degradation. The information is distributed by intensity modulation of light using an either directly or externally modulated laser (see Fig. 4) and is detected primarily directly since the evolution of optical amplifiers. The FO link gain and noise performance will impact signal-to-noise performance, while the nonlinearity of various elements in the optical system will contribute to a limited dynamic range. The nonlinear phase and amplitude variation with input RF power will result in AM-AM and AM-PM conversion. Moreover, in dense wavelength-division multiplexed systems, where channel capacity increases by multiplexing various colors of light, stimulated Raman scattering in optical fiber could introduce distortion and channel interference.

First, analytical expressions are presented for gain, noise figure, and dynamic range, and sources of phase noise degradation in directly and externally modulated FO links are presented. Next, fiber nonlinearity is introduced in a dense WDM system. Finally, the performance of a multifunction circuit, realized on the basis of a long Fabry–Perot laser structure that is monolithically integrated with an electroabsorption modulator, where efficient transmission of data and carrier signals with high SFDR (spurious-free dynamic range) and low phase noise degradation are achieved, is reviewed.

3.1. Directly Modulated FO Link

The gain of a fiberoptic link can be calculated in terms of microwave scattering parameters using the signal flow diagram (SFD) technique [18]. The transducer gains of the optical transmitter and optical receiver are derived separately and then combined to yield the gain of the complete link. The link gain is expressed as

$$G = \frac{P_{\text{out,Tx}}}{P_{\text{av,Rx}}} = G_{\text{TX}} \times |H_L|^2 \times G_{\text{RX}}$$

$$= \frac{|S_{21D}|^2 |S_{21L}|^2 (1 - |\Gamma_{\text{las}}|^2) (\eta_L K_L L K_D \eta_D)^2}{|1 - \Gamma_{\text{las}} S_{22L}|^2 |1 - \Gamma_{\text{SD}} S_{11D}|^2}$$

When a directly modulated semiconductor laser diode is employed in the optical transmitter, the SFD is obtained by considering the forward-bias junction resistance of the laser diode to be the port 2 termination of a two-port network consisting of the microwave impedance-matching circuit and driving circuit combined with the other device parameters of the laser. Whereas a reverse-biased p-i-n

Figure 4. Overall structure of a fiberoptic link. Note that for the directly modulated system the optical source is internally modulated whereas in the externally modulated link the electrooptic property is used to perform intensity modulation in a Mach–Zehnder modulator.

photodiode is employed in the optical receiver, the SFD is obtained by considering the junction resistance of the diode to be the port 1 terminating load to a two-port network consisting of the microwave impedance-matching circuit and the other device parameters of the detector. The link current transfer function H_L is defined as the ratio of detector current to RF current across the laser. This is a measurable quantity that is a function of the electrooptic device quantum efficiencies as well as optical attenuation and coupling efficiency, where η_L is the laser diode external quantum efficiency, η_D is the detector responsivity, L is the optical attenuation in the fiber, and K_L , K_D are the laser-to-fiber and fiber-to-detector coupling efficiencies, respectively. Nonlinear fiber performance due to stimulated Brillouin and Raman scattering processes for long-fiber-length L is ignored for the moment, but this issue will be discussed later.

The four contributions to the noise power of the directly modulated fiberoptic link. The total noise power at the output of the detector is the sum of all these individual noise powers:

$$\begin{aligned} N_{\text{out}} &= N_{\text{RIN}} + N_{\text{shot}} + N_{\text{th,Tx}} + N_{\text{th,Rx}} \\ &= N_{\text{RIN}} + N_{\text{shot}} + N_{\text{th}} \end{aligned}$$

The dominant term is the laser RIN (relative intensity noise) noise power, which is expressed as

$$\begin{aligned} N_{\text{RIN}} &= \text{RIN}(f)(I_b - I_{\text{th}})^2 (\eta_L K_L L K_D \eta_D)^2 \\ &\times \frac{|S_{21D}|^2}{|(1 - \Gamma_{\text{SD}} S_{11D})|^2} B Z_0 \end{aligned}$$

The next dominant noise source is shot noise of the detector, including dark current noise

$$\begin{aligned} N_{\text{shot}} &= 2e[(I_b - I_{\text{th}})(\eta_L K_L L K_D \eta_D) + I_d] \\ &\times B \frac{|S_{21D}|^2}{|(1 - \Gamma_{\text{SD}} S_{11D})|^2} Z_0 \end{aligned}$$

followed with the thermal noise of the transmitter:

$$\begin{aligned} N_{\text{th,Tx}} &= 4kT_a B (\eta_L K_L L K_D \eta_D)^2 \text{Re}\{Y_{\text{th1}}\} \\ &\times \frac{|S_{21D}|^2}{|(1 - \Gamma_{\text{SD}} S_{11D})|^2} Z_0 \end{aligned}$$

Finally we obtain the thermal noise of the detector:

$$N_{\text{th,Rx}} = 2kT_a B (1 - |\Gamma_{\text{in}}|^2)$$

The only noise source at the input of the link is the thermal noise in the transmitter circuitry: $N_{\text{in}} = kT_a B$. The noise figure of the fiberoptic link is defined as

$$\text{NF}_{\text{link}} = \frac{(\text{SNR})_i}{(\text{SNR})_o} = \frac{P_{\text{in}} * N_{\text{out}}}{P_{\text{out}} * N_{\text{in}}} = \frac{1}{G_{\text{link}}} * \frac{N_{\text{out}}}{N_{\text{in}}} \quad (1)$$

3.2. Externally Modulated FO Link

The small-signal gain of an externally modulated fiberoptic link is derived using the SFD technique as was applied to direct modulation. When a Mach-Zehnder interferometric modulator is employed in the optical transmitter to impress a microwave signal on the optical carrier in a single-mode fiber, the transmitter SFD is obtained by considering the capacitance C_M across the modulator terminals to be the port 2 termination of a two-port network consisting of the microwave impedance-matching circuit and other device parameters in the equivalent circuit of the modulator. The output power of a fiberoptic link depends on the amplitude of photocurrent I_{det} generated in the detector, which is in turn proportional to the RF voltage V_M across the capacitor C_M . This gain is represented as

$$\begin{aligned} G &= \left(\frac{\pi L K_D \eta_D P_{\text{in,op}} Z_0}{2V_\pi} \right)^2 \\ &\times \frac{|S_{21M}|^2 |S_{21D}|^2 |1 + \Gamma_M|^2}{|1 - S_{22m} \Gamma_M|^2 |1 - S_{11D} \Gamma_{\text{SD}}|^2} \end{aligned}$$

where V_π is bias voltage required for 100% optical modulation and $P_{\text{in,op}}$ is the optical output of the modulator. Figure 3 compares the achievable gain of directly and externally modulated fiberoptic links. Note that a higher gain is achieved when optical source and detector with efficient light coupling and responsivity are employed. Finally, gain of the externally modulated FO link monotonically increases as the optical power squared. Four noise sources contribute to the output noise power of the link. The dominant term in the case of large input optical power is the shot noise followed by excess RIN noise of the laser. The shot noise of the detector, including dark current, is expressed as

$$\begin{aligned} N_{\text{shot}} &= 2e \left[\left(\frac{\eta_{\text{op}} \eta_D P_{\text{in,op}}}{2} \right) + I_d \right] \\ &\times B \frac{|S_{21D}|^2}{|1 - \Gamma_{\text{SD}} S_{11D}|^2} Z_0 \end{aligned}$$

The excess noise of the laser is related to optical source RIN noise, which could be significantly lower than that for the semiconductor laser diode:

$$\begin{aligned} N_{\text{excess}} &= \left[\text{RIN} \left(\frac{\eta_{\text{op}} \eta_D P_{\text{in,op}}}{2} \right) - 2e \right] \\ &\times \left(\frac{\eta_{\text{op}} \eta_D P_{\text{in,op}}}{2} \right) B \frac{|S_{21D}|^2}{|1 - \Gamma_{\text{SD}} S_{11D}|^2} Z_0 \end{aligned}$$

The thermal noise sources of the transmitter and of the detector are presented respectively as

$$\begin{aligned} N_{\text{th,Tx}} &= kT_a B \left(\frac{\pi \eta_{\text{op}} \eta_D P_{\text{in,op}} Z_0}{2V_\pi} \right)^2 \\ &\times \frac{|S_{21m}|^2 |S_{21D}|^2 |1 + \Gamma_M|^2}{|1 - \Gamma_M S_{22m}|^2 |1 - \Gamma_{\text{SD}} S_{11D}|^2} \end{aligned}$$

$$N_{\text{th,Rx}} = 2kT_a B (1 - |\Gamma_{\text{in}}|^2)$$

Figure 5. Comparison of experimental and simulation results of directly and externally modulated fiber optic links at HF [17]. (Courtesy of Ed Ackerman of Photonics Inc.)

The total noise power at the output of the detector is the sum of all these individual noise powers. As in the direct-modulation case, the noise power at the input to the external modulation link is simply $kT_a B$. Therefore the noise figure is given by Eq. (1). Note that the total shot noise increases as optical power; therefore the signal-to-noise ratio increases as optical power increases in the externally modulated links. However, the challenge is to develop high-speed high-power-handling-capability photodetectors.

Figure 5 depicts comparison measured and analytical calculated gain results of directly and externally modulated fiber optic links. The optical power can be high in externally modulated fiber optic links when a solid-state laser is employed as an optical source. A low- V_π Mach-Zehnder (MZ) modulator and operation in the quadrature point of $V_b = V_\pi/2$ (i.e., $\phi = 90^\circ$) along with a high-power-handling-capability photodiode allows for the highest reported gain for FO links. Naturally a higher responsivity (i.e., η_L and η_D) laser diode and photodiode result in a lower insertion loss.

3.3. Dynamic Range

Spurious-free and compression dynamic range are directly related to linearity of the optical modulator (i.e., laser diode in the case of directly, and MZ modulator in the externally modulated FO links). The third-order intercept point and 1 dB compression point for the directly modulated are calculated [18] on the basis of the optical modulation index m :

$$P_{in,int} = \frac{m_{int}^2 (I_b - I_{th})^2 |1 - S_{22L} \Gamma_{Las}|^2 Z_0}{|S_{21L}|^2 (1 - |\Gamma_{Las}|^2)}$$

$$P_{in,1dB CP} = \frac{m_{1dB CP}^2 (I_b - I_{th})^2 |1 - S_{22L} \Gamma_{Las}|^2 Z_0}{|S_{21L}|^2 (1 - |\Gamma_{Las}|^2)}$$

In a similar fashion, the third-order intercept point and 1 dB compression point are derived for externally modu-

lated fiberoptic links as follows:

$$P_{in,int} = \frac{8V_\pi^2 |1 - S_{22m} \Gamma_M|^2}{\pi^2 Z_0 |S_{21m}|^2 |1 + \Gamma_M|^2}$$

$$P_{in,1dB CP} = \frac{0.950454^2 V_\pi^2 |1 - S_{22m} \Gamma_M|^2}{\pi^2 Z_0 |S_{21m}|^2 |1 + \Gamma_M|^2}$$

Using the derived relationship for intercept and compression points, spurious-free and compression dynamic range are calculated using the following expressions:

$$SFDR = \frac{2}{3} \times 10 \log_{10} \left[\frac{P_{out,int}}{kT_a GNF} \right] \text{ dB} \cdot \text{Hz}^{2/3}$$

$$CFDR = 10 \log_{10} \left[\frac{P_{out,1dB CP}}{kT_a GNF} \right] \text{ dB} \cdot \text{Hz}$$

3.4. Fiber Nonlinearity

WDM optical systems are employed in radio-over-fiber and optically controlled phased-array antenna architectures. In pushing these systems to the limits of transmission capability, aspects such as fiber nonlinearities need to be understood. These aspects include the nonlinear fiber phenomena of SRS (stimulated Raman scattering) [20], SBS (stimulated Brillouin scattering) [21], and XPM (cross-phase modulation) [22]. These nonlinear effects become noticeable particularly in WDM subcarrier-multiplexed (SCM) systems that may cover many closely packed video channels cover long distances. These nonlinearities result in optical power transfer to higher and lower optical frequencies. Each nonlinear effect creates a distortion level that becomes intolerable above the acceptable threshold level. Threshold requirements are based on electrical nonlinear distortion requirements, composite second-order (CSO) and composite triple (or third-order) beat (CTB) (particularly CTB), which have been determined in published works such as Refs. 23 and 24.

Figure 6 shows the SRS crosstalk level for a two-channel WDM system, while the fiber length is varied and for

Figure 6. Measured and simulated SRS-induced crosstalk versus fiber length for an input optical power level of 4 dBm, fiber dispersion of $17 \text{ ps mm}^{-1} \text{ km}^{-1}$ RF frequency of 151.85 MHz, and a channel spacing of 9.4 nm.

Figure 7. Measured and simulated SRS crosstalk versus RF frequency with a fiber length of 20 km, fiber dispersion of $17 \text{ ps nm}^{-1} \text{ km}^{-1}$, channel spacing of 9.4 nm, and a 4 dBm (2.5 mW) input power per channel; also, a simulation of 40 km using only the Phillips–Ott model [25].

9.4 nm channel spacing, and input power of 4 dBm, a dispersion of $17 \text{ ps nm}^{-1} \text{ km}^{-1}$, and a subcarrier frequency of 152 MHz. The two curves in the figure represent the high- and low-dispersion fibers. The more dispersive fiber generates lower XT due to the walkoff effect. As is expected, the crosstalk level begins to increase as the fiber length increases. However, the XT level reaches a peak value and then decreases as the length is increased further. As the length is increased beyond 70 km, eventually the SRS level reaches a steady-state value. This behavior shows a sinusoidal dependence of crosstalk on fiber length for dispersive fiber but a monotonic increase for the dispersion-shifted fiber. The importance of this result is that, due to the walkoff effect, the crosstalk level for a length of fiber may not increase as the fiber length increases. Hence, the crosstalk level can be reduced or increased depending on the fiber length. In comparison of the measurement and simulation (Model 1: Wang et al. model [24] and Model 2: Phillips–Ott model [25]), the maximum error is less than 5%. Measurement results of the SRS crosstalk while increasing the RF frequency from 50 to 725 MHz in steps of 50 MHz is depicted in Fig. 7. Also included in the figure is a simulation of Phillips–Ott model [25]. As depicted in Fig. 7, the SRS crosstalk level changes as the

frequency is increased, following a behavior similar to a sinc function (i.e., $\sin x/x$) squared fashion.

3.5. Phase Noise Degradation

The FO distribution link contributes residual phase noise to the reference signal, which is a function of operation frequency. This impact is significant mostly in the directly modulated fiberoptic links where the RIN of the optical source is far stronger than the externally modulated FO links. Moreover, directly modulated fiberoptic links are preferable to externally modulated links because of their lower cost than. The phase noise of the reference signal could be degraded if residual phase noise were too close to the signal noise floor level. Therefore, an appropriate selection of reference frequency is necessary to avoid significant degradation after passing through the FO link. For example, as shown in Fig. 8, to generate a 12-GHz local oscillator (LO) at front end, a reference signal at frequency of 100 MHz (UHF), 4 GHz (C band), and 12 GHz (X band) can be sent through FO link. Since the phase noise contributions for FO links are different at these frequencies, an optimum frequency for reference signal can be found to have the least phase noise degradation due to the FO link.

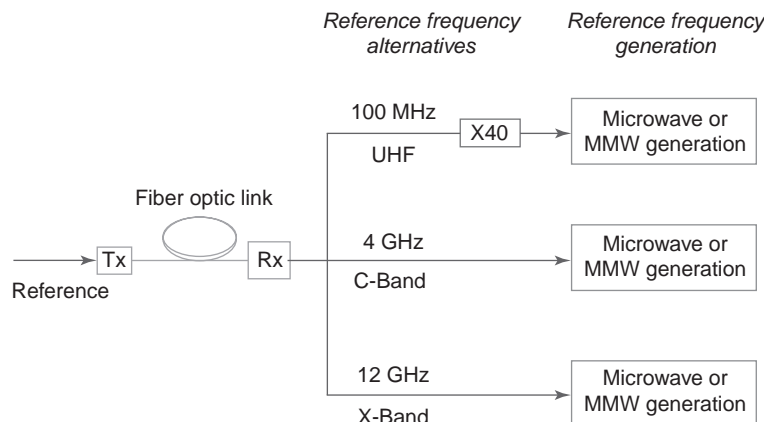

Figure 8. Distribution of frequency reference and generation of MMW signal using various frequency references used in a FO-based local-oscillator (LO) synchronization network.

The optical spectra of a modulated optical signal are expressed as $P_{\text{opt}}(1 + m \cos(\omega_m t + \delta\phi_m(t)) + n_{\text{RIN}}(t)) \cos(\omega_{\text{opt}} t + \phi_{\text{opt}}(t) + \delta\phi_{\text{opt}}(t))$, where P_{opt} is the averaged optical power and m is the optical modulation index at modulating microwave carrier ω_m . The focus of present work is $\delta\phi_m$, the residual phase noise added to the microwave carrier from the laser diode noise source. n_{RIN} is the relative intensity noise; ω_{opt} is the optical frequency; ϕ_{opt} is the optical phase signal due to side modes and modulation, and $\delta\phi_{\text{opt}}$ is the phase noise of the optical signal. Since most fiberoptic links for antenna remoting applications use intensity detection, only the noise signals in optical intensity affect the microwave carrier signal, namely, $\delta\phi_m$ and n_{RIN} . The n_{RIN} could contribute to the FM noise of the reference signal through nonlinear AM/PM conversion [27].

The laser diode SSB phase noise of the n th harmonic of the modulating signal \mathcal{L}_{out} has contributions from three noise terms: (1) the input reference signal phase noise, \mathcal{L}_{in} , (2) the low-frequency noise of the laser diode upconverted to the carrier frequency \mathcal{L}_{up} ; and (3) the RIN noise at the offset microwave carrier \mathcal{L}_{RIN} . This behavior is quite analogous to microwave systems [28]. Therefore at angular offset carrier frequency of Ω , \mathcal{L}_{out} can be approximately expressed as [29]:

$$\mathcal{L}_{\text{out},n\omega}(\Omega) = n^2 \mathcal{L}_{\text{in},\omega}(\Omega) + n^2 \mathcal{L}_{\text{up},\omega}(\Omega) + \mathcal{L}_{\text{RIN},n\omega}(\Omega) \quad (2)$$

The factor of n is the harmonic order of the modulation signal, if any nonlinearity of the laser diode is exploited to generate the n th harmonic [28]. (If the fundamental frequency is employed, then $n = 1$.) The subscript ω indicates the modulation frequency. The upconversion factor of low-frequency RIN to phase noise is the dominant noise source. Calculation of this upconversion factor depends on the derivative of the RF phase with respect to the RF derive amplitude and is $C_{\text{up},\omega} = \frac{1}{2} (\partial\theta(\omega)/\partial P_o)^2 P_o^2$, which θ is phase of optical signal at the modulating frequency ω . The dependence of phase on the optical output power in a directly modulated system is a bit more complicated than in an externally modulated system since the nonlinear be-

havior is dependent on modulation index of laser diode and the relationship of its operation frequency compared to the relaxation oscillation frequency. This process is nonlinear and at certain frequencies results in AM-PM compression. The results are related to modulation index through the a parameter, which is a function of modulation frequency and averaged optical power [18].

Since RIN noise in semiconductor laser diodes is strong up to 100 MHz because of mode partition noise, it is predicted that the spectral purity of the UHF reference signal is greatly degraded, resulting in a higher FM noise. Moreover, the X-band modulating signal is close to the relaxation oscillation frequency where RIN is peaked. The best frequency for reference signal distribution through DMFO link is the C-band signal as depicted in Fig. 9, where the phase noise of the 12-GHz LO signal is generated from the reference signal through the abovementioned DMFO link. Clearly, the signal generated from a C-band signal has the best phase noise performance. The signal from UHF reference degrades greatly because the residual phase noise of the FO link is higher than the reference phase noise at offset frequency higher than 100 Hz.

3.6. Monolithically Integrated Mode-Locked Laser

A monolithic version of a laser with external cavity is realizable using semiconductor fabrication process and reported by a number of researchers. Figure 10a shows a schematic drawing of the monolithic laser with an integrated EA (electroabsorption) modulator. Stacked structure consisting of two MQW layers, a MQW (multi-quantum well) for laser diode (MQW-LD) and a MQW for EA modulator (MQW-MD) are employed. The Fabry-Perot (FP) cavity length for our experiment is cleaved approximately for a length of 2170 μm . This total length is composed of a 1970- μm -long gain section, a 150- μm -long modulator, and a 50- μm -long separation region. The facet of the modulator section is coated with high-reflectivity film ($R \approx 85\%$). The facet of the gain section is as cleaved. The laser is mounted in a high-frequency package. The schematic diagram of the long FP laser with integrated EA modulator is shown in Fig. 10b.

Figure 9. The simulated phase noise of a LO signal at 12 GHz, is generated from different reference signals through a directly modulated FO link as depicted in Fig. 8.

Figure 10. (a) Conceptual representation of the long FP laser integrated with an electroabsorption modulator; (b) mechanical fixture used for mounting of the laser diode for injection-locking, mode-locking, and optoelectronic conversion evaluations.

The gain section of the laser diode is forward-biased at different bias currents, and the EA section is reverse-biased by different voltage levels. A resonance peak is observed that is associated with the longitudinal mode separation in the long FP laser. The longitudinal-mode separation is calculated as $\Delta f = c/2nL \approx 19.3$ GHz, where $c = 300$ mm · GHz is the speed of light in free space, $n \approx 3.5$ is the index of refraction of the waveguide, and $L \approx 2.17$ mm is the FP cavity length. This resonant frequency has a frequency tuning sensitivity of ≈ 1 MHz/mA. The optical oscillations are stabilized using an injection-locking process [27], where a single oscillation peak that appears as the gain section is modulated by a frequency reference of $P_m \geq -1$ dBm at $f_m = 19.258$ GHz. The familiar one-sided injection-locking spectra are observed outside the injection-locking range and the close-in to carrier phase noise is significantly reduced within the locking range. The measured close-in to carrier phase noise degradation at 100 Hz offset carrier is depicted in Fig. 11, where 31 and 6 dB degradation are measured for the injected power of $P_m = +0.5$ dBm in the resistively and reactively-matched modules respectively. However for

injected power level of +4.5 dBm, a close-in to carrier phase noise identical to the reference source is measured for the reactively matched case Fig. 11.

The resonance frequency could also be stabilized using fundamental mode locking by modulating the EA section by a synthesized source. The close-in to carrier phase noise are measured and comparison is made against the reference signal from an HP83640A source. The results are summarized in Table 2 for different laser operation points. As indicated, a very small phase noise degradation is observed; however, the results for $V_m = -1$ V are better

Table 2. Phase Noise Degradation of LO Signal as Function of Various Offset Frequencies and Laser Operation Points

f_m (GHz)	V_m (V)	$\mathcal{L}(\Omega)$ (dBc/Hz)		Δ (dB)	
		$\Omega = 100$ Hz	$\Omega = 1$ kHz	$\Omega = 100$ Hz	$\Omega = 1$ kHz
19.13400	-4.5	-75.4	-81	2.6	2.4
19.29469	-2.5	-77.0	-82	1.0	1.1
19.29406	-1.0	-77.6	-82	0.4	0.4

Figure 11. Measured FM noise degradation at 100-Hz-offset carrier for the injection locked inter-modal oscillation. The measured injection-locking power of the long FP laser diode is also depicted at the crossover point for the resistively (\blacktriangle) and reactively matched (\blacktriangle) lasers.

than the results for $V_m = -4.5$ V for the same laser current of $I_b = 140$ mA.

Since this stabilized signal has much cleaner close-in to carrier phase noise than does the free-running oscillation, it could be employed as the LO signal. The laser diode's gain section is forward-biased ($I_b = 140$ mA), and the EA modulator section is reverse-biased ($V_m = -1$ V). This operating point is selected because of the efficient mode-locking process while maintaining the least amount of phase noise degradation of the carrier signal. The laser diode optical output is collimated to a single-mode optical fiber using a polarizing collimator with an overall fiber coupling efficiency of 12%. The optical fiber output is connected to an optical receiver integrated with RF analyzer, which automatically dis-embeds the calibrated optical receiver response from the measurement and displays it in the optical domain. The electrical domain power levels, in dBm, are easily calculated by multiplying the depicted optical domain results, displayed in dBm, by a factor of 2.

Next the gain section of this laser is modulated by S-band signals (2.2 GHz \pm 50 MHz). Strong nonlinearity of the mode-locked laser at the LO signal of 19.3 GHz upconverts the S-band signals to 17.1 and 22.5 GHz as shown in Fig. 12. The data modulation power level is changed over a wide range. An optical conversion loss is defined as the ratio of the generated mixed RF signal (19.3 ± 2.2 GHz) to the IF signal (2.2 GHz). The optical conversion loss is as low as 1.4 dB, resulting in an electrical conversion loss of 2.8 dB. The optoelectronic conversion loss for the lower sideband (LSB) at 17.1 GHz is higher than the upper sideband (USB) of 22.5 GHz by 1.3 dB (i.e., 2.6 dB electrical) [31].

On the other hand, a modulation loss greater than 51 dB is measured when the gain section is directly modulated by the RF signal at 17.1 GHz. The spurious-free dynamic range (SFDR) of this optoelectronic mixer is also evaluated. The intermodulation distortion (IMD) measurements are conducted for two modulating tones that are 5 MHz apart (e.g., $f_1 = 2.200$ GHz and

$f_2 = 2.205$ GHz). Both tones are upconverted by a stable LO signal of 19.360 GHz and IMDs of the upconverted RF signals are measured at LSB and USB frequencies. Based on the mode-locked laser IMD and RIN noise measurement results for the upconverted RF tones, SFDR LSB and USB RF signals are ≈ 88 dB \cdot Hz^{2/3} and 89 dB \cdot Hz^{2/3}, respectively.

4. FIBEROPTIC DISTRIBUTION FOR PHASED-ARRAY ANTENNAS

One of the simplest methods antenna remoting is based on the concept of direct replacement of the electrical interconnects by FO links. However, there are challenges associated with reliability of optical components, cost of system integration, and the architecture employed for achieving the best attributes possible.

4.1. Device Innovations and Reliability

A vast number of research work reported in the literature have focused on the device improvements to meet the performance requirement of commercial fiberoptic communication. Performance of sampled directly and externally modulated fiberoptic links operating at S band is rendered in Table 3 (circa 1995), where the best performance is achieved for DFB laser monolithically integrated with the EA modulator. The performance of the mode-locked laser is quite acceptable for many telecommunication systems. (The results of the MZ modulator may appear worse than what is reported in the literature, but in this case a semiconductor laser with optical power of only a few mW is used as a source.) Monolithically integrated EA modulator with sampled grating DBR laser (SGDBR) [32] has been developed where SFDR of 120 dB \cdot Hz^{2/3} is achieved over a large tuning bandwidth. However, the harsh military and space environment imposes additional burdens on the performance of lightwave technology components.

Figure 12. Optoelectronic mixing of data signal with local-oscillator signal in the mode-locked long FP laser diode: (a) experimental results for operation conditions $I_b = 140$ mA, $V_m = -1$ V, $f_m = 19.360$ GHz, $P_m = +15$ dBm, $f_{\text{data}} = 2.200$ GHz, and $P_{\text{data}} = -25$ dBm—data, lower sideband RF, and local-oscillator signals (center frequency 11.0 GHz and frequency span 20.0 GHz); (b) simulation results based on traveling-wave equation [30].

Figure 13. Conceptual representation of an optimized optical transmitter using eight series-mounted laser diodes with monolithically integrated external optical cavity coupled to the lensed fibers using a Si V-groove fiber alignment system.

4.2. Packaging Requirements

As indicated in the gain expressions of directly and externally modulated fiberoptic links, a dB improvement in the optical coupling improves insertion gain by 2 dB. However, mechanical tolerances of optical fibers and sources are in submicrometer range, hence making the low-cost integration of optical components with optical fibers challenging at the least. Moreover, this process has to be done in a cost-effective manner. Another important aspect of the light coupling is that reflection has to be minimized since any optical feedback introduces modulation of the dynamic response, which resembles the transmission characteristics of FP resonators. Therefore, optical isolators combined with angle polished fibers are required to reduce the light feedback level below 50 dB in certain applications. Another important aspect is temperature control of semiconductor devices to avoid any sensitivity to temperature in harsh environments of space. Finally, directly modulated fiberoptic links or externally modulated systems using EA modulators experience input impedance that corresponds to high-reflectivity coefficients (i.e., approximately short for a laser diode and open for an EA modulator). To avoid high reflection loss, impedance matching circuits are needed to be developed, which is not easy to accomplish over a large fractional bandwidth. Figure 13 depicts a designed structure of monolithically integrated optical

source with an EA modulator [33], which is used for distribution of both LO signal and data signal. This structure is also based on cascading a number of lasers with a monolithically long FP cavity in series, hence increasing the forward PN junction resistance, while maintaining the same RF current modulating all the gain sections. In essence, since the input impedance of laser diode (i.e., a forward-biased p-n junction) is about 4Ω , by series combination of the impedances, a level closer to 50Ω is achieved.¹ Moreover, a lower Q_{ex} factor is obtained, which simplifies the matching circuit design. Finally, the fiber coupling is achieved cost-effectively by combining a number of lensed fibers mounted on a silicon V groove. This process will enable packaging of a large number of laser diode sources.

4.3. Architecture Innovations

In large-aperture phased-array antennas or ROF systems, the RF signal could be downconverted to the IF signals for further processing at the centralized receiver. This architecture, shown in Fig. 14, is the conventional one. The challenges for implementation of optically controlled

¹A similar approach is currently pursued in quantum cascade lasers, although the latter is a unipolar device. For more information, see, for example, the paper by Faist et al. [34].

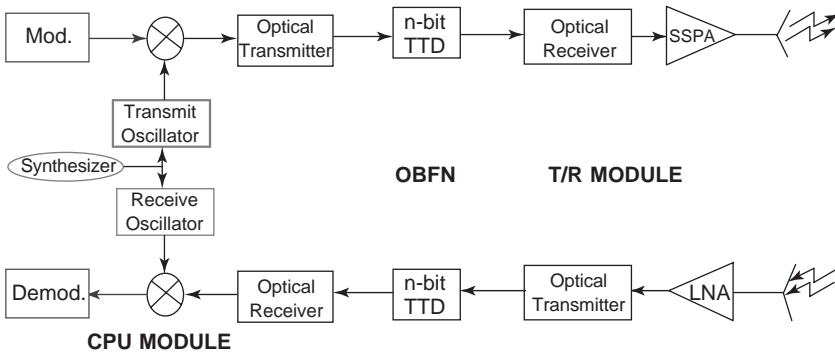

Figure 14. CPU-level data mixing architecture for transmit/receive-mode operation. Note that real-time-delay are required for broadband operation without beam squint.

phased array using this architecture are (1) a high-dynamic-range fiberoptic links are required at ultrahigh frequencies, (2) phase and frequency control must be maintained in the distribution network all the way to the central processor, and (3) as will be shown later, a higher resolution for a true time-delay device is required. On the other hand, the T/R-level data mixing architecture, shown in Fig. 15, provides a great opportunity to perform downconversion of the RF signals to IF and avoid the limitations encountered in the CPU-level data mixing. Additional requirements are: (1) the need for stabilized LO at each element to coherently down-or upconvert the received RF or IF signals, (2) increase in the number of optical links, and (3) the requirement of phase control in addition to TTD to obtain a squint-free radiated beam. Nonetheless, experimental comparison of a 2×4 MMIC-based C-band phased-array antenna was conducted, where a superior dynamic range was measured for T/R-level data mixing architecture over CPU level 1 [35]. These apparent limitations were avoided using a cascaded ILPLL oscillator [36], a self-oscillating mixer [37], and an optoelectronic mixer using MLL [38]. The most important advantage of T/R-level data mixing is its reduction in the number of resolution bits required in real-time-delay devices to generate a squint-free-beam. This issue is highlighted next.

Figure 16 depicts radiation pattern of a 25-element linear phased array (with $\lambda/2$ separation) designed for operation at center frequency of 33 GHz with bandwidth of 3 GHz (i.e., each graph is composite of three simulated graphs at frequencies of 31.5, 33, and 34.5 GHz). The simulation results are for CPU-level data mixing. The re-

quired time delay is achieved using a switched delay line TTD (real-time-delay device) with minimum time resolution of 10 ps. As this simulation result indicates as the beam is pointed away from broadside, sidelobe levels increase to only -6 dBc, and the mainbeam decreases by 2 dB. On the other hand, Fig. 17 depicts the simulated performance of the same phased array when it is constructed on the basis of T/R-level data mixing. This structure employs a 2π analog phase shifter based on the concept of cascaded oscillators [36] along with a TTD with a time resolution of 30 ps (i.e., decreasing the time delay number of bits by factor of ~ 4). As this figure clearly indicates, no reduction in mainbeam peak level or increase in sidelobe levels is observed for any scan angles. In fact, the sidelobe levels are compatible with the expected theoretical level of 13.6 dB for a uniform array.

5. MICROWAVE PHOTONIC SIGNAL PROCESSORS

One of the most significant advantages of microwave photonics is not the antenna remoting concepts, but rather the opportunity to perform signal processing in the optical domain. The primary figure of merit is the time-bandwidth product, which could exceed 10^4 , hence leading to significant rejection and filtering using various delay lines. A few realizations of signal processors using microwave photonic techniques are discussed next.

5.1. Memory Loop

Fiberoptic-based memory loops are used for recirculation of the incoming RF pulses. The simplified schematic dia-

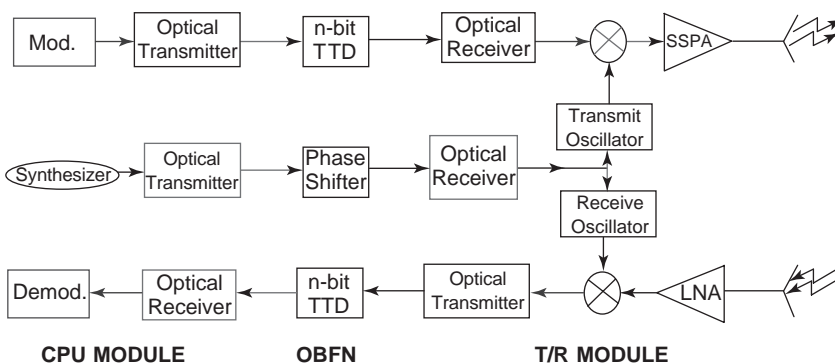

Figure 15. T/R-level data mixing architecture for transmit/receive-mode operation, where distributed local oscillators need to be synchronized to a frequency reference. Note that both real-time-delay and phase shifter devices are required for beam-squint-free operation in broadband systems.

Figure 16. Simulated radiation pattern of 25-radiating-element linear multibeam phased-array antenna based on a CPU-level data mixing architecture where a real-time-delay line with 10 ps resolution is employed to generate beams at different angles ($f_{LO} = 24$ GHz, $f_{data} = 7.5\text{--}10.5$ GHz, $f_{RF} = 31.5\text{--}34.5$ GHz).

gram of a fiberoptic-based recirculating memory loop is shown conceptually in Fig. 18. This system consists of four basic elements: a switch, an electrical amplifier, a fiberoptic time-delay element, and a gain equalizer. The gain equalizer is composed of a YIG tunable filter and an attenuator. The RF input pulse is routed through the switch to the time-delay device. The switch closes the loop and thus controls the recirculation. As the signal reenters the microwave circuit, it is amplified and rerouted through the fiber. As a result, a pulsetrain is obtained that has a pulse repetition interval corresponding to one recirculation time through the loop.

The number of recirculations is not limited by dispersion, and for higher recirculation the following steps are established (1) reducing the insertion loss and noise figure of the fiberoptic link and (2) flattening the frequency response of the closed-loop system. Using a 1-km optical

Figure 17. Simulated radiation pattern of 25-radiating-element linear multibeam phased-array antenna based on a T/R-level data mixing architecture where a real-time-delay line with 30 ps resolution along with analog phase shifter for LO is employed to generate beams at different angles ($f_{LO} = 24$ GHz, $f_{data} = 7.5\text{--}10.5$ GHz, $f_{RF} = 31.5\text{--}34.5$ GHz).

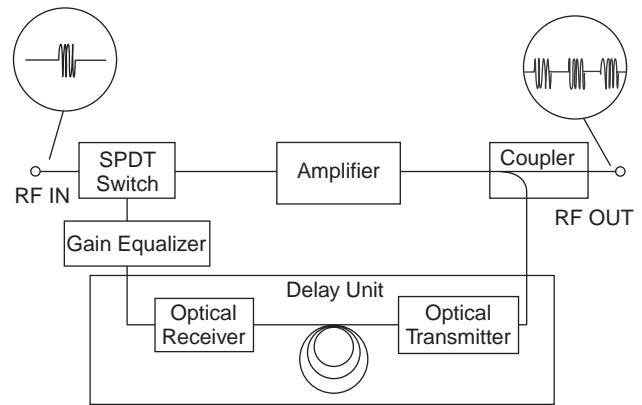

Figure 18. Conceptual drawing of a fiberoptic-based recirculating delay line. It is composed of a SPDT switch, electronic amplifier, coupler, optical delay element, and gain equalizer.

delay line over 2–4 GHz with an insertion loss of -11 dB (flatness of 4 dB) and a spurious-free dynamic range of $87 \text{ dB} \cdot \text{Hz}^{2/3}$, a short electrical pulse has recirculated for as long as a millisecond. The spectral purity of the recirculated signal is evaluated, and the spectral purity of the output pulses is as shown in Fig. 19 after 10, 20, and 35 recirculations. The phase noise degradation is measured for offset carrier frequencies of 10, 50 and 100 Hz.

Since the frequency response of the open loop is not, in practice, flat over the bandwidth, to enhance the performance of the memory loop, a gain equalizer is required. The amplification of the recirculating signal can be realized in either the electrical [39] or the optical domain. For broadband microwave signal processing, however, where the incoming signals in the frequency range of 2–18 GHz are analyzed, pulse recirculation in the optical domain is preferable to that in the electrical domain.

The maximum number of recirculations in the loop in terms of the characteristics of the system components can then be numerically evaluated as a function of gain flatness C . In particular, the maximum number of recirculations n_{max} is limited to the maximum number allowable by NF_{Tmax} and the open-loop noise figure NF_B as follows [39]:

$$NF_{Tmax} \approx \frac{1}{2} (NF_B - 1) \left[\frac{1}{C^n} \frac{1 - C^n}{1 - C} + n \right]$$

The implication of nonflat frequency response of the delay unit is that the noise will increase at a faster rate at frequencies where open-loop gain is greater than unity. Therefore, the nonflat frequency response and high noise figure of the delay element will restrict the maximum time delay attainable by the memory loop. Naturally, to overcome the n_{max} limitation, while achieving long total time delays of $n\tau$, one could increase the unit time delay τ , but the long unit delay will produce a void in the time domain for the short input pulses.

5.2. Advanced Optical Signal Processing Techniques

The use of passive optical components such as optical isolators, array waveguide grating, superposed array

Figure 19. Spectral purity and phase noise degradation compared to the input electrical pulse at various offset carriers as a function of number of recirculations.

grating, and spatial light modulators provides for a number of signal processing techniques, such as interference mitigation [40–42] and adaptive waveform generation [43]. The basic principle of these techniques is based on translating spectrum to time using dispersive fibers or delay lines. As the number of taps increases, increased resolution in frequency domain can be observed. On the other hand, using mode-locked pulses with short sampling periods will increase the time resolution. As the tap weights and unit time delay are adjusted, an arbitrary waveform in time domain is generated that corresponds to the desired transfer function. Figure 20 depicts the structure of a tunable filter, where a tunable filter with a Q as high as 800 is demonstrated [44]. Although discrete grating arrays are simpler for design implementation, but superposed arrays are quite practical for sampling bandwidth in the terahertz range [44].

Moreover, tapped delay lines are employed in combination with positive and negative optical amplitude to adjust transfer function and shape of the transversal filter. High-birefringence materials combined with a polarizer are employed to create all-optical transversal filters. Figure 21 depicts the shape of filter impulse response. The desired impulse response is converted to the desired bandpass filter. Moreover, notch filters could be developed using RF interference in the optical fiber while the other frequencies are transmitted through without much attenuation. Interference mitigation by 50 dB is experimentally demonstrated at 75 MHz [44].

6. OPTICAL ADC TECHNIQUES

Another application of microwave photonics is in the development of the analog-to-digital converter (ADC). Opto-electronic devices have demonstrated ultrafast switching speed, and mode-locked solid-state lasers have achieved high-speed and accurate optical pulses as low as 10 fs. With capability of sampling electrical signals of resolutions of subpicoseconds, implementation of optical ADC has long intrigued many researchers because of the

following advantages: (1) optical sampling has time jitter that is about two orders of magnitude lower than that of an electronic clock, (2) optical sampling decouples the electrical clock signal used for optical sampling from the sampled electrical signal, and (3) an optical sampled or quantized signal is easy to distribute by fiber and to remotely control. Also, many photonic ADC approaches also produce output as Gray codes directly, eliminating the need for additional encoding circuits. However optical

quantization is generally limited to resolution of a few bits, and this remains a major challenge. There are two approaches to quantize the information after sampling by optical signal: (1) hybrid optoelectronic ADC, where electrical quantizers are employed; and (2) all-optical ADC, where optical quantization is implemented.

6.1. Hybrid Optoelectronic ADC

Hybrid Optoelectronic ADC, also called “optically assistant ADC”, employs optical sampling followed by electronic quantization. It attempts to combine advantages of both optical and electronic ADC technologies: high-speed rate of optical sampling and high resolution of electronic quantization. But the speed of electronic devices is much lower than the optical sampling rate. So the sampled optical signal has to be downconverted to a lower speed and channeled to parallel electronic quantizers. For example, 100 Gsps sampled pulses can be split into eight channels in time domain, and the pulse rate in every channel is 12.5 Gsps. Most optical sampling transducers are implemented with Mach-Zehnder modulators [45], where the output intensity of the MZ interferometer is a function of the applied voltage

$$I_{out} = I_i \cos^2 \left[\left(\frac{\varphi_0}{2} \right) - \left(\frac{\pi V}{2V_\pi} \right) \right]$$

where $\varphi_0 = 2\pi nL/\lambda_0$, the optical distance of a branch, and V_π is the half-wave voltage, defined as the applied voltage

at which the phase shift changes by π . Optical sampling operates in a small range around V_π , the output is approximately linearly proportional to applied voltage V . To extend the linear range of MZ modulator, a number of linearization approaches were demonstrated. In photonic ADC, the linearization can be implemented in digital domain by directly inverting the transfer function in DSP.

The key issue in hybrid optoelectronic ADC is to channelize high-speed sampled optical pulses and ensure that channels match in both amplitude and time. Based on approaches of channelization, three major schemes are proposed: (1) time interleaving [46], (2) WDM channelization [47], and (3) time stretching [48]. The optical sampling and time interleaving is employed by Juodawlkis et al. [46] to implement an ADC with bandwidth up to 505 Msps by using 1–8 optical demultiplexers and 14-bit electrical quantizers. A dual-output LiNbO₃ MZ modulator is used for linearization processing and a 65 dB SFDR and 47 dB SNR, corresponding to an effective resolution of 7.5 bits. The sampled optical pulses are split into eight channels by optical time-division demultiplexers, which are composed of three stages of 1×2 switches controlled by 505-MHz driving signals. Therefore the 16 parallel high-resolution electronic quantizers are operating at 63 Msps [47]. To achieve an interleaving SFDR of 80 dB, the converter-to-converter gains must be matched to $\sim 0.01\%$, the offset must be matched to $\sim 0.01\%$ of the signal amplitude, and the converter-to-converter crosstalk must be less than one part in 10^4 .

On the other hand, using optical dispersive components, a multiwavelength optical wave is smeared (for continuous spectrum) or split (for discrete wavelengths) in time, and borrowing a concept from WDM communication, the sampled optical signal can be channelized in both wavelength and time domains. The RF signal is sampled by the WDM pulses and then channelized by a WDM demultiplexer. Clark et al. demonstrated a 100-Gsps photonic ADC based on the time- and wavelength-interleaved scheme [47] using a mode-locked fiber laser (MLFL) that generates 12.5 GHz pulsetrain, and a 100-GHz sampling optical pulse is obtained by $8 \times$ multiplexer. The pulses propagate through different fiber delays and attenuators, which then are recombined in the WDM. The delay fibers and attenuators can be adjusted for time matching and amplitude equalizing, respectively. The time-interweaved pulsetrain is then demultiplexed into eight channels according to wavelengths. The resulting parallel pulses are then quantized by >12.5 -Gsps quantizers, but an 8-bit ADC operating at only 781 Msps has been achieved with SNR 22–26 dB, which corresponds to about 4 bits. The resolution of wavelength-channelized ADC is still limited since it faces difficulties similar to those encountered by the time interleaving ADC. The time uncertainty and amplitude uniformity between channels are difficult to control.

Bhushan et al. demonstrated a record ultrafast sampling rate of 130 Gsps using the time stretching approach [48]. The idea behind this ADC is similar to wavelength-channelized ADC, but in the time-stretched approach an RF input signal modulates a broadband optical continuous wave (CW) other than that sampled by optical pulses with discrete wavelengths. The detected analog optical signal is sampled and quantized by electronic ADC. Figure 22 shows a limited time application of time-stretch pre-processing, where a passively mode-locked fiber laser with 20 MHz repetition rate followed by a 17-nm filter is used to generate broadband short pulses. The optical pulse propagates through a dispersive fiber of length L_1 and is dispersed in time to yield a time aperture of 0.8 ns. The wave is then modulated by the RF signal to be converted. The modulated wave is sent to another piece of dispersive fiber of L_2 to be stretched in time domain. The ADC obtains a stretch ratio of $M = 16.2$ by correct choice of either L_1 or L_2 , where the stretched signal is detected and digitized by a single 8-Gsps electronic ADC of an oscilloscope. So the

effective sampling rate is about 130 Gsps ($8 \text{ Gsps} \times 16.2$) with SNR ~ 45 dB, corresponding to 7.5 bits of resolution.

On the other hand, for continuous signals in time, a parallel architecture must be used in order to preserve the information. In this process an arrayed waveguide grating (AWG) is employed to sample a portion of the optical spectrum, and since each optical wavelength corresponds to a different propagation time delay, the filter performs sampling in time. Then each segment is time-stretched by the same factor M prior to entering a slow electronic ADC; however, both time alignment and amplitude in balance between various arms of are crucial importance.

6.2. All-Optical ADC

There are quite a few ways to implement optical quantization, but probably the best-known photonic ADC is based on a patent from 1977 [49]; a revised design called “optical folding-flash” ADC was patented in 1995 [50]. Figure 23 shows a block diagram of a 4-bit optical folding-flash ADC. The geometric scaling of V_π or electrode length is eliminated by a parallel–serial combined configuration. This scheme uses identical electrode length but sets DC bias at different points on the interferometer transfer characteristic curve. The resulting transfer function of MSB-2 and LSB branch is obtained by multiplying the functions of all stages at different bias, showing doubled frequency compared to the previous bit. However, this scheme also presents some additional challenges: (1) the MSB is susceptible to high noise levels because of the slowly changing slope at the digital edges, and (2) the transit-time limitation is still not eliminated; moreover, the hardware complexity increases exponentially in terms of interferometer number as $2^{(b-1)} + 1$ and strongly relies on accurate bias.

Another way to quantize an optical signal is to exploit variable electroabsorption semiconductor modulators demonstrated by Hayduk [51]. The quantization is achieved using an architecture that relates the received analog voltage to an optical intensity, which is based on the same concept as the electronic flash ADC, in which $2^N - 1$ comparators with different threshold values are used. The use of passive materials in this flash photonic ADC architecture with no external voltage requirement gives this module very low power dissipation. The authors claim that the ADC has the potential to operate at more

Figure 22. Time-limited signal converted by time stretching ADC [45]. (Courtesy of Prof. B. Jalali from UCLA.)

Figure 23. Optical folding-flash ADC [47]. a) various bias points of all optical ADC, b) realization of MZ modulators for quantization, c) the received signal.

than 100 Gbps combined with a resolution as high as 12–14 bits. But this scheme is susceptible to amplitude fluctuation and unbalanced energy splitting. A similar idea is also employed in all-optical ADC quantization using photodetectors with different sensitivities [52].

In the two ADC schemes mentioned above, the RF signal is sampled and quantized by optical amplitude. However, the amplitude errors strongly depend on source fluctuation, device linearity, and loss along the optical link. So it is difficult to build a construct high-resolution all-optical ADC based on optical amplitude. An all-optical ADC operating in spectrum domain is demonstrated by Zmuda et al. [53], as shown in Fig. 24. The input signal is sampled by a tunable laser and quantized by processor filters with binary behavior. The output wavelength of the tunable laser is modulated by the applied electrical field, so the electrical amplitude is represented as wavelength in spectrum domain. The postsampled light is processed by a parallel optical filter array. If the spectrum line falls into the passband, the output is represented as “1”; otherwise a “0” will be read. Each filter has periodic equally spaced passband and stopband and organized in a Gray code manner.

The major challenges for this scheme are the filter design of sharp transition and tunable laser. A 4-bit optical ADC using Bragg grating filters and a ring cavity tunable laser is proposed and analyzed. Because of the convergence time limitation of the Fabry–Perot cavity, only 4 bits of resolution can be achieved at 10 Gbps. Moreover, the performance of Bragg grating filters (see Fig. 25) show limited resolution. The authors proposed a folding circuit to enhance its resolution, where a Mach–Zehnder interferometer performs the optical folding circuit and a first-order linearization circuit corrects the nonlinear folded signal. Thus, two low-resolution ADCs are coupled with the folding circuit to achieve $M + N$ bits of resolution. The author claimed that the ADC would be able to operate at conversion speeds in excess of 10 GHz with up to 10–12 bits of resolution. However, it is not clear how the upper M -bit ADC achieved the additional 6–8 bits. But it indicates a promising way to perform analog-to-digital conversion in spectrum domain.

7. NEAR-IR OPTICAL SPECTROSCOPY

Near-infrared (NIR) spectroscopy is a new, noninvasive technique employed to analyze living tissue. In NIR spectroscopy, the main aim is to extract the optical properties (absorption and scattering) of the living tissue. Absorption information is used to characterize the concentration of biological chromophores, such as hemoglobin (in oxy and deoxy forms), which in turn indicates the physiological changes in blood. Scattering data provide information on

Figure 24. Optical ADC using tunable laser and filters [53].

Figure 25. Performance of Bragg grating filters.

composition, density, and organization of tissue structures, such as cells and subcellular organelles [54,55]. Therefore, NIR techniques provide information about disease-related functional and structural changes. More specifically, it has been shown that physiological changes such as ischemia, necrosis, and malignant transformation can produce important perturbations in tissue optical properties [55]. The importance of the NIR spectrum lies in the fact that in this region tissue absorption is much lower than in other parts of the spectra (see Fig. 26). Apart from tissue information content, this region is attractive since NIR instruments are inexpensive to construct and are easily portable. These features render NIR instruments as an attractive alternative to other techniques, such as MRI (magnetic resonance imaging). Moreover, NIR light is not an ionizing radiation; therefore, it can be used as a usual clinical monitoring of patients in radiation therapy.

The modulated NIR could be employed for greater spatial and temporal information and could be explained on the basis of the following physical principle. When photons enter a turbid (multiply scattering) medium, the photons scatter randomly in all directions, diffuse through the medium, and are absorbed during this diffusion process. When source detector separation is large enough and scattering dominates the absorption, the diffusion theory provides a very suitable approximation for photon transport

$$\frac{1}{c} \frac{\partial \Phi(r, t)}{\partial t} - D \nabla^2 \Phi(r, t) + \mu_a \Phi(r, t) = S(r, t)$$

where Φ is the fluence rate (W/cm^2), c is the speed of light in the tissue, S is the source term, μ_a is the absorption, and D is the diffusion constant, which is related to the reduced scattering constant μ'_s by $D = 1/(3\mu'_s)$. In an infinite medium for a point source, the photon diffusion wave (PDW) can be

Figure 26. Absorption spectrum of Hb (deoxy-hemoglobin), HbO2 (oxy-hemoglobin), and water in the NIR region.

Figure 27. Normalized amplitude attenuation (a) and phase shift (b) of photon diffuse waves as a function of frequency.

expressed analytically as

$$\Phi(r, t) = \frac{S}{4\pi D} \frac{\exp(ikr)}{r}$$

where k is the complex wavevector (i.e., $k = k_{\text{real}} + ik_{\text{imag}}$) and is described as combination of modulating frequency, diffusion, and absorption coefficients as $k = \sqrt{-\mu_a/D + i\omega/(c \cdot D)}$. The backscattered PDW has phase lag and amplitude attenuation relative to the source as

$$\Theta_{\text{lag}}(r, \omega) = k_{\text{imag}} \cdot r$$

$$A_{\text{att}}(r, \omega) = \exp(-k_{\text{real}}r)/(4\pi Dr)$$

Figure 27 shows the solution of amplitude attenuation and phase shift of photon diffuse waves with respect to frequency (up to 1 GHz) for breast tissue with optical absorption and scattering coefficients properties of $\mu_a = 0.05 \text{ cm}^{-1}$, $\mu_s = 10 \text{ cm}^{-1}$. NIR techniques are also being used for brain imaging as seen in Fig. 28 [57,58]. The

Figure 28. Brain activation image: MRI image is shown on the left, and the image from diffuse optical tomography is depicted on right. (Courtesy of Prof. Britton Chance of University of Pennsylvania.)

image on the left is obtained from MRI. The image on the right is obtained from diffuse optical tomography.

The NIR technique uses continuous-wave (CW), time-domain, and frequency-domain instruments according to their applications and information content. CW systems are very inexpensive but suffer from limited resolution. Frequency-domain (FD) instruments are more compact and cheaper, and FD algorithms are easier to handle than those of the time-domain techniques; hence FD instruments are more attractive. In FD photon migration concept is also easier. When light is modulated by frequencies in the megahertz region, diffuse photon density waves (PDW) are generated, propagating with a wavelength of several centimeters [59–62]. At the detector one measures the amplitude decay and phase shift data of these waves (see Fig. 27). Amplitude and phase data are used to map the optical absorption and scattering properties of the medium. Optical constants in turn are used to obtain hemoglobin concentration, blood volume, and oxygen saturation. Greater accuracy of the extracted results is achieved when a frequency-swept mode is employed, and as the modulation frequency increases to the microwave region, a higher spatial resolution is attained.

8. CONCLUSIONS

This article provides a personal perspective of microwave photonics and its evolution toward a mature field. From its fundamental beginning of light interaction with semiconductor devices and circuits, the goal has been to take advantage of isolation between optical and electrical systems. Moreover, the injection photogenerated electron–hole pair influences the dynamics of microwave devices, leading to the development of novel devices. Light interaction with microwave devices and circuits has seen a new resurgence, particularly in applications dealing with integrated optical detectors with microwave functions. HBT (heterojunction phototransistor)-based devices seem to provide high gain and speed performance.

Fiber-fed phased-array antennas and wireless communications have been the second driver for the microwave photonics. The performance of analog fiberoptic links is analyzed in terms of link gain and dynamic range for data signal distribution; performance of FO links are also analyzed in terms of AM/PM conversion employed in remoting of the frequency reference to stabilize the distributed local oscillators. Moreover, distortion induced by SRS in dense WDM systems is discussed. Fiberoptic links based on direct modulation could meet cost-performance requirements for many applications, even though monolithically integrated EA modulators are becoming very attractive. Another innovation is in the design of multi-function circuits, such as the monolithically, integrated FP laser with EA modulator, where simultaneous transmission of frequency reference of data signals is accomplished. The optical oscillation in this novel device could be stabilized as a LO signal using either injection locking or mode locking. The achieved close-in to carrier phase noise of the stabilized LO signal is lower in the case of injection locking than mode locking for the same modulating power level. However, the nonlinear behavior of the mode-locked laser provides opportunity for efficient optoelectronic mixing of LO and data signals, while maintaining a very high SFDR. This multifunction circuit creates the possibility of generating a RF signal from the frequency reference and data signals, thus bypassing the need for integration with electrical mixers in up/downconversion.

Among the technologies that are unique to microwave photonics is the issue of optical signal processing, which could lead to very large time-bandwidth products, hence resulting in high frequency selectivity. Memory loop devices, transversal filters, and tapped delay lines are attractive solutions that command unique advantages over the electrical signal processing techniques. Moreover, the optical ADC is considered another important advantage over electrical systems because of its lower timing jitter, hence achieving a high resolution ADC at the Gbps level. This technology is critical in the development of digital receivers for software radiocommunication systems. Finally, new applications for microwave photonics are emerging in the medical imaging using the photon density wave. The RF modulated light at microwave frequency at wavelengths associated with absorption peaks of oxy- and deoxyhemoglobin provides a higher spatial resolution with function imaging of the biological tissues. This technique is currently being pushed for clinical applications to medical imaging of brain, breast, and skin tissues.

There many innovations in the field of microwave photonics that, because of space limitations in this article, impossible to cover here. However, the author wishes to recommend as further reading a number of special issues of *IEEE Transactions on Microwave Theory and Techniques* that are dedicated to reviews of the latest innovations in microwave photonics as further reading.

Acknowledgment

The author wishes to acknowledge the contribution of many of his students, particularly Dr. Murilo Romero, Dr. Edward Ackerman, Dr. Reza Saedi, Mr. Adam McIn-

vale, Dr. Tsang-der Ni, Dr. Xiang-dong Zhang, Dr. Manouchehr Ghanevati, Dr. Joong-Hee Lee, and Dr. Xiaobo Hou. Moreover, technical discussions with his colleagues Prof. Asher Madjar, Technion, Tel Aviv, Israel; Dr. Kenji Sato, NTT, Yokosuka, Japan; Dr. Hiroyo Ogawa, CRL, Yokosuka, Japan; Prof. Robert Minasian, University of Sydney, Australia; Prof. Peter Herczfeld, Drexel University, Philadelphia; Prof. Bahram Jalali, UCLA, Los Angeles; Prof. Britton Chance, University of Pennsylvania, Philadelphia; and Prof. Tibor Berceli, Budapest University of Science and Technology, Budapest, Hungary are greatly appreciated.

1. INTRODUCTION

A power amplifier (PA) is a system component whose main task is to increase the power level of the signal at its input up to a predefined level. As contrasted to low-level amplifiers, often specified in terms of small-signal gain, the absolute output power level is the PA main feature. This characteristic on one hand forces the selection of the active devices composing the PA on the basis of their output power capabilities; on the other hand, in order to fully exploit such capabilities, the devices are typically operated under large-signal regimes, forcing the exploration of nonlinear operating regions. A PA is therefore an intrinsically non-

linear system component, whose large-signal operating conditions often lead to detrimental effects on the output signal, resulting in a distorted replica of the input. Moreover, the linear approximation underlying small-signal amplifier design techniques is no longer strictly valid and hence does not allow their direct application to PA design. Dedicated methodologies therefore have to be adopted, even if preliminary and first-guess simplified approaches are often employed. The present contribution is aimed at addressing the microwave power amplifier design and performance. Radiofrequency (RF) or other approaches at lower operating frequencies (below 1 GHz) are therefore not covered in detail, except where explicitly stated.

Microwave PA system applications span a broad range of areas [1], including telecommunications, radar [2–4], electronic warfare, heating [5,6], and medical microwave imaging [7–12], which represent only a few examples. Given such extremely diversified fields, PA specifications differ greatly on operating, technological, and design requirements. Examples of such differences range from traveling-wave-tube (TWT) amplifiers in satellite payloads to solid-state amplifiers for personal wireless communication handsets, from microwave heating tubes to amplifiers composing hyperthermia apparatuses.

The large differences in system applications are reflected back into the technologies adopted for realization of the PA active module. The early days of the microwave era were characterized by an extensive, widespread use of vacuum-tube devices [13–16] for both generation and amplification of microwave signals. If microwave electronics may be dated back to the pioneering work of H. Hertz and J. C. Bose [17–20], a major push toward high-power microwave generation and use came from the World War II military application in the radar field, with the introduction and use of the cavity magnetron by British researchers and the klystron as a high-power source in 1939/40. The klystron evolved in Stanford University toward a high average power amplifier, leading to modern applications involving clustered cavity klystron and traveling-wave tubes [21–23].

In such a scenario, solid-state devices and related amplifiers are relatively recent players, being the first GaAs MESFET, with good performance at X band, commercially available since the early 1970s, despite the device introduction in the early work of Stuetzer and Shockley [24,25]. The technology rapidly advanced and, in the 1970s, the development of techniques for semiconductor crystal growth such as molecular-beam epitaxy (MBE) permitted optimized p-n-junction structures to be realized, allowing a series of two- and three-terminal devices to be fabricated with frequency operation ranging from a few gigahertz well into the millimeter-wave region [26–28]. To the two-terminal device category can be assigned IMPATT transit-time and Gunn transferred electron devices, which have been and are still used for both frequency generation and amplification, as negative-resistance amplifiers, in the millimeter-wave frequency region. The broader and much more frequently adopted category of three-terminal active devices includes the already mentioned metal semiconductor field-effect device (MESFET), the high-electron-mobility transistor (HEMT; demonstrated by Mimura in

1980 [26]) with its pseudomorphic (PHEMT) and metamorphic (MHEMT) variants, the heterojunction bipolar transistor (HBT; introduced by Kroemer in 1957 [29]), and finally, due to the more recent major advances of high-frequency silicon technology, MOS and bipolar silicon transistors, including laterally diffused MOS structures (LDMOS, [30,31]) and silicon-germanium (SiGe) HBTs [32,33] as key representatives. Nevertheless, the “work horse” technology for microwave power amplification is indeed based on III-V technologies, mainly of the GaAs type. The latter technology is capable of providing, as the output of a single device, output power levels close to 50 dBm [34] with operating frequencies approaching W band. In the upper frequency range, InP solutions are more appropriate, even if they provide very limited output power levels.

Even if “combined device” concepts utilizing both solid-state and vacuum-tube devices have been proposed, the former are generally utilized for low-moderate power output while the latter is indeed necessary whenever high power and high frequency of operation are addressed as schematically indicated in Fig. 1.

Performance of the given device type may be readily demonstrated to exhibit a well-known behavior if considered in their frequency limit region, i.e. following the law:

$$P \cdot f^2 \approx \text{const} \tag{1}$$

where P and f represent output power and the operating (narrowband) frequency, respectively.

The single solid-state device output can be combined utilizing a series of different techniques, and therefore solid-state power amplifiers with output powers compara-

ble to the ones of a vacuum-tube source (i.e., in the kilowatt region) may be obtained in the microwave frequency region (up to X band). On the other hand, practical limitations arise from the systematic application of combining techniques as operating frequency increases, thus imposing the use of vacuum-tube sources.

The increase in solid-state single-device performances will therefore lead to new device concepts and new developing technologies. Among the latter ones, SiC [35] and GaN wide-bandgap semiconductor technologies are actually being explored; whereas SiC MESFET and HEMT have demonstrated 4–5 W/mm output power density throughout X band [36], nitride-based components are extremely promising, setting a new upper limit to device performance in the range of 20 W per millimeter of device periphery, as compared to the 1–2 W limit of GaAs FET-based technologies and the 2–4 W of the HBT ones [37–39]. Even if experimentally demonstrated in the microwave range, such performances are expected to be exported to higher operating frequencies, well into the millimeter-wave spectrum.

The more recent trends toward increasingly high power densities, pushed mainly by radar and electronic warfare applications, is the latest development of the tremendous growth experienced by the high-frequency semiconductor industry. In fact, since the early 1990s, mobile and personal communications systems, ranging from cellular telephony to wireless LAN, with the corresponding demand for high-quality radiolinks, is posing a major challenge to high-frequency technologies and subsystem performances, especially in the microwave frequency region.

The demand for portable apparatuses, whose main characteristic is battery duration and overall size, logically

Figure 1. Single-device output power as a function of frequency for solid-state and vacuum devices. [From V. L. Granatstein et al., Vacuum electronics at the dawn of the twenty-first century, *Proc. IEEE* 87(5):702–716 (May 1999).]

translates into a low-power electronic system. Since the PA in the transmitter section clearly represents the main source of supply power consumption, such feature is directly transferred to its specifications. A difficult tradeoff is therefore demanded of the PA designer, balancing among the contrasting goals of high transmitted power, low power consumption, and, for many telecommunication systems, linear operation. Given the widespread diffusion of many telecom applications, all of the abovementioned specifications have to be fulfilled keeping unit cost to a minimum. Such goals and the resulting compromise may vary depending on the type of radiolink to be established and overall system specifications, but their challenge has heavily influenced industrial, technical, and research directions in the PA field since early 1990s.

As a consequence, the high-frequency semiconductor industry has finally moved toward high-volume production. In particular, the search for an high output power is pushing, from the technological point of view, toward the design of active devices with high power densities, simultaneously exhibiting high reliability, and reproducibility, and at a reasonable cost. Six-inch wafers are currently adopted for high-volume production in GaAs, as compared with the former prototyping 3- or 4-in. low-volume productions, with a corresponding increase in reproducibility, wafer uniformity, and yield, at a lower cost. As a consequence, many beneficial effects on PA performance in terms of process maturity and stage performance have been realized. From the device side, GaAs FET discrete packaged power devices are actually produced and commercialized, allowing high output power (≤ 40 W in S bands in partially matched conditions or > 100 W directly in push-pull configuration for base-station applications [34]) even in X or Ku band (> 20 W in internally matched configuration in 14–14.5 GHz range [34]).

Where intrinsic difficulties of material growth and resulting quality are encountered, metamorphic solutions have been proposed, allowing the growth of high-quality materials on a solid and reliable bulk substrate; this is the case for high-indium-content devices and structures utilizing GaAs wafers. The inherent volume and cost advantages are evident, with minor performance degradation; the latter is due mainly to quality of the transition between materials, gradually accommodating the lattice mismatch, which can be appropriately optimized.

2. BASIC DEFINITIONS AND PERFORMANCE PARAMETERS

Regardless of the specific application, a PA may be ultimately considered, from the energy perspective, as a component converting DC power from supplies (P_{DC}) into microwave power (P_{out}), driven by an input power (P_{in}). This process is schematically depicted in Fig. 2.

The effectiveness of this conversion process is usually described in terms of the amplifier's efficiency η , or conversion efficiency, defined as the ratio between output RF and supplied DC power:

$$\eta \equiv \frac{P_{out}}{P_{DC}} \cdot 100 \quad (\%) \quad (2)$$

Figure 2. Energetic schematic representation of PA operation.

Efficiency is often further specified as “drain efficiency” or “collector efficiency,” in the case of a solid-state PA based on field-effect or bipolar transistor respectively.

Amplifier efficiency is in one of the key parameters in specifying overall system performances; as noted above, for a given amount of output power required by system specification for the PA, the efficiency actually fixes the DC power budget and hence the supply power. A reduced supply power resulting from high-efficiency performance is a key goal of mobile apparatuses, typically battery-operated, whose operating time depends strictly on the transmitting section power requests.

Moreover, since practical and physical constraints impose an actual efficiency lower than the theoretical maximum of 100%, high-efficiency performances imply in turn a low power dissipated on the power-amplifying device, therefore reducing actual size and weight of the eventually required heatsinks. On the other hand, for a given available DC power, high-efficiency performance allows higher transmitted power with a corresponding increase in overall system capabilities.

As frequency increases, however, the PA gain decreases, as a result of its active constituents gain rolloff behavior. Considering the input-output transfer characteristics of the PA, its power gain is defined as

$$G \equiv \frac{P_{out}}{P_{in}} \quad (3)$$

and usually expressed in logarithmic units [decibels(dB)]. The contribution to the output power coming directly from the input drive cannot be neglected since it constitutes, at microwave frequencies and beyond, a significant portion of the total amount. As a consequence, defining the *added power* P_{add} , that is, the net increase in the signal power from the PA input to its output, we obtain

$$P_{add} \equiv P_{out} - P_{in} = P_{out} \cdot \left(1 - \frac{1}{G}\right) \quad (4)$$

Power-added efficiency (PAE or η_{add}) is defined as the ratio between the added power and the supplied DC power:

$$\eta_{add} \equiv \frac{P_{add}}{P_{DC}} = \frac{P_{out} - P_{in}}{P_{DC}} = \frac{P_{out} \cdot \left(1 - \frac{1}{G}\right)}{P_{DC}} \quad (5)$$

$$= \eta \cdot \left(1 - \frac{1}{G}\right)$$

An alternative definition of η_{add} , less frequently used in common practice, is [40]

$$\eta_{\text{add}} \equiv \frac{P_{\text{out}}}{P_{\text{DC}} + P_{\text{in}}} = \eta \cdot \frac{1}{1 + \frac{\eta}{G}} \quad (6)$$

i.e. the ratio of output power to the total input power fed into the amplifier (RF plus DC; see Fig. 2). The two definitions (5) and (6) practically converge for high-gain amplifiers, while giving substantially different results for low-gain amplifiers, especially when hardly driven into compression (note that the conventional η_{add} definition may lead to negative results). If nonconstant envelope signals have to be treated by the PA, an average efficiency can be introduced [40,41], defined as in (2), where the quantities in the expression are replaced by input and output powers averaged over an envelope period and weighted by the envelope probability density function.

The conversion from DC to RF power implies that a fraction of the supplied power is actually dissipated on the active power device. The main contribution to the latter is spent at the active device output, and is given by

$$P_{\text{diss,out}} \equiv \frac{1}{T} \cdot \int_T v(t) \cdot i(t) \cdot dt \quad (7)$$

where $v(t)$ and $i(t)$ are the device output voltage and current, integrated over a period (T) of the RF signal. To increase the conversion efficiency, as will be discussed later, a possible strategy consists in the minimization of such dissipated power, namely, in the proper shaping of device output voltage and current waveforms.

For cascaded (matched) PAs, as depicted in Fig. 3, the overall efficiency η_{tot} is easily computed by

$$\eta_{\text{tot}} = \frac{P_{\text{out}}}{P_{\text{DC},1} + P_{\text{DC},2}} = \frac{\eta_2}{1 + \frac{P_{\text{DC},1}}{P_{\text{DC},2}}} = \frac{\eta_2}{1 + \frac{\eta_2}{\eta_1 \cdot G_2}} \quad (8)$$

Since the DC supply power for the final stages ($P_{\text{DC},2}$) is usually much higher than the driver supply ($P_{\text{DC},1}$), overall efficiency is dominated from the former amplifier. On the contrary, for a low-gain final amplifier, the driver’s effect also becomes crucial for overall conversion efficiency.

Regardless of the definition adopted for η_{add} , its maximization is to be achieved at the nominal drive level for the PA, that is, while the latter is delivering the specified output power. In such operating conditions, the amplifier is typically driven into compression, thus leaving its almost linear region and exploring the nonlinear active-device physical limitations, as depicted in Fig. 4, where a typical $P_{\text{in}}-P_{\text{out}}$ power sweep is plotted.

Figure 3. Cascade connection of two PAs.

Figure 4. Sample $P_{\text{in}}-P_{\text{out}}$ power sweep (a) and corresponding amplifier gain (b); $P_{-1\text{dB}}$ can be derived from both.

From the power sweep in Fig. 4, a commonly used compression level figure of merit, $P_{\text{out},-1\text{dB}}$, can be derived, defined as the output power corresponding to a deviation of 1 dB from the ideal linear behaviour. The corresponding input power level, $P_{\text{in},-1\text{dB}}$, usually marks the border between “highly nonlinear” and “almost linear” operating conditions.

The peak drain/collector or power-added efficiency usually occur at higher drive levels, corresponding to 2–4 dB PA gain compression (Fig. 5). In such a region the active-device behavior is therefore highly nonlinear, and correspondingly design methodologies for high efficiency operation must cope with such intrinsic deviation from linearity.

PAs are normally classified into “operating classes” where the device output current conduction angle α (i.e., the fraction of the RF signal period where a nonzero current is flowing) is considered in detail, and where the classification in Table 1 holds.

The classification above is typically adopted regardless of the PA drive level, in order to simply indicate the biasing region of the active device, as determined by its quiescent supply conditions (Fig. 6).

Even for class A or B PAs, for which the conduction angle is fixed by definition, if the drive level is increased

Figure 5. Typical power-added efficiency in a PA as a function of input drive.

Table 1. Classification of PAs in Terms of Output Current Conduction Angle α

Operating Class	Current Conduction Angle (α)	Dependence on Drive Level	Bias
A	$\alpha = 2\pi$	No	Midway between Device Pinchoff and Saturation Regions
AB	$\pi < \alpha < 2\pi$	Yes	Above pinchoff
B	$\alpha = \pi$	No	Device pinchoff
C	$\alpha < \pi$	Yes	Below pinchoff

up to compression regions (i.e., if the amplifiers are *overdriven* or *saturated*), a variation of current conduction angles occurs. It is clear that the two definitions may lead to misleading interpretations. Nevertheless, above all in communication systems characterized by non-constant-envelope transmitted signals (as in the case of QAM or in digital cellular communications with GSM and NADC standards), the transmitter has to satisfy tight requirements, not only in terms of efficiency but also linearity and signal spectral purity.

Several indicators of PA linearity are used, depending on the system specifications and modulation schemes that are adopted. In order to introduce and define them, a simple third-order approximation of the PA transfer characteristic is usually assumed

$$y(t) = A \cdot [x(t) + k_2 \cdot x^2(t) + k_3 \cdot x^3(t)] \quad (9)$$

where $x(t)$ and $y(t)$ are the input and output signals to the amplifier, respectively (they may be regarded as normalized voltages or currents), A is the small-signal voltage (or current) gain, and k_2, k_3 are the first two coefficients of a McLaurin expansion of the PA transfer characteristic, truncated to the third order. Please note that the approximation above, relating the output signal to the instantaneous input value, actually describes a memoryless system, and therefore memory effects cannot be accounted for using this description.

If a single-tone excitation is assumed for the input signal, with amplitude X and frequency f

$$x(t) = X \cdot \cos(2 \cdot \pi \cdot f \cdot t) = X \cdot \cos(\omega \cdot t) \quad (10)$$

Figure 6. Class of operation defined as output current conduction angle (left) or simply by the device quiescent bias point (right).

the corresponding input power P_x (on a unitary normalizing resistor) is

$$P_x = \frac{X^2}{2} \quad (11)$$

Output power at frequency $f(P_y)$ and large-signal gain G are easily obtained as

$$\begin{aligned} P_{y,f} &= A^2 \cdot \left(1 + \frac{3}{2} \cdot k_3 \cdot P_x\right)^2 \cdot P_x \\ &= G_{\text{lin}} \cdot \left(1 + \frac{3}{2} \cdot k_3 \cdot P_x\right)^2 \cdot P_x \end{aligned} \quad (12)$$

$$G = \frac{P_{y,f}}{P_x} = G_{\text{lin}} \cdot \left(1 + \frac{3}{2} \cdot k_3 \cdot P_x\right)^2 \quad (13)$$

where $G_{\text{lin}} = A^2$. Since usually k_3 is negative, the previous derivation accounts for large-signal gain compression, namely, decrease from the ideal linear constant value (G_{lin} above).

In the same way, from the single-tone excitation, harmonic generation at $2f$ and $3f$ arise, leading to a corresponding output power at harmonic frequencies $P_{y,2f}$ and $P_{y,3f}$ given by

$$P_{y,2f} = \frac{G_{\text{lin}} \cdot k_2^2}{2} \cdot P_x^2 \quad P_{y,3f} = \frac{G_{\text{lin}} \cdot k_3^2}{4} \cdot P_x^3 \quad (14)$$

therefore justifying the increase in harmonic power by n dB per dB of input power increase, where n is the order of the harmonic under consideration, as in Fig. 7.

The harmonic distortion (HD) due to the n th output harmonic component is therefore easily defined by

$$\text{HD}_{nf} \equiv \frac{P_{y,nf}}{P_{y,f}} \quad (15)$$

resulting in the approximated expressions for second- and third-harmonic distortion (HD_{2f} , HD_{3f}) in the simple cubic memoryless model [9]:

$$\text{HD}_{y,2f} = \frac{G_{\text{lin}} \cdot k_2^2}{2} \cdot P_x \quad \text{HD}_{y,3f} = \frac{G_{\text{lin}} \cdot k_3^2}{4} \cdot P_x^2 \quad (16)$$

Similarly, a total harmonic distortion (THD) is defined summing up all harmonic distortion components in the

Figure 7. Output power in a single-tone test at fundamental frequency (red), second- (green) and third- (blue) harmonic components.

output signal:

$$THD \equiv \sum_{n \geq 2} \frac{P_{y,nf}}{P_{y,f}} \quad (17)$$

The quantities above are typically measured in decibel over the carrier power (dBc).

The model (9) is indeed an instantaneous model, that is, a memoryless description of the PA input–output characteristics. Real-world amplifiers are dynamic systems with memory, whose nonlinear behavior affects not only the amplitude but also the phase of the output signal. In fact, if the input signal to the PA is assumed to be

$$x(t) = X(t) \cdot \cos[2 \cdot \pi \cdot f \cdot t + \varphi(t)] \quad (18)$$

the output signal may exhibit nonlinear phenomena in both amplitude and phase

$$y(t) = G[X(t)] \cdot \cos\{2 \cdot \pi \cdot f \cdot t + \varphi(t) + \Phi[X(t)]\} \quad (19)$$

giving rise to the AM/AM compression and AM/PM conversion effects (Fig. 8), described by a nonlinear relationship between input and output amplitudes (which actually represents the amplifier’s output power compression) and a phase that depends on the input signal drive level:

$$G[X(t)] \neq A \cdot X(t) \quad \Phi[X(t)] \neq \text{const} \quad (20)$$

In particular, the AM/PM conversion effect represents a change in the phase of the output that depends on the input drive level; this effect is potentially dangerous not only in communication systems, giving rise for instance to distorted QAM constellations, but also in phased-array applications where the phase of each signal exiting the respective PA actually determines the active antenna pointing characteristics. Nevertheless, the PA description in terms of its AM/AM and AM/PM characteristics leads to a narrowband model; it is valid until the amplitude and

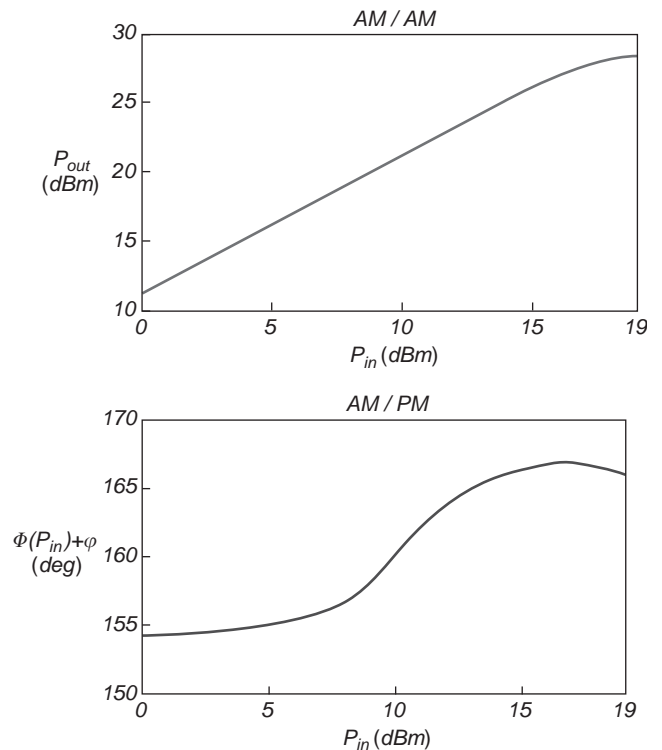

Figure 8. Typical AM/AM compression and AM/PM conversion curves for a PA.

phase modulating signal frequencies are much lower than the carrier one. Regardless of its applicability to narrow-band operation of PA, the AM/AM compression–AM/PM conversion model has been widely adopted, also forming the base for blackbox (or behavioral) modeling of PA operation. Such a behavioral model may be derived from Volterra analysis [42,43] or directly from experimental data [44]. The Volterra series approach may also be generalized to extend the model validity to broadband operation of the PA [45].

Resorting to the memoryless PA model (9), a two-tone test may be performed, attempting in this way to simulate the simultaneous treatment of two different signals and therefore their mutual interaction caused by the nonlinear PA. Much in the same way, this test may give insight on a narrowband signal, whose components (the tones in the test) may interfere, leading to a distorted output. This is clearly an approximation since the two signals are in reality much more complex than a simple sinusoid; on the other hand, the two-tone test is simple enough to be easily carried out experimentally. The input signal in this case is given by two closely spaced tones at frequencies f_1 and f_2 ($f_1 < f_2$) with amplitudes X_1 and X_2 , respectively:

$$\begin{aligned} x(t) &= X_1 \cdot \cos(2 \cdot \pi \cdot f_1 \cdot t) + X_2 \cdot \cos(2 \cdot \pi \cdot f_2 \cdot t) \\ &= X_1 \cdot \cos(\omega_1 \cdot t) + X_2 \cdot \cos(\omega_2 \cdot t) \end{aligned} \quad (21)$$

In such a two-tone test, the frequency spacing ($f_2 - f_1$) is much lower than the single frequencies, to replicate a narrowband excitation. By inserting an input drive such

Table 2. Output Components in a Two-Tone Test Grouped by Originating Term in Truncated Series Expansion

Originating Term	Output Frequencies	Corresponding Amplitude	
$x(t)$	f_1, f_2	X_1, X_2	Linear term
$x^2(t)$	$2f_1, 2f_2$	X_1^2, X_2^2	Second harmonic
	DC	X_1^2, X_2^2	Rectified component
	$f_1 - f_2$	$X_1 \cdot X_2$	Second-order intermodulation
$x^3(t)$	$f_1 + f_2$	$X_1 \cdot X_2$	Second-order intermodulation
	f_1, f_2	X_1^3, X_2^3	Compression
	f_1, f_2	$X_1 \cdot X_2^2, X_1^2 \cdot X_2$	Capture
	$3f_1, 3f_2$	X_1^3, X_2^3	Third harmonic
	$2f_1 - f_2, 2f_2 - f_1$	$X_1^2 \cdot X_2, X_1 \cdot X_2^2$	Third-order intermodulation
	$2f_1 + f_2, 2f_2 + f_1$	$X_1^2 \cdot X_2, X_1 \cdot X_2^2$	Third-order intermodulation

as that described above into the PA truncated expansion, a series of output frequency components results, which are grouped in Table 2, by the term in the expansion (linear, quadratic, or cubic) from which they originated.

The terms in Table 2 are plotted as a function of frequency in Fig. 9. From Table 2 and Fig. 9, a series of conclusions can be drawn. Firstly, the interaction between the two input frequencies does create, in the nonlinear PA, a series of frequency components that are not present if the PA is separately excited by the single frequencies. In fact, while DC, harmonic components, and compression terms are already generated from the single-tone excitation, intermodulation frequencies and “capture” terms arise from the interaction between the two tones. The latter contributions, giving rise to *out-of-band* and *in-band* components, actually have a power rising as 3 dB per dB increase of the single tone’s power (Table 2). In particular, the capture term (often referred to as “suppression” term) tends to decrease power output at a given fundamental frequency (say, f_1) proportionally to the square of the power of the other (f_2) fundamental frequency; this phenomenon is particularly effective for high drive levels, and may eventually lead to the cancellation of one of the signal components at the PA output, thus justifying the “suppression” denomination.

Moreover, if signal purity is concerned, harmonic contributions (at DC, second, and third harmonic of each input excitation) together with second-order intermodulation and the terms at $2f_2 + f_1$ and $2f_2 + f_1$ (all in blue in Fig. 9) are far away from the useful part of the output signal (at f_1 and f_2 , in green in Fig. 9), and are therefore

easily eliminated by simple filtering. Other contributions, much closer to the desired input replica, cannot be filtered out; from the simple derivation above, they consist in frequency terms located at $2f_2 - f_1$ and $2f_1 - f_2$ (commonly referred to as *third-order intermodulation components*, giving rise to *intermodulation distortion*, (IMD) and at the input signal frequencies f_1 and f_2 (in-band distortion, given by the compression and suppression/capture terms).

Considering one of the two third-order intermodulation components and sweeping the input tone’s power, the *third-order intercept point* (IP3) is defined as the output (IP3_{out}, or input, IP3_{in}) power level at which the third-order IMD component level equals the ideal linear output power of the PA. Such definition is graphically depicted in Fig. 10. Even if both useful output signal power and IMD power tend to saturate for some input drive level, the IP3 definition consists in the ideal extrapolation of both output signal components (black and blue lines, respectively, in Fig. 10), ideally rising by 1 and 3 dB per dB increase in input drive respectively, and in the search for their intercept (the IP3). On the basis of such construction, it is clear that the resulting input drive level (IP3_{in} in Fig. 10) is well into the PA nonlinear operating region and is by far beyond typical PA operating drives. Similar intercept points can be defined (even if seldom used) by extension for higher-order intermodulation products, such as IP5 (for fifth-order distortion, located at $3f_2 - 2f_1$) or IP7 (for seventh-order distortion, located at $4f_2 - 3f_1$).

Resorting to the power-series expansion (9), it can be demonstrated that the IP3 output power level (IP3_{out}) can

**Figure 9.** Frequency allocation of the output components originating in a two-tone test.

Figure 10. Third-order intercept point definition.

be related to the 1-dB compression point ($P_{-1\text{dB,out}}$) by

$$IP3_{\text{out}} \approx P_{-1\text{dB,out}} + 10.6\text{ dB (dBm)} \quad (22)$$

In real-world PAs, this expression typically overestimates $IP3_{\text{out}}$ by 2–3 dB. The approximations inherent to the truncated expansion adopted are in fact valid in a limited range for input drive level, which is typically violated for the IP3 region. For such large drive levels, fifth- and higher-order contributions arise and significantly modify the results of the simplified approach. In any case, once the PA $IP3_{\text{out}}$ is known, actual IMD level relative to the output signal level may be estimated from

$$P_{\text{IMD}} = 3P_{\text{out,dBm}} - 2IP3_{\text{out}} \quad (23)$$

Another frequently adopted indicator of the PA nonlinear behavior is the C/I or *carrier-to-intermodulation ratio*,

defined as the ratio between useful output power and IMD output power, usually measured in dB below the carrier (dBc):

$$C/I \equiv \frac{P_{\text{out}}}{P_{\text{IMD}}} \quad (24)$$

where $P_{\text{IMD}} = P_{2f_2-f_1}$ (or $P_{\text{IMD}} = P_{2f_1-f_2}$). Such C/I is clearly dependent on the input power to the PA, decreasing by 2 dB per dB increase of the input drive. Combining the two relationships (23) and (24):

$$C/I = 2(IP3_{\text{out}} - P_{\text{out,dBm}}) \text{ (dBc)} \quad (25)$$

For moderate drive levels (say, up to 10 dB below $P_{-1\text{dB,out}}$), the third-order intermodulation component is the dominant distortion. It is therefore possible to define a linearity range for the PA as the range of input drive levels for which the P_{IMD} stays below the noise floor of the amplifier, usually specified as thermal noise at ambient temperature; such linearity range, whose lower bound is determined by the useful output power emerging from the noise floor, is usually indicated as the *spurious-free dynamic range* (SFDR; Fig. 11).

From knowledge of the PA noise figure (NF), its bandwidth B and (available) gain G , the SFDR is given, at room temperature, by

$$SFDR_{\text{dB}} = \frac{2}{3} \cdot [IP3_{\text{out,dBm}} - NF_{\text{dB}} - G_{\text{dB}} - \left(\frac{B}{1\text{ Hz}}\right)_{\text{dB}} + 174\text{ dBm}] \text{ (dB)} \quad (26)$$

The quality factors defined above for linearity evaluation are related to single- or two-tone tests, in an attempt to mimic in this way the behavior of the PA in response to a narrowband or multicarrier input. Real-world input signals to a PA may deviate substantially from the

Figure 11. Definition of the spurious-free dynamic range; shaded area represents thermal output noise power at ambient temperature.

Figure 12. Input and output power densities for adjacent-channel power ratio definitions.

single-tone approximation, since modulation formats and bandwidth occupation may differ to a great extent. In order to account for signal distortion and the related spectral regrowth in the case of bandlimited input signals, an *adjacent-channel power ratio* (ACPR) is introduced. With reference to Fig. 12, several definitions are adopted in this respect; the most commonly used refers to the *total ACPR* (ACPR_{TOT}), the ratio between the total output power in the signal bandwidth to the total output power in adjacent channels:

$$ACPR_{TOT} \equiv \frac{\int_B P_{out}(f) \cdot df}{\int_{LS} P_{out}(f) \cdot df + \int_{US} P_{out}(f) \cdot df} \quad (27)$$

Clearly, if a single sideband is concerned, a *lower-sideband ACPR* (ACPR_{LS}) or *upper-sideband ACPR* (ACPR_{US}) can be defined, using the proper adjacent-channel power in the definition

$$ACPR_{LS} \equiv \frac{\int_B P_{out}(f) \cdot df}{\int_{LS} P_{out}(f) \cdot df} \quad (28)$$

$$ACPR_{US} \equiv \frac{\int_B P_{out}(f) \cdot df}{\int_{US} P_{out}(f) \cdot df}$$

Moreover, a *spot ACPR* (ACPR_{SPOT}) can be introduced, utilizing the adjacent-channel power contained in a predefined bandwidth (B_x) at a given offset (see Fig. 12), defined by

$$ACPR_{SPOT} \equiv \frac{\int_B P_{out}(f) \cdot df}{\int_{B_x, offset} P_{out}(f) \cdot df} \quad (29)$$

The various ACPR figures clearly give a deeper insight into the distortion properties of a PA than do their single- or two-tone counterparts, as they are related to a specific bandlimited input signal. Nevertheless, if the input signal is approximated by a number of equally spaced equal-amplitude tones, closed-form relationships may be found between the figures [46,48].

Other indicators of PA linearity and appropriate tests are the noise power ratio and cochannel power ratio [47,48].

3. BASIC CONCEPTS IN PA DESIGN

Power limiting mechanisms in active devices reside in their inherent physical constraints. For a FET device (but also for a bipolar one, with different physical effects taking place), such constraints are both on output current and voltage: for the former, current saturation related to input junction forward conduction and device channel pinchoff; for the latter, device ohmic behavior and breakdown (related to both channel and gate-drain junction). Such physical limitations are graphically depicted in Fig. 13, where sample output device characteristics are shown.

Figure 13. Sample device output characteristics and physical limitations on output current and voltage.

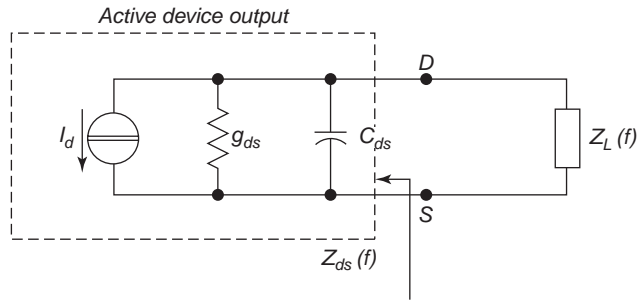

Figure 14. Schematic representation of the active-device output connected to an external load Z_L .

Collectively, such limitations pose an upper limit to the maximum swings that output current and voltage may experience, reflecting in a limit corresponding to the device output power.

Small-signal amplifier design is based on well-established techniques. After the active device to be employed is selected together with its operating (bias) point, from knowledge of the device scattering parameters and depending on the amplifier specifications, input and output matching network characteristics (i.e., the impedances to be presented at the device input and output ports) are readily obtained via closed-form expressions [49–51].

If a simplified device model is considered, as depicted in Fig. 14, composed of a controlled current source (controlled by the input voltage if a FET is considered) shunted by its output small-signal admittance (represented by an output conductance g_{ds} and capacitance C_{ds}), the condition that is imposed, compatibly with device stability, for maximum power transfer from the device output to the external load is the well-known conjugate matching

$$Z_L(f) = Z_{ds}^*(f) \leftrightarrow \begin{cases} G_L(f) = g_{ds} \\ B_L(f) = -j \cdot 2\pi f \cdot C_{ds} \end{cases} \quad (30)$$

where

$$Z_L(f) = G_L(f) + j \cdot B_L(f) \quad (31)$$

$$Z_{ds}(f) = G_{ds}(f) + j \cdot B_{ds}(f) = g_{ds} + j \cdot 2\pi f \cdot C_{ds} \quad (32)$$

The conjugate matching condition therefore implies the compensation of the active-device output reactive part and a match in its small-signal output conductance, ensuring at the same time the maximization of the amplifier small-signal gain. If the active-device output characteristics are now considered, the load line dictated by the small-signal matching condition (curve A) can be superimposed, as depicted in Fig. 15. If the same condition is adopted, driving the amplifier to operate into large-signal regime, a reduced current swing results, producing in turn an earlier compression of the device output power (current-limited operation). On the other hand, if the external load is selected in order to fully exploit the maximum current swing, (as in B, Fig. 15), a reduced voltage swing is produced (voltage-limited operation), again driving active device output into compression. The optimum situation is in

Figure 15. Active-device output characteristics with superimposed the conjugate-matched load line (A); with voltage-limited (B), and optimum loading (C). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the simultaneous maximization of current and voltage swings (as in C, Fig. 15), often referred to as *load-line matching* condition. The typical output power behavior corresponding to the three situations described in Fig. 15 is shown in Fig. 16 as a function of the input drive level.

Nevertheless, PAs that are load-line-matched exhibit poor output VSWR in the system in which they are employed. If necessary, this problem can be solved through the use of output isolators (clearly decreasing output power and efficiency by their losses) or resorting to balanced configurations if possible; also in this case the insertion loss of the combining structure actually affects overall power performance.

In order to have some quantitative indication of the optimum loading in the simplified conditions described above, the device output characteristics are often substituted by their piecewise linear approximation, leading to a “box model” for the active-device current source. Such a model is depicted in Fig. 17 for the case of a constant transconductance (g_m) device (equally spaced output characteristics, left) and linear transconductance (linearly increasing transconductance, right). The case of a linear variation, introduced by Kushner [52,53], tries to mimic the decrease in transconductance typically observed while

Figure 16. Output power for three loading conditions: current-limited (A), voltage-limited (B), and optimum loading (C).

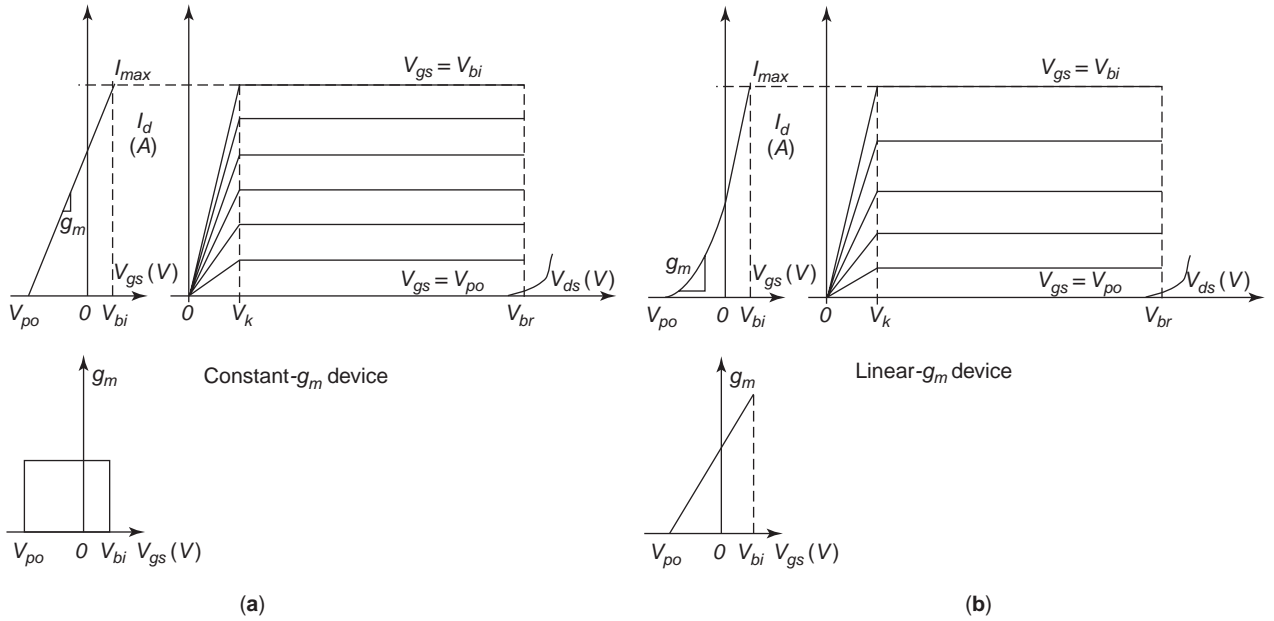

Figure 17. Piecewise linear approximation of the device output characteristics in the case of constant (a) and linear (b) transconductance.

decreasing the device gate bias toward pinchoff. On the other hand, such approximation actually generates artificial distortion components even with low driving signals, while requiring, for its actual implementation, a nonuniform doping profile.

In Fig. 17 V_k is the device “knee” voltage, marking the transition between the device ohmic and saturation regions, V_{br} the breakdown voltage (drain–gate junction breakdown), I_{max} the maximum drain current (occurring for fully opened channel, that is, for $V_{gs} = V_{bi}$ where V_{bi} is the input junction built-in voltage) and V_{po} the device pinchoff voltage. We now assume a purely resistive loading of the active device at fundamental and all harmonic frequencies, and we drive the device up to its limit linear behavior (i.e., without overdriving it into highly nonlinear regimes). In both cases, if the device is biased at $V_{ds,DC}$ for class A and class B operation as in Fig. 18, and the minimum drain voltage is assumed to be $V_{ds,min} = V_k$, defining

$$\gamma = \frac{V_k}{V_{ds,DC}}, \quad R_A = 2 \cdot \frac{V_{ds,DC} - V_k}{I_{max}} \quad (33)$$

the optimum resistive loads $R_{L,opt}$ for class A and B bias conditions (i.e., for the device biased at $I_{d,DC} = I_{max}/2$ and $I_{d,DC} = 0$ respectively) are reported in Table 3, together with maximum drain–source voltage ($V_{ds,max}$), dissipated power (P_{diss}), drain efficiency (η), and output power at fundamental frequency (P_{out}). Several observations may be performed on the results in Table 3.

Clearly, the output power directly depends on the maximum currents and voltages sustained by the active device, namely, I_{max} and V_{br} (implicitly in Table 3 through the limit it imposes on the maximum voltage $V_{ds,max}$ and hence on $V_{ds,DC}$). The limit imposed by the device maximum current may be overcome by increasing device gate periphery and/or through the use of device power combining tech-

niques. The former approach, often used in monolithic design, can be carried out by increasing device finger width and/or increasing the number of device fingers (if a interdigitated device structure is considered, as in the case of power transistors), as schematically depicted in Fig. 19.

Such device scaling actually enables one to increase power output capabilities. Nevertheless, such an option is related to the availability of an affordable monolithic technology (it is clearly not applicable to hybrid design approaches). Moreover, the scaling properties of a given technology are strictly valid for moderate scaling only. For the same total gate periphery, in fact, while output power is almost constant (at a given frequency), large-signal gain decreases with unit gate width, thus affecting efficiency performances as demonstrated experimentally in Fig. 20.

Moreover, an increase in device periphery actually increases device parasitic effects, thus leading to a further reduction in gain and frequency of operation. From the thermal management point of view, scaling up device periphery induces an increase in dissipated power; the resulting increase in device junction operating temperature has detrimental effects on device performance in terms of both actual performance and reliability, especially if high-reliability applications such as satellite payload transmitters are concerned. The commonly adopted solution to this effect consists in device substrate thinning, thus decreasing thermal resistance and the temperature difference between the device channel and its backside. Clearly, from the design point of view, a viable solution is in the exploitation of “cold” biasing regions (i.e., decrease in bias toward class B), accurately accounting for the consequences both on output power and linearity.

A second possibility for increasing output power performances consists in an increase of the drain voltage swing. This task can be accomplished mainly by increasing the

Figure 18. Class A and B operating conditions for purely resistive loading.

device breakdown voltage. Unfortunately the latter is an intensive quantity, depending mainly on material properties and device fabrication process. The more recent increasing interest in wide-bandgap materials [viz., gallium nitride (GaN) and silicon carbide (SiC)] is in fact motivated from the intrinsic high breakdown field that devices based on such alloys exhibit, with typical values in the range of 100 V, as contrasted to the few tens of the traditional GaAs-based FET devices. On the other hand, as shown in Table 3, PA drain efficiency and output power are limited by the presence of a nonnegligible “knee” voltage. The effect of such low-voltage limit is especially important if a low-voltage PA has to be designed; this is the case in mobile handsets and in general in every portable battery-operated transmitter, in which the actual size and weight of the overall apparatus are dictated by the choice of a lightweight and small battery pack. In this case a few volts are available for the PA bias, and any lower limit in the device voltage swing is very important. As an example, assuming a 3 V supply and a 0.9 V knee voltage for the active device, a PA operating in class A decreases its efficiency from the ideal textbook 50% down to a modest 35% (as per Table 3, class A, constant transconductance, with $\gamma=0.7$). The problem becomes even harder to deal with if high-perfor-

mance deep-submicrometer CMOS devices are employed, with knee voltages that can be 2–3 times higher than the ones of typical power transistors.

Up to this point, the two simple cases of class A and B PAs under the maximum linear operation have been considered. The output power and efficiency performances can, however, be greatly improved by making use of harmonic tuning strategies or switching-mode operating classes. To this goal, a first step resides in the use of the tuned-load (TL [52,53]) operating mode of the power stage. With reference to Fig. 21, TL operation consists in loading the active device output with short-circuit terminations (idlers) at harmonic frequencies, maximizing at the same time the fundamental frequency voltage and current swing.

The device output is assumed to operate as a voltage-controlled current source (controlled by the input gate-source voltage) and therefore its time-domain waveform can be expressed as a truncated sinusoid

$$i_d(t) = \begin{cases} \frac{I_{\max}}{1 - \cos\left(\frac{\alpha}{2}\right)} \cdot \left[\cos(\omega \cdot t) - \cos\left(\frac{\alpha}{2}\right) \right] & \text{if } |\omega \cdot t| \leq \frac{\alpha}{2} \\ 0 & \text{otherwise} \end{cases} \quad (34)$$

Table 3. Single-Device PA Performance with Resistive Loading for Classes A and B Bias and Constant and Linear Transconductance

Biasing Class	g_m	$R_{L,\text{opt}} (\Omega)$	$V_{\text{ds,max}} (\text{V})$	$P_{\text{diss}} (\text{W})$	$\eta (\%)$	$P_{\text{out}} (\text{W})$
A	Constant	R_A	$V_{\text{ds,DC}} + (V_{\text{ds,DC}} - V_k)$	$\frac{(V_{\text{ds,DC}} - V_k) \cdot I_{\max}}{4}$	$50 \cdot (1 - \gamma)$	$\frac{(V_{\text{ds,DC}} - V_k) \cdot I_{\max}}{4}$
A	Linear	$\frac{4}{5} \cdot R_A$	$V_{\text{ds,DC}} + \frac{3}{5}(V_{\text{ds,DC}} - V_k)$	$\frac{(0.65 V_{\text{ds,DC}} + 0.85 V_k) \cdot I_{\max}}{4}$	$53 \cdot (1 - \gamma)$	$\frac{(V_{\text{ds,DC}} - V_k) \cdot I_{\max}}{5}$
B	Constant	$\frac{\pi}{\pi - 1} \cdot \frac{R_A}{2}$	$V_{\text{ds,DC}} + \frac{V_{\text{ds,DC}} - V_k}{\pi - 1}$	$\frac{(0.4 V_{\text{ds,DC}} + 0.87 V_k) \cdot I_{\max}}{4}$	$58 \cdot (1 - \gamma)$	$\frac{\pi(V_{\text{ds,DC}} - V_k) \cdot I_{\max}}{8 \cdot (\pi - 1)}$
B	Linear	$\frac{2}{3} \cdot R_A$	$V_{\text{ds,DC}} + \frac{V_{\text{ds,DC}} - V_k}{3}$	$\frac{(0.33 V_{\text{ds,DC}} + 0.66 V_k) \cdot I_{\max}}{4}$	$48 \cdot (1 - \gamma)$	$\frac{32(V_{\text{ds,DC}} - V_k) \cdot I_{\max}}{27 \cdot \pi^2}$

Figure 21. Tuned load loading conditions (a) together with typical voltage and current waveforms superimposed on piecewise linear output characteristics (b).

where $\omega = 2\pi \cdot f$ and α is the drain current conduction angle (Fig. 21), while the output drain voltage, thanks to the short-circuit terminations, is a purely sinusoidal waveform:

$$v_{ds}(t) = V_{ds,DC} - V_1 \cdot \cos(\omega \cdot t) \quad (35)$$

Treatment of the actual device output admittance will be omitted in the following in order to simplify the approach. Nevertheless, the hypothesis of short-circuit output terminations actually help in this assumption (if a real short circuit could be imposed at the device intrinsic terminals, not accounting for device parasitic effects), together with the device output capacitive behavior, effectively short-circuiting very-high-frequency output components. Drain current can be expressed in terms of its Fourier series expansion with coefficients I_n graphically depicted in Fig. 22 as a function of the current conduction angle α .

The fundamental frequency current component is, under the assumptions performed, a function of the current conduction angle only. The drain voltage fundamental component is related to the current one via the fundamental frequency output load $Z_{L,f}$. The latter is to be selected as a purely resistive termination in order to maximize active power generation together with output voltage swing. To this goal, if the device is biased at $V_{ds,DC}$, maximum output voltage fundamental frequency amplitude is given by $V_{1,max} = V_{ds,DC} - V_k$, thus obtaining, for the optimum load at fundamental R_{TL} ,

$$R_{TL}(\alpha) = \frac{V_{1,max}}{I_1(\alpha)} = R_A \cdot \pi \cdot \frac{1 - \cos(\frac{\alpha}{2})}{\alpha - \sin(\alpha)} \quad (36)$$

where the optimum value is expressed evidencing the R_A value (optimum resistance in the case of resistive loading, or *load-line match* for the case of a class A PA; see Table 3). Moreover, in the same way, DC supply power $P_{DC,TL}$, output power at fundamental $P_{out,TL}$, and drain efficiency η_{TL}

can be easily obtained, again normalized to the class A reference values in Table 3:

$$P_{DC,TL} = I_0 \cdot V_{ds,DC} = \frac{P_{DC,A}}{\pi} \cdot \frac{2 \cdot \sin(\frac{\alpha}{2}) - \alpha \cdot \cos(\frac{\alpha}{2})}{1 - \cos(\frac{\alpha}{2})} \quad (37)$$

$$P_{out,TL} = \frac{I_1 \cdot V_1}{2} = \frac{P_{RF,A}}{\pi} \cdot \frac{\alpha - \sin(\alpha)}{1 - \cos(\frac{\alpha}{2})} \quad (38)$$

$$\eta_{TL} = \frac{P_{out,TL}}{P_{DC,TL}} = \eta_A \cdot \frac{\alpha - \sin(\alpha)}{2 \cdot \sin(\frac{\alpha}{2}) - \alpha \cdot \cos(\frac{\alpha}{2})} \quad (39)$$

The quantities described above are presented in graphical form as functions of α in Fig. 23.

The results attainable via a TL approach are briefly discussed:

1. An increase in output power over the reference class A design is possible utilizing a class AB bias with the TL output loading. Such increase in power performance is maintained even moving toward class B bias, where a simple resistive loading implies a decrease in output power with respect to a class A bias. Clearly, such a result does not account for the gain performance, since a maximum swing is assumed, independently on the necessary drive level. In particular, for class A and B biases, the same output power is obtained, but utilizing, for the class B drive, twice the input drive signal (i.e., 6 dB higher input power is necessary).
2. The optimum load exhibit a weak dependence on the current conduction angle, thus allowing almost the same resistive loading from class A to class B bias.

Efficiency performances exhibit a constant increase moving toward low-bias regions, with a limiting value that doubles the class A performance (thus toward the theoretical limit of 100% efficiency). This is true, however, only to a first approximation, since the simplifying assumptions performed on the device characteristics impose a constant breakdown voltage, regardless of the device gate bias; real-world devices have an almost constant gate-drain breakdown, and therefore biasing the device below pinchoff actually decreases the drain-source maximum voltage ($V_{br,ds} = V_{br,gd} - V_{gs}$). Finally, the power dissipated on the active device, $P_{diss,TL}$, shown in Fig. 24, is

$$P_{diss,TL} = \frac{P_{DC,A}}{\pi} \cdot \frac{\sin(\frac{\alpha}{2}) \cdot [2 + \cos(\frac{\alpha}{2})] - \frac{\alpha}{2} \cdot [1 + 2 \cdot \cos(\frac{\alpha}{2})]}{1 - \cos(\frac{\alpha}{2})} \quad (40)$$

As expected, moving from class C bias toward class A operation actually increases the power dissipated on the active device, therefore decreasing the efficiency correspondingly.

A final consideration can be drawn regarding device input terminations. Input loading at fundamental frequency

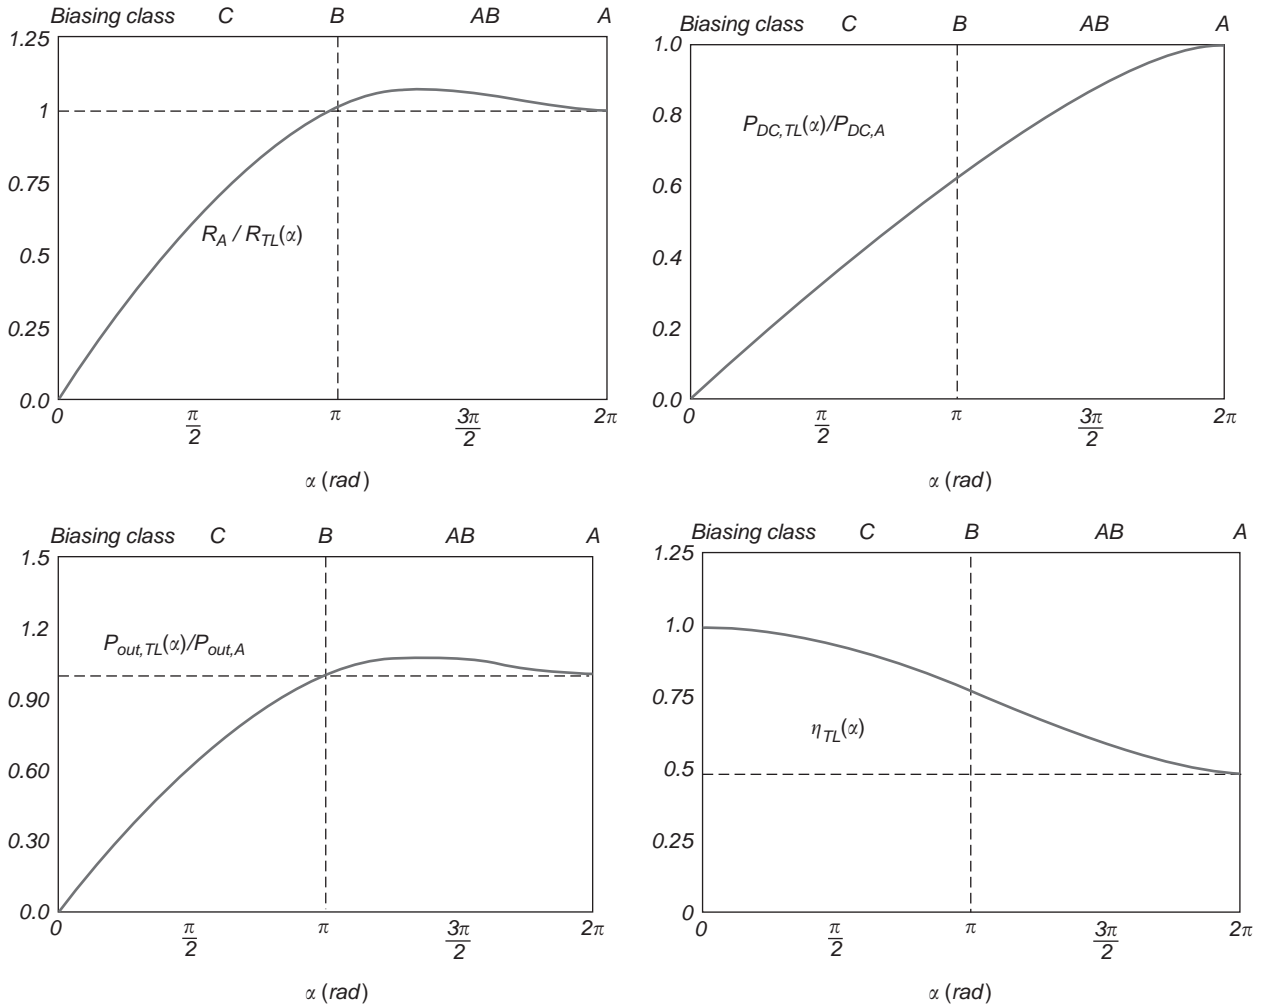

Figure 23. Optimum load R_{TL} , DC power $P_{DC,TL}$, output power $P_{out,TL}$, and drain efficiency η_{TL} for the tuned load operating condition normalized to the corresponding class A (resistive load) quantities.

Figure 24. Power dissipated on the active device $P_{diss,TL}$ for the tuned load operating condition normalized to the class A (resistive load) DC power as a function of the drain current–drain conduction angle.

is to be performed in order to fulfill maximum power transfer to the active device; this is the well-known conjugate matching condition. This condition ensures maximum gain for a given output loading, while ensuring optimum input VSWR. Clearly the device input is, for moderate drive levels, mildly nonlinear and therefore the conjugate matching must be attained under large-signal operating conditions (i.e., the maximum power transfer condition depends on the drive level). Harmonic input loading is seldom investigated, leaving this task to harmonic tuning strategies.

4. POWER BALANCE AND DIFFERENT DESIGN APPROACHES

In order to generalise the approach outlined for the TL operating condition and the approach outlined in Refs. 54 and 55 for switched-mode stages (see Section 6s), with the aim to introduce high-efficiency operating classes, let us consider the power balance in a PA, distinguishing, in the

output power, the two contributions to fundamental ($P_{\text{out},f}$) and harmonic terminations ($P_{\text{out},nf}$, $n \geq 2$). In greater detail, the power balance of a PA system can be stated as

$$P_{\text{DC}} + P_{\text{in}} = P_{\text{diss},\text{in}} + P_{\text{diss},\text{out}} + P_{\text{out},f} + P_{\text{out},nf} \quad (41)$$

where $P_{\text{diss},\text{in}}$ and $P_{\text{diss},\text{out}}$ are the two contributions to the dissipated power (i.e., converted to heat) in the input and output sections of the PA stage, respectively. In this equation, the input power can be thought to be entirely dissipated in the device input (i.e., $P_{\text{diss},\text{in}} \approx P_{\text{in}}$), therefore leading to

$$P_{\text{DC}} = P_{\text{diss},\text{out}} + P_{\text{out},f} + P_{\text{out},nf} \quad (42)$$

which represents a power balance equation related to the output circuit only. The result in (42) is valid at the lower microwave frequencies and, in general, if the active device internal feedback can be neglected. In the output circuit, device current and voltage may be expressed by their Fourier series expansion

$$i_{\text{D}}(t) = I_0 + \sum_{n=1}^{\infty} I_n \cdot \cos(n \cdot \omega \cdot t + \xi_n) \quad (43)$$

$$v_{\text{DS}}(t) = V_{\text{ds,DC}} - \sum_{n=1}^{\infty} V_n \cdot \cos(n \cdot \omega \cdot t + \psi_n) \quad (44)$$

where ξ_n and ψ_n are the phases of the n th output current (I_n) and voltage (V_n) harmonic components, respectively.

On the basis of such assumptions, harmonic terminations to the output of the active device can be defined as the ratio of the respective voltage and current harmonic components:

$$Z_{\text{L},nf} = \frac{V_n \cdot e^{j\psi_n}}{I_n \cdot e^{j\xi_n}} = \frac{V_n}{I_n} \cdot e^{j(\psi_n - \xi_n)} = \frac{V_n}{I_n} \cdot e^{j\varphi_n} \quad (45)$$

obtaining, for the bias DC power, the power dissipated on the device and the power delivered to fundamental and harmonic frequencies:

$$P_{\text{DC}} = V_{\text{ds,DC}} \cdot I_0 \quad (46)$$

$$P_{\text{diss}} = \frac{1}{T} \cdot \int_T i_{\text{D}}(t) \cdot v_{\text{ds}}(t) \cdot dt = P_{\text{DC}} - P_{\text{out},f} - \sum_{n=2}^{\infty} P_{\text{out},nf} \quad (47)$$

$$P_{\text{out},nf} = \frac{1}{2} \cdot V_n \cdot I_n \cdot \cos(\varphi_n) \quad n = 1, 2 \dots \quad (48)$$

Utilising these expressions in the definition of drain efficiency, it follows that

$$\eta = \frac{P_{\text{out},f}}{P_{\text{DC}}} = \frac{P_{\text{out},f}}{P_{\text{diss}} + P_{\text{out},f} + \sum_{n=2}^{\infty} P_{\text{out},nf}} \quad (49)$$

From this expression, the necessary and sufficient condition needed to reach a complete conversion of DC power into useful fundamental power (i.e., 100% efficiency) is that both the following conditions be fulfilled *simultaneously*:

$$P_{\text{diss}} = 0 \quad (50)$$

$$\sum_{n=2}^{\infty} P_{\text{out},nf} = \frac{1}{2} \cdot \sum_{n=2}^{\infty} V_n \cdot I_n \cdot \cos(\varphi_n) = 0 \quad (51)$$

More explicitly, on one hand dissipated power on the active device has to be nulled, and this can be accomplished by correctly shaping voltage and current waveforms in order to ensure a null overlapping; thus the current on the device must vanish for a nonzero voltage and vice versa. Moreover, harmonic *active* power has to be nulled, thus implying either the zeroing of current/voltage harmonic components ($V_n = 0$ or $I_n = 0$ or both) or their proper phasing ($\varphi_n = \pi/2$). Therefore, in low-frequency applications, assuming an infinite number of controllable harmonic terminations, two possibilities are available to ensure the fulfillment of the latter condition:

- *Class F* [56–58] or *inverse class F* [59] strategies, in which $V_n I_n = 0$ for $n > 1$. Note that these are idealized approaches since voltage and current harmonic components, which in a real device are related by load impedances as in Eq. (45), and are considered separately. The class F strategy has been successfully applied in class AB [61,62] amplifier stages. Nevertheless, its application may lead to poor efficiency performances if class C or deep-AB (near-B) biasing classes are adopted [60].
- *Class E* or *switched-mode strategies*, in which $\varphi_n = \pi/2$ for $n > 1$. The active device is operated as a switch, and closed-form design expressions are available [63]. In such conditions, the stage acts more as a DC/RF converter rather than an amplifier. In this case, the power gain of the stage is not controlled and specified during the design phase; it is a specification to be fulfilled by a separately designed driver circuit, using information about the input port characteristics of the power transistor to be driven. Moreover, nothing is said about the input network, except that the input voltage waveform must properly drive the device to operate as a switch (i.e., be deeply pinched off and saturated). In any case, an inspection of expression (49) suggests two possible directions for the efficiency optimization: (1) either the maximization of device output power (for the same DC supply) or (2) the minimization of the dissipated power (considered as the sum of internally dissipated power $P_{\text{diss},\text{out}}$ and harmonic active power $P_{\text{out},nf}$).

The designer's task is therefore in the appropriate shaping of current and voltage waveforms, consisting in the selection of appropriate harmonic terminations leading to the fulfillment of the conditions described above.

5. HARMONIC TUNING APPROACHES

Harmonic tuning approaches for microwave PA design represent indeed a hot discussion topic for both the academic and the industrial communities given the beneficial effect on stage efficiency that can be obtained by a proper selection of harmonic terminations. Contributions in this field range from experimental observation of performance levels [66–68] to introduction of novel topologies as in the case of harmonic reaction amplifiers [64,65], from systematic investigations of experimental performances [70] to design methods for special harmonic tuning configurations [69].

In fact, however, if the operating frequency enters the microwave region, both approaches cited in the previous section (viz., the standard class F and the switching-mode class E) exhibit a degradation in performance. For instance, actual class F amplifiers are usually designed making use of two or three idlers only to control second and third output harmonic impedances. As frequency increases (e.g., >20 GHz), the control of both the second and third harmonic output impedances becomes troublesome, since the active-device output capacitive behavior practically short-circuits higher components, not allowing the desired waveshaping. Moreover, for low-voltage applications, a class F strategy is not the best solution, since different methodologies (based on second-harmonic output impedance tuning) have demonstrated better performance [71]. On the other hand, the switching mode operation of the active device, necessary to implement class E strategy, is not feasible in microwave communication systems, since it requires that the PA operate in saturated conditions, thus often increasing IMD levels and potentially affecting active-device reliability.

Circuit complexity issues and effectiveness of the harmonic control therefore suggest the control of the first two harmonic terminations for a PA stage, leaving higher terminations dominated by the shunting effect of the output device capacitive behavior. Assuming purely resistive terminations for the sake of simplicity, the drain voltage waveform can be expressed as [72]

$$v_{DS}(t) = V_{ds,DC} - V_1 \cdot [\cos(\omega \cdot t) + k_2 \cdot \cos(2 \cdot \omega \cdot t) + k_3 \cdot \cos(3 \cdot \omega \cdot t)] \quad (52)$$

where

$$k_2 \equiv \frac{V_2}{V_1} \quad k_3 \equiv \frac{V_3}{V_1} \quad (53)$$

and

$$V_1 = R_1 \cdot I_1 \quad V_2 = R_2 \cdot I_2 \quad V_3 = R_3 \cdot I_3 \quad (54)$$

Hence, for a given device drive and bias, that is, for given current source harmonic components (I_n), the designer's task is in the selection of proper terminations at fundamental (R_1) and harmonic frequencies (R_2, R_3) maximizing the fundamental component (V_1) of the swing experienced by $v_{DS}(t)$, with the constraints dictated by the device

Figure 25. Voltage waveform $v_{DS}(t)$ (red curve) obtained via the introduction of a third-harmonic component (dashed line) summed to a fundamental frequency component (continuous line) exceeding the physical limitation (V_k). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

physical limitations (knee and breakdown voltages). This is equivalent to the determination of the values of the pair (k_2, k_3), which, for given physical limits and therefore for a given voltage swing, allows maximization of the V_1 component. An example of this effect is reported in Fig. 25, utilising, for simplicity, a third-harmonic component only summed to the fundamental one. In this scenario, for a fixed swing, dictated in this case by the bias voltage $V_{ds,DC}$ and V_k physical limitation, the introduction of a third-harmonic component actually increases the fundamental frequency amplitude beyond the value of the TL case (viz., $V_{ds,DC} - V_k$ in this case).

Analytically, this is accomplished defining the *voltage gain function* δ by the ratio of the resulting fundamental voltage component normalized to the unmanipulated case (the tuned load value, numerically coincident with the distance between the drain bias and the closer physical limit):

$$\delta(k_2, k_3) \equiv \frac{V_1}{V_{1,TL}} \quad (55)$$

The voltage gain δ is plotted in Figs. 26 and 27 as a function of (k_2, k_3) in a three-dimensional and contour plot format.

As it is possible to note, the δ function exhibits a clear maximum for (k_2, k_3) = (−0.55, 0.17) whose value is

Figure 26. Voltage gain function δ versus k_2 and k_3 .

Figure 27. Constant voltage gain function δ contours in the (k_2, k_3) plane.

approximately 1.62. The function is higher than unity (i.e., use of the second and third harmonics effectively increases fundamental drain voltage harmonic component) within the marked region in Fig. 26.

The increase in fundamental frequency output voltage component obtained via a proper selection of the (k_2, k_3) pair, is directly reflected in a corresponding increase in power performances of the PA stage. In fact, under the hypothesis that the controlled source is not affected by the device harmonic terminations (i.e., its harmonics components I_n remain unchanged), the output power, large-signal gain, drain, and power-added efficiency of the stage become

$$P_{out}(k_2, k_3) = P_{out,TL} \cdot \delta(k_2, k_3) \tag{56}$$

$$G(k_2, k_3) = G_{TL} \cdot \delta(k_2, k_3) \tag{57}$$

$$\eta(k_2, k_3) = \eta_{TL} \cdot \delta(k_2, k_3) \tag{58}$$

$$\eta_{add}(k_2, k_3) = \eta_{add,TL} \cdot \delta(k_2, k_3) \cdot \left(\frac{G_{TL} - 1/\delta(k_2, k_3)}{G_{TL} - 1} \right) \tag{59}$$

The harmonic terminations that actually shape output voltage with a given selection of the (k_2, k_3) pair are therefore

$$R_1 = \delta(k_2, k_3) \cdot R_{TL} \tag{60}$$

$$R_2 = \delta(k_2, k_3) \cdot k_2 \cdot \frac{I_1}{I_2} \cdot R_{TL} \tag{61}$$

$$R_3 = \delta(k_2, k_3) \cdot k_3 \cdot \frac{I_1}{I_3} \cdot R_{TL} \tag{62}$$

In the derivations above, clearly the role of the device output conductance (g_{ds}) is not evidenced; the latter clearly poses an upper limit to the impedance values that can

effectively be presented to the active-device internal current source. The effect of actual device output conductance leads to a modification of the approach presented here [60].

Furthermore, the use of even-harmonic components (the second one in this case) actually breaks the natural symmetry of the voltage waveform; the desired flattening while approaching the physical limitation is accompanied by a peaking in the remaining part of the RF cycle, which can actually reach the opposite physical limitation. This effect has to be carefully controlled and is quantitatively evaluated via a voltage overshoot function [72].

However, several important cases can be extracted from Fig. 26. The first one consists in the previously discussed TL condition, corresponding to the origin of the (k_2, k_3) plane, where $\delta(0,0) = 1$. If a single voltage harmonic is controlled at a time, terminating the remaining one on a short-circuit termination, two possibilities arise. The first one is obtained for $k_2 = 0$, consisting in the control of third harmonic only: this situation corresponds to the high-frequency class F design approach [60,73], which is represented in Fig. 26 by the k_3 axis. In this harmonic control scheme the maximum value for the voltage gain function is obtained for $\delta(0, -0.167) \approx 1.15$. In this case, therefore, the use of a high-frequency class F approach results in an increase of 15% in output power, efficiency, and large-signal gain over the tuned-load condition. Maximally flat waveforms are a special case of such design approach [73].

The second possibility consists in setting $k_3 = 0$, therefore controlling the second-harmonic component only [71]. Moving along the k_2 axis in Fig. 26 results in a maximum value for $\delta(-0.35, 0) \approx 1.41$ and in the corresponding increase in power performances. The results attainable via harmonic tuning of the second and third output harmonic components are summarized in Table 4.

It should be noted, however, that the potential increases in the PA power performances are obtained only if the proper loading is imposed on the active-device output.

Table 4. Maximum Theoretical Improvements in Drain Efficiency over the Tuned Load Approach Attainable with Tuning Second-, Third-, and Second/Third-Harmonic Output Terminations

Controlled Frequencies		k_2	k_3	δ	η Improvement (%)
F	Tuned load	0	0	1	0
$f, 3f$	High-frequency class F	0	-0.17	1.15	15
$f, 2f$	2nd-harmonic tuning	-0.35	0	1.41	41
$f, 2f, 3f$	2nd/3 rd -harmonic tuning	-0.55	0.17	1.62	62

This is not always possible. In fact, with reference to Fig. 22, output current harmonic components, generated via the clipping effect of the device pinchoff on a sinusoidal input drive, show a different behavior as a function of the current conduction angle. In particular, focusing on the region $\alpha \in [\pi, 2\pi]$ (i.e., from class B to class A bias), the second harmonic current component is always positive, while the third one is negative (clearly taking the fundamental one as a reference). Since actual terminations are passive (i.e., $R_i \geq 0, i = 1, \dots, 3$), this consideration implies that positive k_2 and negative k_3 are feasible:

$$k_2 = \frac{V_2}{V_1} = \frac{R_2 \cdot I_2}{R_1 \cdot I_1} \geq 0 \quad k_3 = \frac{V_3}{V_1} = \frac{R_3 \cdot I_3}{R_1 \cdot I_1} \leq 0 \quad (63)$$

Therefore, if current clipping effects only are exploited, only third-harmonic (high-frequency class F) tuning is directly possible; the simultaneous use of second- and third-harmonic components implies, in fact, from Fig. 26, that $k_2 < 0$ and $k_3 > 0$. An improper use of harmonic tuning may, on the other hand, bring detrimental results on overall power performances, as exemplified in Fig. 28, where the case in Fig. 25 has been repeated with an incorrect phasing of the third-harmonic component.

Clearly the possibility to generate the properly phased current harmonic components is related to the driving waveform, up to now assumed to be purely sinusoidal. In fact, even if a perfectly sinusoidal drive is assumed, the drain current waveform actually reflects not only the hardlimiting clipping phenomena due to the device pinch-off but also the effect of local mild nonlinearities, slightly modifying the “truncated sinusoid” assumption adopted up to now [74]. On the other hand, the driving waveform

can be properly selected, eventually leading to quartic or rectangular input signals [75], allowing in this way the application of harmonic tuning strategies in limited ranges for the drain current conduction angle. The alternative approach (i.e., the exploitation of the device input nonlinearities and therefore the input terminations to the active device) has been the subject of a series of investigations, leading to experimental and theoretical studies, with frequently contrasting results [76–80]; the input nonlinearities of the device itself can be used to generate the harmonic of interest [81], with effects that can be effectively predicted using Volterra-like approaches [82], leading to an harmonic control scheme including input and output terminations, schematically depicted in Fig. 29.

The possibility of effectively controlling input and output harmonic control has been experimentally verified by several authors. In Fig. 30 the measured results are reported for the power performances of four single-device PA stages, designed utilizing TL, second-harmonic tuning, third-harmonic tuning, and second/third-tuning combined. The PA stages, realized in this case using hybrid technology, operate with a 5 GHz fundamental frequency, with a 5% operating bandwidth, and adopt a power 1-mm MESFET device from Alenia Marconi Systems.

A final consideration regarding the linearity performances of harmonic-controlled power amplifiers has to be drawn. The high-efficiency tuning of PA stages designed according to a harmonic control scheme leaves in fact some open questions on the resulting linearity. The proper tradeoff among such requirements is not clearly evidenced to date, even if experimental results demonstrate that a high-efficiency tuning does not necessarily imply detrimental linearity effects [83]. Moreover, harmonic injection techniques have been proposed to optimize linearity performance [84]. In any case however, proper subsystem linearization techniques can be adopted in the case of harmonic tuned PA stages, regardless of the adopted modulation scheme, using predistortion [85], feedback [86], or feedforward [87] approaches. Clearly a system-level linearization approach implies a decrease in efficiency performance and often a major increase in subsystem complexity.

Figure 28. Voltage waveform $v_{DS}(t)$ (red curve) exceeding the physical limitation (V_k) obtained via the introduction of a third-harmonic component (dashed line) summed to a fundamental frequency component (continuous line). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

6. SWITCHING-MODE POWER AMPLIFIERS

In this category, a number of different approaches can be grouped, all characterized by the assumption that the active device (or devices) utilized in the power stage is (are) operated as switches, commuted between the two “completely ON” (i.e., short-circuit-like) and “completely OFF”

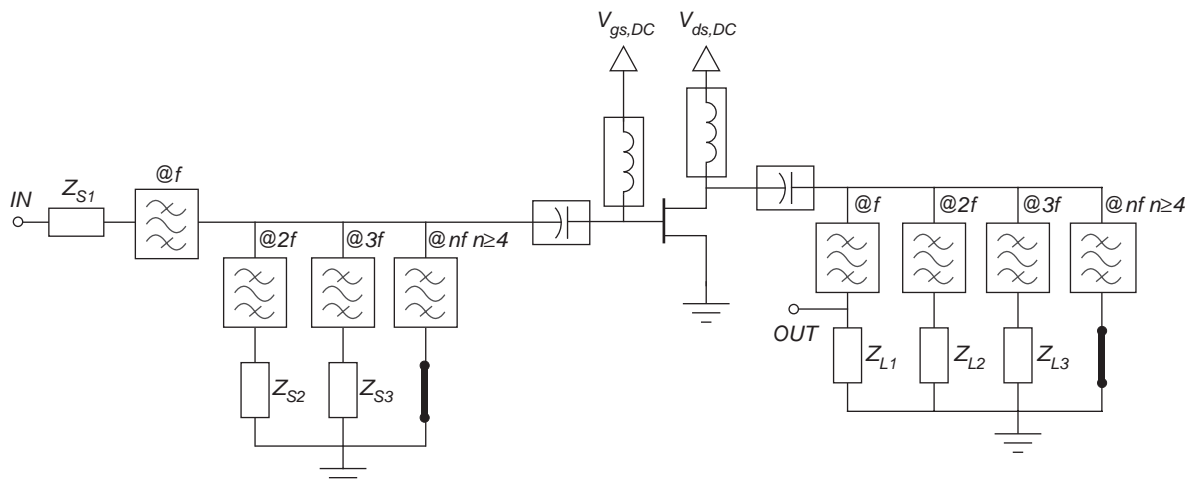

Figure 29. Harmonic control scheme including input and output terminations.

(i.e., open-circuit-like) states. As compared to the approaches described previously, in which the active device is basically represented as a controlled current source replicating with good fidelity the input driving stimulus, switching-mode PAs, ideally driving the active device in the ON and OFF states, indeed exhibit highly nonlinear characteristics. Such inherent lack of linearity is not a problem for constant-envelope modulations, for which a switched-mode operation may infer the great benefit of high-efficiency operation of the transmitter, while preventing their use if amplitude-modulated signals are fed into the amplifier. On the other hand, techniques consisting in the envelope elimination and restoration [88,89], outphasing [90,91], or other high linearity modulating schemes may alleviate the linearity drawback.

A further consideration applies to the large majority of switched-mode PA strategies. As they are based on the assumption of an active device operated as a switch, their effective implementation and resulting performance levels rely largely on the validity of such an assumption. It is

clear that the switching behavior of the device is strictly possible only when the effect of device parasitics is negligible, up to moderately high frequencies, including the low microwave range. The class D and class E amplifiers will be briefly addressed in the following text. For a more complete listing of switched-mode PAs and the relevant references, see Chap. 14 in Ref. 92. The class D amplifier, introduced by Baxandall [93], is composed, in its basic form, of a pair of active devices whose output is fed to an output tuning circuit, as depicted in Fig. 31.

In such a basic configuration, referred to as “complementary voltage switching,” the two devices act as a two-pole switch, whose output voltage tends to be an ideal square waveform, whose harmonic components are effectively filtered by the series-tuned resonator formed by L and C in Fig. 31, therefore delivering a sinusoidal signal to the output load R . The two transistors are driven, in fact, via the transformer, to deliver two output (drain) 180° out-of-phase currents T_1 and T_2 , which pass alternately between ON and OFF states. Assuming a 50% duty

Figure 30. Output power (a) and power-added efficiency (b) measured performances of four single-device PA stages designed utilizing different harmonic tuning strategies.

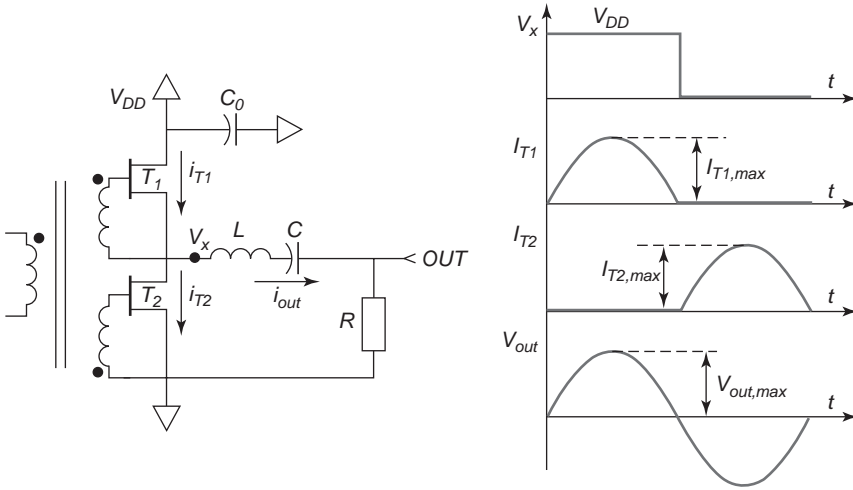

Figure 31. Schematic representation of a basic class D amplifier and basic waveforms.

cycle, the voltage V_x in Fig. 31 may be represented by a square waveform, whose Fourier expansion is given by

$$V_x(t) = \frac{V_{DD}}{2} \cdot \left(1 + \frac{4}{\pi} \cdot \sin(2\pi f \cdot t) + \frac{4}{3\pi} \cdot \sin(3 \cdot 2\pi f \cdot t) + \frac{4}{5\pi} \cdot \sin(5 \cdot 2\pi f \cdot t) + \dots \right) \quad (64)$$

This voltage waveform is applied to the series output R - L - C network. If the L - C series-resonant circuit is tuned to the fundamental switching frequency of operation f and exhibits an acceptable quality factor, the fundamental frequency component of V_x is directly obtained at the output load R , thus obtaining a purely sinusoidal output current:

$$i_{out}(t) = \frac{2 \cdot V_{DD}}{\pi \cdot R} \cdot \sin(2\pi f \cdot t) \quad (65)$$

Under the hypothesis described above, the drain currents in the two transistors (i_{T1} and i_{T2}) are therefore two half-sinusoids, as in Fig. 31, and, from inspection of the previous expression, the peak drain current value for both transistors is therefore

$$i_{T1,max} = i_{T2,max} = \frac{2 \cdot V_{DD}}{\pi \cdot R} \quad (66)$$

while the output power delivered to the load is

$$P_{out} = \frac{1}{2} \cdot \frac{2 \cdot V_{DD}}{\pi} \cdot \frac{2 \cdot V_{DD}}{\pi \cdot R} = \frac{2 \cdot V_{DD}^2}{\pi^2 \cdot R} \quad (67)$$

and the DC input power (i.e., from the power supply) is given by the product of the applied voltage V_{DD} times the mean value of the current through T_1

$$P_{DC} = V_{DD} \cdot \frac{2 \cdot V_{DD}}{\pi^2 \cdot R} = \frac{2 \cdot V_{DD}^2}{\pi^2 \cdot R} \quad (68)$$

thus obtaining a theoretical 100% drain efficiency:

$$\eta_{class D} = \frac{P_{out}}{P_{DC}} = 1 \quad (69)$$

The series-resonant L - C circuit actually provides the adequate harmonic filtering, which can be further improved if the circuit quality factor is not adequate by a subsequent lowpass filter. The bypass capacitor C_0 actually has a DC filtering purpose, which can be further improved by a series choke inductor directly connected to the bias supply V_{DD} .

Maintaining the same operating principle, transformer coupling configurations may be applied, introducing center-tapped output transformers. The dual configuration, that is, the current-switching one, can be implemented as well [92]. The idealized operation of the class D amplifier, however, has to be complemented by some practical constraints arising from actual device operation. In fact, the device ON-state resistance is in series with the output load (regardless of the specific complementary or transformer-coupled voltage switching configuration), thus decreasing the effective output voltage and efficiency. The T_1 transistor is, on the other hand, ungrounded, posing serious problems for the actual implementation of the scheme at high frequencies, for both driver requirements and connection parasitics [94]. Moreover, since actual transistors exhibit a parasitic output capacitance that sums up to the circuit stray capacitances, the result is that, for each RF cycle, the stored energy in such reactance is dissipated during the ON state in the transistor itself. Such energy, whose amount is approximately proportional to the susceptance associated with this parasitic [95], actually produces an increase in the input (DC) power required to the proper operation of the stage for the same output power, with the resulting decrease in stage efficiency.

The abovementioned parasitic output capacitance is one of the major factors responsible for finite transistor switching times, which up to now have been assumed as vanishingly small. As a result, finite transitions between ON and OFF states produce a net decrease in stage drain efficiency [92].

Figure 32. Circuit schematic of a class E power amplifier.

A very popular and effective switching mode PA configuration is the class E amplifier. Introduced and patented by Sokal in 1975 [96,97], the class E configuration has been extensively studied [54,98], receiving, with expiration of the issued patent, renewed interest [63,99–102]. The basic circuit configuration of a class E PA is depicted in Fig. 32, where the active device is represented by a switch.

The capacitor C_p includes both device output parasitic reactance and circuit stray capacitances and is eventually increased by an external capacitor. Its value is not such, however, to short-circuit all voltage harmonics. Ideal current and voltages on the active device, represented in Fig. 33, are such that dissipated power is nulled. If a Fourier analysis is further performed on such waveforms, the phase difference between each current and voltage harmonic component is equal to $\pi/2$, therefore fulfilling both conditions indicated by (50) and (51) for efficiency maximization.

Analysis of the circuit in Fig. 32 can be carried out considering a 50% duty cycle, together with an ideal switch operation (i.e., assuming a null ON-state switch resistance and an infinite OFF-state one). Furthermore, the RF choke is assumed ideal, and no losses are accounted for the external elements in the circuit, the active power is dissipated in the external load R only. The current flowing in the external load may be assumed to be a purely sinusoidal one thanks to the series resonator formed by the L_s – C_s pair, tuned to operate at the circuit fundamental frequency and with an infinite quality factor.

The two currents $i_L(t)$ and $i_{DC}(t)$ are therefore always a sinusoidal one and a constant one, respectively, regardless

Figure 33. Idealized current (i_D) and voltage (v_{DS}) waveforms.

of the switch position. The current flowing through the parallel combination of the active device (switch) and the capacitor C_p is therefore always a DC-offset sinusoid. Clearly, when the switch is ON, all such current flows through it, and when the switch is OFF, the offset sinusoidal current passes through the capacitor only:

$$\begin{aligned}
 i_{DC}(t) &= i_{DC} \\
 &\Rightarrow i_d(t) + i_{C_p}(t) = i_{DC} + i_L \cdot \cos(\omega \cdot t) \\
 i_L(t) &= i_L \cdot \cos(\omega \cdot t)
 \end{aligned}
 \tag{70}$$

The onset of the switch ON state will be determined therefore from the zero crossing of such DC-offset current. An example of the resulting switch current is shown in Fig. 34. The corresponding voltage $v_{ds}(t)$ will be obtained by the integration, over the OFF state of the switch period, of the capacitor charge

$$v_{DS}(t) = v_{C_p}(t) = \frac{1}{C_p} \cdot \int i_{C_p}(t) \cdot dt
 \tag{71}$$

obtaining the corresponding voltage waveform depicted in Fig. 34.

Closed-form design expressions may be derived for the circuit components in Fig. 32. The latter may be found in Ref. 63, and the step-by-step derivation of voltages and currents may be found in Refs. 92 and 94 following a time-domain approach.

With reference to Fig. 32, current and voltage in the “ON state” of the switch are expressed as

$$\begin{aligned}
 i_D(t) &= i_{DC} \cdot [1 - a \cdot \sin(\omega t + \phi)] \\
 v_{DS}(t) &= 0
 \end{aligned}
 \tag{72}$$

Figure 34. Switch current and voltage.

while in the “OFF state” as

$$\begin{aligned} i_D(t) &= 0 \\ v_{DS}(t) &= \frac{1}{C_p} \cdot \int_0^t i_D(\tau) d\tau \\ &= \frac{i_{DC}}{\omega \cdot C_p} [\omega \cdot t + a \cdot \cos(\omega \cdot t + \phi) - \cos(\phi)] \end{aligned} \quad (73)$$

Imposing a null switch (capacitor) voltage at the onset of the ON state, together with its first derivative (optimum operation)

$$v_{ds}(t)|_{t=(T/2)} = 0; \quad \left. \frac{dv_{ds}(t)}{dt} \right|_{t=(T/2)} = 0 \quad (74)$$

it is possible to obtain

$$a = \sqrt{1 + \frac{\pi^2}{4}}; \quad \phi = -\tan^{-1}\left(\frac{2}{\pi}\right); \quad V_{DD} = \frac{i_{DC}}{\pi \cdot \omega \cdot C_p} \quad (75)$$

From the expression derived, noting that the dissipated power is null on the active device (neglecting the switch ON-state resistance), the output power P_{out} equals the input supply power P_{DC} , given by

$$P_{DC} = P_{out} = V_{DD} \cdot i_{DC} = \pi \cdot \omega \cdot C_p \cdot V_{DD}^2 \quad (76)$$

bringing the efficiency of the class E PA stage to unity. If a nonzero ON resistance for the switch (R_{on}) is considered, the stage efficiency becomes

$$\eta = \frac{1 + \frac{\pi}{2} + \omega \cdot C_p \cdot R_{on}}{\left(1 + \frac{\pi^2}{4}\right) \cdot (1 + \pi \cdot \omega \cdot C_p \cdot R_{on})^2} \quad (77)$$

An alternative derivation, based on a phasor-based frequency-domain approach, can be found in Ref. 101. In this case the result can be expressed in terms of harmonic load impedances Z_L , namely, the total impedance loading the active device, given by

$$Z_L = \begin{cases} \frac{0.28015}{\omega C_p} e^{j49.0524^\circ} & \text{at } f \\ \infty & \text{at } nf, n > 1 \end{cases} \quad (78)$$

where the parallel capacitance C_p is related to the rf output power P_{out} by

$$C_p = \frac{P_{out}}{\pi \cdot \omega \cdot V_{DD}^2} \quad (79)$$

This expression implicitly poses an upper limit to the maximum operating frequency of the class E amplifier. In fact, once the capacitor value is determined from optimum circuit conditions, the maximum operating

frequency can be obtained as

$$f_{max} = 0.0177 \cdot \frac{I_{max}}{V_{DD} \cdot C_p} \quad (80)$$

where

$$I_{max} = a \cdot I_{DD} + i_{DC} \quad (81)$$

is the maximum value of the current flowing into the active device. Furthermore, the maximum voltage across the switching device obtained by expression (71) may rise well beyond the DC supply, being given by

$$v_{ds,max} \approx 3.562 \cdot V_{DD} \quad (82)$$

For safe and reliable operation, a value such as this must be kept well below the device breakdown region. On the other hand, the limitation imposed by (82) actually decreases the maximum output power that can be achieved utilizing the class E approach if compared to conventional class AB linear PA design, forcing a much lower bias. Indeed, the class E scheme exhibits several advantages, including the evident scheme simplicity, together with the high efficiency attainable.

Constraint imposed on the output circuit high- Q operation may be severe, however, if high-frequency operation is concerned. The result of a low quality factor for the output series resonant circuit will be a nonzero harmonic current flowing into the output, implying a nonoptimum drain voltage waveform, with possible ringing phenomena. Nevertheless, since the class E amplifier has to be over driven by a driver stage well into device compression regions, its large-signal gain may be well below the level that can be attained by a comparable linear power amplifier (say, 3–5 dB [94]). Given the typical frequency rolloff of power devices, this poses an intrinsic frequency limitation to the applicability of the class E scheme. The frequency limit is further decreased by the intrinsic reactive behavior of the device output (dominated by the device output capacitance) that actually restrict the possible values for the capacitance C_p in the class E scheme, as suggested from (80).

7. LOAD-PULL TECHNIQUES

As widely noted previously, PA performance is determined mainly by the terminations imposed to the active device, mainly at its output but also considering its input nonlinearities. This consideration naturally leads us to consider the possibility of experimentally characterizing the device power performance by means of a setup that actually modifies device terminations and records the related performance [106]. The loads are therefore “pulled” to test device power performance levels at both the device output (*load-pull*) and input (*source-pull*) ports. Such investigation is carried out at fundamental frequency (*fundamental load pull*, i.e., controlling the loading conditions at fundamental frequency) or even at harmonic frequencies

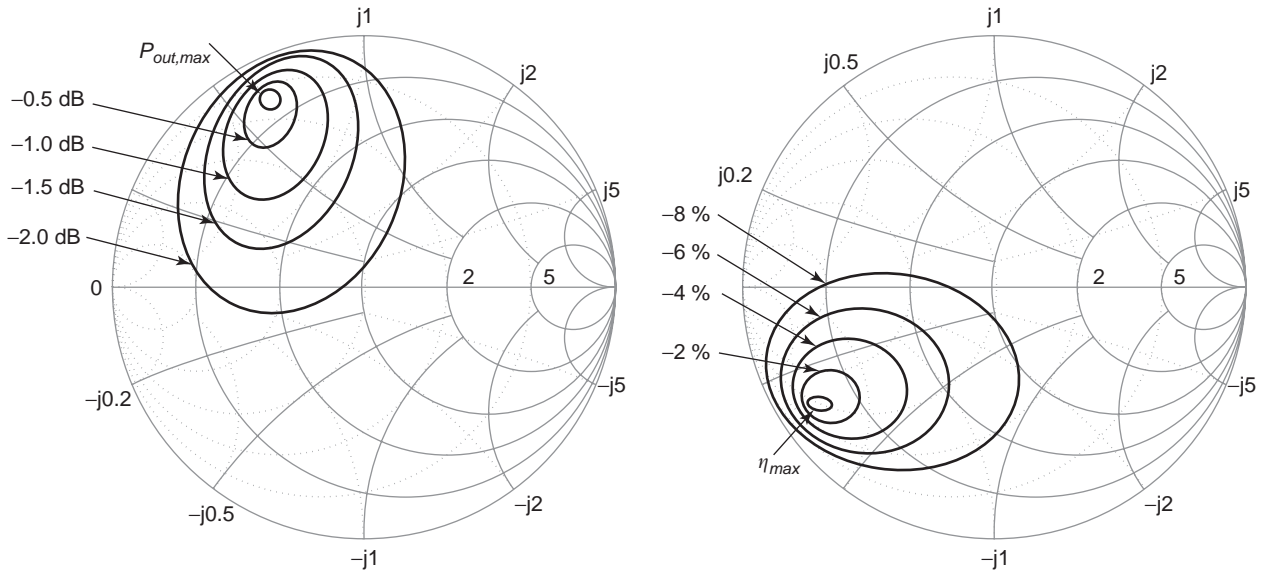

Figure 35. Typical load-pull contours for constant output power and drain efficiency at -1 and -2 dB gain compression, respectively.

(harmonic load pull, i.e. controlling the loading conditions at one or more harmonic frequencies [107–110]).

The result of such a measurement campaign, creating a database of power performances corresponding to a given combination of terminations, driving power, biases, and frequency is typically organized in graphical form. Usually constant-parameter curves are drawn on the corresponding load Smith chart, in order to immediately detect optimality condition. For example, in Fig. 35 the constant output power and drain efficiency curves at -1 dB and -2 dB gain compression respectively are shown in the load reflection coefficient plane.

The load pull therefore gives directly all that is necessary for optimum load selection, as the result of a tradeoff between the performance behaviors of interest. The PA designer therefore needs an automated load-pull measurement bench and physically the selected device, that must be available in the appropriate form, to avoid tedious and risky deembedding procedures. It should be noted, however, that load-pull systems may be fruitfully employed not only as a design tool but also for active-device nonlinear model extraction/verification setup, where the model can be compared and tested using data that have not been used for its extraction.

Before describing the details of the load-pull characterization setup, we present a technique due to Cripps

Figure 36. Simplified scheme of the active-device output and parasitics for application of the techniques in Ref. 103.

[103,104] and further refined by Kondoh [105], allowing determination of load-pull output power contours for a class A biased active device. The technique, based on a series of approximations performed on both the active device and the external circuit, is widely adopted and typically forms the basis for successive investigation (for both load-pull characterization and actual PA design). The active-device output is represented through its voltage-controlled current source I_d , assuming the remaining components and parasitic elements grouped together in the network between Sections 1 and 2 in Fig. 36, eventually constituting device mounting parasitics.

A piecewise linear description of the controlled source is adopted, as outlined in Section 3, and a class A bias is selected (corresponding to $I_{ds,DC} = I_{max}/2$, $V_{ds,DC} = V_{DD}$) as in Fig. 37.

The optimum load $Z_{L,opt}$ imposed at the current source terminals in Fig. 36, simultaneously maximizing current and voltage swings, already determined in Section 3 (see

Figure 37. Piecewise linear representation of the device controlled current source, with superimposed optimum and suboptimum load curves corresponding to a resistive and complex load.

Table 3) as R_A , is a purely resistive one. Its value and the corresponding power delivered by the source are given by

$$\begin{aligned} Z_{L,opt} &= R_{L,opt} \\ &= 2 \cdot \frac{V_{ds,DC} - V_k}{I_{max}} = R_A; \\ P_{L,opt} &= \frac{(V_{ds,DC} - V_k) \cdot I_{max}}{4} \end{aligned} \quad (83)$$

If the source is loaded by a complex termination with the same magnitude $|Z_{L,opt}|$, a lower active output power results as a consequence of the phase difference between voltage and current waveforms. The resulting load curve, that is, the instantaneous plot of current and voltage at the source terminals, is an ellipse, as indicated in Fig. 38.

A lower resistance load ($R_{L,I} < R_{L,opt}$) will cause the device current hard limitations (viz., pinchoff and fully opened channel) to limit the current swing, occurring for a reduced voltage swing and resulting in a reduced output power. The same applies for a higher resistive loading ($R_{L,V} > R_{L,opt}$) in which the voltage limiting mechanism (viz., the device ohmic region) will occur for a reduced current swing. The resulting output power for the current- ($P_{L,I}$) and voltage- ($P_{L,V}$) limited operation are easily computed as follows:

$$P_{L,I} = \frac{R_{L,I}}{R_{L,opt}} \cdot P_{L,opt}; \quad P_{L,V} = \frac{R_{L,opt}}{R_{L,V}} \cdot P_{L,opt} \quad (84)$$

If a reactive part is added in series to the lower-resistance load $R_{L,I}$, the active output power will remain at same level, causing, on the other hand, the load curve to transform into an ellipse, as depicted in Fig. 38. The same applies to the voltage-limited case if a susceptance is added in parallel to the selected load $R_{L,V}$. Clearly in both cases, the output power will be constant until the resulting load curve will incur the voltage (for the current-limited case) or current (for the voltage-limited case) physical limit.

In order to draw a X -dB contour plot (i.e., the locus, on the Smith chart, characterized by an output power given by $P_{L,opt} - X$ dB), the resistive values in the current- and

voltage-limited cases ($R_{L,I}$, and $R_{L,V}$ respectively) are found from (84):

$$R_{L,I} = R_{L,opt} \cdot 10^{-(X/10)}; \quad R_{L,V} = R_{L,opt} \cdot 10^{(X/10)} \quad (85)$$

The X -dB contour can be drawn therefore following constant-resistance (with a value $R_{L,I}$ in the current-limited case) and constant-conductance (with a value $R_{L,V}$ in the voltage-limited case) loci on the Smith chart. The procedure can be repeated for a number of constant-output power loci, resulting in the typical contour plot in Fig. 39, where a 1 dB step has been adopted.

The load at the current source terminals must now be transformed into an external load, thus including device reactive elements and parasitics, together with mounting ones. To this purpose, standard Smith chart transformations apply, moving the reference plane from Section 1 to Section 2 in Fig. 36, and resulting in the final plot on the right side of Fig. 39.

Clearly a series of strong approximations have been applied to get the final result. Nevertheless, the results of the procedure are often in very good agreement with measured load-pull contours, justifying the popularity and widespread use of the Cripps technique. However, if a complete characterization and design charts involving the actual nonlinear nature of the active device are necessary, a load-pull measurement setup has to be used. The measurement systems adopted for load-pull setup may differ greatly. They range from relatively simple scalar setups, based on power meters and/or scalar network analysers, up to vector receivers. In the former case scalar information is available only on the device power performance, but their cost and relative simplicity is indeed a strong point.

Alternatively, vector information can be gained from the use of vector network analyzers (VNA, or from six-port approaches [111]) or by means of time-domain measurement systems [adopting, e.g., a microwave transition analyzer (MTA)]; in this case more complete vector information on the device can be extracted, together with higher accuracy on the results, due to the vector calibrations that can be adopted in the case of VNA (e.g., [112–117]) or with time-domain waveform capabilities in the case of a

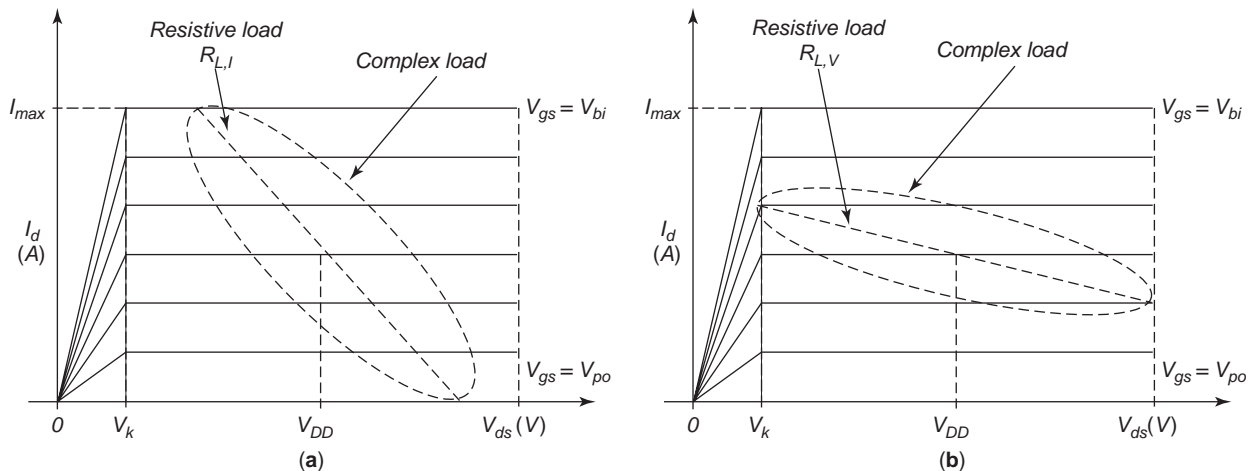

Figure 38. Current- (a) or voltage-limited (b) load lines.

MTA [118,119]. In both cases, however, such improved capabilities are obtained at the expense of an higher bench complexity and cost.

The load to be synthesized can be realized by means of passive systems (*passive load*, resulting in *passive load-pull* systems); the latter consist in mechanical (typically realized via a slotted transmission line with slugs) or electrical (i.e., PIN-diode-based) tuners [120–122]. A typical passive scalar load-pull system is schematically depicted in Fig. 40.

The adopted single- or double-slug tuners have to be accurately precharacterized by means of a VNA, or alternatively the scheme can be extended to include a series of electromechanical switches connecting alternatively the tuners to the DUT or to the VNA input for on-site impedance measurements. Tuners are generally GP-IB-controlled, and tuner position repeatability is guaranteed by precision stepped motors. Moreover, above all for mechanical tuners, the power-handling capability suffices for most power applications.

On the other hand, the synthesized reflection coefficient is limited in magnitude by the unavoidable tuner

and setup (cables, on-wafer probes, etc.) losses. Such limitation implies that highly reflective loads cannot be realized and presented to the active device. Especially for high-power devices this precludes the investigation of maximum power regions for the output fundamental load, since the optimum termination (approximately) results from the ratio of the bias voltage to device maximum current [explicitly for the class A, PA (33)]. This effect is clearly amplified if higher and higher frequencies (and hence higher losses) are explored. Moreover, if an harmonic load pull has to be performed, where optimum harmonic terminations may be typically close to purely reactive ones (see Section 5), a further drawback arises.

In order to overcome the problem, several solutions have been proposed [123], based on the use of either tuner prematching networks (at the device level) or pre-matching tuners (at the measurement system level; see Fig. 41).

In this way, higher reflection coefficient magnitudes are attainable. Nevertheless, especially in the case of pre-matching tuners, precharacterization is indeed a problem,

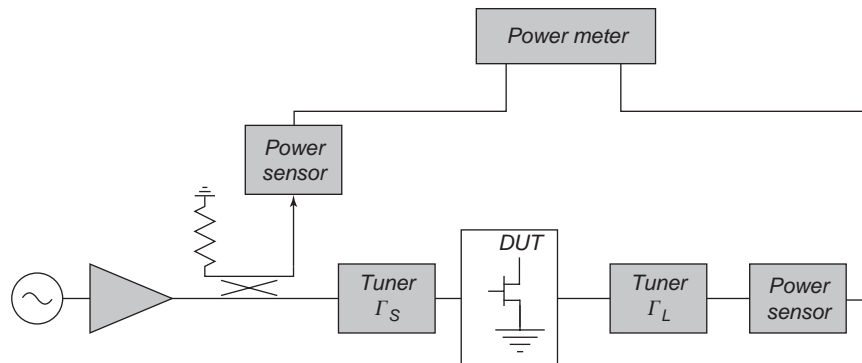

Figure 40. Schematic representation of a passive scalar load-pull setup.

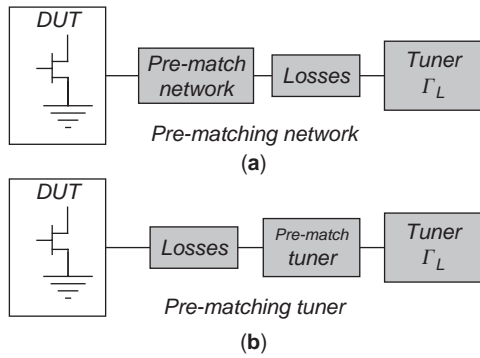

Figure 41. Overcoming setup losses with prematching networks (a) or prematching tuners (b).

since it implies the use of a five-dimensional variables space; moreover, harmonic terminations are not controlled (even if they can be monitored). In the latter case, in order to control harmonic terminations, more than a single tuner can be used or a combination of harmonic resonators, one for each harmonic to be controlled (Fig. 42).

Clearly the first solution increases the bench complexity and losses, but at the same time exhibits a greater flexibility for frequency control and variation, as contrasted with harmonic resonators, whose resonant frequency actually fixes the measurement frequency.

An alternative solution to the use of passive loads consist in the synthesis of the load to be presented at the active-device terminals with active techniques (*active load*, leading to *active load-pull* systems). Basically the active

load is synthesized reflecting back to the device port a power wave whose amplitude and phase are in an externally controlled magnitude–phase relationship with the emitted wave emerging from the device.

Two basic schemes are usually adopted to this goal, following the “two-signal path” and “active loop” techniques, both schematically depicted in Fig. 43.

In further detail, in the two-signal path technique, the device output is fed by a fundamental frequency signal directly generated by the same signal source feeding the device input, while in the active loop technique the reflected power to the device output is the device output signal itself, appropriately amplified and shifted in phase. In the former, technique however, the synthesized output reflection coefficient does vary in magnitude and phase while the source power is swept. Hence, for each input power a different load is presented to the active-device output, and therefore attenuation and phase shift must be controlled to keep the load constant. The same problem holds when the device heats up. On the other hand, such a technique is inherently stable, since no oscillation loop is created in the measurement setup. The latter problem does exist in the active loop scheme, which must be carefully dimensioned in order to avoid spurious oscillations (even at harmonics of the fundamental frequency). The active loop technique exhibits, on the other hand, a stable load termination with input power to the active device. Both techniques allow great flexibility in load control and selection, if compared to the passive approaches. In particular, setup losses are easily compensated by the loop amplifier, in most cases a TWT power amplifier, given the

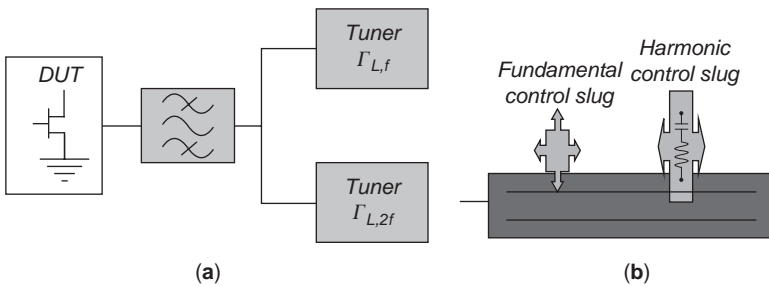

Figure 42. Harmonic control in passive load-pull systems by means of harmonic tuners (a) or resonators (b).

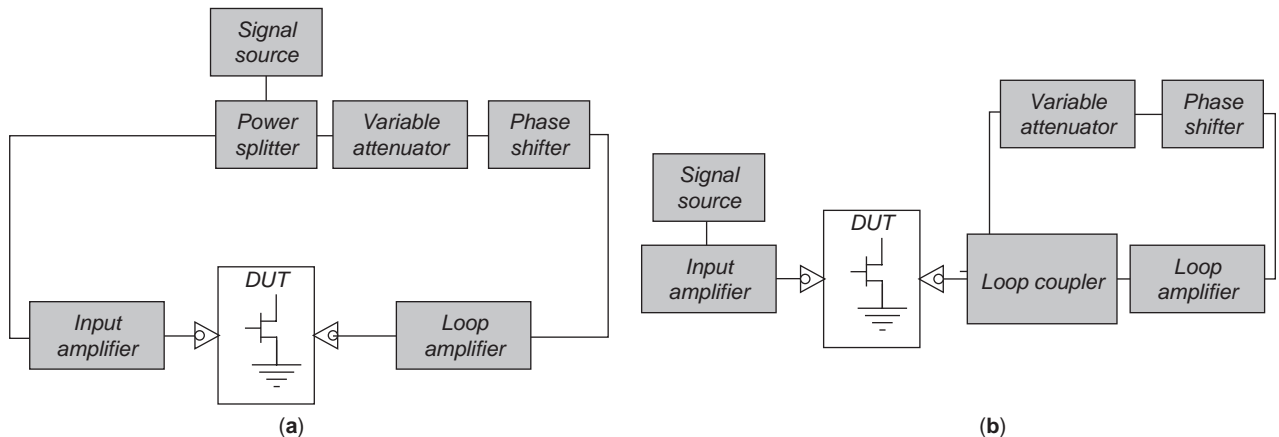

Figure 43. Two-signal path (a) and active loop (b) active load-pull techniques.

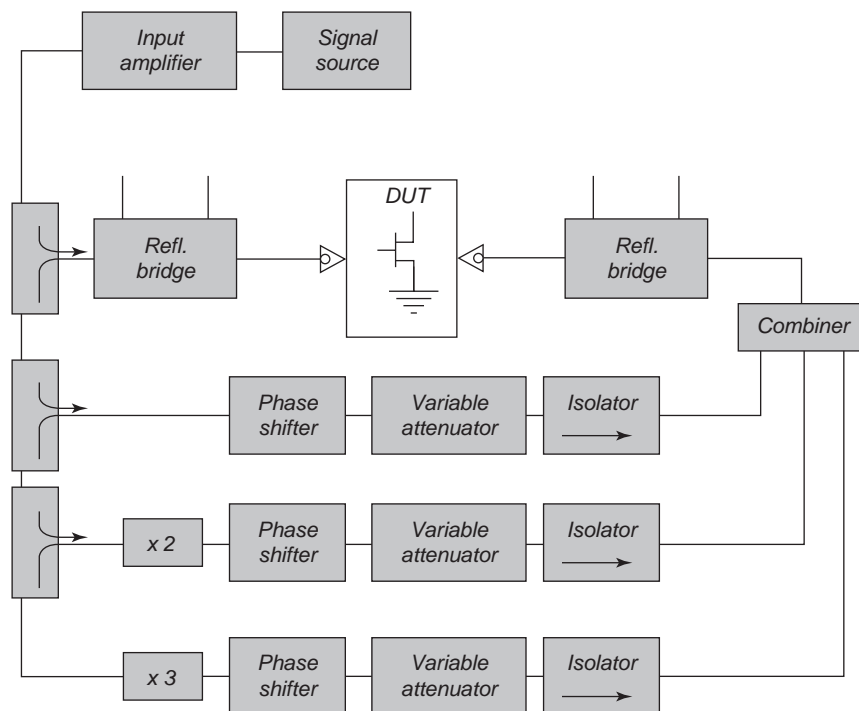

Figure 44. Extension for harmonic load pull of the two-signal path active load-pull technique.

power and linearity requirements. Highly mismatched (or even active) terminations are therefore easily synthesized with an active load-pull approach, clearly with an increased test bench complexity and overall cost.

If accuracy is a concern, in passive load-pull systems it depends mainly on tuner position repeatability, residual S-parameter measurement uncertainty, and power measurement uncertainty. For active systems [124], the main uncertainty source is in power calibration coefficients, which are strongly dependent on the presence of an input power amplifier (TWTA) before the active device under test. Such uncertainty is a strong function of the load reflection coefficient magnitude, rapidly increasing with it. The result is that for low to moderate reflection coefficient magnitudes the output power uncertainty performances of active systems are better than those for passive ones, but

rapidly degrade while approaching highly mismatched load regions.

If an active harmonic load pull has to be performed, the previous schemes can be extended for harmonic control, leading to the setups schematically depicted in Figs. 44 and 45, respectively.

The load-pull techniques can be adopted to test a series of device output performances, not restricted to classical output power, large-signal gain, drain, or power-added efficiency. In particular, depending on the measurement setup, time-domain waveform capabilities can be tested, together with linearity indicators: ACPR or two-tone tests can be performed as well [125,126], thus providing in situ information on the device linearity and allowing the designer to trade off between often contrasting goals directly by means of load-pull charts. As an example, in Fig. 46 a

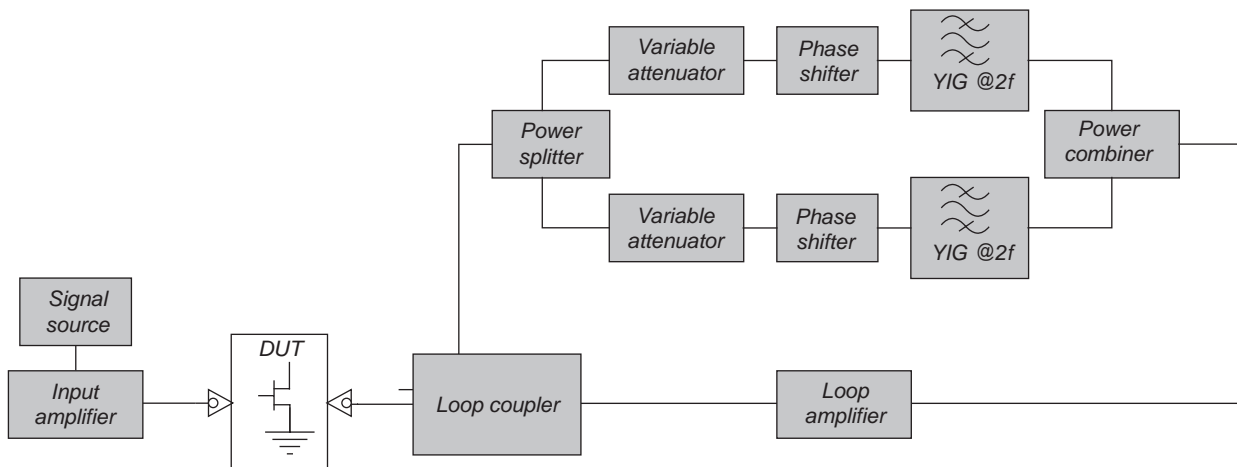

Figure 45. Extension for harmonic load pull of the active loop active load-pull technique.

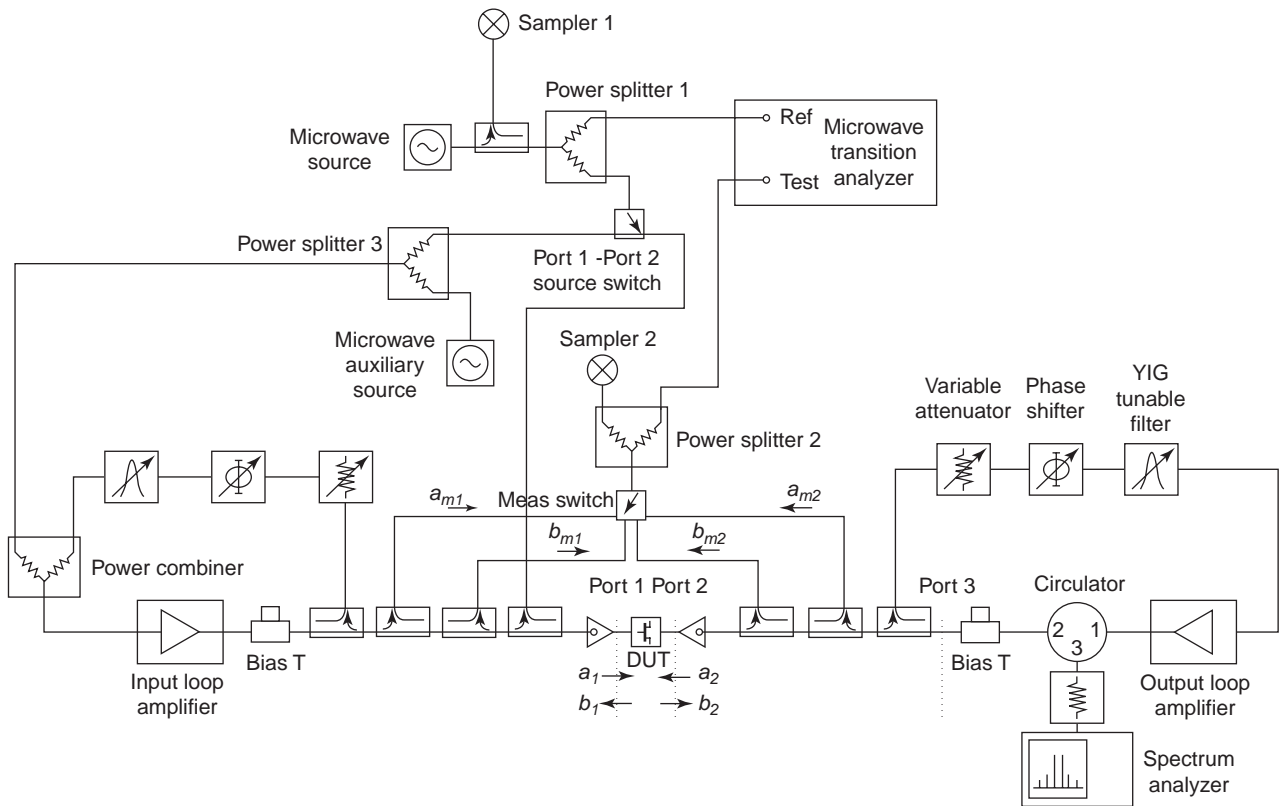

Figure 46. Schematic active load-pull bench with time-domain waveform and spectrum capabilities [127].

harmonic measurement setup [127] is shown, which combines S -parameter capability, real-time load and source-pull (single tone or harmonic) and intermodulation measurements with time-domain waveform measurements.

Any linear vector network analyzer with at least two samplers can be used as linear receiver, while a microwave transition analyzer is used as a nonlinear receiver, measuring the phase relationships between harmonics of the signals at the device under test (DUT) ports. The setup is completed with two active loops (but more loops could be added), controlled independently. The loops can be set at the input or output of the device, and tuned for both single-tone and harmonic measurements.

A final and general consideration regarding load-pull-based PA design has to be stressed. A complete power characterization of a given device is indeed a heavy task, especially if harmonic terminations have to be investigated. If frequencies up to the third harmonic are considered at both device input and output, this easily brings in the control of a six-variable state space, to which a further variable (drive level) is necessarily added. This formidable task is further complicated if fundamental frequency variation and device bias are varied. It is clear, therefore, that load pull has to be matched with some physical insight gained on the power generating mechanisms in the device by means of the harmonic tuning strategies and design procedures described before. Furthermore, an approach consisting in the control and consequent variation of a termination at a time is risky and may lead to suboptimum conditions [128].

8. CAD-BASED TECHNIQUES

Computer-aided design (CAD) tools have experienced a dramatic improvement both in performances and simulation capabilities. Such improvement is due to both increase in computing speed and hardware progress (workstations and PCs), and in the assessment of appropriate analysis techniques.

Modern CAD tools include linear and nonlinear simulation capabilities, coupled with electromagnetic field solvers, layout generation, and system simulation capabilities [129–135]. For the analysis and design of PA circuits obviously the nonlinear simulation capabilities are indeed necessary; the latter may be based on time-domain techniques (derived from widely diffused SPICE-like approaches [136], adapted to deal with microwave problems), adopted mainly for transient analysis, mixed time–frequency-domain techniques [of the harmonic-balance (HB) type, [138]] for steady-state analysis, fully frequency-domain algorithms [137], and finally Volterra series approaches [82]. While Volterra-based approaches find their intended application to circuits exhibiting mild nonlinearities and specifically to the analysis of PA linearity [48], the work horse of all commercial nonlinear CAD software is indeed the HB technique [140,141]. This approach has been extended from the piecewise formulation to include nasty nonlinear problems, such as nonlinear noise analysis, forced autonomous circuits, and input signals with complex modulation schemes. In the latter case, especially important for the analysis of PA

performance in actual operating conditions in communication systems, envelope-based approaches and multitone ones are adopted ([139,142,143]), demonstrating excellent simulation capabilities and numerical efficiency.

The availability, in commercial CAD software packages, of powerful HB simulation engines, together with 2D or 2.5D EM simulators efficiently modeling passive structures and interconnects, is a valuable support for microwave integrated circuit design. Nevertheless, the fidelity of simulated results to measured data is not completely achieved yet; whereas the accuracy of the analysis tool is in fact far beyond the process parameter variations, this is not true if active-device models are considered. Indeed, the effectiveness of a simulated result is to a great extent based on the availability of an accurate device model, especially if nonlinear operation is concerned.

Without entering the wide field of nonlinear device modeling, well beyond the scope of this contribution, a few key points have to be addressed. The active-device nonlinear models currently adopted in CAD tools may be basically classified into two main categories: empirical blackbox models [144–146] and equivalent-circuit based models [147,148]. The former are generally built on a large database of measured data and appropriate expressions to model the active device in the region of interest, while the latter consist in fitting predefined expression for the elements of a given model topology to model parameter data extracted from selected bias and operating conditions.

As a general consideration, the blackbox modeling approach does exhibit a better agreement with measured data, while the equivalent-circuit approach is more compact, is easier to hardwire into commercial CAD tools, and gives a deeper insight into device physical behavior, since its equivalent-circuit elements are directly related to physical mechanisms inside the device.

Nevertheless, equivalent-circuit approaches may suffer from physical inconsistencies [149,150] that may arise from either an improperly selected topology on fitting functions. Moreover, frequency dispersion, temperature, and trapping effects are not easily incorporated into a nonlinear equivalent-circuit device model [151,152]. Pulsed (DC and RF) measurements are utilized to evidence the abovementioned effects, but the resulting model may account for them in a limited range of parameter values (e.g., in a range of biases). Intermodulation prediction is a typical test where most nonlinear general-purpose active-device models may deviate substantially from their corresponding measured behavior. The commonly adopted solution is therefore in the development of a special-purpose model, valid in a limited parameter range that fits well within the desired application. Clearly such special-purpose models are not always available, nor they can be easily extracted. Scaling dimensions of the active device and the properties of the respective model further complicate the picture.

In any case, the adoption of a given device model in the design process is a key point, and the available one (if any) must be investigated in depth in both its field of validity and extraction methods. As previously noted, the outcomes of a design by a nonlinear CAD tool are strongly linked to the accuracy of the device model adopted, and

the adequacy of the latter to the specific design to be performed has to be carefully evaluated beforehand. For example, suppose that a large-signal model for a given device is available, extracted from DC and multibias small-signal S -parameter measured data. If such a model has to be used for optimization of the device output power performance (even in class A operation) and therefore for optimum load impedance determination, the designer cannot expect a high degree of accuracy versus measured power data; DC output curves do not represent actual large-signal RF operating conditions, due to temperature and trapping effects. Only an estimate can therefore be obtained, even with a powerful CAD tool. Similarly, a model optimized for the active-device (i.e., class A) operating region does not represent the same device biased in class C, and the model adopted for tradeoff purposes between class A and B performances should average between the two situations.

Nevertheless, with the precautions stated above, nonlinear CAD tools and active-device models are frequently and effectively utilized for the design of PA stages. After the operating mode of the PA stage is appropriately selected (i.e., a harmonic tuning strategy or a switching mode operating class) on the basis of a preliminary evaluation of attainable performances as compared to the desired specification, together with a preliminary device bias, commonly adopted nonlinear CAD strategies are essentially based on a series of repeated analyses. In particular, a possibility resides in the implementation of a “simulated load pull,” in which the measurement bench is replaced by the nonlinear simulator and its analysis capabilities and the active device is replaced by its model. With reference to Fig. 47, a simulated load pull may be performed in subsequent steps. First, a series of power sweep analyses are performed, each obtained by varying the fundamental frequency load (Z_{L1} in Fig. 47) and adjusting the input termination (Z_{S1}) in order to conjugately match the subcircuit input at fundamental frequency. In such power sweeps, harmonic terminations are kept fixed at a reference value (typically short-circuit termination, so as to simulate a TL scheme or 50Ω). The data gathered are then organized in order to obtain, for each load terminating value, the relevant performances at a given compression level (e.g., -1 dB gain compression or maximum efficiency). The resulting data are organized and plotted as shown in Fig. 35. If the tradeoff attainable with the generated charts fulfills the imposed design goals, the next step is in the actual synthesis of the resulting fundamental and harmonic terminations, that is, in a linear synthesis problem, which can be solved in classical fashion. Otherwise, keeping the fundamental frequency terminations at their optimum values, harmonic terminations may be varied and contour plots of power performances as functions of harmonic terminations are drawn, as in Fig. 48, where constant-power-added-efficiency loci are plotted as a function of the output reflection coefficient at second harmonic.

Applying the information presented above, a new design choice is performed regarding second-harmonic termination. The procedure is then repeated. Clearly the limit is in the number of harmonic terminations that can

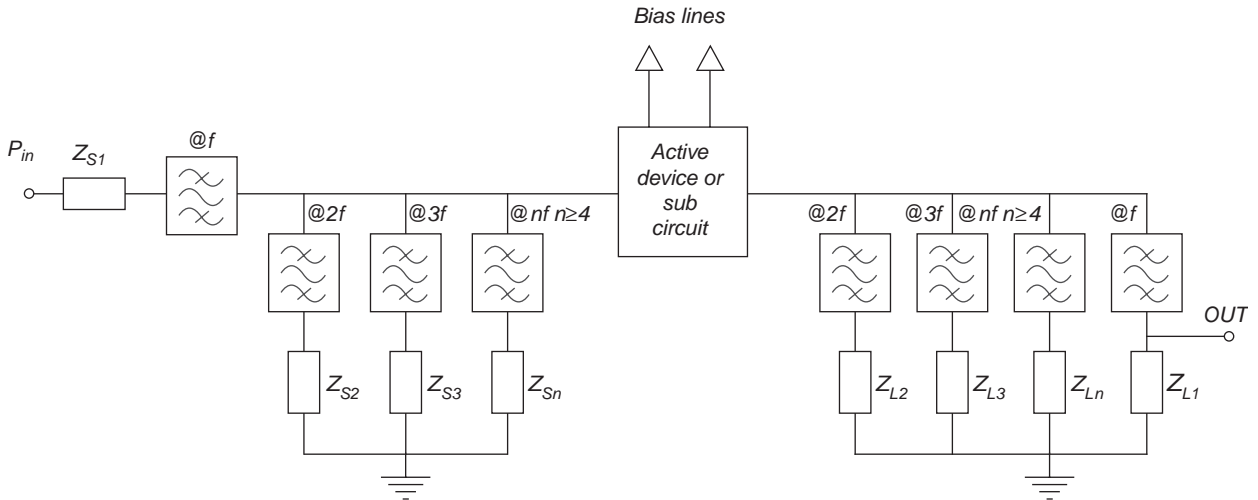

Figure 47. Simulated load-pull scheme.

be effectively controlled and implemented, without sacrificing circuit complexity, size, and clarity. The simulated load pull can be applied as well to the determination of optimum bias levels; the technique is extremely versatile and much faster than the corresponding real load pull. In fact, if a series of operating frequencies have to be investigated, an experimental load-pull characterization may be impractical and time-consuming.

An alternative technique may be implemented, however. Since any iterative analysis technique for a nonlinear microwave circuit (such as the harmonic-balance one) is

based on the actual linearization at each analysis step of the nonlinear part of the circuit, the latter can be used, during the analysis, for external linear circuit optimization [154–156]. In other words, simultaneously and consistently with the nonlinear analysis, a circuit optimization may be carried out, consisting in the fulfillment of optimum design conditions. The latter, for a microwave PA stage, may consist in the imposition of a purely resistive termination at the intrinsic current source terminals of the active-device model (thereby maximizing the stage efficiency) or in the attainment of maximum large-signal

Figure 48. Power-added efficiency on the second-harmonic load plane (from Rohde and Newkirk [153]).

power transfer (i.e., conjugate matching) at the device input terminals.

However, both direct synthesis and simulated load-pull techniques are inevitably based on a proper device model and the difficulties reside in its extraction apply for both validity range and accuracy of the latter.

 College Station, TX

1. INTRODUCTION

Microwave power transmission (MPT) is the wireless transfer of large amounts of power at microwave frequencies from one location to another. MPT is often referred to in the literature as wireless power transmission (WPT) at microwave frequencies. MPT research has been driven primarily by the desire to remotely power unmanned aerial vehicles (UAVs) and by the concept of space solar power first conceived by Dr. Peter Glaser of the Arthur D. Little Company in 1968 [1]. Figure 1 shows a block diagram for the specific application of MPT pertaining to space solar power (SSP). SSP is an MPT system with the addition of solar cells and magnetrons for microwave power generation.

The SSP idea calls for a constellation of solar power satellites (SPSs) to be placed in geosynchronous orbit (“geo”; 36,800 km above Earth) in order to capture the sun’s energy using arrays of solar cells. The satellites each measuring several miles across, would be located in geo to keep them in view of the sun 99% of the time, marking a double improvement over terrestrial solar cells. In addition, the closer the satellites are placed to the sun, the larger their effective collection area since light intensity decreases by the inverse-square of distance. The solar cell

panels output large DC voltages to awaiting cavity magnetrons positioned on various subarrays within each of the SPS’s phased-array apertures. These magnetrons convert the high-voltage DC outputs of the solar panel arrays to microwave power. The microwave energy is then beamed to Earth to “farms” of rectifying antenna (rectenna) arrays that convert the incoming microwave energy back to DC power [3].

Since its inception, SSP has gained considerable attention since it has the potential of providing clean, renewable, and continuous power for generations to come. With the widespread belief that fossil fuel supplies cannot support the projected energy demand based on population growth and increased development, SSP is seen as a possible remedy. In addition, SSP is seen as circumventing pollution problems associated with currently used energy enablers such as nuclear energy and coal. SSP is also seen as meeting future energy demands where other limited clean resources such as hydroelectric power and wind fall short. As an added incentive, SSP can be delivered to the most remote locations without connective infrastructure such as pipes or powerlines. By making SSP an available technology, developed nations will no longer be at the mercy of OPEC, which includes many unstable and/or unfriendly nations [4].

Both the fruition of SSP and the present-day desire to remotely power unmanned aerial vehicles (UAVs) serve as the main driving forces behind current advancements being made in MPT. The use of UAVs for communication and surveillance is seen as an essential capability, especially for the U.S. military. MPT has been shown experimentally as a way for people on Earth to remotely power unmanned high-altitude platforms such as UAVs. Additional uses for MPT include powering space probes from future space stations into deep space and powering robots to enter dangerous environments such as nuclear contaminated areas.

2. MPT SYSTEM ARCHITECTURE

2.1. Traditional Transmitting Aperture

In order to achieve maximum transfer of the microwave energy from the source to the receiver, the transmitting antenna must be designed such that its sidelobes are

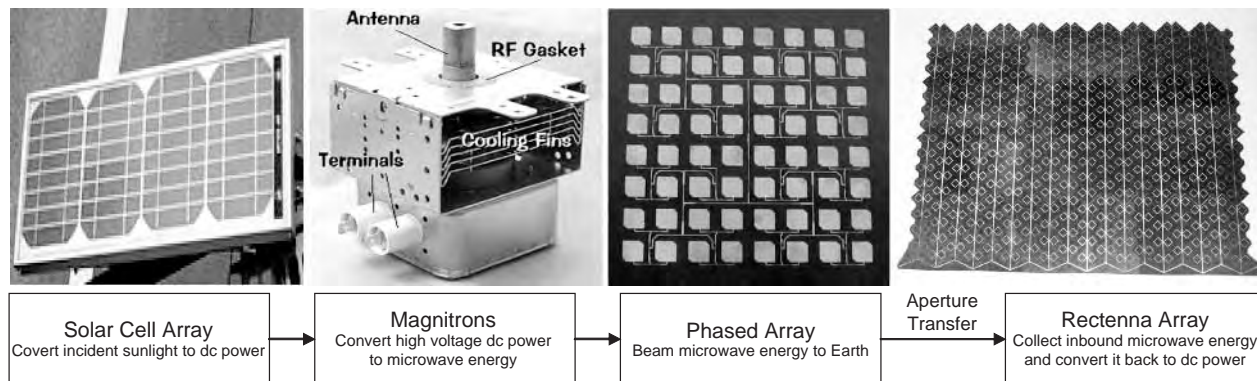

Figure 1. Block diagram of an SSP MPT system, including a BP solar cell array, magnetron, a circularly polarized (CP) phased array [2], and CP rectenna array [2].

reduced to the lowest possible levels and that its proper beamwidth keeps spillover losses to a minimum. In the past, high-gain reflectors and horns antennas have been used to transmit large amounts of power; however, modern systems call for electronically steered phased arrays for greater flexibility in keeping the microwave beam on target. Figure 2 illustrates the geometry of a typical array.

The $m \times n$ array of Fig. 1 contains $m = 2M$ columns and $n = 2N$ rows. One way to achieve low sidelobes is to apply a tapered weighting to the array's aperture. Such tapered weightings include Taylor and Hamming distributions. For its simplicity, Hamming weighting is analyzed in the following. Each u, v element in the array receives power based on the amplitude weighting given by

$$A_{u,v} = \left[\frac{27}{50} + \frac{23}{50} \cos \left(\frac{\left(\frac{2u - (2M + 1)}{2} \right) - \frac{1}{2}}{M + 1} \pi \right) \right] \times \left[\frac{27}{50} + \frac{23}{50} \cos \left(\frac{\left(\frac{2v - (2N + 1)}{2} \right) - \frac{1}{2}}{N + 1} \pi \right) \right] \quad (1)$$

$u = 1, 2, \dots, m$

$v = 1, 2, \dots, n$

where the subscript u pertains to the u th element in \hat{x} and v identifies the v th element in \hat{y} . This applied aperture taper will lower the sidelobes to more than 30 dB below the mainbeam peak so that power is not radiated in undesirable directions. This becomes a serious concern in SSP because of the large amount of power being transmitted. If no taper is applied to the transmitting aperture, that is, if the array has uniform weighting, the worst-case sidelobes will be around -12.5 dB, or 12.5 dB below the peak gain of the radiation pattern.

The array factor (AF) of the transmitting antenna array is defined as

$$\text{AF} = \sum_{u=1}^m \sum_{v=1}^n A_{u,v} \exp j \left(\left(\frac{2u - (2M - 1)}{2} \right) - 1 \right) \times (k\Delta x \sin \theta_t \cos \phi_t + \beta_x) \times \exp j \left(\left(\frac{2v - (2N - 1)}{2} \right) - 1 \right) (k\Delta y \sin \theta_t \sin \phi_t + \beta_y) \quad (2)$$

where $k = 2\pi/\lambda_0$, and Δx and Δy are the element spacings in the \hat{x} and \hat{y} directions. The elevation angle θ_t is the angle measured from the \hat{z} axis toward the \hat{x} - \hat{y} plane, and the azimuth angle ϕ_t is measured from the \hat{x} axis toward the \hat{y} axis. β_x and β_y represent the progressive phase shift in the \hat{x} and \hat{y} directions, respectively, for steering the beam. The array elements should be spaced approximately $\lambda_0/2$ from each other in both \hat{x} and \hat{y} directions to avoid harmful gradient lobes. It is important to be aware that aperture tapering for sidelobe reduction lowers antenna radiation efficiency and broadens the mainbeam of the array's radiation pattern. The efficiency reduction is caused simply by the fact that the outer elements of the array are contributing little to the radiated power. Some of the antenna array's elements positioned farthest from the array's center radiate very little, especially in large arrays, but these remotely positioned elements are still vital for sidelobe reduction.

In the proposed SSP system, a magnetron will be located on a subarray with each antenna element in the subarray having equal power. A graphical representation of multiple subarrays within an array aperture is shown in Fig. 3a. Figure 3a shows a particular array aperture composed of 9×9 subarrays, each having 8×8 elements of equal weight. Thus, the transmitting aperture consists of 72×72 antenna elements. The Hamming taper is applied at the subarray level. If the 72×72 antenna elements are spaced $\lambda_0/2$ in both \hat{x} and \hat{y} directions with no progressive

Figure 2. Two-dimensional even array geometry containing m columns and n rows. In this analysis the number of elements is considered even, and the number of rows is even.

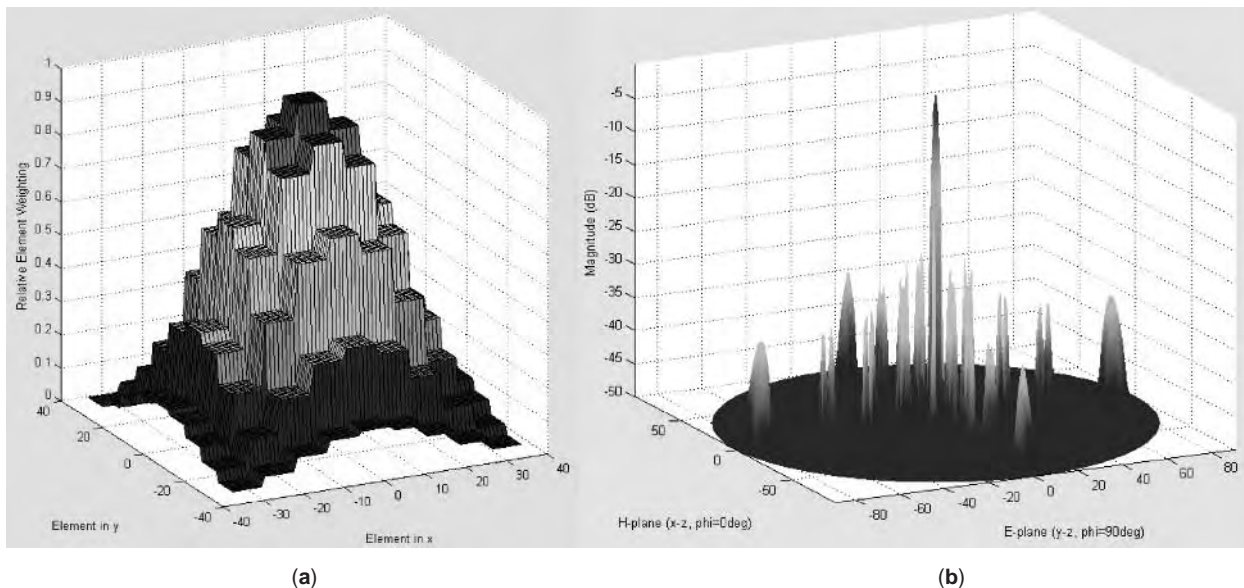

Figure 3. SSP array: (a) amplitude taper for an array containing 9×9 Hamming weighted sub-arrays with each subarray consisting of 8×8 equal-power antenna elements denoting an aperture of 72×72 antennas; (b) corresponding array factor for elements spaced $\lambda_0/2$ in both \hat{x} and \hat{y} directions and no progressive phase shift between the elements.

phase shift, the resultant array factor shown in Fig. 3b is generated. This array factor has worst-case sidelobes of -25 dB at $\pm 13.5^\circ$. The sidelobe suppression can be improved by reducing the subarray size, by increasing the overall size of the array or by applying a monotonic Taylor \bar{n} -bar distribution over the array's aperture. In addition, the size of a subarray is chosen according to the amount of microwave power released by the magnetron into the subarray input port. The overall size of the transmitting aperture is based on the desired transmitting gain and the beamwidth necessary to avoid unnecessary spillover losses.

2.2. Split Gaussian Transmitting Aperture

The temperature of the transmitting aperture becomes an issue in SSP and other MPT applications where the generated power fed to the transmitting array is significantly large. Any array inefficiencies will result in heat being propagated through the transmitting aperture. This heat can destroy sensitive electronics such as phase shifters and could potentially melt the array elements. The array radiation pattern discussed in the previous section is formed using an aperture taper with maximum current weighting delivered to the centermost antenna elements. Consequently, the centermost elements are more susceptible to melting than those moving away from the center.

Two solutions to reducing the temperature at the center of the transmit array are the split Gaussian and the Gaussian with an attenuated center region [5]. These two distributions are illustrated in Fig. 4. These novel weighting schemes distribute power throughout the aperture more uniformly than in the aforementioned traditional transmitting aperture case. As a result, the heat caused by losses in the transmitter is distributed more evenly in the aperture lowering the chance of failure. The split Gaussian has a center weighting equal to the outermost edges. The distribution in Fig. 4b has a center level that can vary.

Both tapers shown in Fig. 4 are radially symmetric for all ϕ_t . If we consider changing the coefficients c_a and c_b of the more versatile Gaussian with the center attenuation region depicted in Fig. 4b, the aperture tapers shown in Fig. 5 result.

These tapers were analyzed by P. Zepeda [5] to a transmit array 250 m in diameter with an operating frequency of 5.8 GHz. The power density of the array's aperture versus center power reduction based on the varying coefficients of Fig. 5 is shown in Fig. 6a. The coefficients also affect the sidelobe performance of the array as illustrated in Fig. 6b. Surprisingly, sidelobe levels below 20 dB are possible with this unconventional aperture distribution. This split Gaussian taper produces sidelobes in the range of the example weighting given in the aforementioned conventional

Figure 4. (a) Normalized split Gaussian taper; (b) normalized Gaussian taper with an attenuated center region.

“Hamming” case with great heat reduction, which is vital to the reliability of the SPS transmitting array.

2.3. Aperture-to-Aperture Transfer

For MPT systems, the transmitting antenna is normally either a high-gain reflecting antenna, a horn antenna, or a large array consisting of many individual elements. Historically, the receiving unit in MPT systems has been a rectenna array made up of cascaded rectennas. Each of these rectennas is a combination receiving antenna and rectifying circuit consisting of a rectifying semiconductor diode. A typical MPT setup is shown in Fig. 7.

The power in watts received at the receiving antenna based on Friis free-space transmission equation is

$$\begin{aligned}
 P_r = & P_t e_{\text{cdt}} e_{\text{cdr}} (1 - |\Gamma_t|^2) (1 - |\Gamma_r|^2) \left(\frac{\lambda_0}{4\pi R} \right)^2 \\
 & \times D_t(\theta_t, \phi_t) D_r(\theta_r, \phi_r) |\hat{\rho}_t \cdot \hat{\rho}_r^*|^2 \\
 & \times (10^{(L_a(z)/10)}) (10^{(L_{ra}(t)/10)})
 \end{aligned} \quad (3)$$

Figure 6. (a) Power density of the transmit array as a function of the center power reduction in percent; (b) sidelobe levels in dB as a function of the center power reduction in percent.

where P_t is the source power transmitted, e_{cdt} and e_{cdr} are the cumulative conductor and dielectric losses of the transmitter and receiver antennas, λ_0 is the free-space wavelength of the energy at the frequency of operation f , and R is the distance separating the midpoints of the transmitting and receiving antenna apertures. The quantity $(\lambda/4\pi R)^2$ is declarative of the path loss L_p between the two antennas.

The quantities $(1 - |\Gamma_t|^2)$ and $(1 - |\Gamma_r|^2)$ represent the mismatch losses at the inputs of the transmitting and receiving antennas. For any fielded MPT system, these mismatch losses should be mitigated to less than 1% reflected power relating to a return loss better than 20 dB. Any reflected power at the receiver port could cause large amounts of reradiated or reflected energy back into free space. This could affect electronic devices in the vicinity of the receiver, especially for an SSP system where large amounts of power could be reradiated. Since large power levels are supplied to the transmitting antenna, any reflected power could damage the transmitter through collective heating. The efficiency of the transmitter falls rapidly as temperature increases.

The variables D_t and D_r are the directive gains (directivities) of the antennas in the oriented direction (θ_t, ϕ_t) and (θ_r, ϕ_r) , respectively. θ_t and θ_r represent the elevation angles and ϕ_t and ϕ_r are the azimuth angles of the transmitting and receiving antennas, respectively. The directive gains of the antenna are related to the antenna

Figure 7. Geometric depiction of a typical MPT setup [6].

measurable gains by

$$G_t(\theta_t, \phi_t) = e_{cdt}(1 - |\Gamma_t|^2)D_t(\theta_t, \phi_t) \quad (4)$$

$$G_r(\theta_r, \phi_r) = e_{cdr}(1 - |\Gamma_r|^2)D_r(\theta_r, \phi_r) \quad (5)$$

If the antennas both have peak directivity broadside of the array's aperture (normal to the aperture plane), maximum power transfer will occur if $\theta_t = \theta_r = 0^\circ$.

The polarization mismatch is calculated by $|\hat{\rho}_t \cdot \hat{\rho}_r^*| = |\cos \psi_p|^2$, where $\hat{\rho}_t$ and $\hat{\rho}_r$ are the polarizations of the transmitting and receiving antennas, respectively, and ψ_p is the angle between their corresponding ϕ -unit polarization vectors. To avoid polarization mismatch using linearly polarized antennas, ϕ_t and ϕ_r must be such that the time-harmonic electric field vectors of each antenna lie in the same ϕ -plane. This polarization mismatch problem can be avoided by making both antennas circularly polarized. Circular polarization also avoids "depolarization" caused by polarization rotation of the electric field vector of the microwave energy as it propagates through the atmosphere. Depolarization is primarily caused by water present in the propagation path and becomes a serious problem during rainfall.

2.4. Atmospheric Absorption

Another important consideration in MPT design is atmospheric attenuation. This attenuation is caused by the presence of oxygen and water in the atmosphere during normal calm conditions and increases as the vertical distance z from the Earth increases. Attenuation is greatest near sea level since oxygen and water levels decrease moving away from the Earth. The atmospheric attenuation is denoted $L_a(z)$ to reflect the height dependence and can be deduced from Fig. 8. Other gases such as carbon dioxide can contribute attenuation, but oxygen and water dominate because of their prevalence.

The choice of operating frequency for an MPT system is governed by atmospheric absorption. The industrial, scientific, and medical (ISM) bands at 2.45 and 5.8 GHz have been chosen for MPT in the past because there attenuation is low relative to higher frequencies and the sizes of the transmitting and receiving antennas are of reasonable size. More importantly, the ISM bands are permissible for

individual use by the Federal Communications Commission (FCC). For this reason, consumer microwave ovens have been designed at 2.45 GHz, and the technology behind their microwave source magnetrons has matured to the point of providing efficiencies over 80% DC-to-RF conversion efficiency at 2.45 GHz. Similar source performance at 5.8 GHz still needs some work, but 5.8 GHz appears to be the frequency of choice for future MPT SSP since it allows smaller antenna apertures. An MPT system designed at 22 GHz would see large amounts of attenuation due to water vapor, especially in humid climates near sea level. Similarly, oxygen would hamper MPT at 60 GHz.

Inclement weather further complicates the problem by adding variable amounts of attenuation. The attenuation loss in dB due to rainfall is [8]

$$L_{ra}(t) = \int_0^{R(t)} a[A(z, t)]^b dz \quad (6)$$

where

$$a = \begin{cases} 4.21 \times 10^{-5} f^{2.42}, & 2.9 \leq f \leq 54 \text{ GHz} \\ 4.09 \times 10^{-2} f^{0.699}, & 54 \leq f \leq 180 \text{ GHz} \end{cases} \quad (7)$$

$$b = \begin{cases} 1.41 f^{-0.0779}, & 8.5 \leq f \leq 25 \text{ GHz} \\ 2.63 f^{-0.272}, & 25 \leq f \leq 164 \text{ GHz} \end{cases} \quad (8)$$

and $R(t)$ is the time-dependent portion of the path between the transmitting and receiving antennas that contains the rain. $A(z, t)$ is the amount of rainfall in mm/h at time t at a distance z km measured from the ground along the path. These atmospheric attenuation problems are well known to satellite communication designers and have the potential of greatly undermining an MPT system. In a dry laboratory environment where R is just within the far field of the transmitter, both $L_a(z)$ and $L_{ra}(t)$ from Eq. (3) can be neglected.

2.5. Rectenna Array

The rectenna array serves as both the absorber of the microwave energy from the transmitter and the rectifier of the microwave energy to DC power [9]. A diagram of a typical rectenna array is shown in Fig. 9.

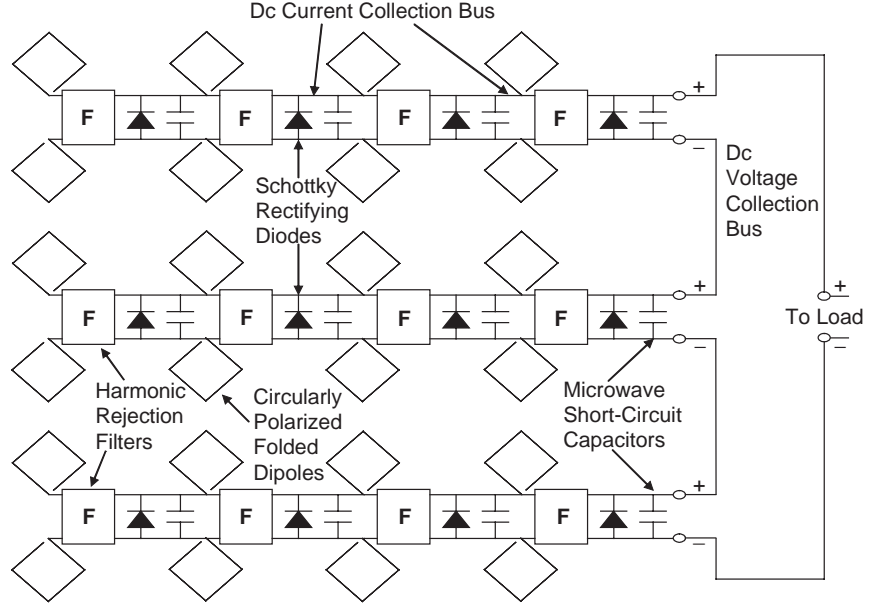

Figure 8. Atmospheric absorption under normal calm conditions [7].

Each rectenna is isolated RF-wise from the next adjacent rectenna by the capacitors that appear as short circuits to the incident microwave energy that strikes them. The antennas in this case are circularly polarized

folded dipoles that send captured microwave energy at frequency f through the harmonic rejection filters (Fs) to the Schottky rectifying semiconductor diodes. The diodes' mixing processes create power at DC (f , $2f$, $3f$, etc.). In

Figure 9. Rectenna array consisting of 12 individual rectennas. Currents add along each row on the current collection bus, and the three row voltage outputs are summed on the voltage collection bus to result in a collective power delivered to the load. The rectenna array is positioned approximately $\lambda_0/4$ above a reflecting metal plane to enhance the gain of each circularly polarized antenna by 3 dB in the desired direction of radiation coming out of the page.

each rectenna, these energies are then led to both the filter F and the capacitor. The DC power is passed through the capacitors along the current collection bus to the peripheral voltage collection bus. Each capacitor appears as a short circuit to the microwave energy returning the microwaves to the diode for further mixing. The capacitors also tune out the imaginary part of the diode impedance to avoid mismatch losses at the diode terminals. Similarly, all microwave circuit components should be matched to each other. Much of the matching of the various components is done experimentally. The filter F rejects harmonic energy at $2f$ and higher back to the diodes for further mixing. F keeps these higher order harmonic frequencies from reradiating, which could interfere with electronic devices in the vicinity of the rectenna array. This additional mixing produces more DC power, increasing the RF-to-DC conversion efficiency η_A of the rectenna array. Some fundamental f energy is lost to the antenna for reradiation, but has been shown to be minimal since the Schottky diodes used currently have very high RF-to-DC conversion efficiencies on the order of 80%.

If the power density on the rectenna array is uniform, the maximum η_A will occur when the rectenna array is loaded with a real resistance equal to [10]

$$R_A = R_L \frac{N_x}{N_y} \quad (9)$$

where N_x is the number of rows in the array and N_y is the number of rows connected by the voltage collection bus. R_L is the optimal load resistance for each individual rectenna, which needs to be calculated or experimentally determined. The diodes are connected in parallel in each row, and the rows are connected in series. The setup for determining the η_A is depicted in Fig. 10.

The RF-to-DC conversion efficiency η_A is defined in terms of the rectenna array's aperture area A_A^{eff} as

$$\eta_A = \frac{P_{\text{DC}}}{P_r} = \frac{4\pi R^2 \left(\frac{V_A^2}{R_A} \right)}{P_t G_t(\theta_t, \phi_t) A_A^{\text{eff}} |\hat{\rho}_t \cdot \hat{\rho}_r^*|^2 (10^{L_a(z)/10}) (10^{L_{ra}(t)/10})} \quad (10)$$

where $A_A^{\text{eff}} = 4ab$. It is important to make sure the rectenna's aperture is positioned such that each of its antennas point toward the transmitter: $\theta_r = 0^\circ$. The rectenna array is composed of numerous elements, each corresponding to a particular transmit gain distribution $G_{xy}(x, y, R)$. The average transmit gain seen across the rectenna array's aperture is [10]

$$G_{\text{avg}}(a, b, R) = \frac{1}{4ab} \int_{-b}^b \int_{-a}^a G_{xy}(x, y, R) dx dy \quad (11)$$

This takes into account the fact that the power striking the rectenna array aperture is normally not a plane wave. In other words, the transmit power density is greatest at (0,0) and decreases toward the rectenna array's edges. The RF-to-DC conversion efficiency can now be expressed as [10]

$$\eta_A = \frac{\pi R^2 \left(\frac{V_A^2}{R_A} \right)}{ab P_t G_{\text{avg}}(a, b, R) |\hat{\rho}_t \cdot \hat{\rho}_r^*|^2 (10^{L_a(z)/10}) (10^{L_{ra}(t)/10})} \quad (12)$$

Some previous designs compensated for the tapered power density present at the rectenna array's surface to increase η_A . One way this compensation is accomplished is by tuning the load resistance or by changing the lengths between

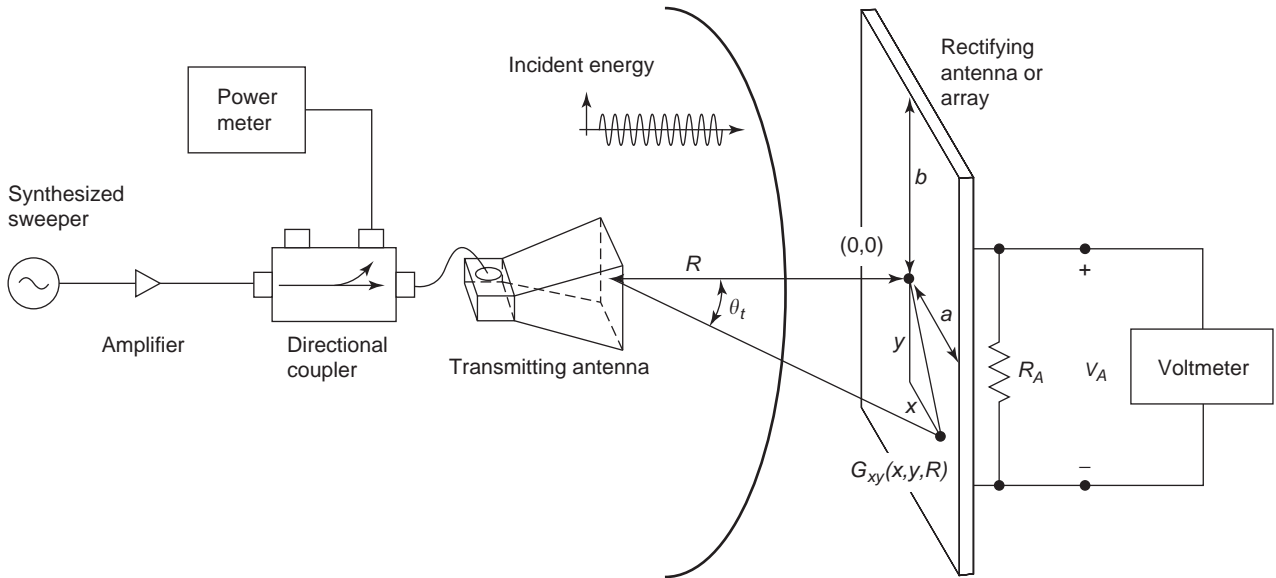

Figure 10. Typical laboratory setup for measuring the RF-to-DC conversion efficiency of a rectenna array. The rectenna array output power is defined by the square of the voltage V_A divided by the load resistance R_A [9].

various components within each rectenna. Typical curves for rectenna performance are shown in Fig. 11.

2.6. Retrodirectivity

The final thing to consider in an MPT design is retrodirectivity. For the SSP example, the rectenna array such as the one illustrated in Fig. 9 is fixed, although some thought has been given to mechanically steering the rectenna panels to vary θ_r . The SPS is proposed to be in geostationary orbit, but if phase errors occur in the phased array or the SPS, which is extremely large in size, undergoes some inertial structural bending even in the slightest amount, the microwave beam can veer off of the rectenna array. To avoid this problem, a feedback loop is established by a pilot beam sent from the rectenna array back to the transmitting phased array in order to determine the proper angle θ_t and set the proper aperture phase taper to keep the beam on the rectenna array [11]. In the case of SSP, a microwave beam rampaging through the countryside could cause some public alarm even if the power density at Earth’s surface is at acceptable safe levels. The pilot beam can also send information about air traffic in the vicinity overhead of the rectenna array so that the microwave beam coming from the SPS can be turned off.

2.7. Other Applications of MPT

Apart from SSP, MPT can be applied to numerous other applications. One such application is in radiofrequency identification or (RFID). In RFID systems, power is transmitted from a reader to a tag device that identifies that which it is mounted to. In some applications the tags are passive, meaning that they contain no battery to drive the tag’s onboard electronics. Some environments such as ones with extreme heat can render batteries useless.

Passive tags rectify a majority of the incident RF power to DC with the use of a rectifying diode in order to drive the electronics. In essence, each of these tags is a rectenna combined with identifying digital electronics. The use of MPT has even been associated with such ideas as remotely powering airplanes, tanks, and naval ships. The main problem is that the required power to move such objects is immense and the rectenna arrays would need to be of ridiculous size such that they become impractical. However, MPT applied to lightweight mobile craft is feasible and has been done in the past. Such craft include high-altitude platforms such as UAVs and blimp airships in which helium is used in conjunction with MPT to move the airships. The main thing for MPT to be applicable is how much power on the receiving end is needed to perform a particular task. For space-to-space applications, MPT is seen as a realizable technology since gravitational effects are minimized. MPT could be a real asset in the future with regard to powering space probes from space stations or even other planets. Some plans have called for making the moon both an MPT transmission site and/or a rectenna array site.

3. HISTORICAL MILESTONES FOR MPT

3.1. Early Years

The earliest example of power transmission by radiowaves was carried out by Heinrich Hertz [12]. Hertz used a spark-gap to generate high-frequency power and to detect the same power on the receiving end. Reflecting antennas were used for transmitting and receiving the energy. In essence, Hertz created a complete system for energy transfer.

Most of the early advances in WPT were achieved at the turn of the twentieth century by Nikola Tesla [13]. Using

Figure 11. Rectenna array circularly polarized measured performance: (a) rectified voltage; (b) output power; (c) RF-to-DC conversion efficiency for various resistive loading values.

the concepts of resonance first displayed by Hertz, Nikola Tesla demonstrated the transmission of low-frequency electrical power using wires over long distances. Tesla built several alternating current (AC) power grids and proved their numerous advantages over the then commonly used direct current (DC) systems backed by Thomas Edison. Much to the dismay of Edison, Tesla proved that AC had much lower conductor losses than did DC and therefore could be transferred over much greater

distances. Tesla continued to carry out experiments in his New York City laboratory and turned his attention to MPT or the transfer of high power wirelessly. While at his laboratory, Tesla drew up plans to apply alternating surges of current running up and down a metallic mast in order to set up oscillations of electrical energy that would propagate over large areas on Earth. These oscillations would create a standing wave around Earth into which receiving antennas could be positioned at the standing-wave maximum amplitude locations. In other words, Tesla wanted to connect the world without wires. This would become Tesla's obsession.

Tesla's first attempt to transmit power without wires at Colorado Springs in 1899. Under a \$30000 grant from Colonel John Jacob Astor, owner of the Waldorf-Astoria Hotel in New York City, Tesla built the huge "Tesla coil" shown in Fig. 12a in a square building over which rose a 200-ft metallic mast with a 3-ft-diameter ball positioned at the top. The Tesla coil resonated 300 kW of low-frequency electric energy at 150 kHz. According to Tesla, when the RF output of the Tesla coil was unleashed into the mast, 100 MV of RF potential was produced on the sphere. Very large discharges of electrical energy were seen by people living in and around Colorado Springs. Unfortunately, no data were collected on whether any significant amount of power would be collected at any distant point.

With the self-heralded success of the Colorado Springs experiment, Tesla obtained financial backing from J. P. Morgan to construct a setup similar to the one in Colorado Springs on 2000 acres of land 60 mi east of New York City at Shoreham, in Suffolk County, Long Island. The building plans called for a wooden tower, namely, the Wardencliff Tower shown in Fig. 12b, 154 ft high that would support a giant copper electrode 100 ft in diameter shaped like a donut at its top. The structure was nearly completed when the financial resources ran dry, and Tesla was forced to halt construction. The installation was eventually torn down, during World War I, by the U.S. government because of its belief that the structure could constitute a possible target. Tesla continued to pursue his dream of connected the world without wires, but his efforts went unnoticed, and, with little outside interest and no financial supporters, Tesla took a step backwards into seclusion. The first radio transmission was achieved not by Tesla but instead by Guglielmo Marconi in 1901. After Tesla's death, the U.S. government seized Tesla's documented works on WPT. The U.S. government saw the technology as the scientific bases for their proposed "death ray" weapon in which WPT would be used to destroy enemy weapon systems. Many of these concealed records were later released to the general public.

From a historical point of view, Tesla was decades ahead of his time. Not until the 1930s was another attempt on WPT carried out. This experiment, performed by H. V. Noble at the Westinghouse Laboratory, consisted of identical transmitting and receiving 100-MHz dipoles separated by 25 ft. No attempts to focus the energy were made, but several hundred watts of power were transferred between the two dipoles. This experiment was demonstrated again to the general public at the Chicago's World Fair of 1933/34.

Figure 12. Tesla's MPT experiments: (a) Colorado Springs; (b) Wardencllyffe tower.

The primary reason why WPT received little interest in the first part of the twentieth century was that knowledgeable engineers and scientists knew that, in order to achieve efficient point-to-point transmission of power, the electromagnetic energy had to be concentrated into a narrow beam, reducing what is commonly referred to today as “spillover loss”. It was theorized at this time that the only way to obtain such confined energy would be to utilize energy at high frequencies and use radiating elements of reasonable size. The other problem was that the existing sources that created high-frequency energy outputted only a few milliwatts of energy—not enough for a feasible WPT system.

In the late 1930s, two inventions were made that solved the high-frequency source problem. The first was the velocity-modulated beam tube first described by O. Heil which after a few modifications became the well-known klystron tube. The second invention was the microwave cavity magnetron developed by Randall and Boot in Great Britain in 1940 and passed to the United States under great secrecy during World War II [14]. These developments allowed the transition of WPT from lower frequencies to microwave frequencies or MPT.

During World War II, with the advent of radar made possible by the introduction of both the klystron and magnetron, antenna development and microwave generation technologies so basic to MPT improved greatly. The U.S. government took notice of the emerging technologies and started proposing applications for the new capabilities.

3.2. Modern U.S. Contributions

In the late 1950s, a number of developments occurred that revealed that WPT approaching 100% was possible. Calculations and experimental results gathered by Goubau and Schwering demonstrated that microwave power could be transmitted with close to 100% efficiency by a beam waveguide consisting of lenses and/or reflecting mirrors [15]. These findings dispelled the previously held assumption that power density always decays by the square of the distance. Another vital development was the high-powered microwave tube amplifier or Amplitron. The last development propelling MPT was the realization of the growing need to communicate by line of sight over long distances, which a platform placed at high altitudes in Earth's atmosphere could afford. Later satellites would be used for this purpose.

The combination of the aforementioned developments motivated the Raytheon Company to propose the Raytheon airborne microwave platform (RAMP) concept in 1959 to the U.S. Department of Defense as a solution to surveillance and communication problems. The proposed platform was a large helicopter positioned at 50,000 ft in a region above the jetstream, where the atmospheric winds are almost nonexistent. To fly at this altitude, the helicopter needed to be powered from Earth by an Amplitron having an output of 400 kW of energy at 3 GHz with an efficiency over 80%. This high-powered Amplitron was developed at Raytheon's Spencer Laboratory in 1960 by William Brown, who is largely regarded as the principal pioneer of practical MPT [16]. The only capability missing was the ability to convert microwave energy to DC power in order to drive motors attached to the rotor blades. The U.S. Air Force awarded several contracts to study this rectification problem. One of the studies, carried out by R. George and E. Sabbagh at Purdue University, showed that a semiconductor diode could be used as an effective rectifier [17]. At the same time, W. Brown at Raytheon carried out research on the use of a thermionic diode rectifier [18]. Now that both high-powered sources on the transmitting side and efficient rectifiers on the receiving side were obtainable, MPT for the first time became both a feasible and possibly useful technology.

The Air Force continued to partner with W. Brown and Raytheon during the early 1960s in order to pursue the emerging MPT technological possibilities. One of the best-known examples of MPT occurred on July 1, 1964 inside Raytheon's Spencer Laboratory. There, a microwave-powered helicopter much smaller than the one proposed in RAMP was flown a few inches off the ground. It was the first heavier-than-air vehicle to be flown and was sustained solely by a 2.45-GHz microwave beam. This helicopter experiment was demonstrated again to the mass media on October 28, 1964. The helicopter shown in Fig. 13 was flown for 10 h at an altitude of 50 ft [19]. The presentation was covered by Walter Cronkite's CBS news program and displayed to the world the real possibilities of MPT. Dipole antennas were used to collect the incoming microwave energy, and the DC energy that powered the propeller was obtained using 4480 semiconductor diodes. This rectifying circuit was built and tested by R. George at Purdue University. It was the first demonstration of a rectifying antenna array in which each antenna element and its corresponding semiconductor rectifying diode

Figure 13. This U.S. Air Force–Raytheon-sponsored demonstration of a microwave-powered helicopter was made to public media in October 1964.

circuit are integrated together. Today such integrated circuits are known as “rectennas”.

After the helicopter flight, the U.S. Air Force elected to discontinue their MPT endeavors. In 1967 W. Brown began to court Dr. Werner von Braun and his staff at NASA’s Marshall Space Flight Center (MSFC) on MPT possibilities in space. In 1970 MSFC awarded Raytheon a contract to improve the overall DC-to-DC efficiency of the MPT system. This DC-to-DC efficiency includes the conversion from DC to RF in the magnetron, the aperture transfer efficiency, and the RF-to-DC conversion of the rectenna array. By multiplying these three efficiencies, an overall system efficiency can be determined.

Raytheon continued to improve various rectenna designs throughout the 1970s under the MSFC contract. Another vital improvement to the MPT system was the design of a dual-mode horn by P. D. Potter of the Jet Propulsion Laboratory (JPL) [20]. The modified horn launched a Gaussian beam with negligible sidelobes to improve the aperture transfer efficiency. Advances to solid-state rectifying diodes in the 1970s improved the RF-to-DC conversion significantly. The MSFC program resulted in drastic improvements in MPT system efficiency.

In 1971, Brown of Raytheon and Glaser, the SPS mastermind, along with members of Northrop Grumman and the solar photovoltaic company Textron, carried out a 6-month study on the SPS concept and concluded that the idea was sound. A letter was then sent to the director

of NASA requesting funding [21]. As a result, NASA’s Lewis Research Center (LeRC) awarded a small contract to Brown and his Raytheon colleagues to improve the overall efficiency of existing MPT systems in order to meet the stringent requirements necessary for a fielded SPS. During the early 1970’s NASA began to shift more and more focus to SSP with JPL, under the guidance of Richard Dickinson, playing a major role in the process. The culmination of efforts occurred in 1974 with the MPT setup shown in Fig. 14a having an overall DC-to-DC conversion efficiency of $54 \pm 1\%$. The operating frequency was 2.446 GHz, and the rectenna’s output power level was 600 W. This efficiency was certified by JPL’s Quality Assurance organization and to this day stands as the highest MPT end-to-end efficiency. The breakdown of the 54.18% overall efficiency is 68.9% for the DC-to-microwave power conversion, 95% for the aperture-to-aperture transfer, and 82.4% for the beam collection and rectification [22,23].

In 1975, another important milestone was shown at the Venus Site of JPL’s Goldstone Facility. In this demonstration shown in Fig. 14b, microwave energy at 2.388 GHz was sent over a 1 mi distance to an awaiting 288 ft² rectenna array. The rectenna array was designed by W. Brown at Raytheon and outputted 30 kW [24]. Both the JPL certified and Goldstone experiments gave NASA the confidence it needed into the viability of MPT and its possible use in Glaser’s SPS concept.

Even with the success of Goldstone, LeRC continued to push for improvements to the transmitting antenna array as well as the rectenna. In 1977, Brown improved the design of rectenna arrays by introducing thin-film etched rectennas in which the DC bussing is achieved in the plane of the antennas [25]. Before etched rectennas, the DC networks were attached behind the antennas, making previous rectenna arrays more complex, much heavier, and more costly. Almost all currently designed rectennas are etched.

Between the years of 1977 to 1980, NASA worked jointly with the U.S. Department of Energy (DoE) to further evaluate SSP possibilities in providing affordable energy to consumers on Earth. The study concluded in a 670-page document that determined that SSP was a feasible technology and should be pursued in the future [26]. One idea coming out of the study was the idea of retrodirectivity or the ability to keep the microwave beam on target. Unfortunately, the NASA sponsored program ended in 1980, and the U.S. lead in SSP came to an end.

Figure 14. Raytheon/JPL MPT experiments: (a) an overall system efficiency of $54.18\% \pm 0.94\%$ was obtained at the Raytheon Company with the demonstration setup shown—the DC power output was 495 W, and the frequency was 2.446 GHz; (b) demonstration of beamed power over one mile distance at the JPL Goldstone facility in the Mojave Desert, CA.

3.3. International Involvement

During the 1980s and early 1990s, the center of MPT research and development shifted to Japan and to a lesser extent Europe and Canada. Since Japan was and remains a large energy consumer with little natural energy resources, the promise of SPS warranted investigation. As a result of the investigation into SPS, Japan carried out in-space experiments. The first of Japan's in-space experiments was the Microwave Ionosphere Nonlinear Interaction eXperiment (MINIX) conducted by Matsumoto and colleagues in 1983. MINIX focused on how the plasma wave dynamic spectrum changes when high-powered microwave energy is transmitted into ionospheric plasma [27,28]. The second in-space experiment was the International Space Year–Microwave Energy Transmission in Space (ISY-METS) in 1993. In ISY-METS microwave energy was transferred from one rocket to a second rocket that carried two different rectenna arrays. ISY-METS represented the first example of MPT in space [29].

In 1980, a program to develop a long-endurance high-altitude platform called the Stationary High Altitude Relay Program (SHARP) was proposed in Canada [30]. The platform was to be the first unmanned, fuel-less, lightweight airplane powered remotely by microwaves, which enabled it to stay afloat for long periods of time. On September 17, 1987, the $\frac{1}{8}$ -scale prototype SHARP with a wingspan of 4.5 m seen in Fig. 15a flew on beamed microwave power for 20 min at an altitude of 150 m. A 2.45-GHz microwave beam was transmitted by a parabolic dish antenna, providing a power density at the airplane of 400 W/m^2 . The dual-polarized rectenna array received enough microwave energy to generate 150 W of DC power to the electric motor in order to lift and fly the 4.1-kg airplane.

Another example of driving a model airplane using microwave power was the MICrowave Lifted Airplane eXperiment (MILAX) conducted by Japan in 1992. The experiment was the first to use an electronic scanned phased array to keep the 2.411-GHz microwave beam on the moving target or, in this case, the airplane shown in Fig. 15b. Two charge-coupled device (CCD) cameras recognized the airplane's pattern feeding the location to a computer that scanned the array to the appropriate location. The transmitting array was located on a sports utility vehicle that was also in motion during the tests. MILAX received nationwide media coverage in Japan and impressed SSP favorably on the Japanese public [31].

3.4. Recent MPT Focus

NASA took notice of the Japanese successes and in 1995 undertook the “Fresh Look Study” to reconsider the challenges of large-scale SSP systems. The study emphasized the most recent technological advancements, which rendered SSP more viable than it was in the late 1980s [32]. In 1998, NASA conducted the “SSP Concept Definition Study”, in which experts within NASA and outside the agency were engaged. The second study backed up findings from the “Fresh Look Study”, but it also narrowed the SSP concepts by invalidating some of the earlier ideas. In 2000, NASA MSFC conducted the SSP Scientific Exploratory Research and Technology (SERT) program. The program broadened the scientific community's involvement and resulted in successful demonstrations on a variety of system-level components.

The SERT program addressed numerous concerns previously outlined by Glaser. Some of these issues relate to economic and societal assessment, environmental effects, resource requirements, and legal issues. The economic assessment studies provided a cost-effectiveness analysis of the SSP system. The societal assessment included the understanding that SSP is for everyone even in the most remote locations where SSP has an obvious advantage. This avoids the situation where a country monopolizes the technology. The environment issues focused on human exposure to the microwave energy, especially with regard to the people working at or near the rectenna array. Studies have shown that the rectenna arrays can be designed to accept power densities within human exposure limits. Questions still remain on how birds would be affected when flying through the microwave beam, and how birds could be convinced not to roost on the warm rectenna arrays. Some focus was also given to possible climate change, although studies have shown negligible effect even in heavy rainstorms when the absorption of microwave power in the troposphere is expected to increase. A concern resonated during SERT meetings was the impact of reradiated energy from the rectenna arrays. This energy could interfere with other electronic devices operating in the same frequency bands, especially since the SPS is radiating large amounts of power with some spillover loss. Research in this area is ongoing, but it has been shown that rectennas can be designed to minimize harmonic energy reradiation with the use of harmonic filtering. The land that a rectenna may need is also a concern. The rectenna would most likely be placed in an

Figure 15. MPT applied to unmanned remotely powered model aircraft: (a) SHARP; (b) MILAX.

arid environment since rain can reduce rectenna efficiency. This would hopefully mitigate the number of birds and people since both reside for the most part along the coasts and waterways. Another concern is that the astronomers will be upset that a large object that reflects sunlight is appearing in the night sky. This is a viable concern, especially since an SSP system will call for a myriad of satellites. Finally, the transport of materials to space to construct the SSPs, is a daunting task. How to use the Space Shuttle's payload bay more efficiently and the elevator to space concept are being studied for transporting the necessary supplies. With the recent nanotube technological breakthroughs, the elevator idea is not as far-fetched as it might seem.

With the renewed U.S. involvement and continuing efforts by Japanese researchers and others, SSP is progressing steadily. Much of the research since 1990 has focused on producing extremely efficient rectenna arrays. One such etched rectenna design funded by the SSP SERT program and demonstrated at the 2002 World Space Congress in Houston, Texas, accepts circularly polarized energy at 5.8 GHz and outputs DC at 82% efficiency [2]. This efficiency was made possible by the recent advances made in reducing the parasitic losses of flip-chip Schottky diodes. The frequency 5.8 GHz was used for its ability to propagate through the atmosphere with relatively low loss and because the receiving and transmitting antennas become reasonably small in terms of SPS construction feasibility. Circular polarization was chosen because of depolarization. Consequently, linearly polarized systems used for SSP would most likely see degradations in efficiency.

Currently, the part of the SSP system that warrants the greatest focus is the photovoltaic solar cells. The state of the art for solar cell sunlight to DC efficiency has remained around 30% since the mid-1990s. The other 70% is predominately heat loss, which can heat the transmitting aperture, lowering the radiated power. Improvements in solar cell efficiency are essential before fielding a functioning SSP system.

4. CONCLUSIONS

Future applications of MPT may apply to SSP, but in the near term MPT will probably be applied to unmanned aerial vehicles (UAVs). UAVs are capable of delivering services such as communications and remote sensing and are finding increasing use for synergistic military applications. The idea of powering space probes from transmitters positioned in outer space also is seen as a realizable and sensible technology. However the "holy grail" for MPT is SSP. SSP is seen by some experts as a way of meeting energy demands for all future generations. The reality is that MPT SSP-associated systems will have relevance until the sun stops emitting light, and by that time, presumably billions of years from now, all life will have ceased to exist, anyway.

MICROWAVE RECEIVERS

JAMES BAO-YEN TSUI
Wright-Patterson Air Force Base
Ohio

A microwave receiver is used to receive information transmitted at microwave frequencies (from 1 to 220 GHz). Most microwave receivers are integral parts of a system, that is, communication or radar, and they are designed together with the transmitter. In other words, the receiver is designed to receive a specific signal with maximum efficiency. For example, the video bandwidth of a pulsed radar receiver matches the bandwidth of the transmitted pulse so as to receive maximum energy in the signal while at the same time limit its noise bandwidth to a minimum value. The receiver of a frequency modulation (FM) radar has a dispersive delay line matching the transmitted signal and compresses it into a short pulse to increase the processing gain. In the global positioning system (GPS) the coarse acquisition (C/A) signals are code-division multiple access (CDMA). In a GPS receiver locally generated C/A codes are used to correlate with an input signal to perform acquisition and signal tracking. In an FM receiver, the frequency variation information is converted into amplitude information through a frequency discriminator. From these examples one can see that each receiver is uniquely designed.

Another type of microwave receiver detects uncooperative signals. This type of receiver is usually referred to as an *intercept receiver*. This type of receiver has some designs in common, because each subtype is designed to detect signals with very limited information. For example, there are police radar receivers and police radar detectors. The police radar receiver, designed to match the transmitted signal to achieve the highest sensitivity, is an integral part of a radar system. The police radar detector used in automobiles is an intercept receiver. The purpose of the radar detector is to detect whether police traffic radar is being used. An intercept receiver does not have the detailed information of the radar signal; instead, it uses coarse information, that is, the frequency range over which the radar operates. Although the intercept receiver has less sensitivity than the radar receiver, the intercepted signal is much stronger than the signal returned to the radar. The signal strength received by a radar receiver is proportional to $1/R^4$, where R is the distance between the radar and the target (or intercept receiver). The intercepted signal strength is proportional to $1/R^2$, which is stronger than the returned signal.

In this article, intercept microwave receivers will be the main subject because of their similarities in design goals. Intercept receivers are very useful in military applications. Used in electronic warfare (EW), they are often referred to as EW receivers. These receivers are used to intercept hostile communication as well as radar signals. It is a more challenging task to design military intercept receivers, because it is a common military practice to design signals that cannot be detected by an intercept receiver and cannot be jammed.

Receivers can sometimes be used to detect unintentional radiation. For example, one can use a microwave receiver to check the microwave power leakage level of a microwave oven. This type of receiver is also useful in military applications. For example, the detection of sparkplug radiation from automobiles can help locate enemy vehicles.

In the past, most microwave receivers were built using analog techniques. Because of recent advances in digital circuits, that is, with today's high-speed analog-to-digital converters (ADC) with their large number of bits and recent high-speed digital signal processing (DSP) techniques, it appears that the trend is to build digital receivers. Some narrowband receivers have already been built using digital techniques. Wideband digital microwave receivers are in the research stage. Digital receivers should be more reliable because they require less maintenance and adjustment.

This article includes descriptions of a generic receiver, followed by a discussion of the important terminology and definitions used in receiver design. A classification of receivers is then presented, with a discussion of analog and digital receivers to follow in subsequent sections. A comparison of different types of receivers concludes the article.

1. GENERIC RECEIVERS

In general, the signals received by an antenna are very weak. It is difficult to process the signals or even to detect

their presence directly. A common approach is to amplify the signals to a higher power level before further processing or detection. This amplification is accomplished through a radiofrequency (RF) chain.

The RF chain usually contains the following components: RF amplifiers, filters, mixers, local oscillators, intermediate-frequency (IF) amplifiers, IF filters, and attenuators. Amplifiers are used to raise the signal power level. Filters are used to limit out-of-band noise as well as spurious responses (undesired frequencies) generated from some components. The mixer and local oscillator are used in combination to shift the input frequency to another frequency, often referred to as the IF. At IF, additional filters and amplification can be provided. In many receivers the input signals are not converted to a different frequency and, therefore, the mixer and local oscillator are not needed. Attenuators are used to adjust the overall gain of the RF chain. The overall gain in the RF chain must be of a specific value. Often commercial amplifiers with specific gain values are used in receiver design and it is difficult to implement the desired value. A common practice is to use amplifiers to provide more gain than the desired value and attenuators to lower the gain to the correct value.

In communication receivers, automatic gain control (AGC) is sometimes used. The AGC changes the gain of the RF chain according to the input signal strength: lower gain for strong signal and higher gain for weak signal. The AGC is seldom used in receivers intercepting pulsed signals, because it is difficult to build an AGC with very fast response time.

After the RF chain in an analog receiver, the signal is detected by a crystal video detector. The detector filters out the RF but retains the information of the signal, often referred to as the *video signal*. Further processing is needed to obtain the necessary information, which includes digitizing the video signal. A basic analog receiver is shown in Fig. 1a. In some analog receivers, there are no RF amplifiers and a crystal video detector is used to detect signals directly. These receivers usually have low sensitivity and can detect only very strong signals.

After the RF chain in a digital microwave receiver, an ADC is used to convert the input into digital data as shown in Fig. 1b. Because the output of the ADC is digital, digital signal processing (DSP) can be used to obtain the necessary information.

2. DEFINITIONS USED IN RECEIVERS

The two most important specifications to describe a receiver are sensitivity and dynamic range. These two parameters can be used to specify all kinds of receivers whether they are intercept receivers or receivers designed for a specific signal. *Sensitivity* can be briefly defined as the capability to receive the weakest possible signal. *Dynamic range* is the maximum signal amplitude range that a receiver can process without distortion. A strong signal above the upper limit of the dynamic range can produce distortion or generate spurious responses. It is desirable to have high sensitivity to receive weak signals and high

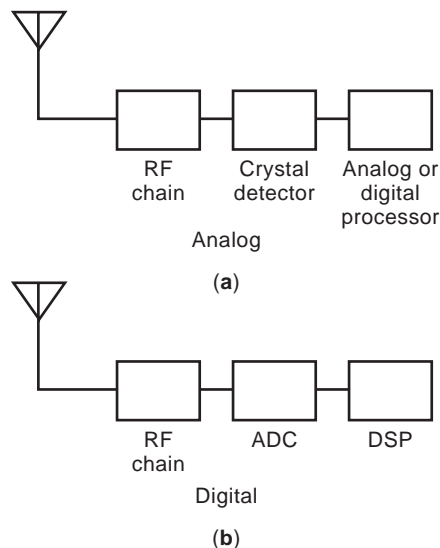

Figure 1. (a) A basic analog receiver with RF amplifier chain, crystal detector, and analog/digital processor. The RF amplifier chain is used to amplify the input signal. The crystal detector changes the RF signal into a video signal. The processor takes the video signal and generates the desired digital information. (b) A basic digital receiver with RF amplifier chain, ADC, and DSP. The ADC digitizes the analog input signals. The DSP processes the digitized data and generates the desired digital information.

dynamic range to receive a broad range of signals. However, high sensitivity often causes lower dynamic range and vice versa. Therefore, in designing a receiver, the tradeoff between sensitivity and dynamic range becomes an important issue.

Sensitivity is closely related to noise floor, the noise figure of the receiver, and the gain in the RF chain. In an analog receiver, the sensitivity depends on the video bandwidth after the detector. In a digital receiver, the DSP algorithm used after the ADC affects the overall bandwidth of the receiver and determines receiver sensitivity. When a receiver can process only one signal, there is only one definition of dynamic range. If a receiver can process simultaneous signals, there are usually three definitions of dynamic range. They are denoted as the single signal, two-signal spur-free, and two-signal instantaneous dynamic range. The lower limit of the dynamic range is always the sensitivity level. The upper limit depends on the definition of the dynamic range. These definitions, terminology and calculations to obtain some of the values, will be discussed in the following paragraphs. Most equations can be found in Ref. 1.

2.1. Receiver Input Bandwidth and Instantaneous Bandwidth

The *input bandwidth* of a receiver refers to the frequency range in which the receiver can detect an input signal. This is also referred to as the *operational bandwidth* or the *overall bandwidth* of the receiver. The *instantaneous bandwidth* means that any signals with sufficient amplitude in the bandwidth will be detected immediately. Usually, the input bandwidth is wider than the instantaneous bandwidth, but in some receivers they are the same. The

instantaneous bandwidth can be assigned to different portions of the input bandwidth. For example, a receiver may have a 16 GHz (2–18 GHz) input bandwidth but a 1 GHz instantaneous bandwidth. This 1 GHz bandwidth can be placed in any one of the bands in the 2–18 GHz range to receive signals in that band. The input bandwidth and the instantaneous bandwidth are not used to determine the sensitivity. They are mentioned here only to distinguish them from the RF bandwidth.

2.2. RF Bandwidth

The RF bandwidth is used to determine the sensitivity of a receiver. In an analog receiver, the filter with the narrowest bandwidth in the RF chain is the RF bandwidth. In some receivers, the input and the instantaneous and RF bandwidths may be the same. In a digital receiver, usually the inverse of the DSP length will be used as the RF bandwidth. For example, if the input is digitized at 1000 MHz, each sample is separated by 1 ns. If 256 samples will be processed through the fast Fourier transform (FFT), the RF bandwidth will be approximately 3.9 MHz ($1/256 \times 10^{-9}$ s).

2.3. Video Bandwidth

The video bandwidth of a receiver is determined by the video circuit following the crystal detector. The desired bandwidth is determined by the input signals. For an electronic warfare (EW) receiver, the video bandwidth is determined by the shortest pulse anticipated. In a digital receiver, it is determined by the processing scheme and is sometimes assumed to have the same as the RF bandwidth.

2.4. Noise

Noise generated by a resistor R can be represented by a noise generator in series with the resistor. Maximum power transfer from a generator to a load occurs when the load impedance is matched to the generator impedance. *Available power* refers to the power that would be delivered to a matched load. The available thermal noise power N_i in watts at the input of a receiver can be expressed as

$$N_i = kTB \quad (1)$$

where k is Boltzmann's constant ($= 1.38 \times 10^{-23}$ J/K), T is the temperature of resistor R , and B is the bandwidth of the receiver in hertz. The power level in a typical receiver system is very low and is usually expressed in milliwatts or in dBm, which is defined as

$$P(\text{dBm}) = 10 \log(P) \quad (2)$$

where the P on the right-hand side is power in milliwatts and the base of the log is 10. The thermal noise at room temperature where $T = 290$ K can be expressed in dBm as

$$P(\text{dBm}) = -174 \text{ dBm/Hz} \quad (3)$$

or

$$P(\text{dBm}) = -114 \text{ dBm/MHz}$$

These two values are commonly used in receiver designs. It should be noted that with an antenna aimed skyward, the noise temperature can be very low.

2.5. Gain

The *gain* of an amplifier is defined as

$$G = \frac{S_o}{S_i} \quad (4)$$

where S_o and S_i are the available output and input signal powers, respectively. The gain is often defined in decibels as

$$G(\text{dB}) = 10 \log(G) \quad (5)$$

When N amplifiers are connected in cascade, the overall gain can be expressed as

$$G = G_1 G_2 \cdots G_N \quad (6)$$

or

$$G(\text{dB}) = G_1(\text{dB}) + G_2(\text{dB}) + \cdots + G_N(\text{dB})$$

where G_1, G_2, \dots, G_N are the gain of each individual amplifier.

2.6. Noise Figure

The noise figure is defined as

$$\begin{aligned} F &= \frac{N_o}{GN_i} \\ &= \frac{\text{noise output of practical receiver}}{\text{noise output of an ideal receiver at temperature } T} \end{aligned} \quad (7)$$

where N_o is the noise at the output of the receiver, G is the gain of the RF chain in the ratio form, and N_i is the input thermal noise ($= kTB$). Substituting Eq. (4) into Eq. (7), the result is

$$F = \frac{S_i/N_i}{S_o/S_o} = \frac{\text{signal-to-noise ratio at input of receiver}}{\text{signal-to-noise ratio at output of receiver}} \quad (8)$$

The noise figure is often defined in decibels as

$$F(\text{dB}) = 10 \log(F) \quad (9)$$

If there are N amplifiers connected in cascade, the noise figure ratio form can be expressed as

$$F = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \cdots + \frac{F_N - 1}{G_1 G_2 \cdots G_{N-1}} \quad (10)$$

where G_1, G_2, \dots and F_1, F_2, \dots are the gain and noise figure of the first, second, ... amplifiers, respectively, and are expressed in power ratio rather than in decibels. From Eq. (10) it can be shown that if the first component in the RF chain is a high-gain amplifier, the overall noise figure can be approximately equal to the noise figure of the first amplifier.

2.7. Sensitivity

The sensitivity of a receiver depends on the noise power at the input of the receiver, which is related to the bandwidth of the RF chain, gain, and video bandwidth for an analog receiver and the DSP algorithm used for a digital receiver. It is often specified along with false-alarm rate and probability of detection. The false-alarm rate is defined as the number of false measurements when there is no input signal. In some cases more restrictions can be added to the definition of sensitivity; that is, the parameters measured by the receiver must be within certain limits. In designing a receiver, the sensitivity can be determined from curves generated based on the RF bandwidth, the video bandwidth, the probability of detection, and the probability of false alarm from this author’s work [1]. Once a receiver is built, one can apply specific requirements to evaluate its sensitivity. The sensitivity is usually frequency-dependent, which means that its value varies across the frequency range of the receiver.

2.8. Tangential Sensitivity

As the sensitivity of a receiver with given false alarm and probability of detection is tedious to calculate and measure, an easily calculable and measurable sensitivity is defined. For an analog receiver, the tangential sensitivity is measured through visual display on an oscilloscope that monitors the output of a video amplifier following the detector. The input must be a pulse signal. On the scope display, when the bottom of the noise trace in the pulse region is roughly tangential to the top of the noise trace between pulses, as shown in Fig. 2a, the receiver is at tangential sensitivity. At tangential sensitivity, the signal-to-noise ratio is 8 dB at the output of the detector with a standard deviation of 0.4 dB. Based on these values, the tangential sensitivity of a digital receiver can be illustrated from the signal-to-noise ratio of 8 dB as shown in Fig. 2b. When there is sufficient gain in the RF chain, the tangential sensitivity is independent of the characteristics of the video detector. This case is referred to as the *noise-limited case*. If there is insufficient gain, the tangential sensitivity depends on the characteristics of the detector and is referred to as the *gain-limited case*. The minimum gain required for the noise-limited case is to raise the noise floor to the tangential sensitivity of the crystal detector (approximately -35 to -45 dBm). Above this gain value, the sensitivity is gain-independent. Most modern microwave receivers fulfill this condition. The tangential sensitivity (TSS) for

Figure 2. (a) Tangential sensitivity of an analog signal from an oscilloscope display. The output signal-to-noise ratio = 8 dB. (b) Tangential sensitivity of a digital signal where the signal-to-noise ratio = 8 dB.

the noise-limited case is

$$TSS = -114 + 10 \log(F) + 10 \log(3.15B_v + 2.5\sqrt{2B_R B_v - B_v^2}) \text{ dBm for } B_v \leq B_R < 2B_v \tag{11}$$

$$B_v \leq B_R < 2B_v$$

$$TSS = -114 + 10 \log(F) + 10 \log(6.31B_v + 2.5\sqrt{2B_R B_v - B_v^2}) \text{ dBm for } B_R \geq B_v$$

$$(6.31B_v + 2.5\sqrt{2B_R B_v - B_v^2}) \text{ dBm for } B_R \geq B_v$$

where -114 is the noise floor of 1 MHz bandwidth, F is the overall noise figure of the receiver, and B_v and B_R are the video and RF bandwidths, respectively.

The tangential sensitivity is usually too low to be used as the operating sensitivity level, because at this level the

false-alarm rate is very high. The rule of thumb is that the operating sensitivity is approximately 6 dB higher than the tangential sensitivity level.

2.9. Single-Signal Dynamic Range

This dynamic range is applicable to all receivers. The lower limit is the sensitivity level. When an input signal is very strong, it may cause some components in the RF chain or the ADC in a digital receiver to become saturated. Under this condition, the output signal will be distorted or spurious signals will occasionally be generated. Depending on the specifications of a certain receiver, the upper limit is determined accordingly.

2.10. Two-Tone Third-Order Intermodulation Products and Third-Order Intercept Point

If the passband of a receiver is less than an octave, the third-order intermodulation products are the lowest-order intermodulation products that can fall within the passband. That is why they are used as the upper limit of the two-tone spur-free dynamic range. The third-order intermodulation is measured with two input signals of equal amplitude. When the input signals f_1 , and f_2 , are strong enough to drive the RF chain into saturation, spurs will be produced at frequencies $2f_1 - f_2$ and $2f_2 - f_1$ as shown in Fig. 3. The outputs at these two frequencies are referred to as *third-order intermodulation*. The amplitude of the third-order intermodulation can be experimentally measured.

Another quantity related to third-order intermodulation is referred to as the *third-order intercept point*. The third-order intercept point can be obtained from the third-order intermodulation in Fig. 4. The straight line with a 1:1 slope represents the gain of an amplifier. Another straight line is drawn that passes the measured third-order intermodulation point with a 3:1 slope that represents the anticipated amplitude change of the third-order intermodulation as a function of input signal. The intercept point between these two lines is the third-order intercept point and the value is often read from the output axis. It should be kept in mind that these two straight lines are projected results. They cannot actually

Figure 3. Third-order intermodulation products. The input signals are at f_1 and f_2 with equal amplitude and the third-order intermodulations are at $2f_1 - f_2$ and $2f_2 - f_1$.

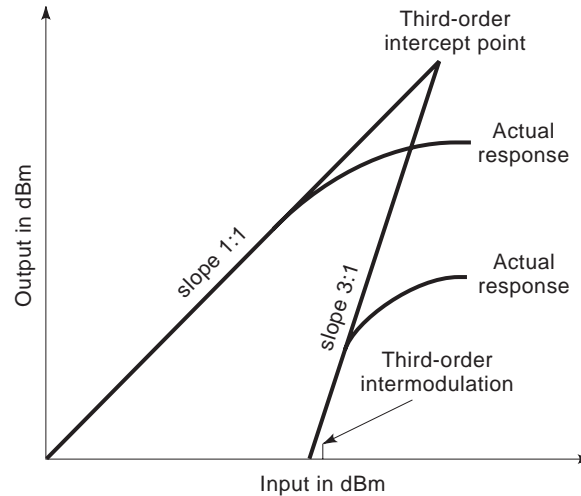

Figure 4. Third-order intercept point. The fundamental output has a slope of 1:1, and the third-order output has a slope of 3:1. The third-order intercept point is where the extrapolated fundamental and third-order outputs intercept. The third-order intermodulation is also shown.

be measured because, when a component is approaching saturation, the actual measured lines will bend downward. This quantity is used to determine the spur-free dynamic range. The third-order intercept point of many microwave components is provided by the manufacturers.

2.11. Third-Order Intercept Point of Cascade Components

The overall third-order intercept Q_i of N components connected in cascade is given by

$$Q = \frac{G_1 G_2 \cdots G_N}{\frac{G_1}{Q_1} + \frac{G_1 G_2}{Q_2} + \cdots + \frac{G_1 G_2 \cdots G_N}{Q_N}} \quad (12)$$

where Q_1, Q_2, \dots are the third-order intercept point of the first, second, ... components. If a component is passive, for example, as with an attenuator, a high third-order intercept value can be assigned to the device and its effect will be negligible from that seen in Eq. (12).

2.12. Two-Signal Spur-Free Dynamic Range

This dynamic range (DR) is usually applied to receivers that can process simultaneous signals. The lower limit is the sensitivity level. The upper limit is reached when two strong signals of equal amplitude begin to generate a detectable third-order intermodulation. For convenience, the detectable level is often chosen to be the noise floor. With this assumption, the two-signal spur-free dynamic range can be written as

$$DR = \frac{2}{3}(Q - G - N_o) \text{ dB} \quad (13)$$

where Q is the third-order intercept point, G is the gain of the RF chain, and N_o is the noise power at the output of

the RF chain and can be expressed as

$$N_o = -114 + F + 10 \log(B_R) \text{ dBm} \quad (14)$$

where -114 is the noise floor of 1 MHz bandwidth, F is the overall noise figure of the receiver, and B_R is the RF bandwidth. To achieve a certain sensitivity and dynamic range in a receiver, the gain of the RF chain must be of a specific value. Although higher gain may improve sensitivity, it degrades the dynamic range. However, a third-order intercept point higher than the designed value will not produce any adverse effect.

2.13. Two-Signal Instantaneous Dynamic Range

This dynamic range is applicable to receivers that can process simultaneous signals. It represents the capability of the receiver to receive a strong as well as a weak signal simultaneously. The *instantaneous dynamic range* is defined as the maximum amplitude separation between two simultaneous signals such that the receiver can measure both correctly. Generally speaking, this dynamic range depends on the frequency separation of the two signals. When two signals are close in frequency, the instantaneous dynamic range is low. When the frequencies of two signals are widely separated, the instantaneous dynamic range is high.

If a microwave receiver is used to intercept radar signals, two additional parameters are important: the throughput time (throughput rate) and delay time.

2.14. Throughput Time (Throughput Rate)

If a receiver can process only one signal at a time, the throughput time is the shortest time between two pulses the receiver can process. If the receiver can process N simultaneous signals, the throughput time is the shortest time between two groups of N simultaneous pulses the receiver can process. The information of a pulsed signal, that is, RF and pulse amplitude, can be obtained from the front of the pulse, but the pulsewidth must be measured at the end of the pulse. Therefore, the throughput time is pulsewidth-dependent. To keep the throughput time an intrinsic characteristic of the receiver, it should be measured with signals of minimum pulsewidth. The inverse of the throughput time is called the *throughput rate*.

2.15. Delay Time

The delay time is measured from the time a pulse reaches the input of a receiver to the time it is completely encoded. If delay lines are used in the receiver to store information temporarily, the delay time can be only a few microseconds. Delay time is important for intercept receivers used to generate information to respond on the same signal. If delay time is too long, the information cannot be used by a jammer to respond on the same signal.

3. CLASSIFICATION OF RECEIVERS

There are many ways to classify microwave receivers. One popular classification uses operating frequency range,

that is, Ku band, X band, or extremely high-frequency (EHF) receivers. Another way of classifying them is by application, for example, satellite receiver, or global positioning system (GPS) receiver. Even the intercept receivers can be subdivided by application, such as warning or electronic intelligent (ELINT) receivers. Although these classifications can reveal some specific information about the receiver, they do not reveal the technology on which the receiver is based.

In this article receivers are classified by their structure and only intercept receivers will be discussed. These receivers are designed to receive different kinds of signals, and all receivers have similar input. Different techniques can be used to build intercept receivers. These techniques, fundamental to receiver designs, are adopted in many other types of receivers. For example, the superheterodyne technique is used in most receiver designs. Almost all communication receivers irrespective of their operating frequency and applications often use superheterodyne techniques.

A very important factor in a receiver is whether the receiver can process multiple simultaneous signals. Since it is usually easy to isolate one desired signal, it is relatively easy to build a receiver that can process only one signal at a time. Most commercial communication receivers belong to this category. A scanning receiver can listen to many stations in a sequential manner, but it can process only one signal at a time. It is relatively difficult to build a receiver that processes more than one signal, especially when high instantaneous dynamic range is required. High instantaneous dynamic range requires the receiver to distinguish a weak signal from a spurious response, which is difficult to achieve. For low instantaneous dynamic range requirement, the problem is not as severe. For example, a GPS receiver must receive simultaneous signals from many satellites. As the signals from different satellites have about the same amplitude, the required instantaneous dynamic range is low and it is relatively easy to build such a receiver. If a large number of simultaneous signals need to be processed, considerable hardware will be required and the receiver can become rather complicated.

The receivers are divided by structure into two major groups: analog and digital. Comparatively speaking, analog receivers are technologically more mature. In fact, most commercial and military receivers are analog. Therefore, several techniques are used in designing analog intercept receivers that will be discussed here. Although the digital receiver is in its infancy, it is anticipated that this kind of receiver will become popular because advances in digital hardware and software can be applied to receiver design and processing.

4. ANALOG INTERCEPT RECEIVERS

This discussion is limited to radar intercept receivers. The receivers will be divided into six types depending on their structures. The first three types, which process only one signal at a time, are the crystal video, superheterodyne, and instantaneous frequency measurement (IFM) receivers. The next three types, which can process simultaneous

signals, are the channelized, Bragg cell, and compressive receivers.

In a radar intercept receiver five parameters will be measured. These parameters are RF, angle of arrival (AoA), pulse amplitude, pulsewidth, and time of arrival (ToA). Pulse amplitude is measured from the amplitude of the detected video pulse. Pulsewidth is measured from the width of the video pulse. The ToA is measured from the leading edge of the video pulse. These three parameters are measured similarly for different receivers. The AoA is measured from several antennas and receivers combined together and will not be included in this article. A digital EW receiver must also be able to generate these five parameters as output.

4.1. Crystal Video Receiver

This is the simplest analog receiver and has existed for many years. The receiver consists of an RF chain and a crystal video detector. In the RF chain there is a wide bandpass filter and RF amplifiers. Along with the detector there is a video filter, a video amplifier, and a comparator as shown in Fig. 5. Sometimes, the RF amplifiers are not available to cover the desired bandwidth or they do not have sufficient gain. Under this condition, the sensitivity of the receiver depends on the sensitivity of the detector and the tangential sensitivity cannot be calculated from Eq. (11). As a result, sensitivity will be poor. To improve sensitivity, the detector is occasionally biased in the forward direction as shown in Fig. 5. However, improving the sensitivity of the detector may decrease bandwidth. At the output of the detector a video filter will be used to limit the output bandwidth. The video filter bandwidth should match the shortest pulsed signal anticipated. For example, if the shortest pulse anticipated is 100 ns, the video filter will be approximately 10 MHz ($1/100 \times 10^{-9}$). The video amplifier is used to amplify the video level to a level that can be properly processed. Sometimes a logarithmic (log) video amplifier is used instead of a video amplifier. A

Figure 5. A basic crystal video receiver. This receiver consists of a wideband filter, an RF amplifier chain, a biased detector, a video amplifier, and a comparator. The wideband filter is used to limit out-of-band signals. The RF amplifier is used to amplify the input signal. The detector is used to change the RF signal to a video signal. The bias applied to the detector is to increase the detector sensitivity. The video filter is designed to match the anticipated minimum pulsewidth to maximize the detection efficiency. The video amplifier is used to amplify the video signal. The comparator is used to detect signals crossing a certain threshold.

log video amplifier takes a video signal as input and generates a video output that is proportional to the logarithm of the input signal. Finally, a comparator is used to determine whether a signal is crossing a certain threshold.

A crystal video receiver usually has a very wide input bandwidth and often covers a bandwidth of an octave or more. A crystal video receiver does not provide frequency information. The only frequency information is the detected signal within the input band of the receiver. The receiver can measure pulse amplitude, pulsewidth, and ToA. When simultaneous signals arrive at the input of the receiver, the receiver can receive and process all of them. However, the receiver does not have the capability to indicate the existence of simultaneous signals. The pulse amplitude measured will be the sum of the amplitudes of the simultaneous signals if the frequency separation of the signals is much greater than the video bandwidth. However, when this condition is not met, the pulse amplitude measured will be the vector sum of the signals. The pulsewidth measured will be from the first leading edge to the last trailing edge of the pulses in the group. The ToA measured will be the first leading edge of the group.

Because of its relatively low sensitivity and poor frequency accuracy, this type of receiver is no longer widely used. However, due to simplicity of the receiver, sometimes it is used to provide AoA information. The AoA information is often obtained through amplitude comparison from four directional antennas and four crystal receivers. In this application, log video amplifiers are used after the detectors. The difference between two adjacent channels is equal to the amplitude ratio due to the logarithmic relationship. The amplitude ratio can be converted into AoA information.

4.2. Superheterodyne Receiver

In the superheterodyne concept, the input signal is changed from one frequency to a different frequency while also maintaining all the signal information. This is very important to the technology, with most of today's communication receivers using superheterodyne techniques. Almost all receiver systems use this methodology at one stage or another. For example, an intercept receiver may have an instantaneous bandwidth of 1 GHz and an input bandwidth of 18 GHz. One common approach is to divide the input bandwidth into eighteen 1-GHz bands and convert each band to a common frequency range through the superheterodyne technique. The intercept receiver is timeshared among these bands to measure the input signals.

A generic superheterodyne receiver is shown in Fig. 6. In this design, the first element is a tunable filter and an RF amplifier. If higher sensitivity is desirable, an RF amplifier can be placed in front of the filter. A combination mixer/oscillator is used to change the input frequency to a different frequency, usually referred to as the IF. The IF can be either higher or lower than the input signal. If the IF is higher than the input frequency, it is called *upconversion*. If the IF is lower than the input, it is referred to as *downconversion*. The IF signal is further amplified and filtered before reaching the crystal detector. Sometimes an

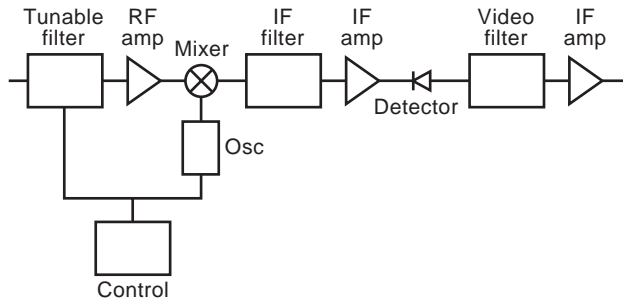

Figure 6. A basic superheterodyne receiver. This receiver consists of a tunable filter, an RF amplifier chain, a mixer and local oscillator, an IF filter, IF amplifiers, a detector, and a video amplifier. The tunable filter and the local oscillator are controlled by the same control circuit, and their frequencies are tracked to filter out unwanted input signals. The RF amplifier is used to amplify the input signal. The mixer and local oscillator combined changes the input frequency to the IF. The IF filter is used to limit spurious signals generated by the mixer. The IF amplifiers are used to amplify the IF signal. The detector changes the RF signal into a video signal, and the video amplifier is used to amplify the video signal.

IF logarithmic (log) video amplifier is used. An IF log video amplifier takes IF as input and generates a video signal proportional to the logarithm of the input. In an IF log video amplifier, many IF amplifiers and detectors are used. Each detector covers approximately 10–15 dB of dynamic range. Therefore, the amplifier can cover a wide dynamic range and provide high accuracy. Along with the detector there are video amplifiers and video filters to shape the video signal.

A mixer is a nonlinear device that converts a signal from one frequency to another. In order to change frequency the device must be nonlinear. However, in receiver design, a mixer is considered to be a linear component with a negative gain (loss) and a third-order intercept point. The desired output IF frequency f_{IF} of a mixer is

$$f_{IF} = f_i \pm f_o \quad \text{or} \quad f_{IF} = f_o \pm f_i \quad (15)$$

where f_i is the input frequency and f_o is the oscillatory frequency. The plus sign is used for upconversion; the minus sign, for downconversion. If $f_i > f_o$, the first part of the equation is used; when $f_o > f_i$, the second part is used. The input frequency is usually downconverted to a lower IF, because amplifiers and narrowband filters are more available at lower frequencies. The IF is fixed at a certain value, and the frequency of the oscillator is tuned across the input bandwidth of the receiver to find signals. Once the input signal is converted to the IF, the signal will be detected and the video signal will be processed. The frequency of the input signal can be measured from the preceding equation, because f_{IF} and f_o are known.

When the input frequency is higher or lower by f_{IF} than the local oscillator frequency, they will be detected by the receiver; these are images of each other. If the input bandwidth is not properly limited, both the signal and its image can be received by the receiver. An image rejection mixer

can be used to separate signals above the local oscillator frequency from signals below it. However, it is often desirable to limit the input band of the receiver either above or below the local oscillator frequency. Limiting the bandwidth to one side of the local oscillator frequency also reduces the noise by 3 dB.

As a mixer is a nonlinear device, many other frequencies will be generated in addition to the desired frequency. These extraneous frequencies are referred to as “spurs.” The frequencies f_i of the spurs, including the desired IF, can be determined by

$$f_i = Mf_1 + Nf_2 \quad (16)$$

where f_1 and f_2 are used to represent the input and oscillator frequencies; M and N are integers (either positive or negative) and the output frequency f_i must be a positive value. In order to limit the spurious outputs, two filters are often used in a superheterodyne receiver. An IF filter with a fixed center frequency f_{IF} is used to reject spurs at the output of the mixer. Because the input bandwidth is much wider than the IF filter, several signals present at the input of a mixer will cause it to generate spurs. A tunable filter with bandwidth comparable to that of the IF filter can be placed at the input of the receiver to limit the instantaneous bandwidth and reduce spur generation. The tunable filter and the local oscillator must be synchronized, and the difference frequency between them must equal f_{IF} . Thus, one control unit is often used to tune the tunable filter as well as the oscillator. The frequency range of the input filter and the oscillator must be wide enough to cover the input bandwidth of the receiver.

Because the filter bandwidth of a superheterodyne receiver is very narrow, the sensitivity is high. The spurious responses generated by the mixer are carefully filtered, so the dynamic range is usually high. It is relatively easy to build superheterodyne receivers with matched performance, that is, amplitude and phase, because of the narrow bandwidth. The probability of intercept of a superheterodyne receiver is low and it cannot process simultaneous signals. Therefore, a superheterodyne receiver alone is seldom used as an intercept receiver. It is often used as part of an intercept system such as one that measures AoA information through multiple antenna and receiver combinations.

4.3. IFM Receiver

An IFM receiver uses the autocorrelations function to measure the input frequency. A signal is correlated with its delayed version. The outputs are lowpass filtered to generate the desired video signals, which in turn can be used to produce the frequency information. There are many different ways to build a correlator by using different RF components such as 90° hybrids and in-phase power dividers. One common approach is shown in Fig. 7.

The input signal is divided into two paths, and in one of the paths a known delay time τ is added. Four hybrids are used to obtain the desired phase relations. The detectors are used to perform multiplication. If the input frequency is f , the outputs of the detectors consist basically of two

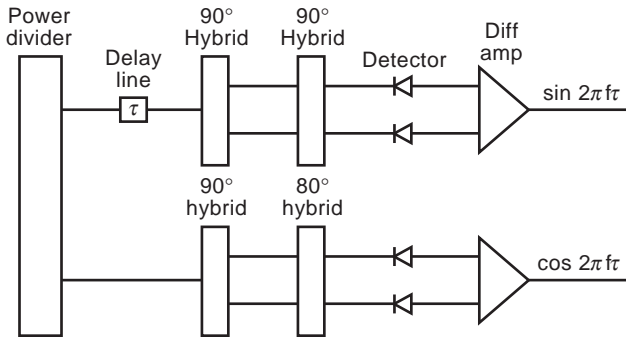

Figure 7. A correlator for the IFM receiver. The correlator consists of a power divider, a delay line of known delay time, three 90° and one 180° hybrids, four detectors, and two differential amplifiers. The power divider divides the input signal into two parallel paths, and the signal in one path is delayed by a known time. The four hybrids are used to provide the necessary phase shifts. The detectors are used to convert RF signals into video signals as well as to perform multiplication of two signals. The two differential amplifiers are used to cancel a DC bias term. The outputs from the correlator are $\sin(2\pi f\tau)$ and $\cos(2\pi f\tau)$.

terms—a double frequency term and a DC term. The outputs of the detectors are lowpass-filtered to stop the high frequency and pass the DC components. They represent the autocorrelation functions of the input signal. The differential amplifiers are used to remove a constant term in the DC components, and the outputs are $\sin(2\pi f\tau)$ and $\cos(2\pi f\tau)$. As the delay time is known, the frequency of the input signal can be found as

$$f = \frac{\theta}{2\pi\tau} \quad (17)$$

where

$$\theta = \tan^{-1}\left(\frac{\sin(2\pi f\tau)}{\cos(2\pi f\tau)}\right) = 2\pi f\tau$$

By measuring the $\sin(2\pi f\tau)$ and $\cos(2\pi f\tau)$, the angle θ can be found and the frequency can be calculated.

As the angle θ calculated from the sine and cosine is less than 2π , this relation limits $f\tau < 1$. If the desired input bandwidth is 2 GHz, the delay time must be less than 0.5 ns. Using this τ value to measure frequency, the accuracy is rather poor because of the poor angle resolution. In order to cover a wide instantaneous bandwidth and at the same time produce fine frequency accuracy, several correlators are needed. Correlators with short delay times are used to resolve ambiguity; correlators with the longest delay line provide frequency accuracy. The longer the delay line, the better the frequency accuracy a correlator can provide. The longest delay line must be shorter than the shortest pulse anticipated and must allow the pulse and its delayed version to have sufficient overlap. The delay-line lengths are commonly selected to be multiples of each other. The two common delay-line ratios are 1 : 2 and 1 : 4. Two examples will be used to illustrate these two design ideas.

To cover a 2 GHz bandwidth, it is common practice to select the unambiguous bandwidth wider than the desired value, that is, 2.56 GHz, and the corresponding shortest delay time is 0.390625 ns ($1/2.56$ GHz). In the 1 : 2 ratio case, the delay-line lengths are 1, 2, 4, 8, 16, 32, and 64, and the shortest delay line is considered as unit length. There are seven correlators in this design. In the 1 : 4 ratio case, the delay-line lengths are 1, 4, 16, and 64, and there are only four correlators. The correlators with the longest delay line have the same design in both cases and they provide the frequency accuracy (usually about 1 MHz). Decoding schemes for the other correlators are slightly different. The decoding scheme of the correlators with a 1 : 2 ratio is simpler than the ones with a 1 : 4 ratio because the former one is required to generate only 1 bit and the latter one must generate 2 bits of information. Therefore, both approaches are popularly adopted in IFM receiver designs.

An IFM receiver uses a very unique RF front-end design. The RF chain of most receivers uses linear components to avoid generating spurs and retain the amplitude information of the input signals. In an IFM receiver it is common practice to use a limiting amplifier in the RF chain. This kind of amplifier raises all signals above a certain threshold to a constant level. Therefore, amplitude information is lost with the limiting amplifier. A separate circuit must be used to measure pulse amplitude. As the limiting amplifier is a nonlinear device, it generates strong spurious responses. When two signals are present in the amplifier, the strong one will suppress the weak one. This is referred to as the *capture effect*. Because an IFM receiver can process only one signal at a time, the capture effect will enhance the receiver performance to measure the strong signal under simultaneous signal conditions.

An IFM receiver has many advantages over other types of intercept receivers. The receiver can cover a very wide instantaneous bandwidth [possibly 16 GHz (2–18 GHz)] and provide fine frequency accuracy on short pulses, for example, 1 MHz accuracy on a 100 ns pulse. As the structure of the receiver is very simple, the receiver can be very compact, low cost, and reliable. The only deficiency is that the receiver cannot process simultaneous signals. Not only is it unable to process simultaneous signals, but simultaneous signals with amplitude within about 5 dB may cause the receiver to produce an erroneous frequency report without reporting the mistake. This is considered a major problem with the IFM receiver and limits its usage. However, the concept of the IFM receiver is very important and can be adopted in many receiver designs, including digital receivers.

4.4. Channelized Receiver

A channelized receiver can intercept simultaneous signals. The basic concept is very simple. It uses a bank of filters with adjacent frequencies to separate signals. Signals with different frequencies will exit from different filters. By measuring the outputs of the filters one can determine the frequencies of the input signals. A basic channelized receiver, shown in Fig. 8, consists of four

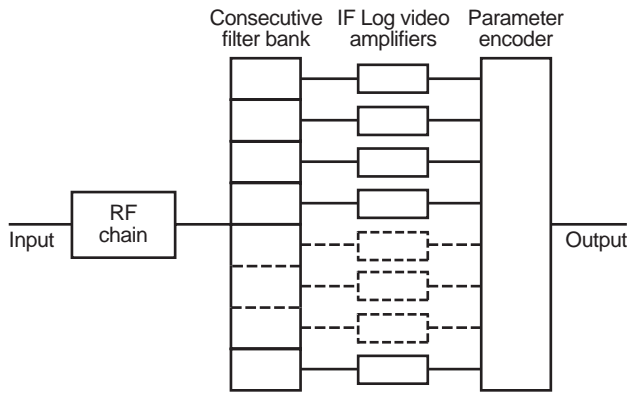

Figure 8. A basic channelized receiver. The receiver consists of an RF amplifier chain, a filterbank with contiguous filters, IF log video amplifiers, and a parameter encoder. The RF amplifier is used to amplify the input signal. The filterbank is used to separate signals with different frequencies into different output ports. The IF log video amplifiers amplify the IF signals and convert them into video signals. The parameter encoder generates the desired digital information from the input video signals.

major components. The first one is the RF chain. The second component is a filterbank with consecutive center frequencies. In order to retain the amplitude information, IF log video amplifiers are used after the filters. The last component is a parameter encoder, which takes the outputs from the filters and converts them into the desired information. These components are discussed here.

The RF chain usually consists of amplifiers, filters, and mixers to shift the input frequency. The RF chain must operate in the linear region to avoid generation of spurs. As the bandwidth of a channelized receiver is wide, some spurs generated from mixers will not be filtered out but be present in the output.

The output of the RF chain is fed to the input of the filterbank. A common way to feed the filterbank is through a power divider. Using a power divider can improve impedance matching to the filters, but they cause insertion loss. Every time a signal is divided into two paths there is a 3 dB loss. These losses must be recovered by placing additional amplifiers in the receiver. Although a frequency multiplexer is a better approach to feed the input of the filter, it is usually difficult to achieve the desired filter requirements. In each filter usually only one signal can be processed. If more than one signal is in one filter, they will be processed as one signal and may produce erroneous results. Depending on the center frequency of the filters and their bandwidth, different techniques can be used to build the filters, for example, surface acoustic wave (SAW) technology and lumped *LC* elements. The two general requirements of these filters are low insertion loss and small size. The filter must also have low sidelobes in the frequency and time domains. The required shape of the filter is usually based on the encoding circuit design.

The outputs of the filters are further amplified by IF log video amplifiers. If the amplitude information after a filter is not of interest, a limiting amplifier followed by a crystal detector can be used to convert the IF into a video signal. With only one signal processed within a filter,

intermodulation and spurs are not of concern. Therefore, in designing a receiver, the third-order intercept point in the IF channel is not of concern. If amplitude is not retained after the IF amplifiers, pulse amplitude information must be obtained from another part of the receiver.

A parameter encoder takes the video signals from all of the filters as input and produces the desired information. Most of the effort in encoder design is directed toward obtaining frequency information. There are usually two ways to obtain frequency information. One is to compare amplitudes from adjacent filter outputs. In this approach, IF log video amplifiers must be used to generate amplitude information at the filter outputs. One problem with this approach is that it is difficult to balance the gain in all the channels. If the gain from one channel changes slightly, that is, due to temperature drift, the encoder must be adjusted accordingly. Sometimes it can be a major problem in a receiver with many channels. Another approach is to detect the transient response of a filter output. If a pulsed signal passes the center of a filter, the transient effect is not significant, which means that the pulseshape is slightly distorted. On the other hand, if a pulsed signal passes the skirt of a filter, the transient effect is very significant, which means that the pulseshape is drastically distorted. By measuring the transient on the output pulse, one can determine whether a signal is in the middle or on the skirt of a filter. In this design, both limiting amplifiers and IF log amplifiers can be used after the filters. The problem with this approach is that the variation on the leading edge of the pulse can change the transient response and the performance of the encoding circuits. In some receiver designs both the amplitude comparison and transient phenomenon are used to obtain better results. The filter shape, which controls the amplitude and the transient of the video signal, is often determined from the encoding circuit design. The encoder design is the most critical element in building a channelized receiver.

In a receiver that can process simultaneous signals, there are two quantities related to frequency measurement. One is frequency resolution, which tells the receiver to separate two simultaneous signals that are close in frequency. The other one is frequency accuracy, which is related to the error in the frequency measurement. The minimum pulsewidth determines the minimum filter bandwidth, which determines the frequency resolution of the receiver. Frequency measurement must be carried out after the transient dies off. The transient is approximately equal to the inverse of the filter bandwidth. During the transient period both the shape and the RF of the pulse change. If the desired minimum pulsewidth is 100 ns, the minimum bandwidth of the filter is approximately 10 MHz and the frequency resolution is close to 10 MHz. However, the receiver can be designed with a filter bandwidth that is much wider than the minimum filter bandwidth. A wideband filter has a shorter transient time. If additional processing, that is, the concept of an IFM receiver is used, better frequency accuracy can be obtained. It is difficult to design a receiver with both high-frequency resolution and frequency accuracy on short pulses because it takes a longer time to generate a fine frequency reading. In general, the anticipated minimum pulsewidth deter-

the minimum filter bandwidth and thus the minimum frequency resolution. This design rule applies to all receivers with simultaneous signal capability.

Because the concept of channelized receivers is very simple, a general misunderstanding is that it is very easy to build. As a result, the design goals might be set too high to achieve. In general, a receiver has fewer problems when the filter bandwidth is wide because the receiver has fewer parallel channels. However, wider bandwidth means poor frequency resolution and lower sensitivity. When a high instantaneous dynamic range is desired, the receiver must detect a weak signal in the presence of strong signals. Sometimes it is difficult to distinguish a spurious response from a weak signal. Therefore, a high-dynamic-range receiver may produce a spurious signal report. When the instantaneous dynamic range requirement is low, the receiver can be designed to produce fewer spurious responses.

The input bandwidth of a channelized receiver is proportional to the number of channels and their bandwidth. When a large number of channels are built, a channelized receiver can be bulky and expensive but have better frequency resolution. If the channel bandwidth is wide, a small number of channels can cover a wide frequency range. Because the encoding circuit also has fewer inputs, the receiver can be relatively small.

4.5. Bragg Cell Receiver

A Bragg cell receiver can be considered another type of channelized receiver where channelization is accomplished by optical means. The term *Bragg cell receiver*

derives from the concept of the Bragg angle of optical diffraction. A basic Bragg cell is shown in Fig. 9. The optical arrangement will be discussed first. A laser is used as a coherent light source. A diode laser is often preferred to a gas laser because of its small size. The beam expander and the collimator are used to form the lightbeam into the desired shape to shine on the Bragg cell. A Bragg cell is used to diffract input light. A Bragg cell is made of a crystal transparent to the laser light. At one end of the crystal is a transducer to change the input electric signals into acoustic signals. At the other end of the Bragg cell is absorption material used to eliminate acoustic wave reflection to avoid the generation of standing waves. The acoustic wave produces variations in the refractive index of the crystal. This refractive index modulation causes the laser beam to deflect. The *time-bandwidth product* (TBP) of a Bragg cell is defined as the time of the acoustic wave traveling through the window of the Bragg cell multiplied by the bandwidth. The laser beam is incident on the Bragg cell at the Bragg angle where the desired diffracted light is at maximum intensity. The light output from the Bragg cell passes through a Fourier transform lens and focuses on a photodetector array. The photodetector changes the optical signal back into a video signal.

The input signal to the receiver is applied to the transducer of the Bragg cell through an RF chain containing amplifiers and filters. There is an impedance matching network to match the output of the RF chain to the input impedance of the Bragg cell. The output power from the RF chain should keep the Bragg cell operating in its linear region. High input power can drive the Bragg cell into the nonlinear region and generate spurious responses.

Figure 9. A basic Bragg cell receiver. The receiver consists of an RF chain, a laser, a beam expander, a collimator, a Bragg cell, a Fourier transform lens, a photodetector array, and a parameter encoder. The RF amplifier is used to amplify the input signal. The beam expander and the collimator shape the laser light into the desired shape. The input signal is converted into an acoustic wave in the Bragg cell to form a grating and diffract the light from the laser. The Fourier transform lens focuses the light on the photodetector array, which converts the light into video signals. The light position on the photodetector array determines the frequency of the input signal. The parameter encoder generates the desired digital information from the input video signals.

The input signal is converted into a traveling acoustic wave in the Bragg cell. The position of the diffracted light-beam on the detector array is related to the frequency of the input signal. If more than one signal is present in the Bragg cell, there will be multiple outputs on the detector array. The maximum number of outputs is equal to the time-bandwidth product of the Bragg cell. The amplitude of the output is related to the power of the input signal.

The video outputs from the photodetector array can be considered as outputs from a filterbank with adjacent frequencies. The parameter encoder takes these outputs and generates the desired information. In a channelized receiver, IF log video amplifiers or limiting amplifiers are used after the filters to provide more RF gain. To provide the same gain in a Bragg cell receiver, a light amplifier must be used in each output channel, however, such a device is not available with today's technology. Thus, the sensitivity of the receiver depends on the laser power and the characteristics of the photodetectors. A laser with higher power can be used to improve sensitivity. As the outputs from the photodetectors are video signals, some of the encoding schemes applicable to a channelized receiver may not be adopted for Bragg cell receivers. Another difference between the photodetector and the crystal detector is that the output from a photodetector is proportional to the input light power and, therefore, proportional to the input power. The output from a crystal detector is proportional to the voltage of the input signal, which is related to the square root of the input power. Therefore, a crystal detector covers more dynamic range.

Compared to a channelized receiver, a Bragg cell receiver has less dynamic range. The major advantage of a Bragg cell receiver is its simplicity and compactness. A Bragg cell receiver including the optical bench (consisting of beamforming lenses and Bragg cell), laser and detector array, but excluding the RF chain, is only a few cubic inches in size. Such a small receiver can provide over 100 parallel outputs. The size of the optical bench can be further reduced using integrated optics. In the integrated optical approach, the entire optical bench can be fabricated on a single chip. The light is transmitted through a light waveguide and the Bragg cell uses SAW technology. All optical components can be made on the chip, and the laser and detector array can be attached from the ends of the chip. Thus, the size can be a few cubic centimeters.

The Bragg cell receiver already discussed here is often referred to as the *power Bragg cell receiver*, because the detector output is proportional to the power of the input signal. In order to improve the dynamic range of a Bragg cell receiver, an interferometric approach can be used. The main goal of this approach is to make the photodetector proportional to the voltage of the input signal rather than the power. In this arrangement, the laser beam is split into two paths through a beamsplitter with a Bragg cell in each path. The input to one Bragg cell is a locally generated spread-spectrum signal covering the entire bandwidth of the Bragg cell. The input signal is applied to the other Bragg cell. The outputs of the two Bragg cells are focused on a photodetector array, and the location represents the input frequency. Each photodetector is used as an optical mixer and the output is an IF signal rather than

a video signal. Thus, IF amplifiers and filters can be used to improve the performance of the receiver. After the IF chain, crystal detectors are used to convert the IF signals into video signals. Although this approach has the potential to improve the dynamic range of the receiver, it sacrifices the simplicity of the Bragg cell receiver. Individual IF channels have to be built separately and the optical bench is equivalent to the filterbank in a channelized receiver.

As in designing channelized receivers, the parameter encoder of a Bragg cell receiver is a major portion of the effort.

4.6. Compressive Receiver

A compressive receiver can also process simultaneous signals. As opposed to a channelized receiver where all outputs are in parallel, the outputs from a compressive receiver are in series. A basic compressive receiver is shown in Fig. 10. In this figure the RF chain is not included. The two major components in a compressive receiver are the local oscillator and the dispersive delay line. The output from the local oscillator is a repetitive FM signal. The frequency range of the FM signal can be very wide and the period very short, such as 1 GHz/200 ns. This receiver is also called a *microscan receiver* because the scan time is short. The input signal after mixing with the local oscillator output is converted into an FM signal. This FM signal passes through the dispersive delay line (often referred to as *compressive line*) and is compressed into a pulse. The position of the pulse relative to the beginning of the scan represents the frequency of the input signal. The amplitude of the compressed pulse represents the amplitude of the input signal.

The instantaneous bandwidth of the compressive line is generally equal to the IF bandwidth of the receiver. The input bandwidth can be either wider or narrower than the IF bandwidth. In one common design, the local oscillator scans the sum of the IF bandwidth and the receiver input bandwidth. In order to compress the FM signal from the output of the mixer into a short pulse, the frequency-time slope of the local oscillator and the slope of the compressive line must be properly matched. In most designs, the compressive line is made from SAW technology with bandwidths of up to 1 GHz and dispersive delays of a few hundred nanoseconds. The local oscillator is often implemented from a dispersive delay line because a short pulse applied to the input of a dispersive delay line generates an FM signal at the output. This signal can be amplified and used as the local oscillator output. Because the frequency of the local oscillator is wider than the compressive line bandwidth, the requirements on the dispersive delay line to generate the local oscillator signal are more stringent. An oscillator built from a dispersive delay line is easier to match the frequency-time slope of the compressive line. The time-bandwidth product of the compressive line is defined as the dispersive delay time multiplied by the bandwidth. The maximum number of compressed pulses generated per scan is approximately equal to the time-bandwidth product of the compressive line. The maximum number of compressed pulses can be

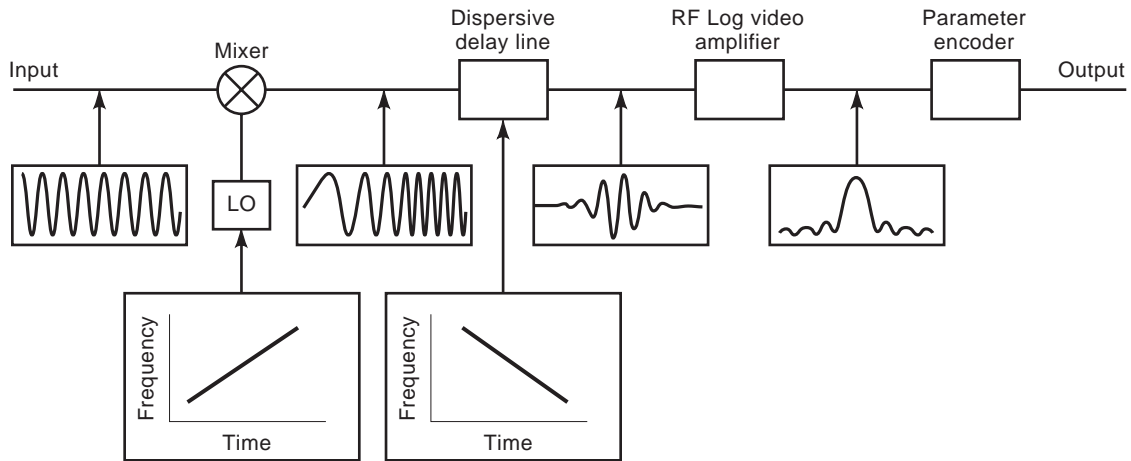

Figure 10. A basic compressive receiver. The receiver consists of a local oscillator, a mixer, a dispersive delay line, an RF log video amplifier, and a parameter encoder. The local oscillator generates a linear FM signal that changes the input to a linear FM signal through the mixer. The dispersive delay line compresses the FM signal into a short pulse. The RF log video amplifier is used to generate the logarithm from the compressed pulses. By measuring the output time of the pulse with respect to the beginning of the scan, the signal frequency can be determined. The parameter encoder converts the scan to scan information to a pulse-by-pulse information.

considered equivalent to the total number of parallel channels in a channelized receiver.

The compressed pulse is very short and is inversely proportional to the bandwidth of the compressive line. The pulse output rate equals approximately the bandwidth of the compressive line. If the bandwidth of the compressive line is 1 GHz, the pulsewidth is close to 1 ns (1/1 GHz) and the output rate is about 1 GHz. The center frequency of the pulse equals the center frequency of the compressive line. The compressed pulse has a main peak and many sidelobes. The sidelobes should be reduced to simplify the frequency encoding circuit design. The sidelobes can be reduced by adding a weighting (window) function to the compressive line. An IF log video amplifier is used to convert the compressed pulse into video pulses for further processing. The video bandwidth of the IF log video amplifier must be wide enough to accommodate the compressed pulsewidth.

A compressive receiver usually intercepts a pulsed signal in many consecutive scans. It is desirable to report the information on the intercepted signal on a pulse-by-pulse basis rather than a scan-by-scan basis. The parameter encoder will sort and combine the scan-by-scan information into pulse-by-pulse information. The outputs from each scan are the number of simultaneous signals intercepted during the scan time. From this operation, it is easily seen that the time resolution in generating pulsewidth and ToA equals the scan time. Thus, it is usually coarser than the time resolution in other types of receivers.

The main function of the parameter encoder is to find the frequency of the input signal. Because the compressed pulse output rate is usually rather high, the encoder must be able to process the signals at the same rate. Although the parameter encoder is quite different from a

channelized receiver, they face the same basic challenges: detecting the signal and avoiding the sidelobes and spurious responses. The bandwidth of a compressive receiver is limited by the technology used in the compressive line as well as the speed of the logic circuit in the parameter encoder.

There are several different ways to design a compressive receiver. One of the most common designs is to make the receiver bandwidth equal to the IF bandwidth. Under this condition, the outputs of the compressive line are present only 50% of the time. This affects the probability of intercept. If a short pulse (less than half the scan time) falls in the silent half, the receiver will miss the pulse. To improve the probability of intercept, another mixer and local oscillator can be added in parallel. The beginning of the FM signal from this local oscillator is shifted to the middle of the original one. For example, if the scan time is 200 ns, the original scan is from 0 to 200 ns and the additional scan is from 100 to 300 ns. Outputs from both channels are combined and fed into the compressive line. With this arrangement, the compressive line can have output 100% of the time. This technique is called the interlace scan. The outputs from the IF log video amplifier are in series, so less hardware is required in the parameter encoder as compared with a channelized receiver; however, operational speed is very high and matches the bandwidth of the compressive line.

The minimum pulsewidth that a compressive receiver can process is approximately equal to the scan time or half the scan time if the interlace scan is used. The frequency resolution is close to the inverse of the minimum pulsewidth. Compared with a channelized receiver, it shows that the same laws of physics govern the performance of both receivers; that is, the frequency resolution is inversely proportional to the pulsewidth.

5. DIGITAL RECEIVERS

A digital receiver consists of three building blocks: the RF chain, the ADCs, and the DSP. Once a signal is digitized the data are less affected by ambient conditions such as temperature changes. In an analog receiver, the performance of the components may change because of temperature variation and aging, while digital circuits do not have these problems. The digitized data can be processed with many different DSP approaches. Although most of the DSP are still hardwired for receiver applications, increasing the processing speed may permit changing receiver functions through software switching. Thus, the software receiver concept is becoming popular. With this concept many different receivers can be implemented using the same hardware. The software receiver idea is particularly popular for military communication receivers because of its potential versatility.

Strictly speaking, an ADC is a nonlinear device. It can be considered as a linear device for a large number of quantization levels. The discussion in the following sections is based on the linear model of an ADC. Nonlinear operation still exists if strong signals drive the ADC into saturation. Under this condition, the output of the receiver may produce many spurious responses. Special procedures must be considered to deal with this phenomenon.

To cover a wide bandwidth, the ADC must operate at high speed. The Nyquist sampling theorem requires that the minimum sampling speed be twice the information bandwidth. To cover a wide dynamic range, the ADC must have a large number of bits. The number of quantization levels is related to the number of bits b as 2^b . If the dynamic range is defined from a signal at the highest level to a signal at the lowest level, it can be readily expressed as

$$DR = 20 \log(2^b) \approx 6b \quad (18)$$

In this equation, the ADC is assumed ideal, that is, the quantization levels are uniform and there is no jitter in the sampling window. In a typical ADC, there are noise, nonuniform quantization level and sampling window jitter. An effective bit is often used to characterize a nonideal ADC. The number of effective bits is less than the actual number of bits and is defined as [2]

$$b_{\text{eff}} = b - \log_2 \left\{ \frac{\text{RMS error (actual)}}{\text{RMS error (ideal)}} \right\} \quad (19)$$

The effective bits change with frequency and have fewer bits at higher frequency. The number of effective bits should be used in Eq. (18) to determine the dynamic range. If the highest spurious response is used as the lower limit of a receiver, the dynamic range varies. However, Eq. (18) provides a simple estimation.

Digital receivers can be divided into two generic groups: narrowband and wideband receivers. Usually, one can consider a narrowband receiver to receive only one kind of signal and the receiver is not required to process simultaneous signals. For each type of signal a

narrowband receiver will be designed individually. There are exceptions to this definition. For example, a GPS C/A (coarse acquisition) code receiver has a narrow bandwidth, because the input signals have the same frequency. However, this receiver can receive multiple signals with different code. A wideband receiver can receive simultaneous signals over a wide frequency range. The input signals can be either known or unknown. For a wideband communication receiver the signals are known. For an intercept receiver the signals are unknown.

Another way of differentiating narrowband and wideband digital receivers is by the frequency tuning schemes. In a narrowband receiver, the frequency tuning is accomplished through analog means by changing the frequency of the local oscillator and selecting the proper filters. For this type of tuning, input to the ADC is usually an isolated signal rather than the full input bandwidth of the receiver. Thus, the ADC and the DSP following it can operate at a lower frequency.

In a wideband digital receiver the frequency tuning method is implemented digitally. The sampling frequency of the ADC and the following DSP must be high enough to accommodate the input bandwidth of the receiver. For example, one can build an FM radio through either a narrowband or a wideband approach. The input bandwidth of an FM radio is 20 MHz (88–108 MHz). If a single FM station is selected by analog tuning, the signal bandwidth is 200 kHz. If the sampling rate is 2.5 the signal bandwidth, an ADC with a sampling speed of 500 (2.5×200) kHz is required. If the frequency will be tuned digitally, the sampling speed must be 50 (2.5×20) MHz. Although the signal information bandwidth is only 200 kHz, the following DSP must match this operational speed of 50 MHz. The potential advantages of digital tuning are superior filter shape and flexible tuning ability.

In the following sections, a narrowband receiver with a band folding concept and a wideband channelized receiver will be presented.

5.1. Narrowband Digital Receiver

The Nyquist sampling theory requires that the minimum sampling speed be twice the signal bandwidth, not twice the highest frequency of signals. For example, the C/A code of the GPS signal is at L_1 band (1575.42 MHz) with a bandwidth of 2 MHz from null to null. The minimum sampling frequency to acquire this signal is 4 MHz, although the signal is at 1575.42 MHz. If the input bandwidth of the ADC can accommodate the 1575.42 MHz frequency, the signal can be sampled directly at slightly higher than 4 MHz. Sampling will alias the input signal to a baseband as shown in Fig. 11. In this figure the sampling frequency is f_s ; thus, the maximum unambiguous bandwidth is $f_s/2$. All the input bandwidth from 0 to $(n+1)f_s$ will fold into the bandwidth $f_s/2$. From this frequency folding property, the RF chain of the receiver should be designed with at least two bandpass filters. The first one should be placed near the front of the RF chain to reject out-of-band signals as in an analog receiver. The second filter should be placed in front of the ADC to limit the out-of-band noise generated from the amplifiers in the RF chain.

Figure 11. A sampling scheme transferring the input to baseband. The sampling frequency is f_s ; the maximum unambiguous bandwidth is $f_s/2$. A signal with bandwidth of $\Delta f < f_s/2$ in the frequency range of nf_s to $(n + 1/2)f_s$ can be transferred to the baseband of 0 to $f_s/2$ through sampling.

One can design a receiver to receive several narrowband signals separated in frequency through sampling at a proper frequency. An example will be used to illustrate this approach. The Y code of the GPS signal at L_2 band has a bandwidth of 20 MHz centered at 1227.6 MHz. If one desires to receive the C/A code at L_1 and the Y code at L_2 of the GPS signals, the total bandwidth is 22 MHz ($2 + 20$). The minimum required sampling frequency should be 44 MHz (2×22). Some specific sampling frequencies can be used to fold the two signals into the baseband. One sampling frequency is 51.6 MHz. Under this condition, the Y code is aliased to 5–25 MHz and the C/A code is aliased to 0.62–2.62 MHz. These two frequency bands are not overlapped in the baseband. In general, it is desirable to fold the two signals into separate regions of the baseband to avoid interference. If interference is not a problem, it is possible to overlap the two signals to save bandwidth. However, overlapping two signals into one frequency range also folds the noise together. The noise floor will increase at the overlap region. This concept can be extended to more than two signal bands.

5.2. Wideband Digital Receiver

The most popular wideband digital receiver is a digital channelized receiver. The basic idea is the same as it is for an analog channelized receiver—to separate the input into many parallel consecutive frequency channels. In a digital channelized receiver, the filterbank is implemented digitally. To cover a wide bandwidth and high dynamic range, the ADC must operate at very high speed and have many output bits.

The simplest way to build a channelized digital receiver is to use discrete Fourier transform (DFT) implemented using the fast Fourier transform (FFT). The FFT should operate on the input data on a continuous manner. The FFT outputs from different time intervals can be considered as the outputs of each individual filter. This technique requires the FFT to operate at high speed. If a receiver covers a 1 GHz bandwidth, the sampling speed must be above 2 GHz. Suppose that the sampling speed is 2560 MHz and a 256-point FFT can produce 256 parallel channels. However, only 128 channels provide useful information, and the other 128 outputs are the complex conjugate of the first ones. It takes 100 ns to accumulate 256 data points and the output channel bandwidth is 10 MHz ($1/100 \times 10^{-9}$ s). As the bandwidth of the receiver is 1 GHz, only the center 100 outputs will be used and the remaining 28 end channels will not be monitored. To pre-

vent missing data, the FFT must perform 256 point FFT at least every 100 ns. If any overlap of the FFT is desired, the processor must operate at a faster speed.

In general, it is difficult to match the digital processing speed to the speed of the ADCs. One common way to solve this problem is to reduce the total number of output channels, but keep the input at 256 data points. This approach reduces the frequency resolution of the receiver. For example, one can perform a 32-point FFT to reduce the output to sixteen 80-MHz channels. Under this condition, a bandpass filter will be used to limit the input bandwidth to 1 GHz, which will partially block the input of the two end channels. The input data are decimated 32 times, then each of the 8 data points will convolve with an 8-point filter as shown in Fig. 12. The coefficients of the 32 filters are obtained from decimating a 256-point filter, which is designed to shape the frequency response of the 16 filters. The 32 outputs from the filters become the input to the 32-point FFT. In order not to miss data, a 32-point FFT must be performed every 100 ns, which is a less stringent requirement than the previous case. If the FFT can operate at a higher speed, the input data can be processed in an overlap mode, that is, performing FFT every 50, 25, or 12.5 ns. This overlap mode is a common practice in channelized receiver design. Finally, the outputs from the FFT must be correctly decoded to generate the desired information. If the receiver is used to intercept radar signals, the encoder will provide the five parameters: frequency, AoA, ToA, pulse amplitude, and pulsewidth.

5.3. Hybrid Receivers

One common hybrid receiver design is to build a wideband receiver such as channelized or compressive receiver with a coarse frequency resolution. For example, one can divide the input bandwidth of 1 GHz into 10–20 uniform bands with a frequency resolution of 100–50 MHz. Once a signal is detected and its coarse frequency is measured, a narrowband receiver or receivers can be used to obtain fine-grain information on the signal. One approach is to rapidly tune a narrowband IFM receiver to measure the

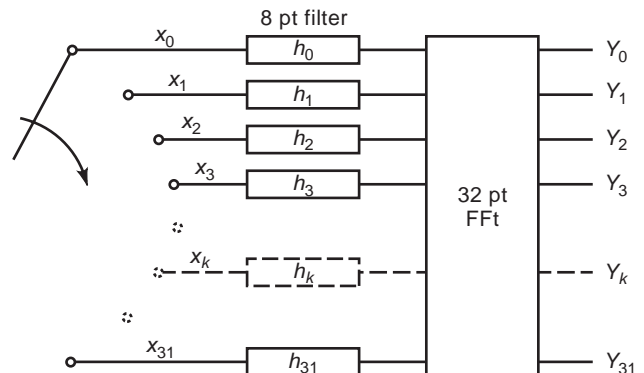

Figure 12. A 32-output filterbank using decimation scheme. The main goal is to perform a 32-point FFT with 256 input data points. The input is decimated into 32 parallel channels. In each channel, there is an 8-point filter. The output from each filter contains 8 input data points. These outputs are used as the input to the 32-point FFT.

Table 1. Receiver Performance

	Crystal Video	Superheterodyne	IFM	Channelized	Bragg ^a Cell	Compressive	Digital ^b Channel
Instantaneous BW	Very wide	Narrow	Very wide	Wide	Wide	Wide	Wide
Simultaneous signal capability	None	None	None	Good	Good	Good	Good
Frequency accuracy	Poor	Excellent	Excellent	Good	Good	Good	Good
Sensitivity	Poor–fair	Excellent	Good	Good	Fair–Good	Good	Good
Single-signal DR	Fair	Excellent	Excellent	Good	Fair–Good	Good	Good
Two-signal instant DR	N/A	N/A	N/A	Good	Fair	Good	Good
Two-signal spur-free DR	N/A	N/A	N/A	Good	Fair	Good	Good
Structure	Simple	Moderate	Simple	Complex	Moderately complex	Complex	Complex
Size	Small	Small/moderate	Small	Bulky	Small–moderate	Moderate	Bulky

^aThis represents the power Bragg cell receiver. The interferometric Bragg cell receiver performance should be comparable to a channelized receiver, but the structure is more complicated.

^bThe digital receiver is in the development stage, and performance should improve in the near future.

frequency of the input signal, because the IFM receiver can provide improved frequency resolution. Another design is to rapidly tune several narrowband receivers that are connected to different antennas to measure the AoA of the input signal. In this design, it is easier to match the amplitude and phase of narrowband receivers. It is a common practice to combine these two approaches in one hybrid receiver design. These approaches can be implemented in both analog and digital receivers. In an analog hybrid receiver design, RF delay lines must be used to temporarily store the input signal while the narrowband receiver or receivers can be tuned to the desired frequency. Wideband low-loss RF delay lines are not available and this is one of the major problems in analog hybrid receiver design. In digital design, since the digitized data can be stored easily, delay lines are no longer required. Once the basic properties of a receiver are understood, they can be combined in various ways to solve specific problems.

6. COMPARISON OF DIFFERENT TYPES OF RECEIVERS

It is difficult to compare the performance of different types of receivers. For example, one can consider a channelized receiver to be complicated if there are a large number of channels. If there are only a few channels, the receiver can be rather simple. The same argument holds for Bragg cell and compressive receivers. To make the assessment meaningful, it is assumed that the four types of receivers—channelized, Bragg cell, compressive, and digital channelized—all have the same number of output channels. The other three types of receivers—crystal video, superheterodyne, and IFM—cannot process simultaneous signals. It is also difficult to put quantitative measures on the performance. For one specific receiver this should be the correct way to present its performance. However, for one type of receiver it may be difficult to do so. For example, one channelized receiver is designed for higher sensitivity and lower dynamic range, and another one is designed for higher dynamic range and lower sensitivity. If the best performance of each receiver is reported, the results can be misleading because they cannot be achieved in one

receiver design. Therefore, the performance is listed in a qualitative manner as in Table 1.

1. INTRODUCTION

Low-temperature thermal plasmas operating at atmospheric pressure are used for a variety of contemporary plasma-enhanced technologies, such as plasma chemistry, materials processing, coating deposition, surface treatment, and waste treatment. Conventional plasma spray sources running at atmospheric pressure are based on electric arc [1] or radiofrequency (RF) [2–6]. The currently employed industrial plasma spray sources have a number of disadvantages [7], including low efficiency of energy consumption, plasma contamination, and low efficiency of precursor consumption.

Generally a microwave plasma electrodeless concept is based on using microwave electromagnetic energy in order to form and sustain a plasma discharge. There are various ways to supply the microwave energy for plasma generation [8].

Ionization of feed gases and precursors by electric field is defined by the ratio of “electric field strength to gas

pressure" [9]. Depending on a working pressure in a chamber, conventional microwave plasma discharges can be classified as follows:

- High-vacuum electron cyclotron resonance plasma
- Low-pressure microwave plasma
- Atmospheric-pressure waveguide-based setup microwave plasma

The electron cyclotron resonance (ECR) plasma is based on the cyclotron phenomenon of electrons in a static magnetic field, which allows transfer of the microwave energy to plasma. The ECR plasma operates in fairly high vacuum (10^{-1} – 10^{-3} Pa) [10–13]. The ECR can be realized through the proper combination of a microwave frequency and strength of magnetic field. The frequency of the alternating electric field is made to match the natural frequency of the electrons orbiting magnetic lines of the magnetic field. For 2.45 GHz the required strength of magnetic field is ~ 875 G. The ECR plasma has the electron density of 10^{10} – 10^{12} cm $^{-3}$ and a high degree of ionization (10%). The disadvantages of ECR plasma sources include

- Difficult process control
- Costly equipment due to the added variable magnetic field and due to high vacuum
- Low rate of deposition (~ 2 nm/min)

For example, ECR has been used for deposition of AlN [14], SiO $_2$ [15], SiN $_x$ O $_y$ [12], microwave plasma heating [16], tungsten incorporated carbon films (W-C:H) [17], and other applications.

Low-pressure microwave plasma discharge (LPMPD) runs at relatively low pressure (133 Pa–13 kPa) [13,18–22]. *Low pressure* implies more collisions between electrons and neutral molecules.

The LPMPD can be realized in either a waveguide setup, where a dielectric tube evacuated to low pressure is put through a *waveguide* [23], or a dielectric jar (or discharge chamber [24,25] evacuated to low pressure, where the dielectric jar is located inside a vessel supplied with microwave power. Quartz (or alumina) is commonly used as materials for the dielectric tube/jar.

The *waveguide* setup utilizes the standing-wave mode of TE $_{01}$. A movable plunger is used to tune the electric field maximum of the standing wave so that the maximum coincidences with quartz tube location.

The LPMPD has a few peculiarities. The electrons have a temperature of 10^3 – 10^4 K and a plasma electron density of 10^9 – 10^{14} cm $^{-3}$. The temperature of heavy particles (ions, radicals, species, etc.) in LPMPD is approximately 500 K. The LPMPD is commonly used for deposition of diamond like carbon [23,26–28], low-pressure plasma cleaning [29], and other procedures.

The *waveguide* setup of atmospheric pressure microwave plasma source is similar to that for the LPMPD. A *waveguide* plasma applicator contains quartz tube at the end of a *rectangular waveguide*. A movable short-circuiting plunger allows the adjustment of a maximum electric

field at the plasma-containing quartz tube. A trigger (tungsten rod) is an integral part of this type of plasma source in order to sustain a plasma discharge. The waveguide setup of atmospheric-pressure microwave plasma source commonly operates with 2.45 GHz *magnetrons* [30–33], but other frequencies, such as 896 MHz [34] and 915 MHz [35], are employed as well. The *waveguide*-based plasma applicator is an inherent part of fluidized-bed microwave plasma reactors operating at atmospheric pressure [36]. The ion density of the waveguide setup of atmospheric-pressure microwave plasma varies within 10^{11} – 10^{12} cm $^{-3}$ [30], $\sim 10^{16}$ cm $^{-3}$ [32,34].

From time to time other microwave plasma sources operating at atmospheric pressure are mentioned in the literature. All of them are difficult to classify in scientific terms because the basic information provided in the industry is very limited. For example, Ecotec (Taiwan) Co. Ltd. enounced a new construction of a microwave plasma surface operating at atmospheric pressure [37]. This microwave plasma burner allows one to obtain a plasma temperature near the nozzle in the range of 3000–4500 K. Plasma is produced just near the end of the central electrode (tube), then drifts outward, and microwave energy is released the gas apart from the nozzle.

2. BACKGROUND

2.1. Single Resonance Mode for Microwave Resonance Plasma Source (MRPS)

To create a required E field and ignite plasma, a high-efficiency resonance cavity with high Q factor should be designed. A *high-efficiency microwave resonance cavity* is defined as a resonant circuit element in a microwave network, where the resonance frequency of the resonant circuit element is a function of its characteristic complex impedance [38,39].

The Q factor of a high-efficiency microwave resonance cavity at the resonance frequency is described by

$$Q = \omega(\text{energy}_{\text{max stored}} / \text{power}_{\text{average dissipated}})_{\text{over a cycle}}$$

When a high-efficiency microwave resonance cavity runs and a load in the form of a plasma slab is present in the cavity, the Q factor is defined by the total energy absorbed by both the resonance cavity and the plasma slab. The plasma slab absorbs all microwave power, and the microwave energy stored by the resonance cavity is negligible small. However, when the plasma slab disappears, the microwave energy stored by the resonance cavity is maximised.

The microwave resonance cavity in question generally employs a TM $_{01n}$ mode since this mode creates a displacement current associated with longitudinal electric field E_z along the axis of the cylindrical guide. In particular, the TM $_{013}$ mode is widely used to increase the Q factor. A schematic representation of this is shown in Fig. 1, where E represents the lines of electric field and H , the magnetic lines.

Figure 1. The field configuration of the TM_{013} mode in the cylindrical resonant cavity: longitudinal section (above) and cross section (on the left).

3. MRPS DESIGN AND OPERATION

3.1. Design

The geometry of a resonant cavity is the key element in the design of the MRPS [40]. Cavity geometry will identify the resonant mode of the microwave electric field and, therefore, ensure that only the required mode oscillates the cavity's length, and the diameter should be carefully calculated. As the radius of the resonant cylindrical cavity is difficult to modify in order to optimize and tune the microwave resonance, the length (L) of the resonant cavity can be tuned with a threaded plug (6) moving it in or out during operation of the resonant cavity (numbers in parentheses refer to points in diagrams).

A block diagram of the instrumentation employed in this research is shown in Fig. 2. The actual design of the cylindrical resonance cavity is displayed in Fig. 3. The

resonant cavity is constructed of a highly conductive material, such as brass and, to reduce ohmic losses (R_s), is covered with silver. Genuine setup of the MRPS, which consists of the TM_{013} cylindrical resonance cavity, waveguide, and a magnetron (1.3 KW, 2.45 GHz), is displayed in Fig. 4. The six-port analyzer is inserted in the scheme for measurement purposes.

In order to maintain two separate chambers of the resonant cavity, a dielectric partition has been built in and hermetically sealed in order to provide vacuum evacuation of chamber 1 (Ch1). The dielectric partition allows for plasma to form only in the Ch1, limited by length l (Fig. 2). The dielectric plate is made of hexagonal boron nitride (hBN), which is transparent for microwave radiation. The hBN plate acts as a pressure-dividing baffle between the Ch1 and the chamber 2 (Ch2), which is always under atmospheric pressure. It allows a lets plasma well to form in Ch1. After evacuation of Ch1 up to 20 kPa, plasma

Figure 3. General view of the microwave resonant cavity.

begins to form under microwave radiation only in the low-pressure area (i.e., in Ch1). Once started, plasma is sustained with microwave energy only in Ch1.

The outlet nozzle was manufactured from stainless steel. It was found that the inlet geometry of the outlet nozzle is crucial because the plasma can concentrate at the sharp edges of the outlet nozzle. Stabilization of the plasma in the center was achieved by rounding the inlet profile of the outlet nozzle.

To introduce microwave energy, a magnetron launcher on the base of a standard section of WR-340 waveguide was attached to the cylindrical wall of Ch2. The aperture (12)—a symmetric iris, which can be an elliptical, circular, or rectangular slot—was used for coupling between a cylindrical cavity and a rectangular WR-340 waveguide operating in the dominant TE_{10} mode. The aperture ensures the maximum amount of microwave energy absorbed within the resonant cavity, instead of being reflected

back toward the magnetron. The optimal shape of the aperture is determined experimentally.

As in TE_{10} mode, a magnetic field component, which is parallel to the long dimensions of the slot, will be coupled through aperture. For the slot orientation perpendicular to the longitudinal z axis of cylinder, the TE_{10} magnetic field couples into the cavity, creating a magnetic field pattern within the cavity, which allows any of the TM_{01n} resonance modes to excite. When the waveguide and aperture is centrally located along the z dimension, the n mode must be even, but for odd values ($n=3$ for TM_{013}) the magnetic field is zero at that point in the cavity. Thus, the axis of the aperture should be approximately $\lambda/4$ from the ends of the cavity [38].

In order to maintain a stable plasma stream at the Laval nozzle, the gas flow should rotate within Ch1 (Fig. 5). Chamber 1 has three inlet nozzles (IN). The IN (3) are symmetrically placed close to the dividing BN plate. The diameter of the calibrated orifices must be optimized with a flowrate of gases, with power of microwave supply, plasma parameters (ion concentration, ionization ratio, etc.) for different atomic (Ar, He, etc.) or molecular (O_2 , N_2 , CH_4 , etc.) gases, and with the throat of the Laval nozzle. The IN should be directed tangentially to the wall and at a small angle of $10\text{--}20^\circ$ to the hBN plate. The plasma torch is formed from the Laval nozzle (5), which can have channels (5) for supplying powders/precursors into the plasma torch. Chamber 1 can have channels (4) for introduction of precursors directly into plasma slab.

The inlet and outlet can be optimized. The gases used are considered to be ideal, and the gas flow through the nozzles is isotropic. For a standard converging-diverging nozzle, the plasma flow is optimized when the plasma velocity at the throat is at the speed of sound. This condition is known as “shocked flow.” For shocked plasma flow, the velocity of the plasma after the throat in the diverging section of the nozzle will continue to increase until the pressure is equal to the ambient outlet pressure. For optimized or shocked flow, the point at which the diverging section of the nozzle ceases to accelerate the flow is dependent on the half-angle of the outlet nozzle and the length of the nozzle. The actual values of the length of the exhaust nozzle can be found only by experiment. The flow may also fluctuate due in proportion to the temperature fluctuations within the resonant cavity and the ambient outlet conditions.

Figure 4. Experimental setup of the microwave resonance plasma source.

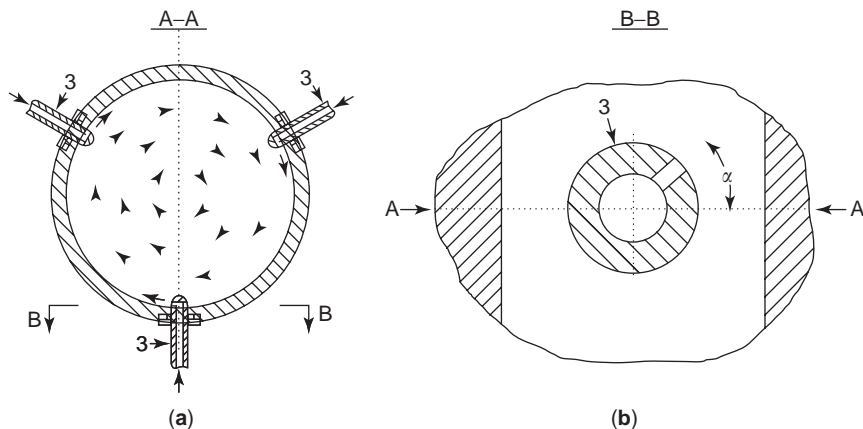

Figure 5. A cross-sectional view (A-A) of the plasma outlet chamber in place of connection of three calibrated orifices (see A-A cross section positioned in Fig. 2).

The MRPS makes available a required ionizing electric field density for plasma discharge and uses microwave energy to produce expanding plasma, which is directed through the convergent-divergent nozzle. Plasma acts as a resistive load that absorbs the incident microwave energy and dissipates it as thermal energy, which is transferred to a flowing gas. It is common to refer to this type of plasma as a “free-floating plasma” since it is located at regions of maximum electric field density within the interior of the cavity and does not have to be attached to an interior solid surface of the resonance cavity.

The MRPS design with the rectangular waveguide for transmission of microwave energy in Ch1 has a number of major advantages:

- It is easy to adjust during MRPS operation.
- Less manufacturing is required.
- It has higher power-handling capability.
- It is more efficient (lower loss per unit length of microwave transmitter).

3.2. Operation

The microwave plasma torch is a flamelike discharge and has a central plume (Fig. 6a). The plasma torch shown in

Fig. 6b is formed from the Laval nozzle (Fig. 6a). The microwave energy is coupled into the resonant cavity via a *rectangular waveguide* and a carefully designed aperture for the best coupling. Tuning can be accomplished by adjusting the position of the fine-tuned piston (6) (Fig. 2). With the piston set near its optimal position, the plasma can be ignited easily with a short burst inside the cylindrical resonance cavity (Fig. 6c).

In maximum region of electric field density, ionization of a carrier gas occurs, producing a microwave resonance-induced plasma discharge. Ionization of a carrier gas by electric field is dependent on the ratio of “electric field strength to pressure (i.e., the E/p ratio). The MRPS discharge will be maintained when the production of newly ionized species scarcely is equal to the rate of losses, namely, recombination and formation of torch.

For ignition of plasma, the exhaust nozzle is capped (Fig. 3) and the air is evacuated from the chamber 1, and then microwave power is introduced to the resonant cavity. After the formation of plasma in Ch1, a fore-vacuum pump is disconnected and the carrier gas begins to flow into Ch1. On the commencement of flow into Ch1, the plasma coalesces and moves toward the outlet nozzle. Once atmospheric pressure is achieved in Ch1, the nozzle cap is removed. From this moment, the microwave

Figure 6. (a) Top view of the plasma torch at atmospheric pressure; (b) side view of the plasma torch at atmospheric pressure; (c) a plasma slab of MRPS operating at atmospheric pressure in plasma-forming chamber.

resonance plasma torch begins to run. Adjustment of the length (L) of the resonant cavity would also occur to maximize the microwave power absorption.

A typical position of the MRIPS is stabilization of the plasma slab at the center of the Ch1 touching the Laval nozzle. The plasma would concentrate at the edge of the outlet nozzle, and swirl in the same direction as the inlet swirl.

4. COMPARISON OF MICROWAVE PLASMA SOURCES

4.1. Equivalent Circuits of Microwave Plasma Sources

4.1.1. Waveguide Setup Plasma Source. An equivalent scheme of *waveguide*-type plasma reactor is shown in Fig. 7. In this equivalent circuit the distributed-circuit parameters are given in the form of equivalent lumped impedances.

Typically, the impedance of the plasma column can be represented by two parallel inductive and active resistances as a central part of a T-shape equivalent scheme in which the symmetric lumped complex impedances Z_1 and Z_2 depend on the geometric dimensions of the *waveguide* and discharge tubes. It is important that the impedance of plasma torch depend on the temperature, pressure, gas flow, and absorbed microwave power. A lossless shorting plunge is represented by shortcut transmitted line with impedance:

$$Z_s = jZ_0 \tan(2\pi d / \lambda_g)$$

where

- Z_s = impedance of the shortcut line
- Z_0 = characteristic of the shortcut line
- d = length o the line
- λ_g = wavelength

To get the maximum value of electric field in the required plasma location ($\leq 20,000$ V/m in the standard WR-340 waveguide at 2.45 GHz), l is usually equal to $(2n + 1)\lambda_g/4$, where n is an integer, so $Z_s \rightarrow \infty$, which is approximately analogous to the open-circuit line. Analysis of this equivalent circuit shows that before plasma have been generated, the input impedance of this system Z_{in} approaches to infinity, as it equals to the series connection of lumped complex impedances Z_2 and Z_s .

The starting plasma is rather difficult because there are no free electrons that act in response to the E field. Incident microwave power is not absorbed by cold gases and is almost completely reflected. The corresponding reflection coefficient rises to $|\Gamma| = 0.95$. Consequently, at atmospheric pressure the microwave discharge in this type of plasma source can be generated and sustained only by a trigger (such as tungsten rod), which is an inherent part of this type of plasma source. Moving off the tungsten trigger leads to sparking of the plasma discharge; therefore, this plasma discharge is classified as a trigger-sustaining plasma. After plasma was generated, the incident power begins to be partially absorbed by the plasma column; however for this type of plasma source, the reflection coefficient still remains high up to $|\Gamma| = 0.5$, so almost 25% of the power is reflected [5]. The Q factor of this type of plasma source is evaluated at ~ 100 – 500 for 2.45 GHz.

4.1.2. Waveguide-to-Coaxial Setup Plasma Source. Generally, this form of plasma generator is used as a coaxial line which has a characteristic impedance lower than that of waveguides. As a result, it is more easy to transform the coaxial plasma apparatus impedance and to match it with the characteristic impedance of a waveguide without much reflection. In this type of plasma source, the waveguide-to-coaxial transformer is loaded by the plasma chamber at the end of the coaxial line. The *coaxial line* is connected to the broadwall of the *waveguide* with its outer conductor terminating on the wall. Another end of coaxial line is connected with various kinds of the plasma discharge chamber. One end of waveguide is connected to power source and another to the lossless shorting plunge. One such configuration of the waveguide-to-coaxial type of plasma source together with an equivalent lumped circuit and an equivalent circuit with distributed circuit elements is shown in Fig. 8.

Equivalent circuits for coaxial line loaded with plasma chamber to *waveguide* junction connected to microwave generator is composed of complex impedances Z_1 , Z_2 and Z_3 and, which are characterize electromagnetic field behaviour and power losses due to evanescent higher-order modes that are exited at each of discontinuity, and power losses due to active losses in waveguide-to-coaxial junction. The equivalent scheme also comprises the lumped impedance of coaxial plasma structure Z_p , and Z_s —the impedance of the waveguide transmitted line with shorting plunge [41].

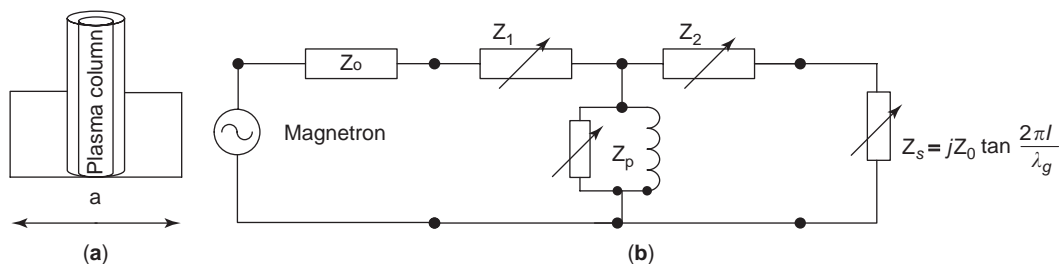

Figure 7. Equivalent scheme of waveguide array plasma source: (a) sketch of plasma slab; (b) equivalent circuit.

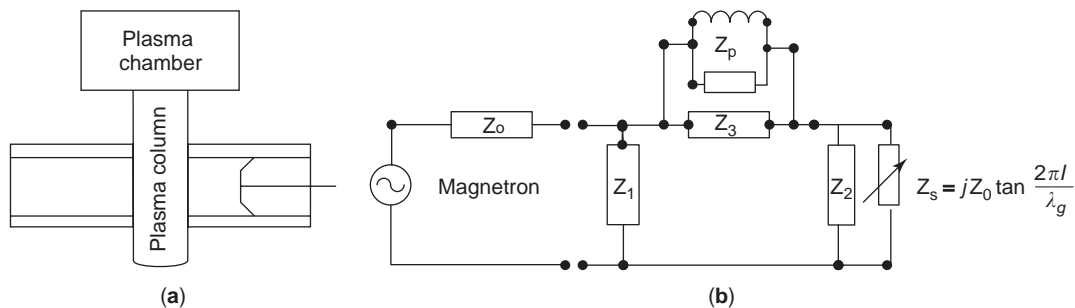

Figure 8. Equivalent circuit with distributed circuit elements.

Figure 8b shows that lumped plasma formation impedance is included in series in the transmitted waveguide; thus there is a very narrow band of impedance matching in order to ignite the plasma. Furthermore, any random destabilizing processes exert influence on absorption of microwave energy by plasma and cause reflection of microwave power. Thus, this kind of microwave plasma design also requires constant sparking ignition.

4.1.3. Microwave Resonance Plasma Source. There is a different scenario when plasma starts inside the high-*Q*-factor resonance cavity [42]. The equivalent scheme comprises the lumped complex impedances Z_1 , Z_2 related to impedances of iris and impedances of high-*Q*-factor resonance cavity X_r , L_r , R_r and the lumped complex impedance of plasma column Z_p , which depend on various factors such as temperature of plasma, gas flow, pressure, and absorbed power, (Fig. 9).

This MRPS uses microwave energy to generate self-sustaining plasma within the resonance cavity that is directed as a plasma torch through a convergent-divergent nozzle. A cold gas passes through the cavity, is ionized and heated by microwave power, and passes out of the cavity through a nozzle to produce the plasma torch.

4.1.4. Equivalent-Circuit Parameters. There are two major theoretical techniques for obtaining the equivalent circuits constants: the energy methods and the admittance methods. The first method analyses energy stored by the circuit's elements followed by a description of equivalent "intrinsic" inductance, capacitance, and resistance. Admittance/impedance method considers voltage and current across the microwave circuit elements and conse-

quently computes the characteristics of the equivalent-circuit elements. The equivalent circuits of stable, passive, and geometrically simple elements can be obtained relatively easily by integrating the electromagnetic field inside the microwave system, using the energy methods or admittance method [43]. But obtaining the equivalent microwave plasma circuit parameters with non-regular-shaped microwave elements and with randomly changing reflected and absorbed by plasma microwave power is usually complicated.

Some researchers applied method of "geometric similarity," when the equivalent complex impedance of part of the plasma column within the waveguide can be found by analogy with the ideally conducting metal rod. In the same approach the equivalent parameters of holes in the wider walls of waveguide, capacitance between plasma column and waveguide walls, and impedance of other elements of scheme were calculated [5]. However, in real discharge systems, width and temperature of the plasma column differ from point to point and can be represented as a lossy dielectric rather than ideal conducting metal rod; therefore, it seems inappropriate to use the method of "geometric similarity" in the GHz frequency range because the wavelength becomes comparable to the waveguide system dimensions, and what geometrically appears to be inductance can possess strong resonance properties in real system.

The most accurate methods used to obtain characteristics of the equivalent scheme is waveguide/cavity perturbation technique, which is one of the most important and widely used techniques to study the microwave impedance of materials and devices and offers both qualitative and fairly accurate quantitative information for engineering purposes [44]. However, even this highly

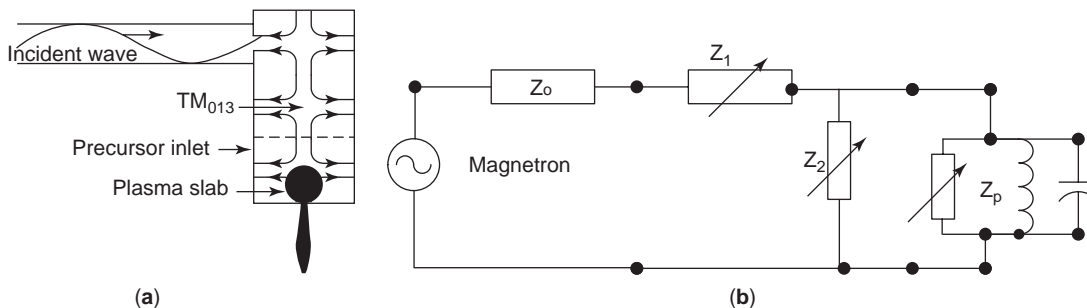

Figure 9. Equivalent scheme of resonance plasma source.

sensitive and relatively simple technique cannot be applied to nonstable, irregular, and fluctuating plasma when most of or all parameters of the equivalent scheme of plasma sources are interdependent and are similar with respect to absorbed power, temperature, type of gas, flow-rate, and so on.

4.2. Incident/Reflected Microwave Power

Because of high rate of electron collisions with neutrals and ions, the plasma in the MRPS is resistive and inherently absorptive. Since the plasma occupies the region where most of the electric field energy is stored in the cavity, the resistive plasma discharge exerts a strong damping on the cavity by absorbing approximately 98% of the incident microwave power (Fig. 10) and transforms the microwave energy into thermal plasma, which is transferred to the flowing gas. Thus, the plasma transforms the cavity from a high-*Q* to a low-*Q* cavity, and any disturbing factors that render the plasma unstable will again increase the *Q* factor of the resonance cavity. Therefore, increasing the electric field sufficiently reignites the plasma. As evaluated [5,45], the coefficient of microwave power

absorption for the nonresonance plasma sources very seldom surpasses 50%.

4.3. Smith Chart

The *Smith Chart* (Fig. 11) illustrates the differences of microwave plasma discharges generated in the resonance microwave plasma source (Fig. 9) and in the nonresonance plasma source (Figs. 7 and 8). In resonance design, the impedance point shifts to the center of the Smith chart (Fig. 11a) after the plasma is ignited and the operation spot is located predominantly, around “1.” In the waveguide, coaxial-to-waveguide, or coaxial design, the operating conditions are randomly distributed throughout Smith chart (Fig. 11b).

4.4. Stability of Microwave Plasma Sources

The most significant feature of these microwave plasma sources is their stability [42]. Therefore it is very important to analyze an influence of disturbing factors, such as gas flow instability, pressure, and absorbed power, doping mass and flow variations, on the main types of microwave plasma sources.

Figure 10. Incident/absorbed microwave power (a) and coefficient of absorption (b) as a function of time for the MRPS.

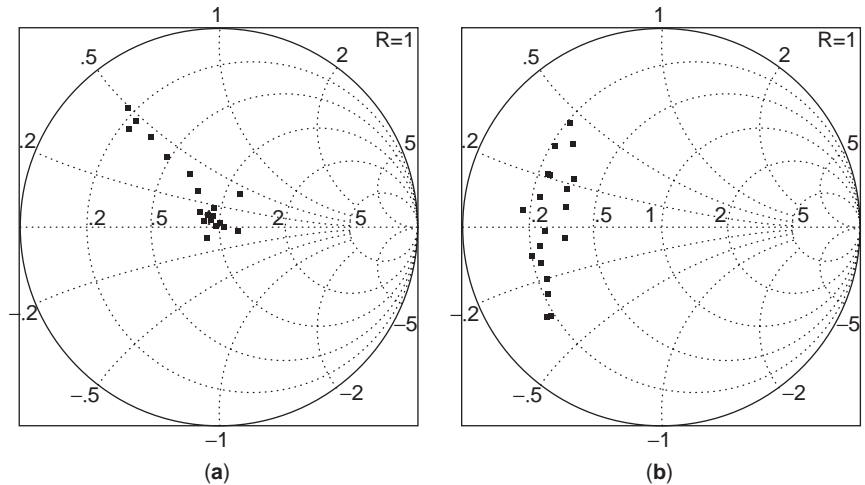

Figure 11. Operational points of resonance (a) and nonresonance (b) plasma sources on Smith chart.

The problem with plasma discharge stability can be solved by analysis of current–voltage characteristics [5]. As a result, the stability criterion was formulated as a rising current–voltage characteristic of the load or by considering the gradient of functional dependence of the required power and the plasma column admittance. But analysis of plasma source performance by considering the plasma source’s equivalent scheme is unreliable as there are uncertainties in parameter calculations and in definition of voltage and current in microwave schemes.

To analyze the instability effect of any of the perturbation factors (temperature of plasma, gas flowrate, pressure, etc.) on plasma sources performance the *Q*-factor method was proposed and applied [42]. If we describe perturbation injurious effect of any of the influencing quantities as *P*, so any change in perturbation factors will represent the absolute value $|\Delta P|$. Now the criterion for stability (*S*) of plasma design can be expressed as

$$S = \delta Q / (\delta |\Delta P|) > 0$$

Thus, when energy stored in the system is increased with a change of any of the influencing quantities, the microwave plasma source will be stable and self-sustained. Therefore, if the stability factor $S > 0$, any injurious effects of the influencing conditions, which cause the plasma to become unstable, will again increases the *Q* factor of the resonance cavity, thus increasing the electric field sufficiently to reignite the plasma.

For illustration, let us consider the conventional low *Q*-factor waveguide setup plasma source (Fig. 7). It is useful

to represent a plasma slab as a “quasidielectric rod” integrated in the microwave system with absorbed microwave power depending on type, pressure, flowrate of gases, and other parameters.

For this type of design, there is a very narrow interval of parameters in which plasma can exist and be stable. Any interchange in condition will result in changes in impedance matches and power balance. For example, when the plasma temperature increases as a result of any destabilizing factors, the concentration of charged particles in plasma increases so that the active component of the plasma column impedance changes. This in turn increases the reflection from the plasma slab. As a result, the *Q* factor of the system and, therefore, the absorbed power decrease, stability factor $S < 0$, that renders plasma generation unstable. When the plasma temperature decreases under the influence of fluctuating factors, the local electric field as well as absorbed microwave power decreases and the plasma extinguishes, and the stability factor $S < 0$. This kind of plasma source requires high stability of the external parameters or a constant “ignition” such as the tungsten trigger.

The microwave plasma stability in the MRPS and in the waveguide setup plasma source can be compared with equilibrium between a ball in a valley and on a hill. Like the MRPS, any destabilizing factors (ΔD) return the ball to equilibrium position (Fig. 12a). In case of the MWTPS, the destabilizing factors (ΔD) move the ball away from the equilibrium state (Fig. 12b).

Stability of MRPS, intensity of microwave power absorption, and the size of a plasma slab have been

Figure 12. Mechanical analogy of plasma stability in the MRPS (a) and the waveguide array plasma source (b).

investigated, depending on type and flowrate of the gases (air, CO₂, N₂, He, etc.) [46]. It was revealed that the volume of microwave plasma slab for given applied microwave power is inversely proportional to ionization potential of applied gases and their flowrate. Because of peculiarities in MRPS design, a precursor mixture totally passes through the plasma stage, significantly enhancing the efficiency of the MRPS in comparison with microwave waveguide-type plasma sources.

5. SOME PLASMA CHARACTERISTICS OF MRPS

A chemical kinetic modeling of the MRPS action on CO₂ reduction was realized [47] on the basis of experimental data published earlier [46]. The software CHEMKIN [48] was employed for modeling the chemical kinetics. The plasma model was built up. It was shown [47] that the predicted electron (T_e) and ion (T_i) temperatures are very close at ~ 7000 K for this case [46]: $T_e \approx 7500$ K and $T_i \approx 6500$ K when the gas mixture flow is around 2 L/min. Therefore, this plasma can be classified as thermal plasma with a temperature of approximately 7000 K. These calculations predicted that the nonthermal effect (i.e., $T_e \approx 7500$ K and $T_i \approx 2500$ K) becomes remarkable when the gas flowrate is > 10 L/min. At a flowrate of 100 L/min, the predicted temperatures electrons and ions were $T_e \approx 6500$ K and $T_i \approx 500$ K respectively, which corresponds to the nonequilibrium plasma state.

6. ADVANTAGES OF MRPS

The MRPS has a number of advantages over a conventional thermal plasma sources (arc plasma, RF plasma, etc.) in that no electrodes are necessary. No electrodes are needed for the generation of the microwave resonance plasma that eliminates a potential source of the plasma contamination. The absence of a cathodic sheath with high potentials leads to a very-low-energy ion bombardment of a given surface, minimizing surface damage. The MRPS provides a downstream plasma torch unidirectional-acting on surfaces that allows surface engineering of 3D-shaped workpieces, which have to be rotated.

Incorporation of waveguide for introduction of the microwave energy into the resonant cavity has a number of advantages over the design using the coupling probe connected to a coaxial cable, namely:

- Noncontaminating plasma source
- Easy to adjust during MRPS operation;
- Simpler and cheaper design (coaxial is more expensive than waveguide)
- Less manufacturing required
- Higher power-handling capability;
- Higher efficiency (lower loss per unit length of microwave transmitter).

The novel MRPS described is a synergy of microwave technique and a technique intended for materials processing, plasma chemistry, plasma surface treatment, plasma

sterilization, and other applications. Microwave technology, together with materials science, promises research opportunities with great potential in areas such as nanotechnology, composite materials, and biomaterials. Potential benefits include enhanced performance, extended life, cheap lifecycle costs, reduced environmental impact, improved cost-effectiveness and value-added use of materials through advanced manufacturing.

7. POTENTIAL APPLICATIONS OF MRPS

7.1. Surface Treatment

The microwave resonance plasma technique proposed in this research of both deposition of coatings and surface treatment at atmospheric pressure has great potential in surface engineering. It is common to use a conventional plasma spray technology for coating at atmospheric pressure [7]. A plasma surface treatment (nitriding, oxinitriding, nitrocarburizing, etc.) is applied mostly by vacuum-based methods such as direct-current glow discharge (DCGD), and plasma immersion ion implantation (PI³).

In order to demonstrate the possibility of the novel MRPS for surface treatment by nitriding and oxinitriding, typical materials such as titanium with a microhardness of 300–350 VH₅₀ and its alloys, stainless steels 304 and 316 and mild steel 5140, were chosen for nitriding by MRPS at atmospheric pressure [40,49]. Operational MRPS parameters for nitriding/oxinitriding were incident power 800–1000 W and gas flow 1–5 L/min. The gas flowrates of nitrogen and air were controlled by flowmeters accurate to approximately 5% of the maximum flowrate. The MRPS creates a stable plasma torch of 3–6 cm long.

The steel 5140 of chemical composition [(0.38–0.45)C, (0.15–0.35)Si, (0.7–0.9)Cr] and stainless steels, 305 and 316 were nitrided by the MRPS. X-ray and metallographic investigations of the nitrided layer on the steel surface showed the formation of the amorphous layer (Fig. 13a). Nitriding of steel 5140 in pure nitrogen plasma starts at $\sim 50^\circ\text{C}$ of the substrate. Temperature increase of the substrate up to 100°C leads to transformation of nitriding to oxinitriding. This transformation is accompanied by changing of color from light orange to dark pink. Above 100°C of steel 5140 substrate, the surface nitriding transformed to oxidization and the color of the oxidized surface became violet. Stainless-steel 304/316 substrates

Figure 13. Scanning electron microscopic cross sections of 5140-steel (a) and Ti (b) after microwave plasma nitriding at atmospheric pressure.

commenced nitriding at $\sim 60^\circ\text{C}$. Above 150°C , the stainless steels started to oxidise, and the surface acquired a violet color.

The MRPS nitriding demonstrated that the Ti surface exhibits a somewhat distinct “golden” color that is characteristic of titanium nitride. Diffusion of implanted nitrogen seldom occurs in the operative temperature range of the DCGD and the PI^3 , because of the affinity of Ti for nitrogen. In case of the MRPS nitriding, the proper layer of TiN_x with a hardness of $\sim 1500 \text{ VH}_{200}$ is formed on the Ti surface (Fig. 13b). It was observed that a thin surface layer (5–10 μm) of X-ray amorphous TiN was formed immediately. The introduction of (21 vol% of O_2 and 79 vol% of N_2) into the MRPS had no significant effect on the performance of the nitrided layers for the given air plasma.

Titanium begin to nitride at $\sim 100^\circ\text{C}$ of substrate. This Ti nitriding transformed to oxidization and the treated Ti surface became violet above $\sim 200^\circ\text{C}$. Addition of oxygen (up to 21 vol% of O_2) to the pure nitrogen plasma shifted the starting temperature of nitriding ($\sim 60^\circ\text{C}$) for steel 5140 and at $\sim 100^\circ\text{C}$ for stainless steels 304/316. In the case of Ti, nitriding started at $> 120^\circ\text{C}$. Transitional temperatures, from which oxinitriding passes to oxidizing, became lower, such as $\sim 75^\circ\text{C}$ for steel 5140, $\sim 115^\circ\text{C}$ for stainless steel (SS) 304/316, and $\sim 175^\circ\text{C}$ for Ti.

Reflectance Fourier transform infrared (FTIR) spectroscopy was employed to study the changes in chemical composition of the nitrided layers. In particular, the reflectance FTIR spectra of steel 5140 nitrided by the MRPS are displayed in Fig. 14. The maximum absorption (~ 0.7) of the nitrided layer is reached at $\sim 1400\text{--}1600 \text{ cm}^{-1}$. The band, where absorption is more than 0.5, is between 1700 and 1000 cm^{-1} .

FTIR spectroscopy of conventionally plasma (ion) nitride steel 5140 by direct-current glow discharge (DCGD) detected the strong absorption (> 0.5) within the range of $800\text{--}2000 \text{ cm}^{-1}$. Absorption (~ 0.85) peaked

at $\sim 1150 \text{ cm}^{-1}$. Comparing these spectra, one can note the significant differences between plasma–material interaction for MRPS and that for the conventional DCGD, creating an equilibrium nitrided layer consisting of microcrystalline nitrides on surface.

Titanium surface nitrided by MRPS radically differs from that for steel 5140. An intense absorption peak was detected at approximately 850 cm^{-1} . The MRPS nitriding forms a sharp band of nitrogen–titanium bonding.

7.2. Amorphization and Nanostructuring of Surface

The MRPS operating at atmospheric pressure [50] allows the modification of a microcrystalline surface structure, which becomes amorphous to X-rays [51]. In particular, the X-ray amorphous nitride layers were formed on the surfaces of Ti, SS 304, SS 316, and plain steel 5140 [50–52], using a nitrogen-based mixture for the MRPS. Generally, it is possible to alloy the amorphous layers by boron, carbon, chromium, and other elements by employing appropriate precursors in both gaseous and solid state.

This ability of novel MRPS to amorphize a surface microcrystalline layer up to $\sim 10 \mu\text{m}$ thick, combined with alloying, was used in this study to transform an original microcrystalline surface layer into a nanocrystalline state via an amorphous state. The novelty of this research is to amorphize a microcrystalline surface by MRPS. The subsequent heat treatment in order to transform the metastable amorphous phase to a nanocrystalline state is described in Ref. 53.

7.3. Nanostructured Biomaterials

A feasibility study of plasma nitriding/oxinitriding has demonstrated that a novel low-cost plasma torch developed on the basis of the microwave resonance phenomenon can be practical for nanotechnology [45,54], in particular for bioengineering coatings such a nanostructured

Figure 14. FTIR spectra of 5140 steel treated by the novel MRPS nitriding and the conventional DCGD nitriding. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

zirconium/titanium oxide, carbyne-containing nanocomposites [55–58], diamondlike carbon, and carbon nitride.

Novel materials are required for cardiovascular therapies, such as replacement of blood vessels and heart valves and the provision of devices that intimately contact components of the cardiovascular system, for example, dialysis and oxygenation membranes, interventional catheters, and cardiovascular stents. Improved biocompatibility of these implants could result in patients requiring lower doses of medication to prevent blood clotting.

MRPS allows the deposition of nanostructured biomaterials and coatings on metal/nonmetal surfaces using a variety of carrier gases and the precursor materials, which can be powders, liquids, or gases. This technology is also capable of surface engineering of complex 3D shapes that might be required for artificial implants. Advantages of the proposed method overall include an enhancement of biocompatibility and extended service life of artificial implants.

One current trend in biomedical applications is to use novel carbon-based biomaterials. Carbynes, which possess a higher degree of biocompatibility and low litho- and thrombogenic activity [59], have shown promise in modifying coating on a surface of biocompatible material for use in reconstructive surgery. For example [55,57,58], nanocomposite coatings (nc-W₃C/nc-carbynes) containing carbynes as a binder demonstrated a high hardness (35–40 GPa), chemical inertness, a low friction coefficient (0.1–0.12), and excellent biocompatibility.

7.4. Plasma Chemistry

Environmental pollution by exhaust/flue gases is a topical subject of the greenhouse effect. For example, a petrol engine, which consumes of ~14 L of liquid petrol per 100 km, throws ~38 L/s of exhaust gases. Currently, an incredible amount of effort has been undertaken to reduce such emissions and has been responsible for the longstanding interest in the theoretical and experimental research of plasma exhaust/flue gas treatment. Currently it is suggested that microwave plasma treatment of exhaust/flue gases is able to solve the problem of exhaust/flue gas environmental pollution. Exhaust gases represent a multicomponent gaseous system. After, the combustion of petrol, which consists of ~96% of octane [CH₃·(CH₂)₆·CH₃], exhaust gases correspond predominantly to a mixture of vapor (H₂O), carbon dioxide (CO₂), and nitrogen (N₂):

Nitrogen is the ballast gas component because air, which is used for combustion, is a mixture of oxygen (~20 vol% O₂ vol%) and nitrogen (~80 vol% N₂). Nitrogen amounts to 75% of total volumetric portion of exhaust gases: CO₂-H₂O-N₂ ≈ 1–1–6. These three gaseous components define microwave plasma chemistry treatment of exhaust gases. Small additions of oxygen (2–5 vol%) and carbon monoxide (~0.15 vol%) play a minor role.

Figure 15. Volumetric portion of gases before (BP) and after (AP) plasma treatment of carbon dioxide as a function of CO₂ flowrate.

The microwave plasma chemistry of the CO₂-H₂O-N₂ gas system is important for technical application. In particular [46], an attempt was made to investigate the plasma chemistry of the gas mixture of CO₂-N₂ and CO₂-H₂O as potential precursors for a coating deposition of superhard carbon nitride, diamondlike carbon, carbyne-based nanocomposites, and other compounds.

The results of the microwave plasma chemistry experiment are shown in Figs. 15–17. As can be seen in Figs. 15 and 16, carbon dioxide decomposes on carbon monoxide and oxygen. According to the formula CO₂ ⇒ CO + 0.5O₂ (ΔH = 29.78 kJ/mol), two decayed molecules of CO₂ create two molecules of CO and one molecule of O₂. Comparison of the experimental volumetric portions of the gases after microwave plasma treatment (Fig. 15) reveals good agreement between these experiments with the equation given above. Visible traces of solid carbon isolated in any form have not been detected.

This scenario changed radically when nitrogen was added on a ratio of CO₂-N₂ = 6. Yield of CO increased significantly. Every alternate CO₂ molecule was dissociated. Visible traces of solid carbon were not detected. The most unexpected result was that the addition of nitrogen

Figure 16. Volumetric portion of gases before (BP) and after (AP) plasma treatment of (N₂ + CO₂) mixture as a function of (N₂ + CO₂) flowrate where N₂/CO₂ ≈ 6.

Figure 17. Concentration of nitrogen oxides after plasma treatment of N₂ + CO₂ mixture as a function of (N₂ + CO₂) flowrate where N₂/CO₂ ≈ 6.

initiated an extra yield of carbon monoxide. As stated earlier [5], a small addition of nitrogen does not affect the yield of carbon monoxide. In this case, the CO yield increases in by a factor of 1.5.

Nitrogen oxides are inherent byproducts of microwave resonance plasma treatment when a gaseous mixture contains nitrogen and oxygen in any combination. Nitrogen oxides are usually formed in plasma at temperatures exceeding 2000°C. In the course of the experiments (Fig. 17), the concentration of nitrogen oxides increased in proportion to the volumetric portion of nitrogen and carbon dioxide beyond the upper limit of 4000 ppm (particles per million) when NO_x was measured using a gas analyzer [46].

The experiments showed a very rapid decomposition of carbon dioxide into the main stable species CO and O₂. Comparison of the decomposition of carbon dioxide without and with nitrogen addition revealed that the ratio between carbon monoxide and oxygen is altered by a factor of 1.5 at steady state.

The characteristics of atmospheric pressure microwave resonance plasma chemistry of carbon dioxide are

- No visible dissociation of carbon dioxide up to solid carbon in any form when using the gas mixture of CO₂ + He
- Effect of increasing the yield of CO by a factor of 1.5 when using nitrogen addition to gas mixture of CO₂ + He

8. EVALUATION

The design of the novel MRPS source based on the TM₀₁₃ mode has a number of advantages over the conventional plasma spray sources, including

- High (~98%) efficiency of microwave energy consumption
- High efficiency of precursor consumption
- Simple and reliable design
- Noncontaminating thermal plasma source

- Ease of operation
- Variety of carrier gases for thermal plasma
- Selective surface treatment/coating
- Operating at atmospheric pressure
- Stability of the plasma torch
- Reliability of the MRIP source
- No inherent problem of erosion (no electrodes)
- Low capital and running costs
- Retrofittable design
- Compactness
- Low maintenance requirements
- Simple surface preparation for modification.

It is believed that the MRPS could find interesting applications in plasma thermal spray technology for deposition of coatings and in plasma chemistry for materials processing. The novel MRPS is innovative for deposition and coating of bionanomaterials.

The research and development have demonstrated the commercial potential of the MRPS [40,60]. The MRPS can be a commercial processing tool for the solid-state amorphization of a surface layer, which is a transitional stage for nanocrystallisation under an appropriate thermal annealing.

Acknowledgments

The authors would like to thank Prof. Kai Chang (Texas A&M University) for this opportunity to contribute to the *Wiley Encyclopedia of RF and Microwave Engineering* by preparing this article, and Kris Parrish and Cassandra Craig (John Wiley & Sons, Inc., Hoboken, NJ) for their assistance in preparation of this article, Mrs. Fiona O'Donnell (Hawthorn library of Swinburne University of Technology, Melbourne, Australia) for inestimable information support, as well as Mrs. Andrea Meyer (IRIS, Swinburne University of Technology, Melbourne, Australia) for their assistance in polishing the manuscript.

1. INTRODUCTION

The scattering properties of a terrain generated by an impinging electromagnetic wave are generally represented by a quantity proportional to the average scattered power called the *scattering coefficient*. This quantity is dependent on the exploring frequency, view angle, polarization, and the geometric and electric properties of the terrain. Hence, it is a quantity that relates the geometric and electric properties of the terrain and the sensing system parameters to the scattering phenomenon. Its precise definition will be given in the next section.

The scattering of waves that takes place at a surface boundary between two homogeneous media is called *surface scattering*. For natural ground surfaces where the roughness can be described only statistically, the scattered field will vary from location to location. Such a variation in the received signal is called *fading*, and the associated field amplitude and power distributions are its *fading statistics*. A meaningful signature of the rough surface is the statistically averaged, received power. It follows that this average power must be a function of the statistical parameters of the surface such as the standard deviation of the surface height (RMS height) and its height correlation function. In remote sensing it is the scattered field that is received by the observing antenna. Thus, scattering is the key mechanism. However, in the presence of an inhomogeneous medium such as a vegetation layer, sea ice, or a snow layer, the propagating fields within the medium are equally important, since they are part of the sources of the scattered field. For an inhomogeneous layer with irregular boundaries, an incident wave will generate

1. INTRODUCTION

The scattering properties of a terrain generated by an impinging electromagnetic wave are generally represented by a quantity proportional to the average scattered power called the *scattering coefficient*. This quantity is dependent on the exploring frequency, view angle, polarization, and the geometric and electric properties of the terrain. Hence, it is a quantity that relates the geometric and electric properties of the terrain and the sensing system parameters to the scattering phenomenon. Its precise definition will be given in the next section.

The scattering of waves that takes place at a surface boundary between two homogeneous media is called *surface scattering*. For natural ground surfaces where the roughness can be described only statistically, the scattered field will vary from location to location. Such a variation in the received signal is called *fading*, and the associated field amplitude and power distributions are its *fading statistics*. A meaningful signature of the rough surface is the statistically averaged, received power. It follows that this average power must be a function of the statistical parameters of the surface such as the standard deviation of the surface height (RMS height) and its height correlation function. In remote sensing it is the scattered field that is received by the observing antenna. Thus, scattering is the key mechanism. However, in the presence of an inhomogeneous medium such as a vegetation layer, sea ice, or a snow layer, the propagating fields within the medium are equally important, since they are part of the sources of the scattered field. For an inhomogeneous layer with irregular boundaries, an incident wave will generate

scattering throughout the volume of the layer. Such a scattering mechanism is called *volume scattering*. In general, there will also be surface scattering at the boundaries and hence surface–volume interaction, multiple volume scattering, and surface scattering are also present within the inhomogeneous layer. When the phase relationship between scatterers is needed in volume scattering calculation, the type of scattering is said to be *coherent*. Otherwise, the total scattered power can be calculated by adding the scattered power from individual scatterers, and the associated scattering is said to be *incoherent* or independent. In the radiative transfer formulation [1] coherent calculation is used to derive the *scattering phase function*, which describes single scattering by a single scatterer in a sparse medium or a group of scatterers in a dense medium.

A region with vegetation cover can be viewed as a vegetation layer above an irregular ground surface. The volume occupied by the vegetation biomass relative to the total volume of a vegetation layer is generally less than 1%. For this reason a vegetation medium is taken to be a sparse medium where multiple scattering beyond the second order is assumed to be negligible. A more precise definition of a *sparse medium* is a situation in which the scatterers are in the far field of one another. The usual condition for *far field* is that the range between scatterers is greater than $2D^2/\lambda$, where D is the largest dimension of the scatterer and λ is the operating wavelength in the medium in which the wave is propagating. Under this condition the phase of the propagating wave is a linear function of the range. In such a medium it is possible to ignore phase relations (or coherency) between scatterers in scattering calculations. A vegetated medium does not really satisfy this far-field condition. However, estimates of scattering using far-field calculations have been shown to give results that compare well with measurements [2].

A snow-covered region consists of an inhomogeneous layer of ice particles sitting above an irregular ground surface. The volume fraction of ice particles in snow generally ranges from about 10 to 40%, while the ice particle size is in the range of 0.03–0.3 cm. Two scenarios are possible:

1. Within the distance of a wavelength there are two or more scatterers. Such a medium is called an *electrically dense medium*. In this case two or more scatterers scatter as a group and a scattering phase function for the group is needed in the scattering calculation.
2. The adjacent scatterers are not in the far field of each other, but the average spacing between them is more than a wavelength. In this case the scattering phase function is for a single scatterer, but the far-field approximation is not applicable. Such a medium is a *spatially dense medium*.

A general dense medium may be spatially and electrically dense. Hence, the general scattering phase function for snow must include both of these effects [3–5]. In a dense medium scattered fields from scatterers interact at all range values. They are said to interact in the *near field*,

when the range between scatterers is small compared to the operating wavelength.

2. BASIC TERMS IN SCATTERING

In radar remote sensing the quantity measured is the radar cross section for an isolated target or the scattering coefficient for an area extensive target. To measure the radar cross section of a target, the size of the target must be smaller than the coverage of the radar beam; the converse is true in measuring the scattering coefficient. Intuitively, an object can scatter an incident wave into all possible directions with varying strength, and this scattering pattern should vary with the incident direction. To compare between the scattering strengths of objects in a given direction, some common reference is needed. For the radar cross section of an object, the common reference is an idealized isotropic scatterer. Thus, the radar cross section of an object observed in a given direction is the cross section of an equivalent *isotropic scatterer* that generates the same scattered power density as the object in the observed direction. Mathematically the *radar cross section* σ_r of an object observed in a given direction is the ratio of the total power scattered by an equivalent isotropic scatterer to the incident power density on the object

$$\sigma_r = \frac{4\pi R^2 |E^s|^2}{|E^i|^2} \equiv 4\pi |S|^2 \quad (1)$$

where R is the range between target and the radar receiver; E^i is the incident field; E^s is the scattered field along the direction under consideration, and S is the *scattering amplitude* of the object defined by $(R|E^s|)/|E^i|$. For an area extensive target such as a randomly rough soil surface, the scattered field comes from the area illuminated by the radar antenna. To avoid dependence on the size of the illuminated area A_0 , we want to define a per unit area quantity, the *scattering coefficient* of the surface σ^0 , which is the statistically averaged radar cross section of A_0 divided by A_0 . Let $\langle \rangle$ be the symbol for *statistical* or *ensemble average*. Then, σ^0 can be written as

$$\sigma^0 = \frac{\langle \sigma_r \rangle}{A_0} = \frac{4\pi R^2 \langle |E^s|^2 \rangle}{A_0 |E^i|^2} \equiv \frac{4\pi \langle |S|^2 \rangle}{A_0} \quad (2)$$

When the transmitting and receiving antennas of the radar are collocated, the radar is said to operate in the *monostatic mode*. If the locations of these antennas are separated, it is said to operate in a *bistatic mode*. The scattering coefficient corresponding to the bistatic operation is referred to as a *bistatic scattering coefficient*.

2.1. Wave Polarization Consideration

In remote sensing of the Earth environment we generally encounter plane-wave reflection from and transmission through a weakly finitely conducting medium. This problem has been extensively treated in Ref. 6. As shown in Fig. 1, a plane wave incident at a plane boundary is said to be *horizontally polarized* or a TE wave, if its electric field

Figure 1. Reflection and transmission at a plane boundary between a dielectric upper medium and a finitely conducting lower medium.

vector is perpendicular to the *plane of incidence*, which is the plane parallel to the wave propagation direction and the normal vector to the boundary, the xz plane in Fig. 1. In this case the magnetic field vector is parallel to the plane of incidence. The incident wave is said to be *parallel* or *vertically polarized* or a TM wave, if the direction of the electric field vector is parallel to the plane of incidence. The law of reflection requires the incident and reflected angles to be the same, $\theta_r = \theta$, and *Snell's law* for dielectric media shows that the angle of transmission can be computed from

$$\theta_t = \sin^{-1} \left[\frac{(\mu_1 \epsilon_1)^{1/2} \sin \theta}{(\mu_2 \epsilon_2)^{1/2}} \right] \quad (3)$$

where μ and ϵ denote, respectively, the permeability and permittivity of a medium. When the lower medium is finitely conducting but the conductivity is small, Eq. (3) still gives a good estimate of the transmission angle, and the attenuation of the transmitted field in medium 2 may be estimated by the loss factor, $\exp[-0.5\sigma_2\eta_2|z|]$, where σ_2 is the conductivity, z is the distance into medium 2, and $\eta_2 = (\mu_2/\epsilon_2)^{1/2}$ is the intrinsic impedance of medium 2. The reader is referred to Ulaby et al. [6] for θ_t and attenuation calculations, when the loss is not small.

For most naturally occurring media, $\mu_1 \approx \mu_2 \approx \mu_0$. From Eq. (3) we see that if $\epsilon_1 > \epsilon_2$ the sine of θ_t may exceed unity for some range of θ . The θ for which $\sin \theta_t = 1$ is called the *critical angle* θ_c . When $\theta > \theta_c$, $\sin \theta_t > 1$, and there is no real angle of transmission. Physically, the incident field is totally reflected.

The *Fresnel reflection and transmission coefficients* for horizontal polarization with $\mu_1 \approx \mu_2 \approx \mu_0$ may be written for the electric fields as [6]

$$R_h = \frac{E^r}{E^i} = \frac{k_1 \cos \theta - k_2 \cos \theta_t}{k_1 \cos \theta + k_2 \cos \theta_t} = \frac{\eta_2 \cos \theta - \eta_1 \cos \theta_t}{\eta_2 \cos \theta + \eta_1 \cos \theta_t} \quad (4)$$

and

$$T_h = \frac{E^t}{E^i} = 1 + R_h \quad (5)$$

where $k_{1,2} = \omega(\mu_0\epsilon_{1,2})^{1/2}$ is the wavenumber of the medium. For finitely conducting lower media, $k_2 \cos \theta_t$ is actually a complex quantity. Its exact representation may be found in Ref. 6. For media with a small conductivity, it is possible to approximate R_h, T_h by replacing ϵ_2 by $\epsilon_2 - j\sigma_2/\omega$ and use (3) to calculate θ_t . For example,

$$k_2 \cos \theta_t \approx \omega \left[\mu_0 \left(\epsilon_2 - j \frac{\sigma_2}{\omega} \right) \right]^{1/2} \cos \theta_t \quad \text{and} \quad (6)$$

$$\frac{\eta_2}{\cos \theta_t} \approx \left[\frac{\mu_0}{\epsilon_2 - j \frac{\sigma_2}{\omega}} \right]^{1/2} \frac{1}{\cos \theta_t}$$

Analogous relations for the Fresnel reflection and transmission coefficients of vertically polarized waves for the magnetic fields can be obtained by interchanging the positions of k_1, η_1 with those of k_2, η_2 as

$$R_v = \frac{H^r}{H^i} = \frac{k_2 \cos \theta - k_1 \cos \theta_t}{k_2 \cos \theta + k_1 \cos \theta_t} = \frac{\eta_1 \cos \theta - \eta_2 \cos \theta_t}{\eta_1 \cos \theta + \eta_2 \cos \theta_t} \quad (7)$$

and

$$T_v = \frac{H^t}{H^i} = 1 + R_v \quad (8)$$

Although it is not possible for R_h to be zero with $\epsilon_1 \neq \epsilon_2$ between dielectric media for some incident angle, it is possible for R_v to be zero. This particular incident angle is called the *Brewster angle* θ_B . At this incident angle $T_v = 1$, $R_v = 0$ for dielectric media. The Brewster angle can be found from

$$\theta_B = \tan^{-1} \left(\frac{\epsilon_2}{\epsilon_1} \right)^{1/2} \quad (9)$$

To extend the scattering coefficient σ^0 to include polarization dependence, let p denote the incident polarization and q the scattered polarization. The symbols p and q may represent either vertical or horizontal polarization. Then, we can add "q" and "p" as subscripts to the scattering coefficient as σ_{qp}^0 .

2.1.1. Like and Cross Polarizations. Radar measurements are generally acquired in both like (or copolarized) and cross polarizations. The polarization of an antenna used for measurement is defined to be the same as that of the wave that it transmits, and the polarization of the wave is the direction of its electric field vector. The term, *like polarization*, means transmitting and receiving with matched antennas

$$|\mathbf{a}_r \cdot \mathbf{a}_t| = 1 \quad (10)$$

where $\mathbf{a}_t, \mathbf{a}_r$ are the polarizations of the transmitting and receiving antennas, respectively. The *cross or orthogonal polarization* is defined to be with zero reception:

$$|\mathbf{a}_r \cdot \mathbf{a}_t| = 0 \quad (11)$$

To illustrate the meaning of Eq. (10), consider the transmitting antenna with polarization defined by Eq. (12), which represents a left-hand *elliptically polarized* plane wave from a transmitting antenna. The term *left-hand* means that when the thumb of the left hand is in the direction of propagation, the fingers are pointing in the direction of rotation of the electric field vector as time increases (Fig. 2):

$$\mathbf{E}_t = \mathbf{x} \cos \tau_t \cos(\omega t - kz) - \mathbf{y} \sin \tau_t \sin(\omega t - kz) \quad (12)$$

The angle τ_t defines the relative magnitudes of the semi-axes of the ellipse and is known as the *ellipticity angle*. A sign change in τ_t or z would make the wave right-handed. If the receiving antenna is chosen to have the same polarization, its radiated field will have the same mathematical form but expressed in coordinates for the receiving antenna (the primed coordinates in Fig. 2). As illustrated in Fig. 2, transmitting and receiving antenna systems must point in opposite directions. This means that when the radiated field of the receiving antenna is expressed in the coordinates of the transmitting antenna, its propagation phase must take the form $\omega t + kz$. The coordinate system for the receiving antenna may be related to that of the transmitting antenna as follows:

$$\begin{aligned} \mathbf{x}' &= \mathbf{x} \\ \mathbf{y}' &= -\mathbf{y} \end{aligned} \quad (13)$$

Thus, the radiating field from the receiving antenna expressed in the coordinates of the transmitting antenna is

$$\mathbf{E}_r = \mathbf{x} \cos \tau_r \cos(\omega t + kz) + \mathbf{y} \sin \tau_r \sin(\omega t + kz) \quad (14)$$

Figure 2. Illustration of the polarizations of transmitting and receiving antenna systems. A left-hand elliptically polarized transmitted field is shown.

When we convert it to phasor form, it becomes

$$\mathbf{E}_r = (\mathbf{x} \cos \tau_r - j\mathbf{y} \sin \tau_r) \exp[j(\omega t + kz)] \equiv \mathbf{a}_r e^{j(\omega t + kz)} \quad (15)$$

Similarly, from Eq. (12) the polarization unit vector in phasor form for the transmitting antenna is

$$\mathbf{a}_t = \mathbf{x} \cos \tau + j\mathbf{y} \sin \tau$$

when we set $\tau_t = \tau_r = \tau$. Clearly it is the complex conjugate of \mathbf{a}_r and $|\mathbf{a}_r \cdot \mathbf{a}_t| = 1$. The polarization states of both antennas are *left-hand elliptic*. Hence this case is referred to as *like polarization*. The special case, where τ is zero, yields linear polarization in \mathbf{x} direction for both the transmitting and receiving antennas.

To illustrate cross- or orthogonal polarization, consider the receiving antenna defined by Eq. (14) and set $\tau_r = \tau_t - \pi/2$. Thus, the polarization vector of the receiving antenna expressed in the transmitting coordinates after setting $\tau_t = \tau$ becomes

$$\hat{\mathbf{a}}_r = \mathbf{x} \sin \tau + j\mathbf{y} \cos \tau \quad (16)$$

If we take the dot product according to Eq. (11), we find that $\mathbf{a}_r \cdot \mathbf{a}_t = 0$. When we check the polarization state of the receiving antenna, it is *right-hand elliptic*. Thus, left-hand elliptic and right-hand elliptic polarizations are mutually orthogonal. The special case, when τ is zero, yields linear polarization with \mathbf{x} direction for the transmitting antenna and \mathbf{y} direction for the receiving antenna. These directions are clearly orthogonal.

3. RADIATIVE TRANSFER FORMULATION

In this section we present the basic development of the radiative transfer theory and its formulation for scattering from and propagation through an inhomogeneous layer with irregular boundaries. In the classical formulation of the radiative transfer equation [7] the fundamental quantity used is the *specific intensity* I_ν . It is defined in terms of the amount of power dP (watts) flowing along the \mathbf{r} direction within a solid angle $d\Omega$ through an elementary area dS in a frequency interval $(\nu, \nu + d\nu)$ as follows:

$$dP = I_\nu \cos \alpha dS d\Omega d\nu \quad (17)$$

where α is the angle between the outward normal \mathbf{s} to dS and the unit vector \mathbf{r} . The dimension of I_ν is expressed in $\text{W m}^{-2} \text{sr}^{-1} \text{Hz}^{-1}$. In most remote-sensing applications, the radiation at a single frequency is considered. Thus, it is more convenient to consider the intensity I at a frequency ν , which is defined as the integral of I_ν over the frequency interval $(\nu - d\nu/2, \nu + d\nu/2)$. In terms of intensity, the amount of power at a single frequency can be written as

$$dP = I \cos \alpha dS d\Omega \quad (18)$$

The *equation of transfer* governs the variation of intensities in a medium that absorbs, emits, and scatters radia-

tion. Within the medium, consider a cylindrical volume of unit cross section and length dl . The change in intensity may be a gain or a loss. The loss in intensity I propagating through the cylindrical volume along the distance dl is due to absorption and scattering away from the direction of propagation, and the gain is from thermal emission and scattering into the direction of propagation

$$dI = -\kappa_a Idl - \kappa_s Idl + \kappa_a J_a dl + \kappa_s J_s dl \quad (19)$$

where κ_a, κ_s are the *volume absorption* and *volume-scattering coefficients*. In Eq. (19) J_a and J_s are the *absorption source function* (or emission source function) and the *scattering source function*. Equation (19) is the radiative transfer equation in which the definition of J_s is

$$J_s(\theta_s, \phi_s) = \frac{1}{4\pi} \int_0^{2\pi} \int_0^\pi P(\theta_s, \phi_s; \theta, \phi) I(\theta, \phi) \sin \theta d\theta d\phi \quad (20)$$

where $P(\theta_s, \phi_s; \theta, \phi)$ is the phase function accounting for scattering within the medium to be defined in the next subsection. It is clear from Eq. (20) that J_s is not an independent source of the medium but is itself a function of the propagating intensity. On the other hand, J_a is an independent source function proportional to the temperature profile of the medium; namely, it is the source function in passive remote sensing problems. As such, it should be dropped in active remote sensing problems in which the source is an incident wave from the radar transmitter outside the scattering medium.

For the active sensing problem to be considered in this section, we will treat partially polarized waves by introducing the *Stokes parameters*. Then, we will generalize the scalar radiative transfer equation to a matrix equation. In so doing, it is helpful first to establish the relation between the scattered intensity and the incident intensity and then to relate these intensities to the corresponding electric fields.

3.1. Stokes Parameters, Phase Matrices, and Radiative Transfer Equations

For an elliptically polarized monochromatic plane wave, $\mathbf{E} = (\mathbf{E}_v \mathbf{v} + \mathbf{E}_h \mathbf{h}) \exp(j\mathbf{k} \cdot \mathbf{r})$, propagating through a differential solid angle $d\Omega$ in a medium with intrinsic impedance η , where \mathbf{v} and \mathbf{h} are the unit vectors denoting vertical and horizontal polarization, respectively, the *modified Stokes parameters* I_v, I_h, U , and V in the dimension of intensity can be defined in terms of the electric fields as

$$I_v d\Omega = 0.5 \operatorname{Re} \left\langle \frac{|\mathbf{E}_v|^2}{\eta^*} \right\rangle \quad (21)$$

$$I_h d\Omega = 0.5 \operatorname{Re} \left\langle \frac{|\mathbf{E}_h|^2}{\eta^*} \right\rangle \quad (22)$$

$$U d\Omega = \operatorname{Re} \left\langle \frac{\mathbf{E}_v \mathbf{E}_h^*}{\eta^*} \right\rangle \quad (23)$$

$$V d\Omega = \operatorname{Im} \left\langle \frac{\mathbf{E}_v \mathbf{E}_h^*}{\eta^*} \right\rangle \quad (24)$$

where $*$ is the symbol for complex conjugate, $\eta = [\mu/(\epsilon - j\sigma/\omega)]^{1/2}$ for finitely conducting medium and the right-hand side of Eq. (21) or (22) is the *average Poynting vector* representing power density in units of watts per meter squared. These four parameters have the same dimension and hence are more convenient to use than amplitude and phase, which have different dimensions. It has been shown that the amplitude, phase, and polarization state of any elliptically polarized wave can be completely characterized by these parameters [8].

3.1.1. Phase Matrix for Rough Surfaces. To relate the scattered intensity to the incident intensity, consider a plane wave illuminating a rough surface area A_0 . The relation between the vertically and horizontally polarized scattered field components E_v^s, E_h^s and those of the incident field components E_v^i, E_h^i is

$$\begin{bmatrix} E_v^s \\ E_h^s \end{bmatrix} = \frac{e^{jkR}}{R} \begin{bmatrix} S_{vv} & S_{vh} \\ S_{hv} & S_{hh} \end{bmatrix} \begin{bmatrix} E_v^i \\ E_h^i \end{bmatrix} \quad (25)$$

where S_{pq} (where subscripts ‘‘p, q’’ = vertical or horizontal) is the *scattering amplitude* in meters, R is the distance from the center of the illuminated area to the point of observation, and k is the wavenumber. Consider $|E_v^s|^2/\eta^*$

$$\frac{|E_v^s|^2}{\eta^*} = \frac{1}{R^2} \left(\frac{|S_{vv}|^2 |E_v^i|^2}{\eta^*} + \frac{|S_{vh}|^2 |E_h^i|^2}{\eta^*} + 2 \operatorname{Re} \frac{S_{vv} S_{vh}^* E_v^i E_h^{i*}}{\eta^*} \right)$$

where

$$\begin{aligned} & 2 \operatorname{Re} \frac{S_{vv} S_{vh}^* E_v^i E_h^{i*}}{\eta^*} \\ &= 2 \operatorname{Re} \left[\operatorname{Re}(S_{vv} S_{vh}^*) + j \operatorname{Im}(S_{vv} S_{vh}^*) \right] \\ & \times \left[\frac{\operatorname{Re} E_v^i E_h^{i*}}{\eta^*} + j \operatorname{Im} \frac{E_v^i E_h^{i*}}{\eta^*} \right] \} \\ &= 2 \operatorname{Re}(S_{vv} S_{vh}^*) \operatorname{Re} \frac{E_v^i E_h^{i*}}{\eta^*} - 2 \operatorname{Im}(S_{vv} S_{vh}^*) \operatorname{Im} \frac{E_v^i E_h^{i*}}{\eta^*} \end{aligned}$$

Recognizing the relation above, we can obtain the following quantities using Eqs. (25) and (21) through (24):

$$\begin{aligned} & 0.5 \operatorname{Re} \frac{\langle |E_v^s|^2 \rangle}{\eta^*} \\ &= \frac{\langle |S_{vv}|^2 I_v + |S_{vh}|^2 I_h + \operatorname{Re}(S_{vv} S_{vh}^*) U - \operatorname{Im}(S_{vv} S_{vh}^*) V \rangle d\Omega}{R^2} \end{aligned} \quad (26)$$

$$\begin{aligned} & 0.5 \operatorname{Re} \frac{\langle |E_h^s|^2 \rangle}{\eta^*} \\ &= \frac{\langle |S_{hv}|^2 I_v + |S_{hh}|^2 I_h + \operatorname{Re}(S_{hv} S_{hh}^*) U - \operatorname{Im}(S_{hv} S_{hh}^*) V \rangle d\Omega}{R^2} \end{aligned} \quad (27)$$

$$\begin{aligned} & \text{Re} \left\langle \frac{E_v^s E_h^{s*}}{\eta^*} \right\rangle \\ &= \frac{\langle [2 \text{Re}(S_{vv} S_{hv}^*) I_v + 2 \text{Re}(S_{hh}^* S_{vh}) I_h] \rangle d\Omega}{R^2} \\ &+ \frac{\langle [\text{Re}(S_{vv} S_{hh}^* + S_{vh} S_{hv}^*) U - \text{Im}(S_{vv} S_{hh}^* - S_{vh} S_{hv}^*) V] \rangle d\Omega}{R^2} \end{aligned} \quad (28)$$

$$\begin{aligned} & \text{Im} \left\langle \frac{E_v^s E_h^{s*}}{\eta^*} \right\rangle \\ &= \frac{\langle [2 \text{Im}(S_{vv} S_{hv}^*) I_v + 2 \text{Im}(S_{hh}^* S_{vh}) I_h] \rangle d\Omega}{R^2} \\ &+ \frac{\langle [\text{Im}(S_{vv} S_{hh}^* + S_{vh} S_{hv}^*) U - \text{Re}(S_{vv} S_{hh}^* - S_{vh} S_{hv}^*) V] \rangle d\Omega}{R^2} \end{aligned} \quad (29)$$

The left-hand sides of these equations are in watts per square meter. To convert them to intensity, we need to divide both sides of the equation by the solid angle subtended by

but are defined for spherical waves. They differ from the plane wave definition in the normalizing solid angle $(A_0 \cos \theta_s)/R^2$. The element of the phase matrix relating I_v^s to I_v^i is $\sigma_{vv}^0/\cos \theta_s$. To summarize, all possible incident intensities from all directions contributing to \mathbf{I}^s along a given direction, we integrate over all solid angles:

$$\mathbf{I}^s = \frac{1}{4\pi} \int_{4\pi} \mathbf{P} \mathbf{I}^i d\Omega \quad (33)$$

This equation is the generalized version of Eq. (20), for partially polarized waves. Here \mathbf{I}^s , \mathbf{I}^i are column vectors whose components are the Stokes parameters. The detailed contents of the phase matrix written in terms of scattering amplitudes are summarized below

$$\mathbf{P} = \frac{4\pi \langle \mathbf{M} \rangle}{A \cos \theta_s} \quad (34)$$

where the *Stokes matrix* \mathbf{M} is

$$\begin{bmatrix} |S_{vv}|^2 & |S_{vh}|^2 & \text{Re}(S_{vv} S_{vh}^*) & -\text{Im}(S_{vv} S_{vh}^*) \\ |S_{hv}|^2 & |S_{hh}|^2 & \text{Re}(S_{hv} S_{hh}^*) & -\text{Im}(S_{hv} S_{hh}^*) \\ 2\text{Re}(S_{vv} S_{hv}^*) & 2\text{Re}(S_{vh} S_{hh}^*) & \text{Re}(S_{vv} S_{hh}^* + S_{vh} S_{hv}^*) & -\text{Im}(S_{vv} S_{hh}^* - S_{vh} S_{hv}^*) \\ 2\text{Im}(S_{vv} S_{hv}^*) & 2\text{Im}(S_{vh} S_{hh}^*) & \text{Im}(S_{vv} S_{hh}^* + S_{vh} S_{hv}^*) & \text{Re}(S_{vv} S_{hh}^* - S_{vh} S_{hv}^*) \end{bmatrix}$$

the illuminated area A_0 at the point of observation, $(A_0 \cos \theta_s)/R^2$, where θ_s is the angle between the scattered direction and the direction normal to A_0 . Eq. (26) becomes

$$\begin{aligned} \frac{0.5R^2 \text{Re}(|E_v^s|^2)}{(\eta^* A_0 \cos \theta_s)} &= \frac{\langle |S_{vv}|^2 I_v + |S_{vh}|^2 I_h + \text{Re}(S_{vv} S_{vh}^*) U \rangle d\Omega}{A_0 \cos \theta_s} \\ &- \frac{\langle \text{Im}(S_{hv} S_{hh}^*) V \rangle d\Omega}{A_0 \cos \theta_s} \end{aligned} \quad (30)$$

The term on the left-hand side of this equation is the intensity of the scattered field. In view of Eq. (2), we can rewrite the equation in terms of the scattering coefficients as

$$I_v^s = \frac{(\sigma_{vv}^0 I_v + \sigma_{vh}^0 I_h + \sigma_{vvvh}^0 U + \sigma_{hvhv}^0 V) d\Omega}{4\pi \cos \theta_s} \quad (31)$$

Similarly, we can convert the left-hand sides of Eqs. (27)–(29) into intensities and rewrite all four resulting equations into a matrix equation. This matrix equation relates the scattered intensities \mathbf{I}^s to the incident intensities \mathbf{I}^i through a dimensionless quantity known as the *phase matrix* \mathbf{P} :

$$\mathbf{I}^s = \frac{1}{4\pi} \mathbf{P} \mathbf{I}^i d\Omega \quad (32)$$

The components of \mathbf{I}^i are the Stokes parameters as defined by Eqs. (21)–(24) for the incident plane wave. The components of the scattered intensity \mathbf{I}^s are also *Stokes parameters*

3.1.2. Phase Matrix for an Inhomogeneous Medium. Consider a homogeneous medium embedded randomly with scatterers. Each scatterer is characterized by a *bistatic radar cross section* σ_p due to a p -polarized [$p=v$ or h (vertical or horizontal)] incident intensity. The *scattering cross section* of the scatterer Q_{sp} is defined as the cross section that would produce the total scattered power surrounding the scatterer due to a unit incident Poynting vector of polarization p

$$Q_{sp}(\theta, \phi) = \frac{1}{4\pi} \int_{4\pi} \sigma_p d\Omega_s = \int_{4\pi} (|S_{vp}|^2 + |S_{hp}|^2) d\Omega_s \quad (35)$$

where θ, ϕ indicate the incident direction and integration is over the scattered solid angle. The *volume scattering coefficient* for the inhomogeneous medium and polarization p is

$$\kappa_{sp} = N_v Q_{sp} \quad (36)$$

where N_v is the number of scatterers per unit volume [8] or the *number density*. The *volume scattering coefficient* κ_{sp} represents the scattering loss per unit length and has the units of Np/m (nepers per meter). In the case of a continuous, inhomogeneous medium defined by a spatially varying permittivity function, the scattering amplitudes S_{vp}, S_{hp} are for an effective volume V . The

volume scattering coefficient is defined as [9]

$$\kappa_{\text{sp}} = \frac{1}{V} \mathbf{Q}_{\text{sp}} \quad (37)$$

Another important parameter for characterizing an inhomogeneous medium is its absorption loss, represented by the *volume absorption coefficient*, κ_{ap} . This quantity may be defined in terms of the average relative permittivity ϵ_{ap} of the medium, where p denotes the incident polarization. Letting k_0 be the free-space wavenumber, we define the absorption coefficient for p polarization as

$$\kappa_{\text{ap}} = 2k_0 |\text{Im} \sqrt{\epsilon_{\text{ap}}}| \quad (38)$$

This equation may be used for either a continuous inhomogeneous medium or a discrete inhomogeneous medium. In the latter case the *absorption cross section* \mathbf{Q}_{ap} for one particle and p polarization can be defined as

$$\mathbf{Q}_{\text{ap}} = \frac{\kappa_{\text{ap}}}{N_{\text{v}}} \quad (39)$$

From Eqs. (36) and (39) the total cross section, also known as the *extinction cross section*, for a scatterer is

$$\mathbf{Q}_{\text{ep}} = \mathbf{Q}_{\text{ap}} + \mathbf{Q}_{\text{sp}} \quad (40)$$

and the *extinction coefficient* is $\kappa_{\text{ep}} = N_{\text{v}} \mathbf{Q}_{\text{ep}}$. In Eq. (40), \mathbf{Q}_{ep} is the effective area that generates the total scattered and absorbed power due to a unit incident Poynting vector of polarization p . The ratio of κ_{sp} to κ_{ep} is the *albedo* of the random medium. Conceptually, either \mathbf{Q}_{ep} or \mathbf{Q}_{sp} may be used in place of $\text{Acos} \theta_s$ in Eq. (34) to define the phase matrix of a single scatterer. However, unlike $\text{Acos} \theta_s$, \mathbf{Q}_{ep} and \mathbf{Q}_{sp} have polarization dependence in general [10] and hence are matrices. Let us denote them as \mathbf{Q}_{e} and \mathbf{Q}_{s} . The choice of the definition for the *phase matrix* depends on the assumed form of the scattering source term in Eq. (19). When the term is written as $\kappa_{\text{s}} \mathbf{J}_{\text{s}}$, the definition is [11]

$$\mathbf{P}_{\text{s}} = 4\pi \mathbf{Q}_{\text{s}}^{-1} \langle \mathbf{M} \rangle \quad (41)$$

If the term is written as $\kappa_{\text{e}} \mathbf{J}'_{\text{s}}$, then the definition should be [8]

$$\mathbf{P}_{\text{e}} = 4\pi \mathbf{Q}_{\text{e}}^{-1} \langle \mathbf{M} \rangle \quad (42)$$

Both definitions have appeared in the literature. Clearly, the phase matrix is a term created for convenience; the scattering source term is the fundamental quantity. Thus, while Eq. (41) is not the same as Eq. (42), the source terms are the same in both cases, as they should be:

$$\kappa_{\text{s}} \mathbf{J}_{\text{s}} = \kappa_{\text{e}} \mathbf{J}'_{\text{s}} = \int_{4\pi} N_{\text{v}} \langle \mathbf{M} \rangle \mathbf{I} d\Omega \quad (43)$$

In view of Eqs. (43) and (19), the radiative transfer equation for *partially polarized waves* in a discrete

inhomogeneous medium is

$$\begin{aligned} \frac{d\mathbf{I}}{dl} &= -\kappa_{\text{e}} \mathbf{I} + \frac{\kappa_{\text{e}}}{4\pi} \int_{4\pi} \mathbf{P}_{\text{e}} \mathbf{I} d\Omega + \kappa_{\text{a}} \mathbf{J}_{\text{a}} \\ &= -\kappa_{\text{e}} \mathbf{I} + \frac{\kappa_{\text{s}}}{4\pi} \int_{4\pi} \mathbf{P}_{\text{s}} \mathbf{I} d\Omega + \kappa_{\text{a}} \mathbf{J}_{\text{a}} \end{aligned} \quad (44)$$

or

$$\frac{d\mathbf{I}}{dl} = -\kappa_{\text{e}} \mathbf{I} + \int_{4\pi} N_{\text{v}} \langle \mathbf{M} \rangle \mathbf{I} d\Omega + \kappa_{\text{a}} \mathbf{J}_{\text{a}} \quad (45)$$

In a continuous, inhomogeneous medium, it is more convenient to use the *Stokes matrix* instead of the phase matrix. Making use of Eq. (37), we have

$$\frac{d\mathbf{I}}{dl} = -\kappa_{\text{e}} \mathbf{I} + \int_{4\pi} \frac{\langle \mathbf{M} \rangle}{V} \mathbf{I} d\Omega + \kappa_{\text{a}} \mathbf{J}_{\text{a}} \quad (46)$$

In Eq. (46), V is the effective illuminated volume as given in Eq. (37) and will cancel out upon evaluating $\langle \mathbf{M} \rangle$. It is clear from Eqs. (45) and (46) that the fundamental quantity in scattering is the *scattering amplitude*, while phase function is an artificially created quantity.

The radiative transfer equation is formulated on the basis of energy balance. The phase changes of the scattered wave and its cross-correlation terms are ignored in the solution of the transfer equation. For a sparsely populated random medium it is not necessary to track the phase change between scatterers. In a *dense medium* a group of scatterers may scatter coherently. Thus phase relation among scatterers must be taken into account in the derivation of the phase function. However, phase effects in multiple scattering calculations can still be ignored because the mechanism of multiple scattering tends to destroy phase relation between scatterers. To date, the radiative transfer formulation is still the most practical approach to compute multiple scattering from an inhomogeneous medium. Furthermore, it provides a natural way to combine surface boundary scattering with volume scattering from within an inhomogeneous layer, as we shall see in the next section.

4. SCATTERING FROM AN INHOMOGENEOUS LAYER WITH IRREGULAR BOUNDARIES

For bounded media, scattering or reflection may occur at the boundary. Both incident and scattered intensities are needed in the boundary conditions. Therefore, it is necessary to split the intensity matrix into upward \mathbf{I}^+ and downward \mathbf{I}^- components and rewrite Eq. (45) as two equations. For active sensing applications, the thermal source term is not needed. It is also a standard practice to express the slant range in terms of the vertical distance, that is, let $l = z/\cos \theta$ (Fig. 3)

Consider the problem of a plane wave in air incident on an inhomogeneous layer above a ground surface. The geometry of the scattering problem is depicted in Fig. 3. The inhomogeneous layer is assumed to have such

Figure 3. Scattering geometry for an inhomogeneous layer above a homogeneous half-space.

characteristics that the *upward intensity* \mathbf{I}^+ and the *downward intensity* \mathbf{I}^- satisfy the radiative transfer equation. On rewriting (45) in terms of these intensities we obtain [1]

$$\begin{aligned} \mu_s \frac{d}{dz} \mathbf{I}^+(z, \mu_s, \phi_s) &= -\kappa_e \mathbf{I}^+(z, \mu_s, \phi_s) \\ &+ \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \kappa_s \mathbf{P}_s(\mu_s, \mu, \phi_s - \phi) \mathbf{I}^+(z, \mu, \phi) d\mu d\phi \quad (47) \\ &+ \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \kappa_s \mathbf{P}_s(\mu_s, -\mu, \phi_s - \phi) \mathbf{I}^-(z, \mu, \phi) d\mu d\phi \end{aligned}$$

$$\begin{aligned} \mu_s \frac{d}{dz} \mathbf{I}^-(z, \mu_s, \phi_s) &= \kappa_e \mathbf{I}^-(z, \mu_s, \phi_s) \\ &- \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \kappa_s \mathbf{P}_s(-\mu_s, \mu, \phi_s - \phi) \mathbf{I}^+(z, \mu, \phi) d\mu d\phi \quad (48) \\ &- \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \kappa_s \mathbf{P}_s(-\mu_s, \mu, \phi_s - \phi) \mathbf{I}^-(z, \mu, \phi) d\mu d\phi \end{aligned}$$

where $\mu_s = \cos \theta_s$; $\mu = \cos \theta$, \mathbf{I}^+ , \mathbf{I}^- are column vectors containing the four *modified Stokes parameters* and \mathbf{P}_s is the *phase matrix*.

To find the upward intensity due to an incident intensity \mathbf{I}^i , where $\mathbf{I}^i = \mathbf{I}_0 \delta(\mu - \mu_i) \delta(\phi - \phi_i)$, $\delta(\cdot)$ is the *Dirac delta function* and (θ_i, ϕ_i) denotes the direction of propagation of the incident wave, we need to solve Eqs. (47) and (48), subject to the following boundary conditions. At $z = -d$ the upward and downward intensities are related through the ground-scattering phase matrix \mathbf{G} as

$$\begin{aligned} \mathbf{I}^+(-d, \mu_s, \phi_s) &= \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \mathbf{G}(\mu_s, -\mu, \phi_s - \phi) \\ &\times \mathbf{I}^-(-d, \mu, \phi) d\mu d\phi \quad (49) \end{aligned}$$

If the ground surface is flat, \mathbf{G} may be written in terms of the reflectivity matrix \mathbf{R}_g as

$$\mathbf{G} = 4\pi \mathbf{R}_g \delta(\mu_s - \mu) \delta(\phi_s - \phi) \quad (50)$$

At the top boundary $z = 0$, the upward and downward intensities are related through the surface-scattering and transmission *phase matrices* \mathbf{S}_R and \mathbf{S}_T [12]

$$\begin{aligned} \mathbf{I}^-(0, \mu_s, \phi_s) &= \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \mathbf{S}_R(-\mu_s, \mu, \phi_s - \phi) \mathbf{I}^+(0, \mu, \phi) d\mu d\phi \\ &+ \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \mathbf{S}_T(-\mu_s, -\mu, \phi_s - \phi) \mathbf{I}^i(0, \mu, \phi) d\mu d\phi \quad (51) \end{aligned}$$

Once $\mathbf{I}^+(0, \mu_s, \phi_s)$ is determined within the inhomogeneous layer, the upward intensity transmitted from the layer into air can be found using the transmission scattering matrix of the surface, \mathbf{S}_T as

$$\begin{aligned} \mathbf{I}^+(\mu_s, \phi_s) &= \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \mathbf{S}_T(\mu_s, \mu, \phi_s - \phi) \\ &\times \mathbf{I}^+(0, \mu, \phi) d\mu d\phi \quad (52) \end{aligned}$$

The total scattered intensity in air is given by the sum of $\mathbf{I}^+(\mu_s, \phi_s)$ and \mathbf{I}_s , where \mathbf{I}_s is the intensity due to random surface scattering by the top layer boundary:

$$\mathbf{I}_s = \frac{1}{4\pi} \int_0^{2\pi} \int_0^1 \mathbf{S}_R(-\mu_s, -\mu, \phi_s - \phi) \mathbf{I}^i(0, \mu, \phi) d\mu d\phi \quad (53)$$

The explicit forms of the matrices \mathbf{R}_g , \mathbf{S}_R , and \mathbf{S}_T are available in Fung [1]. The expressions for \mathbf{S}_R and \mathbf{S}_T are for an irregular boundary. The \mathbf{G} matrix is assumed to have the same mathematical form as \mathbf{S}_R . Once the total scattered intensity for a p -polarized component I_p^s of the intensity matrix is found, the scattering coefficient for this component is defined relative to the incident intensity $I_q^i = I_{q0} \delta(\mu - \mu_i) \delta(\phi - \phi_i)$ of polarization q along (μ_i, ϕ_i) direction as

$$\sigma_{pq}^0 = \frac{4\pi I_p^s \cos \theta_s}{I_{q0}} \quad (54)$$

The transfer equations given by Eqs. (47) and (48) can be solved exactly by using numerical techniques [13,14]. Analytic solutions by iteration are available to the first order in *albedo* [1, Chapter 2], which is also known as the *Born approximation*. Generally, it is practical to carry the iterative solution process to the second order in albedo. This additional complexity is justified only for cross-polarization in the plane of incidence, because its first-order solution is zero. For like polarization the difference between the first- and second-order results is generally within experimental error.

4.1. First-Order Solution of the Layer Problem

In many practical applications the volume scattering from an inhomogeneous layer can be approximated by using a first-order solution whenever the albedo of the medium is smaller than about 0.3. Furthermore, because volume

scattering has a slow varying angular behavior over incident angles in the range between 0° and 70° , we can approximate the transmission across an irregular boundary by a plane boundary. Under these conditions the first-order solution to the radiative transfer equations consists of four major terms: (1) *volume scattering* by the inhomogeneous layer transmitted across the top boundary, (2) scattering by the bottom layer boundary passing through the layer into the upper medium, (3) scattering between layer volume and lower boundary passing through the layer into the upper medium, and (4) *surface scattering* by the top boundary. Note that only the last term represents pure surface scattering and does not involve propagation through the layer volume. The second and third terms are dependent on contributions from the lower boundary and can be ignored in dealing with half-space or very thick layer.

The volume backscattering term for p polarized scattering has the form [1]

$$\begin{aligned} \sigma_{\text{vpp}}^0(\theta) &= 0.5 \cos \theta_t \frac{\kappa_s}{\kappa_e} T_p(\theta, \theta_t) T_p(\theta_t, \theta) \left(1 - \exp\left(\frac{-2\kappa_e d}{\cos \theta_t}\right) \right) \\ &\quad \times P_{\text{spp}}(\theta_t, \pi; \pi - \theta_t, 0) \\ &= 2\pi \cos \theta_t T_p(\theta, \theta_t) 1 - \exp\left(\frac{-2\kappa_e d}{\cos \theta_t}\right) \\ &\quad \times \frac{\langle |S_{\text{pp}}(\theta_t, \pi; \pi - \theta_t, 0)|^2 \rangle}{\sigma_e} T_p(\theta_t, \theta) \end{aligned} \quad (55)$$

where θ_t is the angle of transmission, $T_p(\theta_t, \theta)$ is the Fresnel power transmission coefficient for p polarization, d is the depth of the layer, $S_{\text{pp}}(\theta_t, \pi; \pi - \theta_t, 0)$ is the scattering amplitude and the *ensemble average* is over the distribution of the orientation of the scatterer, and $\kappa_e = N_v \sigma_e$; N_v is the number density of scatterers and the extinction cross section is given by

$$\sigma_e = - \left(\frac{4\pi}{k} \right) \text{Im}[\langle S_{\text{pp}}(\pi - \theta_t, 0; \pi - \theta_t, 0) \rangle] \quad (56)$$

The *extinction coefficient* κ_e is the controlling factor for propagation through the layer. Both the scattering and the extinction coefficients are dependent on the scattering amplitude of the scatterer. In Eq. (55) we provide two forms of the scattering coefficient because for some problems such as *Rayleigh scattering* the phase function P_{spp} is known, and for others only the scattering amplitude is available.

Surface backscattering from the lower boundary is given by the *surface scattering coefficient* from the lower boundary, $\sigma_{\text{spp}}^0(\theta)$, modified by propagation loss through the layer and transmission across the top boundary as

$$\sigma_{\text{lpp}}^0(\theta) = \cos \theta T_p(\theta, \theta_t) \frac{\sigma_{\text{spp}}^0(\theta_t)}{\cos \theta_t} T_p(\theta_t, \theta) \exp\left(\frac{-2\kappa_e d}{\cos \theta_t}\right) \quad (57)$$

The explicit form of the surface scattering coefficient $\sigma_{\text{spp}}^0(\theta)$ is given in the next section. Finally, we give the expression for the volume–surface interaction term

resulting from the incident wave transmitted through the layer, reflected by the lower boundary, and then scattered by layer inhomogeneities back into the direction of the receiver. By reciprocity, the wave that traverses the same path in the reverse direction makes the same contribution to the receiver. This term has the form

$$\begin{aligned} \sigma_{\text{lpp}}^0(\theta) &= \cos \theta T_p(\theta, \theta_t) \frac{\kappa_s d |R_p(\theta_t)|^2}{\cos \theta_t} T_p(\theta_t, \theta) \exp\left(\frac{-2\kappa_e d}{\cos \theta_t}\right) \\ &\quad \times \{P_{\text{spp}}(\pi - \theta_t, \pi; \pi - \theta_t, 0) + P_{\text{spp}}(\theta_t, \pi; \theta_t, 0)\} \\ &= \cos \theta T_p(\theta, \theta_t) \frac{N_v d |R_p(\theta_t)|^2}{\cos \theta_t} T_p(\theta_t, \theta) \exp\left(\frac{-2\kappa_e d}{\cos \theta_t}\right) \\ &\quad \times (4\pi) \{ \langle |S_{\text{spp}}(\pi - \theta_t, \pi; \pi - \theta_t, 0)|^2 \rangle \\ &\quad + \langle |S_{\text{spp}}(\theta_t, \pi; \theta_t, 0)|^2 \rangle \} \end{aligned} \quad (58)$$

In Eq. (58), $|R_p(\theta_t)|^2$ is the p -polarized *Fresnel reflectivity* and N_v is the *number density*.

The relative importance of each of the four terms and the actual contents of the phase function or scattering amplitude are dependent on applications. This is illustrated in the subsequent sections.

5. SCATTERING FROM SOIL SURFACES

When an incident electromagnetic wave impinges on an irregular surface, it induces a current on it. The waves radiated by this current is called the *scattered wave*. To calculate surface scattering, one needs to solve the integral equation that governs this induced current on the surface. In general, there is no closed-form, analytic solution for this integral equation. An approximate solution to it is available in Chapter 4 of Ref. 1 and in Ref. 15. It is shown in Chapter 5 of Ref. 1 that the classical backscattering coefficients under high and low frequency conditions for rough surfaces, that is, those based on the Kirchhoff and the small perturbation approximations, are special cases of this scattering coefficient. Hence, we can examine rough surface scattering properties over the entire frequency band with this coefficient. Only single-scatter, backscattering from a randomly rough soil surface is considered here. Readers interested in bistatic scattering and multiple surface scattering are referred to Fung [1,15] and Hsieh et al. [16], respectively.

5.1. Backscattering from a Randomly Rough Soil Surface

To compute backscattering from a soil surface, we need to know both the electric and geometric properties of the surface. In general, the permeability of the soil can be taken to be the same as air, and only the complex dielectric constant is needed. An empirical formula for the relative complex dielectric constant of soil is available from Ulaby et al. [17]. It has the form

$$\epsilon_r = \left[1 + \frac{\text{SBD}(4.7^{0.65} - 1)}{2.65} + m v^b (\epsilon_w^{0.65} - 1) \right]^{1/0.65} \quad (59)$$

where SBD stands for soil bulk density in g/cm^3 , mv is the volumetric soil moisture, and ϵ_w is the permittivity of water given by

$$\epsilon_w = 4.9 + \frac{(\epsilon_{w0} - 4.9)}{1 + jfT_\tau}$$

$$T_\tau = \frac{1.1109}{10} - \frac{3.824T}{10^3} + \frac{6.938T^2}{10^5} - \frac{5.096T^3}{10^7}$$

$$\epsilon_{w0} = 88.045 - 0.4147T + \frac{6.295T^2}{10^4} + \frac{1.075T^3}{10^5}$$

f = frequency in GHz

T = Temperature in degree centigrade and

$b = 1.09 - 0.11S + 0.18C$ is the parameter accounting for the percent of clay C and the percent of sand S in the soil

For a randomly rough surface not skewed by natural forces such as the wind, it is sufficient to describe the geometry of the surface by its first- and second-order statistics. They are the surface *root mean squared* (RMS) height σ and its *autocorrelation function* $\rho(\xi)$, normalized to its height variance σ^2 . The general forms of the back-scattering coefficients for vertically σ_{vv}^0 , horizontally σ_{hh} , and cross- σ_{vh} polarized scattering based on an improved integral equation method (IIEM) [15,16] are given below by Eqs. (60) and (64).

$$\begin{aligned} \sigma_{pp}^0 &= \frac{k^2}{4\pi} \exp[-4k_z^2 \sigma^2] \left\{ \left| (2k_z \sigma) f_{pp} + \frac{\sigma}{4} (F_{pp1} + F_{pp2}) \right|^2 \right. \\ &\quad \left. w(2k \sin \theta, 0) + \sum_{n=2}^{\infty} \left| (2k_z \sigma)^n f_{pp} \right. \right. \\ &\quad \left. \left. + \frac{\sigma}{4} F_{pp1} (2k_z \sigma)^{n-1} \left| \frac{2w^{(n)}(2k \sin \theta, 0)}{n!} \right| \right\} \end{aligned} \quad (60)$$

where $p = v, h$, $f_{vv} = 2R_v / \cos \theta$, $f_{hh} = -2R_h / \cos \theta$, and

$$\begin{aligned} F_{vv1} &= \frac{4k}{\sqrt{\epsilon_r - \sin^2 \theta}} \left\{ (1 - R_v)^2 \epsilon_r \cos \theta + (1 - R_v)(1 + R_v) \right. \\ &\quad \times \sin^2 \theta \left(\sqrt{\epsilon_r - \sin^2 \theta} - \cos \theta \right) \\ &\quad \left. - (1 + R_v)^2 \left[\cos \theta + \frac{\sin^2 \theta}{2\epsilon_r} \left(\sqrt{\epsilon_r - \sin^2 \theta} - \cos \theta \right) \right] \right\} \end{aligned}$$

$$\begin{aligned} F_{vv2} &= 4k \sin^2 \theta \left[(1 - R_v)^2 \left(1 + \frac{\epsilon_r \cos \theta}{\sqrt{\epsilon_r - \sin^2 \theta}} \right) \right. \\ &\quad - (1 - R_v)(1 + R_v) \left(3 + \frac{\cos \theta}{\sqrt{\epsilon_r - \sin^2 \theta}} \right) \\ &\quad \left. + (1 + R_v)^2 \left(1 + \frac{1}{2\epsilon_r} + \frac{\epsilon_r \cos \theta}{2\sqrt{\epsilon_r - \sin^2 \theta}} \right) \right] \end{aligned}$$

$$\begin{aligned} F_{hh1} &= \frac{-4k}{\sqrt{\epsilon_r - \sin^2 \theta}} \left\{ (1 - R_h)^2 \cos \theta + (1 - R_h)(1 + R_h) \right. \\ &\quad \times \sin^2 \theta \left(\sqrt{\epsilon_r - \sin^2 \theta} - \cos \theta \right) \\ &\quad \left. - (1 + R_h)^2 \left[\epsilon_r \cos \theta + \frac{\sin^2 \theta}{2} \left(\sqrt{\epsilon_r - \sin^2 \theta} - \cos \theta \right) \right] \right\} \\ F_{hh2} &= -4k \sin^2 \theta \left[(1 - R_h)^2 \left(1 + \frac{\cos \theta}{\sqrt{\epsilon_r - \sin^2 \theta}} \right) \right. \\ &\quad - (1 - R_h)(1 + R_h) \left(3 + \frac{\cos \theta}{\sqrt{\epsilon_r - \sin^2 \theta}} \right) \\ &\quad \left. + (1 + R_h)^2 \left(1 + \frac{1}{2} + \frac{\cos \theta}{2\sqrt{\epsilon_r - \sin^2 \theta}} \right) \right] \end{aligned}$$

The quantities $w, w^{(n)}$ are the surface spectra corresponding to the two-dimensional *Fourier transforms* of the surface correlation coefficient $\rho(x, y)$ and its n th power, $\rho^n(x, y)$, defined as follows in polar forms:

$$w(\kappa, \varphi) = \int_0^{2\pi} \int_0^{\infty} \rho(r, \phi) e^{-j\kappa r \cos(\varphi - \phi)} r dr d\phi \quad (61)$$

$$w^{(n)}(\kappa, \varphi) = \int_0^{2\pi} \int_0^{\infty} \rho^n(r, \phi) e^{-j\kappa r \cos(\varphi - \phi)} r dr d\phi$$

If the surface roughness is independent of the view direction, the correlation coefficient is isotropic depending only on r . In this case Eq. (61) becomes

$$w(\kappa) = 2\pi \int_0^{\infty} \rho(r) J_0(\kappa r) r dr, \quad (62)$$

$$w^{(n)}(\kappa) = 2\pi \int_0^{\infty} \rho^n(r) J_0(\kappa r) r dr$$

where $J_0(\kappa r)$ is the zeroth-order Bessel function. It is worth noting that the first term in (60) reduces to the first-order perturbation model when $h\sigma$ is small.

In Eq. (60) R_v, R_h are the Fresnel reflection coefficients, which can be generalized by replacing them with a reflection transition function [18] that allows the argument of the *Fresnel reflection coefficients* to change from the incident angle to the specular angle as the operating frequency changes from low to high or roughness from small to large. They are defined as follows

$$R_{vt} = R_v(\theta) + [R_{v0} - R_v(\theta)] \left(1 - \frac{S_t}{S_{t0}} \right) \quad (63)$$

$$R_{ht} = R_h(\theta) + [R_{h0} - R_h(\theta)] \left(1 - \frac{S_t}{S_{t0}} \right)$$

where R_{v0}, R_{h0} are the Fresnel reflection coefficients evaluated at the specular angle, which means normal

incidence for backscattering:

$$S_t = \frac{|F_t|^2 \sum_{n=1}^{\infty} \frac{(k\sigma \cos \theta)^{2n}}{n!} w^{(n)}(2k \sin \theta)}{\sum_{n=1}^{\infty} \frac{(k\sigma \cos \theta)^{2n}}{n!} \left| F_t + \frac{2^{n+2} R_{v0}}{e^{(k\sigma \cos \theta)^2} \cos \theta} \right|^2 w^{(n)}(2k \sin \theta)},$$

$$F_t = 8R_{v0}^2 \sin^2 \theta \left(\frac{\cos \theta + \sqrt{\epsilon_r - \sin^2 \theta}}{\cos \theta \sqrt{\epsilon_r - \sin^2 \theta}} \right)$$

$$S_{t0} = \left| 1 + \frac{8R_{v0}}{F_t \cos \theta} \right|^{-2} \text{ is the limit of } S_t \text{ as } k\sigma \rightarrow 0.$$

The functional form of this transition function indicates that $1 - S_t/S_{t0} \rightarrow 1$ as frequency or surface RMS height becomes large and goes to zero as frequency or surface RMS height is small. For very large dielectric values the magnitudes of R_{vt} , R_{ht} approach unity. Thus, the reflection coefficients with transitional properties R_{vt} , R_{ht} provide a desired change when either frequency or roughness changes.

In a practical application, it is not realistic to expect that a ground surface can always be represented as a continuous surface at all frequencies. In many cases, there are isolated vegetation, pebbles, rocks, and other material sitting above a ground surface. They may be negligible at low frequencies but not at higher frequencies when their physical size is comparable to the incident wavelength, λ .

For cross-polarized backscattering the single-scattering contribution is zero. Its backscattering coefficient based on multiple surface scattering with a chosen shadowing function is

$$\sigma_{vh}^0 = \frac{S(\theta)k^4}{64\pi^3} \int_0^1 \int_0^{2\pi} \left(\sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \exp[-2(k_z\sigma)^2] \right. \\ \left. \times \frac{(k_z\sigma)^{2(m+n)}}{m!n!} S(v) |F_{vh}(v, \varphi)|^2 W^{(m)} W^{(n)} \right) d\varphi dv \tag{64}$$

where $S(\theta)$, $S(v)$ are the shadowing functions, $W^{(m)} = W^{(m)}[k(v \cos \varphi - \sin \theta), k v \sin \varphi]$, $W^{(n)} = W^{(n)}[k(v \cos \varphi + \sin \theta), k v \sin \varphi]$,

$$F_{vh} = \frac{v^2 \cos \varphi \sin \varphi}{\cos \theta} \left\{ \left(\frac{1-R}{q} - \frac{1+R}{q_t} \right) \times (1-3R) \right. \\ \left. - \left(\frac{1-R}{q} - \frac{1+R}{\epsilon_r q_t} \right) (1+R) + \left(\frac{1+R}{q} - \frac{1-R}{q_t} \right) (1+3R) \right. \\ \left. - \left(\frac{1+R}{q} - \epsilon_r \frac{1-R}{q_t} \right) (1-R) \right\}$$

The reflection coefficient in Eq. (64) is defined as the difference between the vertically and horizontally polarized Fresnel reflection coefficients divided by 2, $(R_v - R_h)/2$. In F_{vh} , $q = (1 - v^2)^{0.5}$ and $q_t = (\epsilon_r - v^2)^{0.5}$.

The integration variable v has been normalized to the wavenumber k so that to cover all propagating modes, we only need to integrate to a value less than one as denoted by 1^- .

5.2. Theoretical Model Behaviors

In this section we illustrate the surface backscattering coefficient given by Eq. (60) on the type of correlation function, roughness scales, and the dielectric constant.

5.2.1. Effects of Surface Correlation. To show the effect of the surface correlation function on surface scattering, the backscattering coefficients based on correlation coefficients (1) exponential-like, $\exp[-(r/L)(1 - \exp[-r/x])]$, $x > 0$; (2) x -power, $(1 + r^2/L^2)^{-x}$, $x > 1$; and (3) Gaussian, $\exp[-r^2/L^2]$ are shown in Figs. 4 and 5 for several values of x for the first two correlations with the Gaussian correlation serving as a reference. In Fig. 4 we see that the exponential-like correlation generally causes the backscattering function to appear exponential over small angles of incidence ($0^\circ < \theta < 30^\circ$) and the amount of dropoff over large angles is dependent on the choice of the x value.

Figure 4. Effects of exponential-like correlation on backscattering with $k\sigma = 0.52$, $kL = 5.2$, and dielectric constant = $25 - j2.5$. Backscattering based on the exponential-like correlation function with several values of x are shown relative to the backscattering curve with Gaussian correlation. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 5. Effects of x -power correlation on backscattering with $k\sigma = 0.52$, $kL = 5.2$, and dielectric constant $= 25 - j2.5$. Backscattering based on the exponential-like correlation function with several values of x are shown relative to the backscattering curve with Gaussian correlation. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

A larger value of x makes the dropoff closer to the Gaussian. This is because a larger x will cause a wider range of the correlation function to be Gaussian-like. However, the angular trends remain exponential over all angles. In Fig. 5 we use the x -power correlation to calculate the backscattering coefficient. Over small angles of incidence there is a significant change in the angular trends from exponential to Gaussian as x increases. Beyond 30° , the angular trends are nearly linear. Similar to the exponential-like function, the dropoff over large angles of incidence is greater for larger x .

5.2.2. Effects of σ and L . Next we show the effect of the surface RMS height σ . This is illustrated in Fig. 6. Here the exponential-like correlation function is used. The parameter kL is chosen to be 5.2 in Fig. 6. The backscattering coefficient is seen to rise in level as σ increases from 0.2 to 0.8 except near vertical incidence. Intuitively,

as RMS height increases, we have a rougher surface and more backscattering at larger angles of incidence. The overall effect is that scattering tends to be more isotropic. This is why scattering near vertical incidence rises initially and then decreases. Now we consider the effects of the surface correlation length L on the backscattering coefficient in Fig. 7, when $k\sigma$ is fixed at 0.42. An increase in L is seen to cause a significant rise in backscattering near vertical and a faster dropoff at large angles of incidence in both vertical and horizontal polarizations. The nearly parallel angular curves over large angles of incidence is due to the use of the exponential-like correlation function.

5.2.3. Dependence on Dielectric Constant. Generally, a larger dielectric constant for the surface represents a greater discontinuity and hence should lead to a stronger backscattering over all angles of incidence. In backscattering, cross-polarized scattering is due to multiple scattering.

Figure 6. Backscattering curves are shown for vv and hh using exponential-like correlation at 5 GHz, $kL = 5.2$, $\epsilon_r = 25 - j2.5$, when the RMS height, σ , varies from 0.2 to 0.8 cm. There is an initial rise with a subsequent drop near vertical, when σ is greater than 0.6 cm. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 7. Backscattering curves are shown for vv and hh using exponential-like correlation at 5 GHz, $k\sigma = 0.42$, $\epsilon_r = 25 - j2.5$, when the correlation length L varies from 2 to 10 cm. There is continued rise near vertical as L increases along with a faster dropoff indicating an effectively smoother surface. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Thus, a change in the dielectric constant has a greater influence on cross polarization in the backscattering direction. This point is illustrated in Fig. 8 with the x -power and Gaussian correlation functions. There is a large rise in the level of the backscattering curve as the dielectric constant increases. The general shape of the angular curves are similar but the overall angular dropoff is larger for Gaussian correlation.

5.3. Comparisons with Soil Measurements

In making comparisons with measurements it is important to realize that different scales of roughness could be responsible for scattering at two different frequencies. If so, a single parameter correlation function cannot be used for both frequencies without changing the value of its correlation length. This is why for multifrequency measurements it is generally not possible to use the same

surface parameter for all frequencies. On the other hand, when the same roughness scale is responsible for scattering at two frequencies, only one correlation parameter needs to be used.

In Fig. 9, we show a comparison between the surface model given by Eq. (60) and measurements from a rough soil surface in Ref. 23, where ground truth data were acquired by researchers. The roughness parameters are known to be $\sigma = 1.12$ cm and $L = 8.4$ cm. Dielectric values are fixed at $\epsilon_r = 15.34 - j3.7$ and $\epsilon_r = 15.23 - j2.1$ for 1.5 and 4.74 GHz, respectively. Except for the 50° point at 1.5 GHz, a very good agreement is realized in levels and trends between the model predictions using an exponential-like correlation with $x = 0.8$ cm and data at 1.5 GHz. At 4.75 GHz, an x value of 0.25 is used. A good agreement is realized in VV except at 20° and 60° . For HH polarization, the agreement is good except at 20° and 70° . In Fig. 10 we show another comparison with data collected by

Figure 8. Cross-polarized backscattering coefficient with $k\sigma = 0.315$, $kL = 2.1$ for (a) x -power correlation with $x = 1.5$ and (b) Gaussian correlation. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 9. A comparison with measurements from Ref. 24 using surface parameters provided: $\sigma = 1.12$ cm, $L = 8.4$ cm with $\epsilon_r = 15.34 - j3.7$ for 1.5 GHz and with $\epsilon_r = 15.23 - j2.1$ for 4.75 GHz. The correlations selected are $\exp[-(r/L)(1 - \exp[-1.25r])]$ and $\exp[-(r/L)(1 - \exp[-4r])]$. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Ulaby et al. [17] over an asphalt surface at 17 and 35.6 GHz from 10° to 70° incidence. At both frequencies the RMS height and correlation length are chosen to be 0.12 and 0.6 cm. The dielectric values are 16 and 12 using the exponential-like correlation with x equals 0.25 and 0.05, respectively. The overall agreements for both fields are good and some finer adjustments have been made of the exponential-like correlation function through the choice of x . This effect has been shown in Fig. 4.

6. SCATTERING FROM A VEGETATED AREA

A vegetation layer may be viewed as an inhomogeneous layer without a top boundary. In general, the scatterers within the layer are collections of leaves, stems, branches, and trunks. At frequencies around 8.6 GHz or more leaves are usually the dominant scatterer and attenuator beyond 20° off the vertical in the backscattering direction. To

illustrate volume scattering by leaves, we consider only backscattering from a half-space of disk- and needle-shaped leaves in this section. Readers are referred to Chapter 11 of Fung [1] for scattering by combinations of leaves, branches, and trunks.

To use Eq. (55) for volume scattering calculation from leaves, we need the scattering amplitude of disk- and needle-shaped leaves. A basic approach to this problem is to use the scattered field formulation based on the volume equivalence theorem

$$E^s(\mathbf{r}) = \frac{k^2(\epsilon_r - 1)}{4\pi} \int_V \frac{\exp(-jk|\mathbf{r} - \mathbf{r}'|)}{|\mathbf{r} - \mathbf{r}'|} \mathbf{E}_{in} dV' \quad (65)$$

where k is the wavenumber in air, ϵ_r is the relative permittivity of the scatterer (leaf), \mathbf{E}_{in} is the field inside the scatterer, and integration is over the volume V of the scatterer defined in terms of the prime variables. Clearly,

Figure 10. Comparison with measurements from asphalt road from Ref. 17. The exponential-like correlation function with $x = 0.25, 0.05$ is used with $\sigma = 0.12$ cm, $L = 0.6$ cm, and dielectric values of 16 and 12 at 17 and 35.6 GHz, respectively. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

the scattered field can be found, if the field inside the scatterer is known. To facilitate integration we need to express the integration variables in the local frame (principal frame of the scatterer) and then relate the local frame to the reference frame. This setup will also allow arbitrary orientation of the scatterer relative to the reference frame, since the angular separations between the two frames can be varied. Furthermore, the leaves of a given species will have an orientation distribution and we need to average over this distribution in order to find the scattering coefficient.

6.1. Scattering Amplitudes of Scatterers

To derive the scattering amplitudes for leaf-type scatterers, we need to allow the leaves to be arbitrarily oriented and obtain an estimate of the fields inside the leaf. Three types of leaf shape are considered: elliptic disk, circular disk, and needle. Because of a lack of symmetry, the orientation of an elliptic disk is specified by three

$$\begin{bmatrix} x'' \\ y'' \\ z'' \end{bmatrix} = \begin{bmatrix} (\cos \alpha \cos \beta \cos \gamma - \sin \gamma \sin \alpha) & (\sin \alpha \cos \beta \cos \gamma + \cos \alpha \sin \gamma) & -\sin \beta \cos \gamma \\ -\cos \alpha \cos \beta \sin \gamma - \sin \alpha \cos \gamma & -\sin \alpha \cos \beta \sin \gamma + \cos \alpha \cos \gamma & \sin \beta \sin \gamma \\ \cos \alpha \sin \beta & \sin \alpha \sin \beta & \cos \beta \end{bmatrix} \begin{bmatrix} x \\ y \\ z \end{bmatrix} \equiv \mathbf{U}_e \begin{bmatrix} x \\ y \\ z \end{bmatrix} \quad (68)$$

angles, while the circular and needle-shaped leaves are specified by only two.

6.1.1. Relation between Reference and Local Frames. To relate a reference frame (x, y, z) , to a local frame that is the principal frame of the scatterer (x'', y'', z'') for a symmetric scatterer such as a needle or a circular disk, we need to specify a polar angle β and an azimuthal angle α of rotation between the coordinates. Let z'' correspond to the normal vector to the disk or needle axial axis. From Fig. 11, the two angles between the coordinate systems are defined by first rotating around z'' by α and then around y''

Figure 11. Principal frame of the scatterer relative to the reference frame.

by β , yielding

$$\begin{bmatrix} x'' \\ y'' \\ z'' \end{bmatrix} = \begin{bmatrix} \cos \beta \cos \alpha & \cos \beta \sin \alpha & -\sin \beta \\ -\sin \alpha & \cos \alpha & 0 \\ \cos \alpha \sin \beta & \sin \alpha \sin \beta & \cos \beta \end{bmatrix} \begin{bmatrix} x \\ y \\ z \end{bmatrix} \equiv \mathbf{U} \begin{bmatrix} x \\ y \\ z \end{bmatrix} \quad (66)$$

For an elliptic disk another rotation with respect to the z'' axis by an angle γ defined by

$$\begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} \cos \gamma & \sin \gamma & 0 \\ -\sin \gamma & \cos \gamma & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x'' \\ y'' \\ z'' \end{bmatrix} \equiv \mathbf{U} \begin{bmatrix} x'' \\ y'' \\ z'' \end{bmatrix} \quad (67)$$

is needed, yielding the final relation after redefining the coordinates as

where \mathbf{U} and \mathbf{U}_e are unitary matrices. Their inverses are equal to their transposes. Clearly, \mathbf{U} is a special case of \mathbf{U}_e when $\gamma=0$.

6.1.2. Estimate of the Field Inside a Scatterer. For an elliptic disk the field inside the scatterer in the local frame is related to the incident field, $\mathbf{E}_i = \mathbf{E}_0 \exp(-j\mathbf{k} \cdot \mathbf{r})$ (where $\mathbf{k} = ik\mathbf{i}$; \mathbf{i} is the unit vector in the incident direction and \mathbf{r} is the displacement vector in the reference frame), by Stratton [19]

$$\mathbf{E}_{\text{local}} = \begin{bmatrix} \frac{1}{a_1} & 0 & 0 \\ 0 & \frac{1}{a_2} & 0 \\ 0 & 0 & \frac{1}{a_3} \end{bmatrix} \mathbf{U}_e \cdot \mathbf{E}_i \quad (69)$$

Converting it to the reference frame, we have

$$\mathbf{E}_{\text{in}} = \mathbf{U}_e^{-1} \cdot \mathbf{E}_{\text{local}} \equiv \mathbf{A}_e \cdot \mathbf{E}_i \quad (70)$$

where \mathbf{A}_e is the matrix of transformation relating the incident field in the reference frame to the inner field in the same frame. In Eq. (69) a vector that appears with a matrix is understood to be a column matrix and

$$\begin{aligned} a_1 &= 1 + (\epsilon_r - 1)g_1 \\ a_2 &= 1 + (\epsilon_r - 1)g_2 \\ a_3 &= 1 + (\epsilon_r - 1)g_3 \end{aligned} \quad (71)$$

where the g_i values are the demagnetizing factors that vary depending on the shape of the scatterer. For an elliptic disk-shaped leaf, we have [20]

$$\begin{aligned} g_1 &= \frac{c}{a}(1-e^2)^{0.5} + \frac{K(e, \pi/2) - E(e, \pi/2)}{e^2} \\ g_2 &= \frac{c}{a} \frac{E(e, \pi/2) - (1-e^2)K(e, \pi/2)}{e^2(1-e^2)^{0.5}} \\ g_3 &= 1 - \frac{c}{a} \frac{E(e, \pi/2)}{(1-e^2)^{0.5}} \end{aligned} \quad (72)$$

where $a > b \gg c$ are the semiaxes of the elliptic disk, $e = [1 - (b/a)^2]^{0.5}$, and the elliptic integrals of the first and second kinds are given by

$$\begin{aligned} K\left(e, \frac{\pi}{2}\right) &= \int_0^{\pi/2} \frac{1}{\sqrt{1-e\sin^2\xi}} d\xi \\ E\left(e, \frac{\pi}{2}\right) &= \int_0^{\pi/2} \sqrt{1-e\sin^2\xi} d\xi \end{aligned} \quad (73)$$

For a circular disk-shaped leaf ($a = b \gg c$), we should replace \mathbf{A}_e by \mathbf{A}_c , which is equal to \mathbf{A}_e with $\gamma = 0$ and the demagnetizing factors given by

$$\begin{aligned} g_1 = g_2 &= \frac{1}{2(m^2-1)} \left[\frac{m^2}{\sqrt{m^2-1}} \sin^{-1}\left(\frac{\sqrt{m^2-1}}{m}\right) - 1 \right] \\ g_3 &= \frac{m^2}{m^2-1} \left[1 - \frac{1}{\sqrt{m^2-1}} \sin^{-1}\left(\frac{\sqrt{m^2-1}}{m}\right) \right], \\ m &= \frac{a}{c} \end{aligned} \quad (74)$$

For a needle-shaped leaf ($a = b \ll c$), we should replace \mathbf{A}_e by \mathbf{A}_n , which is equal to \mathbf{A}_e with $\gamma = 0$, and another set of demagnetizing factors given by

$$\begin{aligned} g_1 = g_2 &= \frac{m'(m'^2-1)}{2} \left[\frac{m'}{m'^2-1} + \frac{1}{2} \ln\left(\frac{m'-1}{m'+1}\right) \right] \\ g_3 &= -(m'^2-1) \left[\frac{m'}{2} \ln\left(\frac{m'-1}{m'+1}\right) + 1 \right], \\ m' &= \sqrt{1 - \frac{a^2}{c^2}} \end{aligned} \quad (75)$$

The use of Eq. (71) in (65) with the phase of the incident field $\mathbf{k} \cdot \mathbf{r}$ replaced by $(\mathbf{U}_e \cdot \mathbf{k}) \cdot \mathbf{r}'$ allows the integration variables to be expressed in the local frame to facilitate integration.

6.1.3. Scattering Amplitude of an Elliptic Disk. In this section we show the expression for the scattering amplitude with \mathbf{s}, \mathbf{i} denoting the unit vectors in the scattered and incident directions, respectively. For a \mathbf{p}_s polarized scattered field the amplitude portion of $\mathbf{p}_s \cdot \mathbf{E}_{in}$ is $\mathbf{p}_s \cdot \mathbf{E}_{in} = \mathbf{p}_s \cdot \mathbf{A}_e \cdot \mathbf{E}_0$. From Eq. (65) we can write the \mathbf{p}_s polarized scattered field component for an elliptic disk in

the far field by letting $|\mathbf{r} - \mathbf{r}'|$ equal to $r - \mathbf{s} \cdot \mathbf{r}'$ in the phase and equal to $|\mathbf{r}| = r$ in the amplitude. Then, Eq. (65) reduces to

$$\begin{aligned} \mathbf{p}_s \cdot \mathbf{E}^s(r) &= \frac{k^2(\epsilon_r - 1)}{4\pi} \int_V \frac{\exp[-jk(r - \mathbf{s} \cdot \mathbf{r}')] }{|\mathbf{r}|} (\mathbf{p}_s \cdot \mathbf{E}_{in}) dV' \\ &\approx \frac{k^2(\epsilon_r - 1)}{4\pi r} (\mathbf{p}_s \cdot \mathbf{A}_e \cdot \mathbf{E}_0) \exp(-jkr) \int_V \exp[jk(\mathbf{s} - \mathbf{i}) \cdot \mathbf{r}'] dV' \\ &\equiv \frac{k^2(\epsilon_r - 1)}{4\pi r} (\mathbf{p}_s \cdot \mathbf{A}_e \cdot \mathbf{E}_0) \exp(-jkr) I_e \\ &= \mathbf{p}_s \cdot \left[k^2(\epsilon_r - 1) \frac{\mathbf{A}_e}{4\pi} I_e \right] \cdot \mathbf{E}_0 \frac{\exp(-jkr)}{r} \\ &\equiv \mathbf{p}_s \cdot \mathbf{f}_e(\mathbf{k}_s, \mathbf{k}_i) \cdot \mathbf{p}_i E_0 \frac{\exp(-jkr)}{r} \end{aligned} \quad (76)$$

where $\mathbf{f}_e(\mathbf{k}_s, \mathbf{k}_i)$ is the scattering amplitude matrix for an elliptic disk; $\mathbf{k}_s = k\mathbf{s}$; $\mathbf{k}_i = k\mathbf{i}$. The elements of this matrix defined in accordance with vertical and horizontal polarizations can be written as

$$\begin{aligned} \mathbf{p}_s \cdot \mathbf{f}_e(\mathbf{k}_s, \mathbf{k}_i) \cdot \mathbf{p}_i &= \frac{k^2(\epsilon_r - 1) I_e}{4\pi} \begin{bmatrix} (\mathbf{v}_s \cdot \mathbf{A}_e \cdot \mathbf{v}_i) & (\mathbf{v}_s \cdot \mathbf{A}_e \cdot \mathbf{h}_i) \\ (\mathbf{h}_s \cdot \mathbf{A}_e \cdot \mathbf{v}_i) & (\mathbf{h}_s \cdot \mathbf{A}_e \cdot \mathbf{h}_i) \end{bmatrix} \\ &\equiv \begin{bmatrix} f_{vv} & f_{hv} \\ f_{vh} & f_{vh} \end{bmatrix} \end{aligned} \quad (77)$$

where the vertical and horizontal polarization unit vectors in Eq. (77) are chosen to agree with θ and ϕ unit vectors of a standard spherical coordinate system and form an orthogonal set with \mathbf{s} as

$$\begin{aligned} \mathbf{s} &= \mathbf{x} \sin \theta_s \cos \phi_s + \mathbf{y} \sin \theta_s \sin \phi_s + \mathbf{z} \cos \theta_s \\ \mathbf{v}_s &= \mathbf{x} \cos \theta_s \cos \phi_s + \mathbf{y} \cos \theta_s \sin \phi_s - \mathbf{z} \sin \theta_s \\ \mathbf{h}_s &= -\mathbf{x} \sin \phi_s + \mathbf{y} \cos \phi_s \end{aligned} \quad (78)$$

Similarly, the unit polarization vectors associated with the incident direction form another orthogonal system as

$$\begin{aligned} \mathbf{i} &= \mathbf{x} \sin \theta_i \cos \phi_i + \mathbf{y} \sin \theta_i \sin \phi_i + \mathbf{z} \cos \theta_i \\ \mathbf{v}_i &= \mathbf{x} \cos \theta_i \cos \phi_i + \mathbf{y} \cos \theta_i \sin \phi_i - \mathbf{z} \sin \theta_i \\ \mathbf{h}_i &= -\mathbf{x} \sin \phi_i + \mathbf{y} \cos \phi_i \end{aligned} \quad (79)$$

$$I_e = \int_V \exp[jk(\mathbf{s} - \mathbf{i}) \cdot \mathbf{r}'] dV' = 4\pi abc \frac{J_1(\bar{q})}{\bar{q}} \quad (80)$$

where $\bar{q} = k \sqrt{\{a[\mathbf{U}_e \cdot (\mathbf{s} - \mathbf{i})_x]^2 + \{b[\mathbf{U}_e \cdot (\mathbf{s} - \mathbf{i})_y]^2\}}$.

6.1.4. Scattering Amplitude of a Circular Disk. For a circular disk-shaped leaf, the forms of Eqs. (76), (77), and (80) are valid, but we need to replace \mathbf{A}_e by \mathbf{A}_c because the definitions for the demagnetizing factors g_1, g_2, g_3 are different and we need to set $a = b$ in Eq. (80).

6.1.5. Scattering Amplitude of a Needle. For a needle-shaped leaf, the forms of Eqs. (76) and (77) are valid, but we need to replace \mathbf{A}_e by \mathbf{A}_n because the definitions for the demagnetizing factors g_1, g_2, g_3 are different. The corresponding expression for I_e will be called I_n . Its integral form is the same as Eq. (80), except we have to evaluate it differently. Letting its length be $L = 2c$, we have

$$\begin{aligned}
 I_n &= (\pi a^2) \int_{-L/2}^{L/2} \exp(jz''q_z'') dz'' \\
 &= \frac{\pi a^2 [\exp(jq_z''L/2) - \exp(-jq_z''L/2)]}{jq_z''} \quad (81) \\
 &= \frac{2\pi a^2}{q_z''} \sin \frac{q_z''L}{2}
 \end{aligned}$$

6.2. Theoretical Model Behaviors

We consider the frequency, size, and moisture dependence of the backscattering coefficients σ^0 of a circular- and needle-shaped leaf in this section. To do so, we need an estimate for the dielectric constant for leaves as a function of frequency and moisture content. The empirical formula we use here is from Ref. 21.

6.2.1. Permittivity of Vegetation Given GMC. When the gravimetric moisture content (GMC) is given and denoted by M_g , the nondispersive residual component of the dielectric constant is

$$\epsilon_n = 1.7 - 0.74M_g + 6.16M_g^2$$

The free-water volume fraction is

$$vf_f = M_g(0.55M_g - 0.076)$$

while the volume fraction for the bound water is

$$vf_b = \frac{(4.64M_g^2)}{1 + 7.36M_g^2}$$

With these quantities known, the permittivity of vegetation is given as a function of frequency in gigahertz by

$$\begin{aligned}
 \epsilon(M_g) &= \epsilon_n + vf_f \left\{ 4.9 + \frac{75}{\left[1 + j\left(\frac{f}{18}\right)\right]} - j\frac{22.86}{f} \right\} \\
 &+ vf_b \left\{ 2.9 + \frac{55}{\left[1 + j\left(\frac{f}{0.18}\right)^{0.5}\right]} \right\} \quad (82)
 \end{aligned}$$

6.2.2. Dependence on Moisture Content, Size, and Frequency. In Fig. 12 we see that σ^0 increases over all incident angles as the moisture content of the circular

Figure 12. Dependence of backscattering coefficient on the gravimetric moisture content of a circular disk-shaped leaf ($M_g = 0.1, 0.3, 0.5$). Thickness of the leaf = 0.01 cm and radius = 1.5 cm. Results indicate negligible difference between vertical and horizontal polarizations and a monotonic increase of σ^0 with moisture. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

leaves increases from 0.1 to 0.5 for both vertical and horizontal polarization. In general, there is very little differences between horizontal and vertical polarization because we assumed random orientation distribution for the leaves. Similar results in trend are expected for needle-shaped leaves. In Fig. 13a we show circular leaf size dependence (radius) at 8.6 GHz, 40° incidence at a dielectric constant of $14.9 - j2.5$. There is a steep rise over small-size values reminiscent of the Rayleigh region followed by an oscillatory behavior indicating the resonant region. Finally, it shows saturation where the length or radius of the scatterer exceeds a wavelength. In the Rayleigh region vertical polarization is smaller than horizontal, while the reverse is true in the larger region. A similar plot versus the length of the needle-shaped leaf is shown in Fig. 13b, where we see a similar trend without oscillations and a higher horizontal than vertical polarization in level for length exceeding 2 cm. Similar plots of the extinction cross sections give a monotonic increase with the size of the disk in Fig. 14a and the length of the needle in Fig. 14b. The increase is much faster for the disk than the needle. For the disk-shaped leaf, horizontal polarization is seen to experience more attenuation than the vertical and the role of the polarizations reverses for the needle-shaped leaf. In Fig. 15 we show the frequency dependence of the backscattering coefficient for the two types of leaf. Both horizontal and vertical polarization increase with frequency and the increase is faster for the needle-shaped leaf.

6.3. Comparisons with Vegetation Measurements

The first volume scattering medium considered is a soybean canopy. It is modeled as a half-space of randomly oriented, disk-shaped leaves. Figure 16 shows the comparisons between Eq. (55) and the data from Ref. 22. The agreement between model and data is very good. Then, in

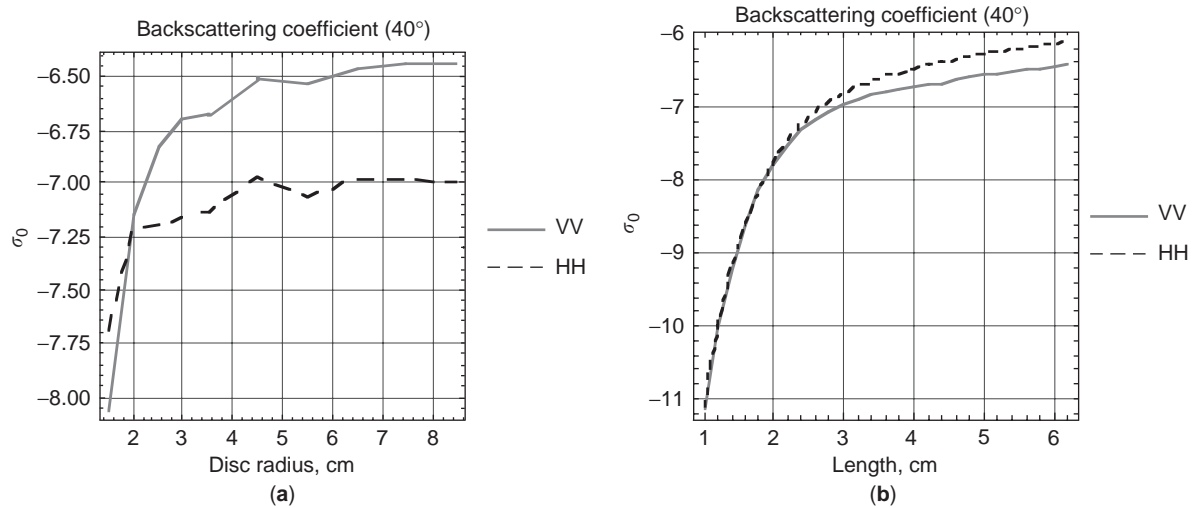

Figure 13. Dependence of backscattering coefficient at 8.6 GHz with (a) the radius of a randomly oriented circular disk-shaped leaf of thickness 0.01 cm and $\epsilon_r = 14.9 - j2.5$; (b) a randomly oriented needle with radius 0.12 cm and $\epsilon_r = 8.36 - j3.12$. There is a Rayleigh region for small size and a saturation behavior when the length or radius of the scatterer exceeds a wavelength. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Fig. 17 we show another comparison of Eq. (55) with data from deciduous trees. Again very good agreement is obtained. Since the leaves of soybeans and trees are clearly different in shape, it follows that while shape should make a difference in scattering, its effect becomes negligible when we consider random distributions. Thus, the volume scattering model is applicable to disk-shaped leaves regardless of their shape whenever the leaf distribution is very wide.

For needle-shaped vegetation, in Fig. 18 we show a comparison with coniferous vegetation. Very good agreement is obtained between Eq. (55) and the data reported in Ref. 23.

7. SCATTERING FROM SNOW-COVERED SURFACE

A snow medium is a densely populated concentration of wet or dry ice particles in air with a volume fraction usually between 0.1 and 0.4. Within the distance of a centimeter there are several needle-like ice particles that are randomly oriented. Because of their random orientation, spherical particles have been used to model snow with a radius of ~ 0.5 mm. As a result of metamorphism, actual snow layer may have a grain size that increases with depth. It is clear that snow is a *dense medium* both spatially and electrically in the microwave region. Recall that the classical radiative transfer formulation is for

Figure 14. Variation of the extinction cross section at 8.6 GHz with (a) the radius of a randomly oriented circular disk-shaped leaf of thickness 0.01 cm and $\epsilon_r = 14.9 - j2.5$; (b) a randomly oriented needle with radius 0.12 cm and $\epsilon_r = 8.36 - j3.12$. For circular leaves extinction cross section is higher for horizontal polarization and for needle-shaped leaves, vertical polarization is higher. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 15. Vertically and horizontally polarized backscattering coefficients from a volume of randomly oriented circular disks, VVc,HHc and needles, VVn,HHn, plotted as a function of frequency at a moisture content of 0.4. Disk thickness = 0.01 cm, radius = 1.5 cm. Needle radius = 0.17 cm, length = 1.67 cm. The level of backscattering is higher for circular disk-shaped leaves, but backscattering increases more rapidly with frequency for needle-shaped leaves. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

sparse media and that the phase function is the product between the average of the magnitude squared of the scattering amplitude $\langle |S|^2 \rangle$ of a single scatterer multiplied by the number density n_0 . This definition of the phase function is applicable to sparse media where independent scattering occurs. For snow the scatterers may scatter as a group in some correlated manner, and near-field interaction may have to be included. For this reason we need an effective number density for correlated scatterers to account for phase coherency and a modified scattering amplitude to include near-field interaction [5]. The effective number density of scatterers is smaller than the actual number because several scatterers are acting

Figure 16. Comparison between volume scattering model and measurements from a soybean canopy shows very good agreement. Leaf thickness = 0.02 cm; radius = 1.5 cm, $\epsilon_r = 29.1 - j6.1$. (From Ref. 22). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 17. Comparison between volume scattering model given by Eq. (55) with measurements from deciduous trees in Kansas. Leaf thickness = 0.01 cm; radius = 1.5 cm, $\epsilon_r = 14.9 - j4.9$. Both data and model indicate negligible difference between horizontal and vertical polarizations in backscattering from trees. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

coherently as one scatterer. This effect can be very significant under large-volume-fraction conditions or when only a few scatterers are within the distance of a wavelength. Because of random orientation when there are too many scatterers lying within a wavelength, the coherence among scatterers can be destroyed. Thus, the most significant correction for dense media is the replacement of the number density by the effective number density.

7.1. An Effective Number Density

From Ref. 4 an effective number density n_{eff} was derived for spherical scatterers. It is assumed that the positions of

Figure 18. Comparison of model given by Eq. (55) with coniferous tree data from Ref. 21. Length = 1.67 cm, radius = 0.17 cm, $\epsilon_r = 8.36 - j3.12$, $f = 9.9$ GHz. The agreement validates the model for coniferous vegetation. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

these scatterers are Gaussian correlated. It has the form

$$n_{\text{eff}} = \frac{1 - e^{-k_{\text{si}}^2 \sigma^2}}{d^3} + \frac{e^{-k_{\text{si}}^2 \sigma^2}}{d^3} \sum_{m=1}^{\infty} \frac{(k_{\text{si}}^2 \sigma^2)^m}{m!} \left[\left(\sqrt{\frac{\pi}{m}} \frac{L}{d} \right)^3 \right. \\ \left. \times \exp\left(\frac{-k_{\text{si}}^2 \sigma^2}{4m}\right) - a(k_x)a(k_y)a(k_z) \right] \quad (83)$$

where

$$a(k_r) = \sqrt{\frac{\pi}{m}} \frac{L}{d} \exp\left(\frac{-k_r^2 L^2}{4m}\right) \text{Re} \left\{ \text{erf} \left(\frac{(md/L) + jk_r L}{2\sqrt{m}} \right) \right\}$$

$$\mathbf{k}_s = k(\mathbf{x} \sin \theta_s \cos \phi_s + \mathbf{y} \sin \theta_s \sin \phi_s + \mathbf{z} \cos \theta_s)$$

$$\mathbf{k}_i = k(\mathbf{x} \sin \theta_i \cos \phi_i + \mathbf{y} \sin \theta_i \sin \phi_i + \mathbf{z} \cos \theta_i)$$

$$\mathbf{k}_s - \mathbf{k}_i = \mathbf{x}k_x + \mathbf{y}k_y + \mathbf{z}k_z \equiv \mathbf{k}_{\text{si}}$$

and σ^2 is the variance of a scatterer from its mean position, L is the correlation length among scatterer positions, and d is the average spacing between adjacent scatterers. For spherical scatterers Ref. 4 has extended the *Mie phase function* to include the near-field interaction by not invoking the far-field approximation. Since the contents of the Mie phase function is complex but well documented in the literature, the reader is referred to Refs. 4 and 16 for its content.

7.2. Comparison with Measurements

In this section we want to show an application of the layer model defined by Eqs. (55), (57), (58), and (61) and the relative contributions of the surface and volume scattering

Figure 19. Comparison between the layer model defined by Eqs. (55), (57), (58), and (60) and snow data reported by Kendra et al. [24]. The notations Vvv,Vvh stand for total volume scattering; Svv,Shh, for total surface scattering; and VV,HH, for total scattering by the layer for vertical and horizontal polarizations, respectively. Dav,Dah denote data. Relative importance between surface and volume scattering is shown. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 20. Comparison between the layer model defined by Eqs. (55), (57), (58), and (60) and snow data reported by Kendra et al. [24]. The notations Vvv,Vvh stand for volume scattering; Svv,Shh, for surface scattering; and VV,HH, for total scattering by the layer for vertical and horizontal polarizations, respectively. Dav,Dah denote data. Relative importance between surface and volume scattering is shown. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

terms to the total backscattering from a snow-covered irregular ground surface. Most of the model parameters have been estimated by Ref. 25, so very little selection is needed. The RMS heights of the snow-air boundary and snow-ground boundary are 0.45 and 0.32 cm; correlation lengths of snow and ground surface are chosen to be 0.7 cm and 1.1 cm, and the snow and ground permittivities are $1.97 - j0.007$ and 4.7. We use exponential correlation function for both surfaces. Within the snow medium, the ice particle radius and permittivity are respectively 0.014 cm and 3.15, snow density is 0.48 g/cm^3 , and snow depth is 60 cm. Using these values, we compute backscattering at 5.3 GHz in Fig. 19 and at 9.5 GHz in Fig. 20. The results are in very good agreement with the dry-snow data, which are available only for vertical polarization. Figure 19 indicates that surface scattering contribution is dominating but that volume scattering from snow also makes significant contribution to total scattering. The volume scattering contribution is larger at 9.5 GHz, where it accounts for about 2 dB of difference.

1. INTRODUCTION

Microwave and millimeter-wave solid-state devices are used in applications in the 3–300 GHz frequency range. These devices can be divided into two large groups: (1) two-terminal devices or diodes and (2) three-terminal devices or transistors. The diodes can be subdivided into passive and active devices, referring to the real part of the impedance as positive and negative, respectively. The active diodes can further be classified to the origin of the negative resistance. The three-terminal active devices are divided into minority and majority carrier devices. The classification is summarized as follows:

1. Two-terminal devices

- a. Passive diodes
 - i. Schottky barrier diode
 - ii. pin (positive–intrinsic–negative) diode
- b. Active diodes
 - i. Transit-time effect based on
 - (1) Avalanche injection: IMPATT (impact avalanche transit time) diode, TRAPATT (Trapped Plasma Avalanche-Triggered Transit) diode
 - (2) Forward injection: BARITT (barrier injection transit time) diode
 - (3) Tunnel injection: TUNNETT (tunnel injection transit time) diode
 - ii. Bulk effect: Gunn diode
 - iii. Tunnel effect: tunnel diode

2. Three-terminal devices

- a. Minority-carrier devices: BJT, HBT (bipolar junction transistor, heterojunction bipolar transistor)
- b. Majority-carrier devices: FET, MOSFET, MESFET, HEMT (field-effect transistor, metal oxide semiconductor FET, metal semiconductor FET, high-electron-mobility transistor)

In this article, we focus on the most frequently used microwave and millimeter-wave devices: the Schottky barrier diode, pin diode, IMPATT diode, BARITT diode, Gunn diode, tunnel diode, MESFET, HEMT, and HBT. Nowadays, there is also an increasing interest in the use of MOS-type transistors for applications in the lower microwave frequency range. For each of these devices, we first briefly explain their physical operation. For a more detailed analysis of the device's solid-state physics, we however refer to the books listed in the Further Reading List. Subsequently, we discuss the devices' properties and frequency limitations, and finally we outline their main application areas.

2. MICROWAVE AND MILLIMETER-WAVE DIODES

2.1. Schottky Barrier Diode

2.1.1. Description. We first mention the p-n junction diode [1], because this component serves as the foundation of many solid-state devices. A p-n junction is formed at the metallurgical interface of two regions in a semiconductor where one region contains impurity elements that create equivalent positive (p-type) charges and the other semiconductor region contains impurities that create negative (n-type) charges.

A Schottky barrier diode is formed by placing a metal layer directly onto a unipolar semiconductor substrate. When the metal and the semiconductor materials are brought into contact, electrons in the material having higher Fermi energy diffuse into the other material that has lower Fermi energy. This process proceeds rapidly until the Fermi energies of the two materials are balanced. In case the semiconductor is n-type (p-type) and the work-function of the semiconductor is smaller (larger) than that of the metal, a potential barrier is formed at the metal-semiconductor boundary, exhibiting rectifying current-voltage characteristics. When reverse-biased, the diode behaves as a voltage-dependent capacitance with low losses since the reverse current is small. Diodes operated under this condition are called *varactors*.

2.1.2. Properties and Frequency Limitations. The small-signal equivalent circuit of the Schottky diode is presented in Fig. 1. It consists of an extrinsic part and an intrinsic part. The extrinsic part consists of the parasitic elements that are inherent to the geometry of the device and hence depends on the way that the device is inserted in the circuit. The parasitic capacitance C_{pg} and the inductance L_s are determined by the metallisations of the access lines to the device. The resistance R_s is the sum of the resistance of the anode metal and the ohmic cathode resistance. The intrinsic part is within the dashed rectangle. The resistance R_{gsf} models the current through the Schottky diode. The capacitance C_{gs} models the change in the depletion

charge with respect to the voltage across the Schottky diode. R_{gs} models the charging resistance of the Schottky junction. The extrinsic elements are independent of the applied voltage, while the intrinsic elements are bias-dependent.

Important figures of merit are the cut-off frequency $f_c(V)$ and the dynamic cutoff frequency f_{cd} . For a given voltage V (typically 0 V) applied across the Schottky diode, the cutoff frequency $f_c(V)$ is defined as follows:

$$f_c(V) = \frac{1}{2\pi R_s C_{gs}(V)} \quad (1)$$

The dynamic cutoff frequency f_{cd} , defined for varactors, gives an indication of the nonlinear variation of the capacitance. It is defined as

$$f_{cd} = \frac{1}{2\pi R_s} \left(\frac{1}{C_{gs,\min}} - \frac{1}{C_{gs,\max}} \right) \quad (2)$$

where R_s is the series resistance and $C_{gs,\min}$ and $C_{gs,\max}$ are the minimum and maximum capacitance values. The cutoff frequency $f_c(V)$ can be maximized by decreasing the series resistance and the capacitance. The ohmic cathode resistance is inversely proportional to the width, while the resistance of the anode metal is proportional to the width and inversely proportional to the square of the number of fingers. The capacitance is proportional to the width. This implies that there exists an optimal width to maximise the figures of merit.

Schottky diodes that have to be compatible with a standard monolithic microwave integrated circuit (MMIC) technology are often realized by connecting the drain and source of a MESFET or HEMT device. Those Schottky diodes typically have cutoff frequencies up to a few hundred gigahertz. The f_c can be increased up to terahertz frequencies by modifying the layer structure and the layout [2]. Schottky diodes aimed for submillimeter-wave applications are typically circular with an anode diameter of less than 2.5 μm .

2.1.3. Applications. Schottky diodes have been used extensively in nonlinear circuit applications. At microwave and also at millimeter-wave frequencies, Schottky diodes are now often replaced by transistors. The reason is the potential conversion gain when employing transistors. Schottky diodes are, however, still the basic nonlinear elements in microwave broadband mixers and in millimeter- and submillimeter-wave nonlinear applications. We can distinguish two modes of operation for Schottky diodes: the varistor and the varactor type.

In the first case, the diode is operated by utilizing the nonlinear characteristics in the forward-biased I - V curve. Varistors have potential very large bandwidths. An important application is the mixer diode. This is a device that converts the input RF signal to a lower- or higher-frequency signal. As mentioned above, the technology can be optimized for a certain application. In the case of mixer diodes, the noise is an important specification. To reduce the noise, the conversion loss should be decreased. This

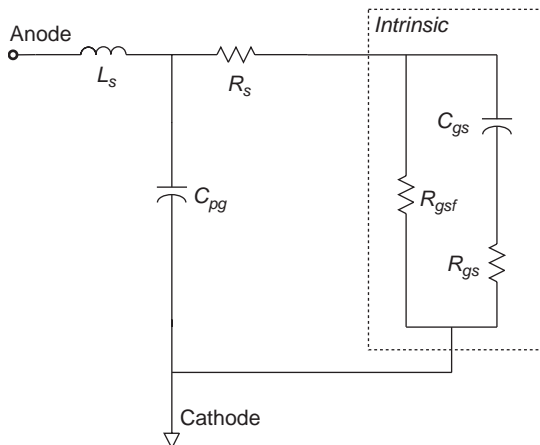

Figure 1. Small-signal equivalent circuit of the Schottky diode in parallel configuration.

can be obtained by a high carrier concentration and high-mobility material. From this point of view, GaAs, which has higher mobility than Si, is currently used for high-sensitivity (low-noise) and high-frequency-operation mixer diodes. In addition to the noise performance, we have to take account of the local oscillator drive level as a performance parameter of mixer diodes. Silicon is superior to GaAs from this point of view. The reason is that the barrier height of the Schottky barrier contact on GaAs is fixed at 0.7–0.8 eV. Therefore, a GaAs mixer diode usually requires a local oscillator drive level of 0 to 10 dBm. On the other hand, a silicon mixer diode can be operated even at a local-oscillator drive level of -10 dBm, because the barrier height can be varied by choosing the Schottky metal.

The second Schottky barrier diode type is the varactor. The term “varactor” originates from the term “variable reactor,” which means that the diode capacitance is variable with the external, reverse bias. Since the power consumption is theoretically zero, the potential power-added efficiency is high, but varactors exhibit a narrow fixed-tuned bandwidth. A first application area of varactors is voltage-variable tuning. Such a varactor has to possess high-capacitance change ratios, high values of the quality factor Q (defined as the ratio of energy stored to energy dissipated), and a wide voltage dynamic range. Since these values are related and generally involve tradeoffs, elaborate design criteria should be established to determine the material and geometric parameters of the diodes. A second application is harmonic generation, such as frequency multipliers. By changing the layer structure, for example, by using hyperabrupt junctions, the series resistance can be decreased and the characteristic of the capacitance as a function of the voltage can be optimized for particular designs. For example for frequency triplers, a symmetric profile around a DC bias of 0 V is preferred, since it suppresses the even order harmonics. This can be realized by means of a multi-quantum-well heterostructure varactor diode. Other varactor applications are nonlinear transmission lines, which require an abrupt $C(V)$ profile, MMIC phase shifters, and mixing detection.

2.2. pin Diodes

2.2.1. Description. In a pin diode, an intrinsic (i) layer is sandwiched between the p^+ and n^+ layers (Fig. 2). When the diode is forward-biased, its impedance goes low with the injection of carriers into the highly resistive intrinsic layer, and the diode acts as a resistance. On the other hand, when the diode is reverse-biased, the impedance becomes very high with spread of the depletion layer in the intrinsic layer and the diode acts as a capacitance.

2.2.2. Properties and Frequency Limitations. The intrinsic small-signal equivalent circuit of the pin diode at forward and reverse bias is shown in Fig. 3. As mentioned above, this scheme needs to be completed by the appro-

Figure 2. Layer structure of the pin diode.

Figure 3. Intrinsic small-signal equivalent circuit of the pin diode in forward (a) and reverse (b) mode.

appropriate extrinsic elements that strongly depend on the device configuration within the microwave or millimeter-wave circuit and possible package. The resistance R_i is the intrinsic-layer resistance, R_s is the series resistance of the p^+ and n^+ layers, C_1 is the reverse-biased depleted capacitance, and C_2 and R_2 are the reverse-biased undepleted capacitance and resistance, respectively.

Important specifications of pin diodes are low insertion loss, high power-handling capability, and fast switching time. In the ideal case, the lowest switching time is determined by the time to sweep away the stored charge in the intrinsic layer and is expressed by the transit time τ

$$\tau = \frac{V_b}{E_{\max} v_s} \quad (3)$$

where v_s is the saturation velocity of electrons, V_b is the breakdown voltage, and E_{\max} is the electric field where breakdown occurs. Therefore, V_b needs to be kept low for faster switching. However, in actual diodes, the switching time is almost entirely governed by the parasitics of the diode. For microwave applications, GaAs pin diodes are often used instead of Si. The reason is that the resistance is lower for GaAs, reflecting the higher mobility.

2.2.3. Applications. pin diodes are used as phase shifters for phased-array radars, switches for pulsed radars, limiters to protect the receiver circuit against overload, and attenuators. In microwave integrated circuit (MIC) design, pin diodes are preferred to Schottky diodes because of their lower series resistance and capacitance, which leads to superior performance. The layer structure of pin diodes is, however, not straightforwardly compatible with standard MMIC technology. Therefore, monolithic integrated phase shifter circuits are realized with Schottky diodes, “cold” FETs, (i.e., with no DC current), or dual-gate FETs.

2.3. IMPATT Diodes

2.3.1. Description. The IMPATT (*impact avalanche transit time*) diode employs the impact ionisation and transit properties of a semiconductor p-n junction to produce negative resistance at microwave frequencies. The diode type was first proposed by Read [3] in 1958. The p^+ -i-p- n^+ layer structure is represented in Fig. 4. In

Figure 4. Layer structure of the IMPATT diode.

operation the diode is reverse-biased into avalanche breakdown. The p layer is the avalanche region, followed by a “drift region,” the i layer, for the generated charge carriers to drift. The electric field in this drift region should be high enough to enable the generated carriers to travel at their saturation velocity.

When the diode is placed in a microwave resonant circuit, RF voltage fluctuations in the bias circuit grow and are forced into a narrow frequency range determined by the impedance characteristics of the resonant circuit. As a result of the avalanche process, the RF current across the avalanche region lags the RF voltage by 90°. This inductive delay is by itself not sufficient to produce an active characteristic. However, when the 90° phase shift is added to that arising from an additional inductive delay caused by the transit time of the carriers drifting through the remainder of the diode external to the avalanche region, a phase shift between the RF voltage and current greater than 90° is obtained. A Fourier analysis of the resulting waveforms reveals a device impedance with a negative real part. That means that the device is active and can be used to generate or amplify RF signals.

2.3.2. Properties and Frequency Limitations. The intrinsic small-signal equivalent circuit of the IMPATT diode is shown in Fig. 5. It consists of the ohmic resistance R_s ; the negative resistance R_d in series with the inductor L_d , which models the inductive delay; and the p-n junction capacitance C_j .

For optimum performance, the drift region is designed such that the electric field throughout the RF cycle is sufficiently high to produce velocity saturation for the charge carriers. In order to achieve this, it is common to design complex structures consisting of alternating layers of highly doped and lightly doped semiconductor regions. They can also be fabricated in a back-to-back arrangement to form double-drift structures. IMPATT diodes can be fabricated from most semiconductors, but are generally fabricated from Si or GaAs.

2.3.3. Applications. IMPATT diodes are particularly attractive for millimeter-wave applications and have been operated as high as a few hundred gigahertz. The devices are capable of good RF output power (mW to W) and good DC-to-RF conversion efficiency ($\approx 10\text{--}20\%$). They have

Figure 5. Intrinsic small-signal equivalent circuit of the IMPATT diode.

Figure 6. Layer structure of the BARITT diode.

moderate bandwidth capability, but relatively poor noise performance due to the impact ionisation process.

2.4. BARITT Diodes

2.4.1. Description. Another diode belonging to the transit-time diode family is the BARITT (*barrier injection transit time*) diode. The mechanisms responsible for the microwave oscillation are the thermoionic injection and diffusion of minority carriers across a forward-biased barrier and a transit-time delay of the injected carriers traversing the drift region. Several structures can be operated as BARITT diode, such as metal-n-metal and p-n-p, p-n-metal.

The first BARITT operation was obtained from a metal-n-metal reach-through diode [4], shown in Fig. 6. It is basically two Schottky diodes connected back to back. When a sufficiently large bias is applied to the device, the electric field will reach through the entire device. Under this condition, thermoionic injection of holes across the barrier, located at the left-side metal–semiconductor interface, occurs. The injected holes traverse the drift region from this barrier to the right-side metal contact.

2.4.2. Properties and Frequency Limitations. The BARITT diode has no avalanche delay because the thermoionically injected carriers are in phase with the AC voltage swings. The consequence is that the efficiency of a BARITT diode is substantially lower than that of an IMPATT diode. This is because during a part of the period, both the AC voltage and current are positive. This implies that AC power is dissipated in the device. This power will cancel some of the AC power generated by the device during the other part of the period. Therefore, the net AC power generated is smaller than the AC power of the IMPATT diode.

2.4.3. Applications. BARITT diodes are used in low-noise millimeter-wave applications, since they are much less noisy than IMPATT diodes. The reason is that the noise associated with carrier injection across the barrier is much smaller than the avalanche noise in an IMPATT diode. Disadvantages are the low efficiency and relatively narrow bandwidth.

2.5. Gunn Diodes

2.5.1. Description. The Gunn diode was developed by Gunn [5] in 1963. The name Gunn diode is given to all two-terminal devices whose operation depends on the transferred-electron effect. Gunn diodes are a type of active diodes. The negative conduction derives from the complex conduction band structure of certain compound semiconductor devices, such as GaAs and InP. In these direct-bandgap materials the central (or Γ) conduction band is in close energy-momentum proximity to secondary, higher-order conduction bands: the X and L valleys.

The electron effective mass is determined by the shape of the conduction bands. The electron effective mass is “light” in the Γ valley, but “heavy” in the higher-order X and L valleys. When the crystal is biased, the current flow is initially due to electrons in the light effective mass Γ valley and hence the conduction is ohmic. However, as the bias field is increased, an increasing proportion of the free electrons are transferred into the X and L valleys, where the electrons have heavier effective mass. The increased effective mass slows down the electrons, with a corresponding decrease in conduction current through the crystal. The net result is that the crystal displays a region of applied bias voltages where current decreases with increasing voltage. This means that a negative conductance is generated. The device is unstable and, when placed in an RF circuit or resonant cavity, oscillators or amplifiers can be fabricated. It is important to note that this device is not a diode in the strict sense, since no p-n or Schottky junction is used. The phenomenon is a characteristic of the bulk material and the special structure of the conduction bands in certain compound semiconductors. Few semiconductors have the conduction band structure necessary for the transferred electron effect.

2.5.2. Properties and Frequency Limitations. The intrinsic small-signal equivalent circuit of the Gunn diode is represented in Fig. 7. The Gunn diode can be modeled as a negative conductance $1/R_d$ in parallel with a capacitance C_j . The bandwidth of the Gunn effect is limited by the speed with which the electrons can transfer from one valley to another and back. This is a scattering process characterized by a time constant. It turns out to be shorter in InP than in GaAs. In GaAs the Gunn effect can be used up to ~ 80 GHz, while in InP frequencies about twice as high can be reached.

2.5.3. Applications. Transferred electron devices are widely used in oscillators from the microwave through high-millimeter-wave frequency bands. They have good RF output power capability (milliwatts to watts level), moderate efficiency ($< 20\%$), and excellent noise and bandwidth capability. Octave band tunable oscillators are easily fabricated using devices such as YIG (yttrium iron garnet) resonators or varactors as the tuning element. Most commercially available solid-state sources for the 60–100 GHz operation generally use InP transferred electron devices. Compared to the IMPATT diode, the Gunn diode produces less output power, but can exhibit lower noise performance.

Figure 7. Intrinsic small-signal equivalent circuit of the Gunn diode and the tunnel diode.

2.6. Tunnel Diodes

2.6.1. Description. Tunnel diodes [6] generate active characteristics by a mechanism involving the physical tunneling of electrons between energy bands in highly doped semiconductors. For example, if a p-n junction diode is heavily doped, the conduction and valence bands will be located in close proximity and charge carriers can tunnel through the electrostatic barrier separating the p- and n-type regions, rather than be thermoionically emitted over the barrier as generally occurs in this type of diode. When the diode is (forward or reverse)-biased, current immediately flows and the junction conduction is basically ohmic. In the forward-bias direction, conduction occurs until the applied bias forces the conduction and valence bands to separate. The tunnel current then decreases, and normal junction conduction occurs. In the forward-bias region where the tunnel current is decreasing with increasing bias voltage, a negative immittance characteristic is generated.

2.6.2. Properties and Frequency Limitations. Tunnel diodes are described by a negative conductance $1/R_d$ in shunt with a capacitance C_j (Fig. 7). Tunnel diodes are limited in operation frequency by the time it takes for charge carriers to tunnel through the junction. Since this time is very short (on the order of 1 ps), the operation frequency can be very high, approaching 1 THz. They have been operated at hundreds of gigahertz, limited by practical packaging and parasitic impedance considerations. The RF power available from a tunnel diode is limited (hundreds of milliwatts level), since the maximum RF voltage swing that can be applied across the junction is limited by the forward turnon characteristic of the device (typically 0.6–0.9 V). Increased RF power can be obtained only by increasing device area to increase RF current, but device area is limited by operation frequency according to an inverse law.

2.6.3. Applications. Tunnel diodes have moderate DC-to-RF conversion efficiency ($< 10\%$), and very low noise figures and are hence useful in low-noise applications, such as microwave and millimeter-wave receivers.

3. MICROWAVE AND MILLIMETER-WAVE TRANSISTORS

3.1. FETs

3.1.1. Description. The fundamental structure of the field-effect transistor (FET) has been proposed by Shockley in 1952 [7]. A FET consists of an n-type semiconductor layer, sandwiched by p-type layers, and ohmic contacts, formed at the edges of the n-type layer. The ohmic contacts are called *source* and *drain*. The p-n junctions serve as a control element and are called the *gate*. When reverse bias is applied across the p-n junctions, space charge regions form. Consequently, current flows from the drain to the source through a channel of the n-type layer bounded by the controlled space charge regions.

Other types of FETs utilize different ideas for the gate from that of the p-n junction type. These types include the

Figure 8. Layer structure of the MESFET.

metal-insulator-semiconductor (MIS), in which a gate electrode is formed on the semiconductor via an insulator, and the metal-semiconductor (MES), in which a Schottky barrier is used as the gate. The best-known MIS transistor type is the MOSFET with an oxide as insulator. The cross section of the MESFET is represented in Fig. 8. Possible operation modes are the common-source configuration and the less frequently used common-gate configuration. The former means that the drain contact is biased at a specified potential (positive drain potential for an n-channel device) and the source is grounded. The flow of current through the conducting channel is controlled by negative DC and superimposed RF potentials applied to the gate, which modulate the channel current and provide RF gain. The current flow is composed of only one type of charge carrier (generally electrons), and the device is hence termed unipolar.

3.1.2. Properties and Frequency Limitations. The small-signal equivalent circuit and the definitions of the typical figures of merit are identical to those of HEMT devices. Therefore, we refer to the corresponding part of the subsequent HEMT section.

3.1.3. Applications. There is an increasing interest in using several types of Si MOSFETs [CMOS (complementary MOS), SOI (silicon on insulator), LDMOS (Laterally Diffused MOSFET) (MOS), etc.] in analog RF applications in the lower microwave frequency band [8,9]. For microwave applications, however, compound semiconductor materials, and in particular gallium arsenide (GaAs) are preferred. The reason is that the electrode mobility and the peak drift velocity of GaAs are 6 times and twice as high, respectively, as those of Si. These properties result in larger transconductance, shorter electron transit times, and lower parasitic resistances. In addition, unlike Si, semiinsulating GaAs substrates can be formed. This contributes to the simple structure of FETs and to an important reduction of parasitics. p-n junctions with fine patterns are difficult to realize in GaAs because of the enhanced lateral diffusion at the surface. MIS structures with a low interface state density, such as SiO_2/Si , are very difficult to obtain. On the other hand, GaAs MESFETs, fabricated for the first time by Mead in 1966 [10], have been widely successful. GaAs MESFETs are the most important active devices used in microwave applications, while the high-performant HEMTs are typically employed at millimeter-wave frequencies. MESFETs can be optimized for small-signal, low-noise operation or for large-signal, RF power applications. Generally, low-noise

Figure 9. Layer structure of the conventional AlGaAs/GaAs HEMT.

operation requires short gate lengths, small gate widths, and highly doped channels. Power devices generally have longer gate lengths, much wider gate widths, and lower doped channels.

3.2. HEMTs

3.2.1. Description. The high-electron-mobility transistor (HEMT), first demonstrated by Dingle et al. in 1978 [11], derives its name from the high low-field mobility of its channel electrons that are captured at the interface between two semiconductor materials with a different bandgap energy and with a similar lattice constant. This type of interface is called a *heterojunction*.

A schematic cross section of the conventional HEMT, based on the AlGaAs/GaAs heterojunction, is shown in Fig. 9. Free electrons provided by the n-doped AlGaAs layer diffuse across the heterojunction into the narrow bandgap GaAs and become captured in the quasitriangular potential well at the interface caused by the conduction band discontinuity (ΔE_c). This leads to a two-dimensional electron gas (2DEG) consisting of electrons that are confined in the direction perpendicular to the heterojunction interface, but free to move in parallel directions. Because of the spatial separation between carriers and dopants, electrons in the channel obtain a very high low-field mobility, especially at low temperatures. The flow of electrons between the source and drain ohmic contact regions is modulated using an external gate voltage applied on a Schottky gate contact. While for a MESFET the bias on the Schottky gate contact controls the depth of the undepleted channel, for HEMTs the gate bias directly controls the carrier density in the channel.

The conventional lattice-matched AlGaAs/GaAs layer structure is now widely replaced by other combinations of compounds leading to improved HEMT characteristics. The main reason is that the conventional HEMT suffers from a small conduction band discontinuity ΔE_c . By incorporating indium in the channel, the conduction band discontinuity can be enhanced leading to three additional types of HEMTs, which are indicated on the energy band-gap versus lattice constant diagram of Fig. 10:

- The pseudomorphic HEMT (PHEMT) grown on a GaAs substrate and based on the $\text{Al}_x\text{Ga}_{1-x}\text{As}/\text{In}_y\text{Ga}_{1-y}\text{As}$ heterojunction

Figure 10. Energy bandgap–lattice constant diagram indicating the four different HEMT families.

- The InP lattice-matched HEMT (LMHEMT) grown on an InP substrate and based on the $\text{Al}_{0.48}\text{In}_{0.52}\text{As}/\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ heterojunction
- The InP pseudomorphic HEMT (InP PHEMT) grown on an InP substrate and based on the $\text{Al}_{0.48}\text{In}_{0.52}\text{As}/\text{In}_x\text{Ga}_{1-x}\text{As}$ ($0.53 > x > 0.80$) heterojunction

For completeness, the relatively new GaAs-based metamorphic HEMT (MMHEMT) is also shown in Fig. 10. This HEMT is grown strain-relaxed on GaAs and is based on the $\text{Al}_{1-y}\text{In}_y\text{As}/\text{In}_x\text{Ga}_{1-x}\text{As}$ ($0.3 > x > 0.5$) heterojunction [12]. Another development is the wide-bandgap device, such as AlGaN/GaN HEMTs [13].

3.2.2. Properties and Frequency Limitations. The small-signal equivalent circuit of the MESFET and HEMT devices is shown in Fig. 11. As has already been indicated above, the small-signal equivalent circuit consists of an extrinsic, bias-independent part and an intrinsic, bias-dependent part. The parasitic capacitances C_{pg} , C_{pd} , and C_{pgd} and the inductances L_s , L_d , and L_g are determined by the metallizations of the access lines to the device. It has to be noted that in case of on-wafer devices, the measure-

ments are typically de-embedded up to the reference plane of the device, which is the device as it will be inserted in the actual circuit design. The effect of the probe pads is hence not included in this small-signal equivalent scheme. The resistances R_d and R_s are caused mainly by the drain and source ohmic contacts, while the gate resistance R_g is determined primarily by the gate Schottky contact. The intrinsic part is within the dashed rectangle. The resistances R_{gsf} and R_{gdf} model the current through the gate–source and gate–drain Schottky diodes. The capacitances C_{gs} and C_{gd} model the change in the depletion charge with respect to the gate–source V_{gs} and gate–drain V_{gd} voltages, respectively. The drain–source capacitance C_{ds} is included in the equivalent circuit to account for geometric capacitance effects between the source and the drain electrodes. The intrinsic gain mechanism of the HEMT is provided by the transconductance g_m , which is a measure of the incremental change in the drain–source output current I_{ds} for a given change in gate–source input voltage V_{gs} . Mathematically, it is defined as $g_m = \partial I_{ds} / \partial V_{gs}$. The output conductance g_{ds} is a measure of the incremental change in drain–source output current I_{ds} with the drain–source output voltage V_{ds} . It is defined mathematically as $g_{ds} = \partial I_{ds} / \partial V_{ds}$. R_{gs} and R_{gd} model the charging resistances in the channel. The transconductance cannot respond instantaneously to changes in the gate–source voltage V_{gs} . The delay inherent to this process is described by the transconductance delay τ . Physically, it represents the time it takes for the charge in the channel to redistribute itself after a fluctuation of V_{gs} .

Important figures of merit for MESFETs and HEMTs [14] are the transition frequency f_T and the maximum oscillation frequency f_{max} . The transition or cutoff frequency f_T is defined as the frequency at which the short-circuit current gain (h_{21}) becomes unity. The h_{21} can be derived from the S parameters as

$$h_{21} = \frac{-2S_{21}}{(1 - S_{11})(1 + S_{22}) + S_{12}S_{21}} \quad (4)$$

In order to get a better physical understanding of the f_T , we express the intrinsic h_{21} in terms of the intrinsic

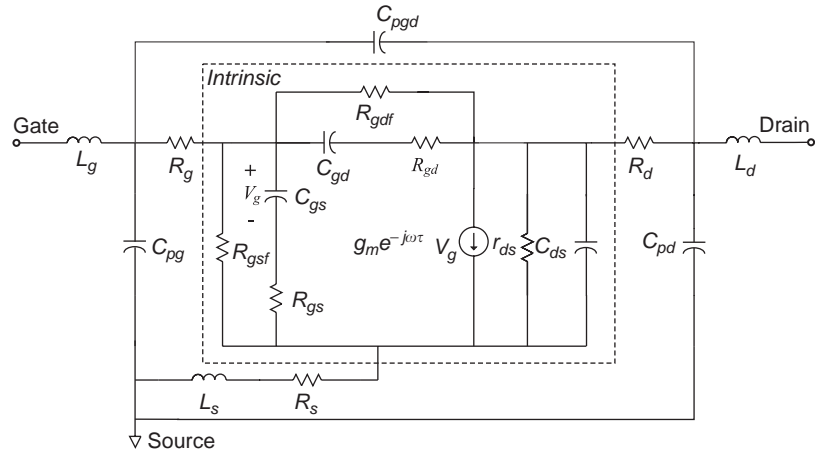

Figure 11. Small-signal equivalent circuit of the MESFET and the HEMT.

small-signal elements

$$h_{21} = \frac{g_m}{2\pi(C_{gs} + C_{gd})f} \quad (5)$$

where f is the frequency. This equation indicates a -20 -dB/decade rolloff for h_{21} and yields the usual approximate expression for the intrinsic f_T :

$$f_{T,i} = \frac{g_m}{2\pi(C_{gs} + C_{gd})} \quad (6)$$

When taking the influence of the extrinsic resistances R_s and R_d [15] and the gate pad capacitance, defined as $C_{pad} = C_{pg} + C_{pgd}$, into account, the expression for the transition frequency can be further refined to

$$\begin{aligned} f_T &= \frac{1}{2\pi\tau_T} \\ &= \frac{1}{2\pi} \left\{ \frac{g_m}{(C_{gs} + C_{gd})[1 + g_{ds}(R_s + R_d)] + C_{gd}g_m(R_s + R_d)} \right. \\ &\quad \left. + \frac{g_{m,ext}}{C_{pad}} \right\} \end{aligned} \quad (7)$$

where $g_{m,ext}$ is the extrinsic transconductance and g_m represents the intrinsic transconductance. The additional terms in this equation can be explained by a resistive divider effect at the output causing a current flow in the output resistance and thus reducing the short-circuit current with a factor $1 + g_{ds}(R_s + R_d)$, and by a Miller effect increasing the effective C_{gd} with a factor $1 + g_m(R_s + R_d)$. The influence of C_{pad} results in an extra charging time of the pad capacitance by the extrinsic transconductance $g_{m,ext}$.

For the derivation of the previous equations only the influence of the capacitances, resistances, and transconductance was taken into account, leading to a -20 -dB/decade rolloff for h_{21} . This fixed slope makes it possible to derive f_T by extrapolation from low-frequency measurements. When also taking the influence of the inductances L_s and L_d into account, a h_{21} deviating from the -20 -dB/decade slope is observed with at high frequencies a resonance behavior. Neglecting C_{gd} , the resonance frequency of the circuit can be, approximated by

$$f_0 = \frac{1}{2\pi} \sqrt{\frac{1}{L_{in}C_{gs}} + \frac{1}{L_{in}C_{gs}} \left[1 - \frac{(R_{in}C_{gs} + g_m L_s)^2}{L_{in}C_{gs}} \right]} \quad (8)$$

with $L_{in} = L_g + L_s$ and $R_{in} = R_g + R_{gs} + R_s$. As a result of this behavior, the use of the original definition for f_T yields a cutoff frequency that is much higher than the extrapolated one. Still, as this artificially high f_T is not related with the physical device operation, the f_T value is generally determined by an extrapolation with a -20 -dB/decade slope of the h_{21} measured at lower frequencies. As the resonance behavior leads to a lower slope for h_{21} at high frequencies, while gate leakage can lead to a flattening

and thus a lower slope of h_{21} at low frequencies, it is important not to rely on an extrapolation with an arbitrary slope as is sometimes found in literature.

To obtain a high extrinsic f_T , it is necessary to have a small transit time of the electrons from the source to drain contact [16] and thus short gates, low access resistances R_s and R_d , a low output conductance g_{ds} , feedback capacitance C_{gd} , and pad capacitance C_{pad} .

The maximum oscillation frequency f_{max} is defined as the frequency for which the two-port becomes passive or the maximum power gain is unity. The derivation of f_{max} is more complicated than that of f_T as there is no standard two-port parameter representing the maximum power gain. While the f_T can be derived directly from the short-circuit current gain h_{21} , the power gain is strongly dependent on the input and output matching networks.

In general, the transducer power gain G_T , which is the ratio of the power delivered to the load and the power available from the source, can be written as a function of the source and load reflection coefficients Γ_S and Γ_L :

$$G_T = \frac{(1 - |\Gamma_S|^2)|S_{21}|^2(1 - |\Gamma_L|^2)}{|(1 - S_{11}\Gamma_S)(1 - S_{22}\Gamma_L) - S_{12}S_{21}\Gamma_S\Gamma_L|} \quad (9)$$

For an unconditionally stable two-port, the maximum transducer gain $G_{T,max}$ is obtained for a simultaneous conjugate match at both ports. For these conditions, $G_{T,max}$ is equal to the maximum available gain (MAG) and is given by [17]

$$G_{T,max} = \text{MAG} = \frac{|S_{21}|}{|S_{12}|} \left(K - \sqrt{K^2 - 1} \right) \quad (10)$$

with K defined by Eq. (15).

The necessary and sufficient conditions for unconditional stability of a two-port network at a given frequency are [18,19]

$$|\Gamma_S| < 1 \quad (11)$$

$$|\Gamma_L| < 1 \quad (12)$$

$$|\Gamma_{IN}| = \left| S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L} \right| < 1 \quad (13)$$

$$|\Gamma_{OUT}| = \left| S_{22} + \frac{S_{12}S_{21}\Gamma_S}{1 - S_{11}\Gamma_S} \right| < 1 \quad (14)$$

where Γ_{IN} is the input reflection coefficient and Γ_{OUT} is the output reflection coefficient of the two-port network. These equations state that for all passive load impedances, the real part of the input impedance must be positive and that for all passive source impedances, the real part of the output impedance must be positive.

The following derived formulation [Eqs. (15) and (16)] often used. Unconditional stability requires that the

two-port meets the two inequalities:

$$K = \frac{1 - |S_{11}|^2 - |S_{22}|^2 + |\Delta|^2}{2|S_{12}S_{21}|} > 1 \quad (15)$$

$$|\Delta| = |S_{11}S_{22} - S_{12}S_{21}| < 1 \quad (16)$$

For high-performance HEMTs, however, the relation $K < 1$ holds up to very high frequencies such that in the normal measurement range the quantity MAG is not defined. For this range in which the transistor is potentially unstable, the maximum stable gain (MSG) can be used as a measure to calculate the potential gain of the device when inserted in an amplifier after being stabilized with a lossless network, such as an inductive negative feedback network at the source, making $K = 1$:

$$\text{MSG} = \frac{|S_{21}|}{|S_{12}|} = \frac{g_{m,\text{ext}}}{2\pi f(C_{\text{gd}} + C_{\text{pgd}})} \quad (17)$$

Unfortunately, the MSG and MAG have different slopes of -10 and -20 -dB/decade, respectively. This makes an extrapolation with a fixed slope, as is done for the f_T , impossible. Therefore the extrapolation of the f_{max} normally relies on the unilateral power gain U or Mason's gain [20]. This figure allows to derive a MAG for an unstable two-port as it is defined as the maximum available power gain when the two-port is simultaneously conjugately matched while the feedback parameter Y_{12} is compensated by an external lossless network. As shown by Rollett [21], this type of neutralization is possible for any two-port. U is expressed by

$$U = \frac{1}{2K} \frac{|S_{21}/S_{12} - 1|^2}{|S_{21}/S_{12} - \text{Re}(S_{21}/S_{12})|} = \frac{1}{4} \left(\frac{f_T}{f} \right)^2 \frac{R_{\text{ds}}}{R_g} \quad (18)$$

A second figure delivering an approximately -20 -dB/decade slope over the whole region is the maximum unilateral transducer gain $G_{\text{TU,max}}$ which is the maximum available gain in the assumption that the device is unilateral ($S_{12} = 0$). For a unilateral device, the maximum gain is reached for $\Gamma_S = S_{11}^*$ and $\Gamma_L = S_{22}^*$, and is given by

$$G_{\text{TU,max}} = \frac{1}{1 - |S_{11}|^2} |S_{21}|^2 \frac{1}{1 - |S_{22}|^2} \quad (19)$$

The error made when setting S_{12} equal to zero can be estimated from the unilateral figure of merit F_U [17]:

$$F_U = \frac{|S_{12}||S_{21}||S_{11}||S_{22}|}{(1 - |S_{11}|^2)(1 - |S_{22}|^2)} \quad (20)$$

The maximum error introduced by using G_{TU} instead of G_T is bounded by

$$\frac{1}{(1 + F_U)^2} < \frac{G_T}{G_{\text{TU}}} < \frac{1}{(1 - F_U)^2} \quad (21)$$

Consistent with the theoretical derivation of the unilateral gain U , the modeled extrapolation to unity of both the

$G_{\text{T,max}}$ and U yield an identical f_{max} . It has to be noted that in practice the slopes of U , $G_{\text{TU,max}}$, and MAG deviate from their respective ideal slopes. Therefore, as measurements only at lower frequencies are usually available, the f_{max} is in practice determined using an extrapolation with a fixed -20 -dB/decade slope.

An alternative way to determine f_{max} is to use the extracted small-signal model. However, as the analytical derivation of f_{max} is rather complicated, a large number of different approximate expressions for f_{max} can be found in literature, such as [22]

$$f_{\text{max}} = \frac{f_{\text{T,i}}}{2\sqrt{g_{\text{ds}}R_{\text{in}} + \pi f_{\text{T,i}}C_{\text{gd}}(R_{\text{in}} + R_g)}} \quad (22)$$

whereby the influence of R_{gd} , C_{ds} , R_{d} and of the transconductance delay have been neglected. From this equation, one can see that to obtain a high f_{max} , it is important to have a high intrinsic f_T or a small transit time, a small gate resistance R_g , source resistance R_s and channel charging resistance R_{gs} , a low output conductance g_{ds} , and a small parasitic C_{gd} associated with gate fringing.

3.2.3. Applications. HEMTs are and will be employed in microwave and especially millimeter-wave (wireless) telecommunication systems, automotive applications, and radio astronomy. Their main application is high-gain and low-noise amplifiers at frequencies ranging to beyond 100 GHz. According to the particular circuit specifications, the circuit designer selects the most appropriate HEMT technology (InP/GaAs-based, lattice-matched or pseudomorphic, etc.). The wide-bandgap devices [13] are applied in high-power applications, such as base-station terminals.

An attractive configuration of the HEMT is the dual-gate HEMT. The dual-gate FET introduced in 1971 [23] is a MESFET with two parallel gate electrodes between drain and source. There are two main topologies for the dual-gate HEMT. In the first topology, an RF signal can be applied to the second gate. The second topology is the cascode configuration, which means that the second gate is RF-grounded. This is equivalent to the cascade connection of a common-source HEMT and a common-gate HEMT. The RF input is the gate of the common-source HEMT and the RF output is the drain of the common-gate HEMT. Figure 12 presents the (non)linear model of the dual-gate (cascode) HEMT. It consists of the cascode connection of the (non)linear models of two equivalent intrinsic single-gate HEMTs, supplemented with appropriate extrinsic elements [24]. The parasitic elements consist of those of the equivalent single-gate HEMT and three additional elements: the feedback capacitance C_{pgd} , the substrate leakage resistance R_{sub} , and the resistance between the two gates R_{int} . The capacitance C_{pg2} represents the extrinsic pad capacitance in case of the dual-gate device, and it represents the large capacitance to RF ground the second gate in case of the dual-gate cascode device. Because of its topology, the cutoff frequency of the current gain f_T is smaller and the MSG is theoretically higher than the figures of merit of the single-gate HEMT [25]. It is important to note that the dual-gate HEMT has suppressed kink and

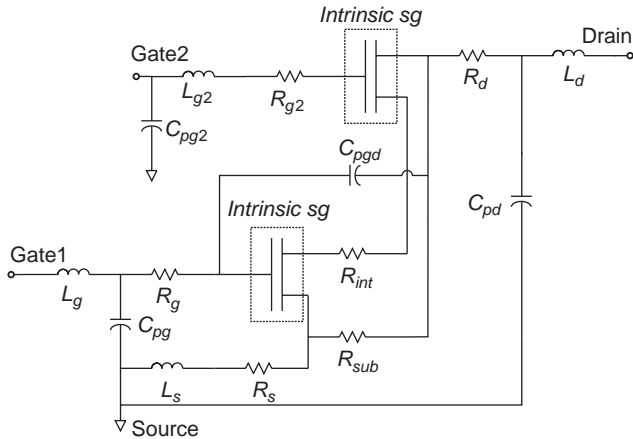

Figure 12. Small-signal equivalent circuit of the dual-gate MESFET and HEMT.

hence impact ionization [26], but the noise is slightly degraded compared to that of single-gate devices. Circuit applications for dual-gate (cascode) HEMTs are multiple [27,28]. The dual-gate cascode configuration is applicable in broadband distributed and variable-gain amplifiers, active phase shifters, oscipliers, and self-oscillating mixers. The dual-gate HEMT is especially encountered in mixers, due to the inherent isolation between the local-oscillator signal and the RF signal.

3.3. HBTs

3.3.1. Description. The bipolar junction transistor (BJT) was invented by Bardeen and Brattain [29] in 1948. It consists of two back-to-back p-n junctions arranged in a sandwich structure. The three regions are designated the emitter, base, and collector. This type of device differs from the field-effect transistors in that both electrons and holes are involved in the current transport process, which explains the term “bipolar.” Two structures are possible: pnp or npn, depending upon the conductivity type common to both p-n junctions. For microwave applications the npn structure is preferred since device operation is controlled by electron flow. Electron transport is faster than that for holes, and hence npn transistors are capable of superior high-frequency performance compared to comparable pnp transistors.

In operation, the base-emitter p-n junction is forward-biased and the collector-base p-n junction is reverse-biased. When an RF signal is applied to the base-emitter junction, the junction allows a current to be injected into the base region. The current in the base region consists of minority charge carriers, namely, carriers with the opposite polarity compared to the base material, such as electrons for an npn transistor. These charge carriers then diffuse across the base region to the base-collector junction, where they are swept across the junction by the large reverse-bias electric field. The reverse-bias electric field in the base-collector region is generally made sufficiently large that the carriers can travel at their saturation velocity. The transit time of the charge carriers across this region is small, except in millimeter-wave transistors,

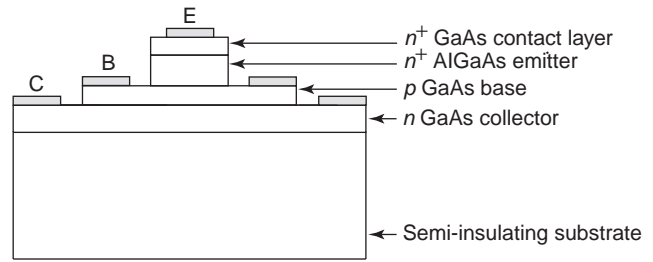

Figure 13. Layer structure of the HBT.

where the base-collector region transit time can be a significant fraction of the total time required for a charge carrier to travel from the emitter through the collector.

The heterojunction bipolar transistor (HBT) is an improved high-frequency bipolar transistor that is fabricated using heterostructures of compound semiconductors. These devices have their emitters fabricated from a wide-bandgap semiconductor, and the remainder of the device is fabricated from a lower-bandgap semiconductor, such as AlGaAs (emitter)/GaAs (base) (Fig. 13). This basic concept was proposed in 1957 by Kroemer [30]. In an npn HBT, the hole current flowing from base to emitter is suppressed by the potential barrier originating from the bandgap difference between the emitter and the base, which implies that a higher current injection efficiency is obtained compared with that of the homojunction bipolar transistor [31]. This allows the base to be more heavily doped than the emitter, leading to a low base resistance and emitter-base capacitance, in contrast with the homojunction bipolar transistor, where the heavily doped base degrades the emitter injection efficiency. These three features—high emitter injection efficiency, low base resistance, and low emitter-base capacitance—are the essential points in obtaining high current gain at high frequencies.

The AlGaAs/GaAs heterojunction has been studied most intensively. More recently, the heterostructure concept has been applied in Si-based devices using SiGe/Si heterostructures. The SiGe base has a lower bandgap than does the Ge emitter, allowing the resistivity to be decreased with respect to homojunction bipolar transistors. AlGaAs/GaAs HBTs generally exhibit performance superior to that of SiGe HBTs, but they require increased processing sophistication, [i.e., MBE (molecular-beam epitaxy) vs. standard epilayer processing] [32]. The SiGe HBT technology has the great advantage of being compatible with standard Si technology.

3.3.2. Properties and Frequency Limitations. The small-signal equivalent scheme of the HBT is presented in Fig. 14. This scheme consists also of a number of extrinsic, bias-independent and intrinsic, bias-dependent components. The parasitics associated with the access lines are represented by the shunt capacitances C_{bcp} , C_{bep} , and C_{cep} , and the series inductances L_b , L_e , and L_c . The distributed base-collector capacitance is modeled as a combination of the effective intrinsic capacitance C_c and the effective extrinsic capacitance C_{bc} [33]. R_e , R_b , and R_c are the emitter, base, and collector series, resistances, respectively. The

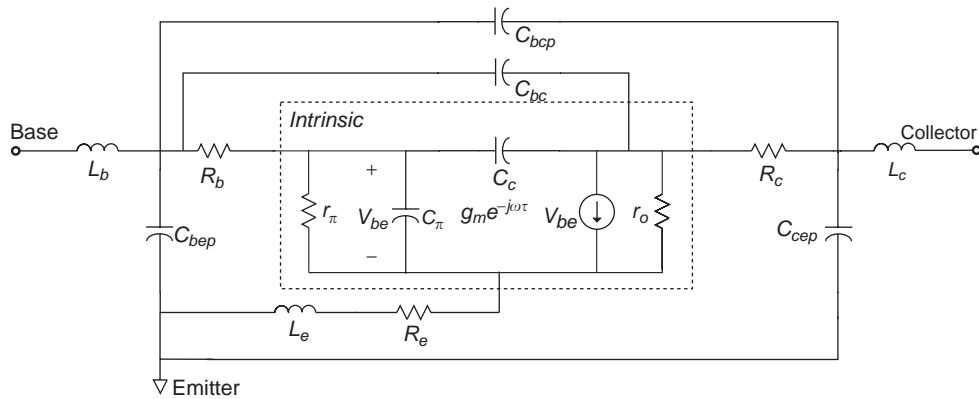

Figure 14. Small-signal equivalent circuit of the HBT.

intrinsic hybrid π network consists of the small-signal input resistance r_π , the collector output resistance r_o , the complex intrinsic transconductance g_m , and the sum of the base-emitter depletion capacitance and the base charging capacitance, denoted by C_π .

The operation of the transistor is primarily controlled by the ability of the minority charge carriers to diffuse across the base region. For this reason microwave transistors are designed with narrow base regions in order to minimize the time required for the carriers to travel through this region. The base region transit time is generally the limiting factor in determining the high-frequency capability of the transistor. The gain of the transistor is also significantly affected by minority-carrier behavior in the base region. The density of minority carriers is significantly smaller than the density of majority carriers for typical operating conditions, and the probability that the minority charge will recombine with a majority carrier is high. If recombination occurs, the minority charge cannot reach the base-collector junction but appears as base current. This, in turn, reduces the current gain capability of the transistor. Narrow base regions reduce the semiconductor volume where recombination can occur and, therefore, result in increased gain. Typical base regions are on the order of 0.1–0.25 μm . The frequency response of a BJT can be determined by an analysis of the total time it takes for a charge carrier to travel from the emitter through the collector. The total time can be expressed as

$$\tau_{ec} = \tau_e + \tau_b + \tau_c + \tau'_c \quad (23)$$

where τ_{ec} is the total emitter-collector transit time, τ_e is the base-emitter junction capacitance charging time, τ_b is the base region transit time, τ_c is the base-collector junction capacitance charging time, and τ'_c is the base-collector region transit time. The total emitter-base time is related to the gain-bandwidth capability of the transistor according to the relation

$$f_T = \frac{1}{2\pi\tau_{ec}} \quad (24)$$

Since the BJT has three terminals, it can be operated in various configurations, depending on the electrode

selected as the common terminal. The two most commonly employed are the common-emitter (CE) and the common-base (CB) configurations. The current gains of the transistor operated in the CE and CB configurations are β of h_{fe} and α , respectively. The CE current gain β is much larger than the CB current gain α , which is limited to values less than unity.

The static common-emitter current gain h_{FE} , which is the ratio of the collector current to the base current, is expressed by [34]:

$$h_{FE} = \frac{\alpha_0}{1 - \alpha_0} \quad (25)$$

where α_0 is the DC current gain with common-base configuration. The AC common-emitter current gain h_{fe} is expressed as:

$$h_{fe} = \frac{h_{FE}}{1 + jh_{FE}\omega/2\pi f_T} \quad (26)$$

Microwave power transistors are usually operated under a common-base configuration [34] since the power gain when operated under that configuration is higher than the gain obtained under a common-emitter configuration. A measure of the RF power gain for the transistor is indicated by the unilateral power gain U , which can be expressed as

$$U = \frac{\alpha_0}{16\pi^2 R_b C_c \left(\tau_{ec} + \frac{R_e C_c}{\alpha_0} \right)} \quad (27)$$

The frequency at which U is reduced to unity, f_{max} , is the maximum frequency at which the device will have active characteristics. This frequency is [35]

$$f_{max} = \sqrt{\frac{f_T}{8\pi R_b C_c}} \quad (28)$$

In order to maximise the high-frequency performance of a BJT, it is necessary to design the device so that it has high current gain f_T , low base resistance R_b , and low collector

capacitance C_c . As R_b and C_c have an influence on f_T , optimization is needed.

Other important specifications for power transistors are the maximum available current density and the breakdown voltage.

3.3.3. Applications. BJTs operating to about 20 GHz are generally fabricated from Si. They are useful in moderate gain, low-noise and low-high-RF power applications. HBTs are employed in both low-noise and high-RF power applications in the microwave frequency range. BJTs and HBTs exhibit better phase-noise performance than do FET devices, but FETs generally have a better noise figure.

1. INTRODUCTION

At microwave frequencies, superconductor materials conduct electric current with a level of resistance that is two or three orders of magnitude lower than that of copper. This property of superconductors can be exploited to produce electronic components and systems with increased efficiency and reduced levels of electronic interference and noise. Microwave superconductor devices provide superior sensitivity and speed while dramatically reducing power consumption, size, and weight. Since 1990, many passive microwave superconductor devices, including delay lines, antennas, matching networks, resonators, and filters, have been fabricated and tested.

In delay-line devices, superconductors provide very high bandwidth and very low loss and dispersion. The best performance can be obtained with stripline designs. These high-performance superconducting delay lines can be used to build finite impulse response filters for signal processing applications. There are a number of systems where superconducting delay lines or finite impulse response filters could be employed but competing technologies; for example, surface acoustic waves (SAWs) show much lower technological risk and are smaller and much cheaper. SAW technology was developed in the 1970s and is today a mature technology and an excellent choice in the range 10 MHz–1 GHz, although they also work at higher frequencies. Superconducting delay-line filters offer a much lower loss and a higher bandwidth than do SAW filters but still have not gained market acceptance for commercial systems.

The extremely low loss of superconductors is the most important benefit for antenna devices. Electrically small antennas have low radiation resistance, and their efficiency can be greatly improved by using superconductors. However, the high Q of the superconducting resonator that forms the antenna also reduces its bandwidth, and a

broadband impedance matching network is needed. To keep the noise figure down, both antenna and matching network can be made superconducting. In fact, antenna miniaturization is an interesting application for superconductors, because it can lead to fully integrated microwave receivers with antenna, matching network and preselect filters within the same package. The technical challenge with superconducting antennas is how to provide the cryogenic environment for operation.

1.1. Superconducting Filters

So far, the most promising device application for superconductors is the resonator-based filter. High Q factors of planar superconducting resonators in the range of 10^4 – 10^5 and higher allow for the fabrication of miniaturized multipole microwave filters with very low insertion loss and very sharp skirts. Generally, a size reduction of the filter leads to reduced performance due to higher insertion loss. However, when using superconductors, the size can be reduced while maintaining or even improving the filter performance. Miniaturization of the filters can be achieved in a number of ways such as using substrates with higher dielectric constant, more compact resonator geometries, or thinner substrates. Many different types of filters have been demonstrated since the 1990s, ranging from conventional designs to completely novel ones that become practical only when using superconductors.

The very low insertion loss of superconducting filters allows for the fabrication of filters with very large number of poles and extremely high out-of-band rejection, approaching the shape of an ideal filter response. The filter response in Fig. 1 corresponds to a 22-pole filter that provides out-of-band rejection of almost 100 dB with an insertion loss at midband of only 0.22 dB [1].

Planar superconducting filters do not perform well at high power levels. The effects in the frequency response can be seen as an increase in insertion loss and a distortion of the shape. In addition to these, the filter generates unwanted harmonics due to its nonlinear behavior. This fact limits the practical use of superconducting filters to low-power applications. As of today, superconducting filters have been included in receiver front-end systems for wireless base stations, where they provide excellent rejection performance to filter out any unwanted interferers.

2. SUPERCONDUCTING FILTER DESIGN

The filter design process follows three steps: design of the filter response, synthesis of the coupling coefficients, and physical realization of the synthesized couplings in a layout. The final layout needs fine adjustments through a few iterations until a good filter is obtained.

2.1. Filter Response

Three basic filter responses are normally used for planar superconducting filters: Chebyshev, Butterworth, and quasielliptic. Those are shown in Fig. 2.

2.1.1. Chebyshev Response. Chebyshev response is widely used because of its relatively high rejection perfor-

Figure 1. Filter response of the 22-pole filter.

mance with a simple design and realization. This filter renders rejection steeper by having ripple in the pass-band. The transfer function of an N -pole filter is given as

$$|S_{21}| = \frac{1}{\sqrt{1 + \epsilon^2 C_N^2}}, \quad C_N = \cosh[N \cosh^{-1}(\omega)]$$

2.1.2. Butterworth Response. Butterworth response is also known as a *maximally flat filter* because it does not have ripple. The transfer function is given as

$$|S_{21}| = \frac{1}{\sqrt{1 + \omega^{2N}}}$$

In terms of filter realization, Butterworth and Chebyshev filters are similar but with slightly different coupling values between resonators.

2.1.3. Elliptic Response. The elliptic response has transmission zeros at finite frequencies ω_i , thus improving rejection performance. The transfer function is given as

$$|S_{21}| = \frac{1}{\sqrt{1 + \epsilon^2 C_N^2}}$$

$$C_N = \cosh \left[N \sum_{i=1}^N \cosh^{-1} \left(\frac{\omega - 1/\omega_i}{1 - \omega/\omega_i} \right) \right]$$

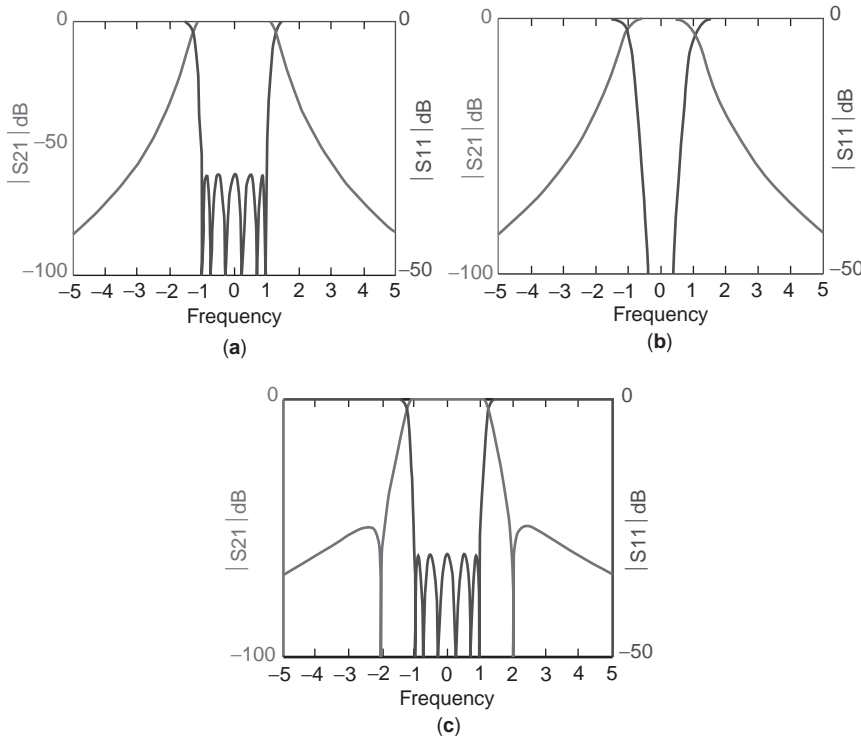

Figure 2. Typically used filter responses: (a) Chebyshev; (b) Butterworth; (c) elliptic. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Transmission zeros make filter realization more difficult because additional cross-couplings between nonadjacent resonators are necessary. Details on how to realize the required cross-couplings are discussed in the following section.

2.2. Cross-Coupling Structures

The cross coupling technique was originally developed for cavity filters [2,3]. When applied to planar superconducting filters [4], steeper rejection slopes can be obtained without increasing the number of resonators. *Cross-coupling* is coupling that is intentionally introduced between nonadjacent resonators in addition to the main coupling between adjacent resonators. The cross-coupling structure creates two signal paths that can cancel each other out at some frequency near the band edge, creating a transmission zero. To achieve the cancellation, the signs of main coupling and cross-coupling have to be opposite. Different cross-coupling structures are described below.

2.2.1. Trisection Cross-Coupling. A trisection cross-coupling structure is realized by introducing an additional coupling path between the first and last resonator in the three-resonator structure shown in Fig. 3a. It is the shortest possible cross-coupling path and the simplest way to implement a transmission zero. The transmission zero can be realized either at the low side or at the high side of the

passband depending on the cross-coupling sign. If the sign is the same as the main coupling sign, the transmission zero appears at the high side of the passband and vice versa. Since every transmission zero is controlled by its corresponding trisection, the filter realization and tuning are straightforward.

Trisection structures can produce both symmetric or asymmetric rejection responses. An asymmetric response like the one shown in Fig. 3b is needed, for example, when transmit and receive bands are next to each other and the rejection slope near the boundary between the two bands is required to be very steep.

2.2.2. Quadruplet Cross-Coupling. This cross-coupling technique is the most commonly used for planar superconducting filters because it realizes a symmetric pair of transmission zeros more efficiently at both sides of the passband using the cascaded four-resonator sections shown in Fig. 4a. The cross-coupling sign has to be opposite the main couplings sign in order to produce transmission zeros. Instead, if the sign of the cross-coupling is the same, the structure is used to obtain linear phase filters for wideband applications such as CDMA systems.

As with trisections, quadruplets can be cascaded when multiple transmission zeros are necessary to achieve the required rejection performance. By cascading multiple quadruplets, multiple pairs of symmetric transmission zeros can be realized. Since every quadruplet controls

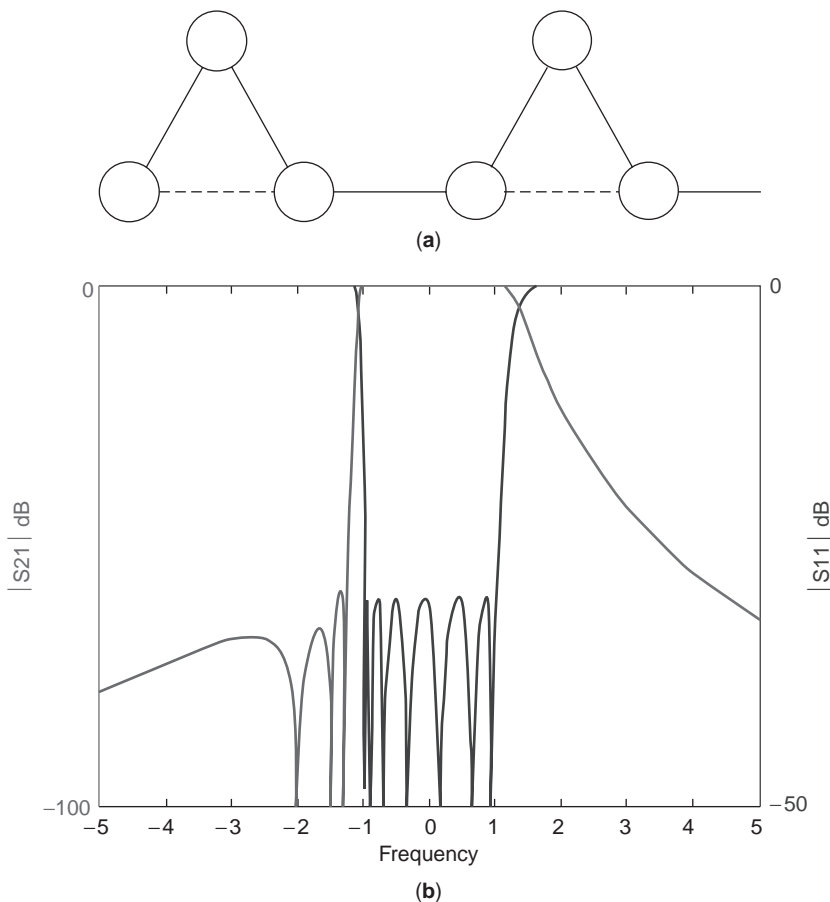

Figure 3. Trisection cross coupling: (a) cross-coupling structure — circles denote resonators, and solid lines and dashed lines denote main coupling paths and cross-coupling paths, respectively; (b) example of asymmetric response — three transmission zeros are produced only on the low side of its passband asymmetrically. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 4. Quadruplet cross-coupling: (a) cross coupling structure — circles denote resonators, and solid and dashed lines denote main coupling paths and cross-coupling paths, respectively; (b) example of response — two pairs of transmission zeros are produced symmetrically on both sides of the passband. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

one corresponding symmetric pair of transmission zeros, the filter realization and tuning is straightforward as in the trisection case.

2.2.3. Other Cross-Coupling Structures. The folded cross-coupling structure shown in Fig. 5 is widely used in conventional cavity filters. It can realize more transmission zeros with the same number of resonators than can the previously discussed cross-coupling structures. However, it is not suitable for planar filters because of the unwanted parasitic coupling between physically close resonators.

2.3. Coupling Synthesis

There is a well-known simple formula for Chebyshev and Butterworth filter synthesis [5]. From this formula, a set of coupling values is obtained and hence the synthesis procedure is very simple. On the contrary, the synthesis of filters with cross-coupling coefficients is not that simple.

Figure 5. Folded cross-coupling: circles denote resonators, and solid and dashed lines denote main coupling paths and cross-coupling paths, respectively.

Many approaches have been reported for the synthesis, but all of them can be divided into two main streams: coupling matrix rotation [6] and curve fitting [7].

A coupling matrix is constructed from the coupling coefficients between resonators, the external loads, and the resonant frequencies of each resonator. The coupling matrix rotation approach starts from a full coupling matrix where every resonator can be coupled to any other one. That full matrix, although it realizes the intended filter response, is not convenient because it requires a complicated filter layout. Therefore, the next task is to obtain an equivalent matrix that realizes the same filter response with a lot fewer coupling components between the filter resonators. Using a matrix rotation technique, the number of nonzero elements of the coupling matrix can be greatly reduced and a much simpler layout obtained. This simpler layout can be realized, for example, by a cascaded quadruplet cross-coupling structure.

The curve fitting approach for the synthesis is based on, first, choosing the preferred cross-coupling structure that is able to realize the target filter response. Then, main couplings and intended cross-couplings are adjusted through optimization until the synthesized filter curve ideally fits the defined filter curve along with the prescribed transmission zero locations. During the optimization process, the remaining couplings, that is, all nonadjacent couplings excluding the cross-couplings, are set to zero. Therefore, the preferred cross-coupling structure is enforced and a filter realization obtained only if a solution exists. This second approach is also useful for the analysis of measured filter data [8]. The actual realized coupling values of a particular filter can be extracted by applying the curve fitting process to measured data of the filter. A curve fitting example with measured data is shown in Fig. 6.

2.4. Filter Realization

Once a coupling structure is defined and a coupling matrix or a set of coupling coefficients is obtained through a synthesis process, the next step is the filter realization. For planar superconducting filter design, the resonators can be either lumped-element or distributed. A serious concern with planar superconducting filters is parasitic couplings because the resonators are physically very close. This parasitic coupling is unwanted coupling between nonadjacent resonators, which has a visible effect on the measured filter response by canceling, adding, or displacing the transmission zeros. The higher the frequency or the narrower the bandwidth of the filter, the more important these parasitic coupling effects become.

2.4.1. Lumped-Element Filters. Lumped-element filters are based on resonators that are much smaller in size relative to the filter operating wavelength. Hence, at high frequencies where the wavelength is short, these filters are very small. Of course, the smaller the filter, the higher the insertion loss, and here comes the advantage of using superconductors. Lumped-element filter technology can be used as long as the required linewidths can be realized by the patterning process. This condition typically means

Figure 6. Measurement analysis; blue curve represents measured data and red curve, fitted data. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

that lumped-element filters can be used up to a few tens of gigahertz, a broad frequency range where superconductors clearly outperform normal conductors.

Since the available surface of superconducting films is rather small, lumped-element filters are very desirable especially when many poles are required or at low frequencies where the filter becomes too large. A pair of 800-MHz multipole pole filters can be fabricated on a

Figure 7. Miniature lumped element filter.

2-in.-diameter wafer (Fig. 7). Obviously, since the filters are smaller, the insertion loss is slightly higher because of the locally high current densities, especially in the inductors of the filter. However, if the superconducting film is of high quality, miniature lumped-element resonators achieve quality factors on the order of 50,000 and higher, depending on the frequency of operation.

Figure 8 shows an example of a lumped-element superconductor filter [9]. Since the center frequency of the filter is quite low, a lumped-element design is a good choice to keep it small enough to fit in a typical 2-in.-diameter wafer. The transmission zero appearing at the high stopband is due to parasitic coupling.

2.5. Distributed Resonator Filters

Distributed resonators provide higher Q factors than do lumped-element resonators. In general, the Q factor is determined by the linewidth of the resonator at locations where the current distribution is high. In lumped-element resonators, the linewidth is typically narrower in order to obtain high inductance values and reduce the resonator size. This size reduction limits the Q factor that can be achieved.

There are two ways to physically realize the cross-coupling in planar superconducting filters. The filter structure in Fig. 9a realizes a cross-coupling between the third resonator and the sixth resonator by laying out the resonators' direction properly [10]. All the couplings are inductive except for the cross-coupling between third and sixth resonators, where the resonators are placed with their respective ends facing each other. Thus, the coupling takes place in a region where the electric field is maximum, unlike the case for the remaining resonators, which couple each other magnetically. By doing this, the sign of the cross-coupling is set opposite the main couplings

Figure 8. An example of a lumped-element filter and its response.

or negative, and a pair of transmission zeros can be obtained.

The filter in Fig. 9b shows an alternative way to realize the cross coupling [11]. In this case, additional transmission lines are introduced between first and fourth, fourth and seventh, and seventh and tenth resonators. These transmission lines produce coupling between those resonators through capacitors at both ends of the line. The coupling transmission lines have to be designed short enough so that they do not resonate themselves. The magnitude of the cross-coupling is controlled by adjusting both the length of the line and the coupling capacitance to the resonators.

The filter layout in Fig. 10a shows a refinement of this second cross-coupling technique, where primary and secondary couplings between a pair of resonators have been used [12]. Applying such a concept, large or small bandwidth filters can be made without very small or very large resonator spacing. In addition, the same cross-coupling layout configuration may be designed to achieve either positive or negative coupling results.

2.6. Filter Tuning

Due to the fabrication variation in the production line, the filter usually needs tuning to adjust its response. Filter tuning may be done by either mechanical tuning or process tuning. Two different mechanical tuning approaches are known. One of these approaches uses a high-dielectric-constant material in order to locally modify the electric field of the resonators. Usually a dielectric rod is used, and the distance to the resonator is adjusted by turning a screw that holds the dielectric rod in the bottom. The other

approach modifies the magnetic field by placing a conductor material close to the resonators. Usually a small superconductor-coated substrate tip is used and tuning is adjusted by changing the distance to the resonator. Both tuning elements should be placed to effectively produce a frequency shift of the resonator and at the same time minimize any change in the coupling values.

The second category of tuning does not use any mechanical actuator, but the resonator itself is modified in the filter fabrication process. One of those approaches is laser trimming. Laser trimmed filters are tuned by scribing a part of the resonators to produce the desired frequency shift. Another process tuning approach is dielectric layer deposition [13]. After the normal filter fabrication process, a dielectric layer is deposited on the resonators. The thickness of this layer and the coverage over the resonator can be adjusted for every individual resonator so that the required frequency shift is obtained. The amount of tuning has to be determined previously by measuring the filter and adjusting the resonant frequencies of the resonators.

2.7. High-Order Filters

The high Q factor of superconducting distributed resonators allows the fabrication of very-high-order filters with very small insertion loss. A first example of a high-order filter is the 32-pole Chebyshev filter shown in Fig. 11 [13]. The basic resonator design is based on a conventional hairpin structure but formed as a letter 'J' shape in order to minimize the coupling ratio between both adjacent and nonadjacent resonators. By adjusting the shape, parasitic couplings between nonadjacent resonators can be reduced and at the same time passband return loss maintained. The circular layout of the resonators along the wafer shape also helps reduce the parasitic couplings and any undesired housing propagation effect.

A second example of a high-order filter is the 22-pole quasielliptic filter shown in Fig. 1 [1]. The basic resonator of this filters, shown in Fig. 12, is also a distributed type. The high current region in the center of the half-wavelength resonator has been opened to facilitate the tuning

Figure 9. Cross-coupling realizations.

Figure 10. A six-pole thin-film superconductor filter layout and its response. Both trisections use primary and secondary couplings. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

process. This filter contains five quadruplet cross-couplings and is able to produce five transmission zeros at each side as shown in Fig. 1. As a result, the rejection slope can be extremely sharp.

3. WIRELESS APPLICATION

The most important application today of microwave superconductor devices is in the wireless communications industry. Due to the spectacular growth of cellular subscribers, this industry has undergone an important deregulation leading to many providers in most countries. Superconducting front-end filters may play an important role in both existing and future wireless base stations by

increasing the overall system capacity and interference suppression capability. This will allow wireless providers to deploy and improve their networks rapidly as they follow the market directions.

3.1. Superconducting Front Ends

So far, mostly receiver front-end preselect filters have been successfully introduced. A wireless receiver front end is the analog circuitry at the base station that performs the signal processing after the antenna and low-loss cable. A typical superconducting front end consists of one or more preselected superconducting filters and a low-noise amplifier (LNA) for every sector of the base station. Both devices are cooled to an operating temperature

Figure 11. Photograph and measurement data of a 32-pole filter.

Figure 12. Resonator shape and cross-coupling structure of a 22-pole filter.

around 60–70 K inside a cryogenic vessel, so that the LNA also improves its noise figure. The system usually incorporates a bypass that would switch to conventional technology filters and LNAs in case of cooler or vacuum failure (Fig. 13). In principle, superconductors could be used in all the components that form the receiver front end. However, a combination of a superconducting filter and a conventional LNA, typically a one- or two-stage high-performance GaAs HEMT or FET circuit, provides the best performance. The front end is followed by a resistive splitter and a bank of parallel receiver chains, each one composed of a conventional mixer, a conventional IF bandpass filter to select different frequency channels, an IF amplifier, and an analog-to-digital converter (ADC) with bandpass sampling.

The main interference challenge for the receiver front end is the intermodulation products (IMPs) that result from frequency mixing of two or more strong out-of-band signals in the nonlinear LNA and mixer. When an IMP falls on the radio channel being received, the result may be a noisy or dropped call. Particularly strong signals can also cause LNA saturation, which greatly diminishes sensitivity. To eliminate interfering IMPs and potential LNA saturation, the causal out-of-band signals must be attenuated and the linear dynamic range of the LNA must be increased. However, conventional filters with very sharp skirts might have unacceptable insertion loss for in-band signals, and LNAs with wide dynamic range and sufficiently low noise are difficult to design. Hence, for this engineering challenge the cryogenic superconducting front end appears to be the perfect solution, providing both extremely high selectivity and great sensitivity.

A limitation, however, arises as a result of the intrinsic compromise between frequency resolution and integration time. The high selectivity of the superconducting filter is accompanied by a large group delay, especially at the passband edges. This strong frequency dependence in the transition region causes intersymbol interference and, therefore, should be compensated by either an

additional analog allpass equalizer in the RF or IF part. Future software radio architectures will employ a wideband receiver followed by a wideband ADC with high sampling rate and resolution. Separation of frequency channels or group delay equalization will be accomplished in a software-controlled manner in digital signal processing (DSP). This approach will allow the realization of reconfigurable transceivers, increasing the flexibility of base-station equipment. However, the realization of these architectures requires a sufficiently high dynamic range in the RF front end, which is limited by the nonlinearities in the mixer and LNA. Adaptive analog prefiltering with superconducting tunable filters could be a solution to overcome this limitation if sufficient progress is made to achieve enough tuning range without excessive loss.

At the system level, cryogenic front ends with superconducting filters provide broader coverage and lower interference levels, resulting in superior quality of service. The broader coverage is a direct consequence of the improved sensitivity of the receiver, thanks to the low insertion loss of superconducting filters and the low physical temperature of both the filter and the LNA (see, e.g., the Front-end apparatus in Fig. 14). The cooled LNA reduces the overall noise figure of the RF front end to about 0.5 dB (typically 0.8–1 dB at room temperature and 0.4 dB at 70 K). The total improvement in insertion loss is in the order of 2–2.5 dB. Even more impressive is the capability to reduce interference. The sharp skirts and high rejection of superconducting filters help to attenuate adjacent channels easily more than 60 dB with a more than acceptable noise figure. Typically, the filter reduces any out-of-band signals to levels where the IMPs generated are negligible compared to thermal noise levels.

3.2. Cooling Requirements

The superconducting wireless application requires 3–10 W of cooling power in the temperature range from 60 to 80 K. In order to achieve these temperatures, the cryocooler has

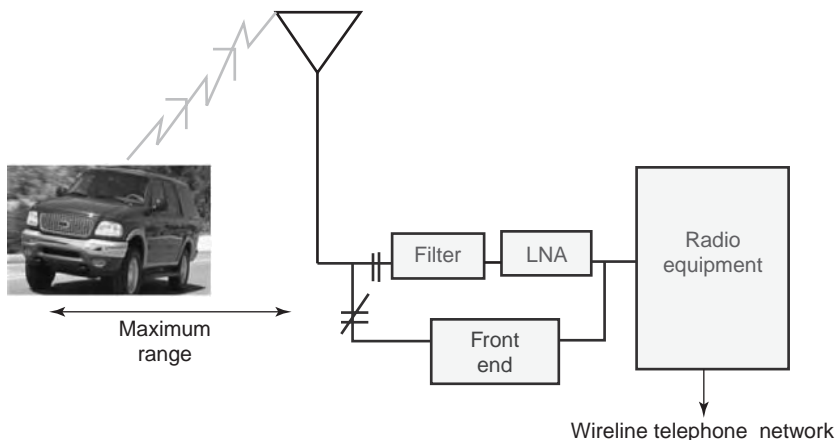

Figure 13. Superconducting front end and bypass with conventional technology, between antenna and base-station radio equipment.

Figure 14. Rack-mountable superconducting receiver front end that incorporates superconducting filters and cooled low-noise amplifiers inside a cryogenic vacuum vessel.

to remove not only the heat that is stored and generated within the RF components and surrounding packaging but also the heat that comes in from the warmer environment that surrounds the cryogenic assembly (see Fig. 15). This parasitic heat is transmitted through conduction and

Figure 15. Detail of superconducting filters mounted inside a cryogenic vacuum vessel.

radiation and must be constantly removed along with the dissipated heat generated by the cryogenically cooled LNAs to maintain the HTS filters at some stable temperature between 60 and 80 K.

The thermal loads from all of these sources are on the order of 3–5 W depending on the system configuration (omnidirectional with two channels or three-sector with six channels.) More complex 6-sector (twelve channel) configurations are expected to require as much as 8 W of cooling power within this temperature range. For a wireless front-end application, the ideal cooler should be capable of a coefficient of performance (CoP) of at least 5%, with CoP understood as net cooling power: input power ratio. Furthermore, it has to be low-cost (\sim \$1000), be small ($<$ 5 kg), and have a maintenance-free life of more than 40,000 h (5 years). Nowadays, the cooler and cryopackage represents the most important part of the total cost of the system, and remains the main challenge in the establishment of a viable business model for commercial wireless products.

Manufacturers of superconductor filter systems are faced with a series of tradeoffs in the features and characteristics of various cryocoolers. The compelling reliability advantage of GM designs is an important consideration but is not the only one. Stirling cryocoolers are smaller, lighter, and less noisy, and hence, a good choice in applications where operating lifetime is less important. Very promising data on the reliability of Stirling cryocoolers has been reported [14] showing no infant mortality and an accumulated lifetime of more than 17,250 h to date.

3.3. Benefits in Wireless Networks

The overall improvement to the wireless network can be measured in a number of different ways depending on the environment (rural, suburban, or urban) and the type of access protocol in the RF link. The characteristics that can be measured are (1) reduced number of dropped and blocked calls, (2) improved voice quality, (3) increased channel availability, (4) increased base-station coverage or reduced number of base stations, (5) reduced mobile transmit power, (6) increased network capacity and minutes of use (MoU), and (7) reduced bit error rate (BER) in digital systems.

Customer field trials have been taking place since 1996 in the United States for the analog cellular spectrum advanced mobile phone service (AMPS), with 824–849 MHz receive and 869–894 MHz transmit bands. Data from multiple trial reports are already available for 1G and 2G wireless networks. In 1G networks the basic benefits are range extension, coverage improvement, voice quality enhancement, and a reduced number of dropped calls. From the viewpoint of the service providers, these benefits have translated into increased minutes of use of their base stations, which is the economic variable of interest. However, major deployment of superconductor subsystems in 1G networks has not yet taken place for a combination of reasons. First, the technology has only relatively recently gained the confidence of the industry and second and most importantly, the main focus of service providers has been the deployment of 2G digital networks in urban and suburban environments where most of their revenues are derived.

Figure 16. Increased coverage with superconducting front end.

However, the benefit of superconducting front ends in 1G networks is clear especially in the rural case. A necessary condition to transform a reduced noise figure of the receiver front end into a system benefit is a low antenna noise figure. This is the case for rural environments where the antenna is exposed to low noise and low interfering signals. Hence, in rural networks the lower noise figure of superconducting filters translates into increased coverage, allowing less base stations for a given area or higher quality of service in shadowed areas. Figure 16 shows a coverage problem that would require an additional base station for the shadowed area that intercepts the road. The coverage can be improved in just a few hours by replacing the conventional front end with a superconducting one. The benefit is clear, since another base station would cost more than \$400,000 plus a few months of work.

On the other hand, in urban areas with a lot of traffic and human-generated noise, the antenna noise temperature can be as high as 2000 K. To maintain the antenna signal-to-noise ratio (SNR), the handset power has to be higher and the receiver must be exposed to high-energy out-of-band signals that might limit the sensitivity with IMPs. Such is the case of the TDMA A-band operator interfered with by high-power Special Mobile Radio (SMR) signals (Fig. 17). By replacing the conventional front end with a superconducting one, all interferers are almost suppressed, greatly reducing the possibility of significant IMPs.

Digital networks have become the dominant technology in the wireless industry. Many analog cellular networks have been converted to digital technology. However, there is mounting evidence that digital technology has unexpected capacity and service limitations as well as significant coverage problems. The coexistence of different digital protocols creates unique interference mechanisms that need to be accounted for. TDMA transmitters are likely to cause interference to CDMA receivers because CDMA systems are designed to operate at the minimum possible power, whereas TDMA systems raise the power level in order to increase coverage and capacity. These limitations represent a significant market opportunity for superconducting front ends. In 2G TDMA networks significant benefits have already been demonstrated in coverage, capacity, and interference suppression, and even better benefits are expected in 2G CDMA networks. The most significant benefit of superconductor technology in 2G base stations is the ability to provide superior interference rejection, which allows service providers to utilize their available spectrum without introducing guardbands

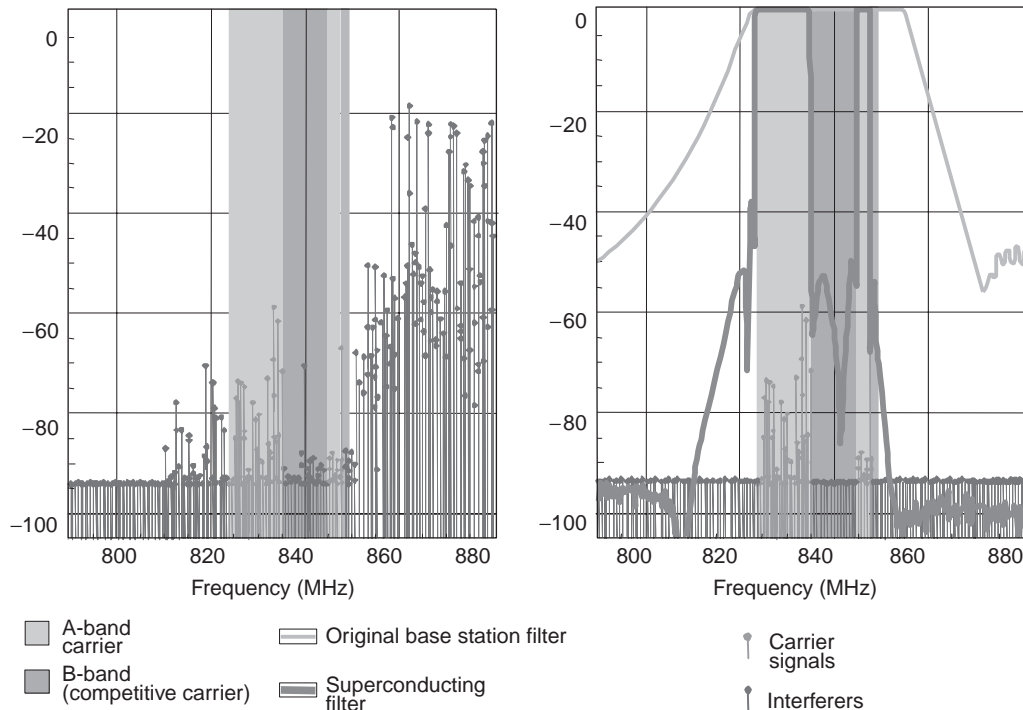

Figure 17. Out-of-band interference suppression with superconducting front end. (Data taken in Half Moon Bay, CA.). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

Figure 18. Percentage change in minutes of use (MoU) for 11 CDMA cell sites before and after a conventional front end was replaced by a superconducting one. Average increase in MoU is 43%. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

or blocked channels. CDMA systems operate in an interference-limited scenario, where the maximum cell radius is determined by capacity considerations. A reduction of receiver noise can be translated into increased capacity and MoU. The replacement of conventional front ends with superconducting ones in 11 CDMA cell sites has, resulted in an impressive average MoU increase of 43% (Fig. 18).

Third-generation (3G) systems will offer high-burst-rate packet communications in addition to high-quality voice and medium-rate data. IMT-2000, the standard for 3G systems adopted by the International Telecommunication Union (ITU), identifies two frequency bands, 1885–2025 MHz and 2110–2200 MHz, which will operate with wideband CDMA (WCDMA) protocol. Currently, portions of these bands are being used by 2G systems, and it is expected that the coexistence of 2G and 3G systems will become a new interference problem.

For example, Japanese 2G Personal Handyphone System (PHS) base stations employ a frequency band that is only 0.55 MHz away from the lowest 20-MHz IMT-2000 block. PHS cell sites are present every 300 m in cities and suburbs in Japan. This situation results in increased BER, increased mobile transmit power and reduced coverage, capacity, and bandwidth. Since the signal quality is degraded, cellphones end users tend to speak loud increasing the transmit power. As a result, the signal-to-interference ratio (SIR) at the base station drops and the cell collapses. When the superconducting front end is introduced, the interference is filtered out and the cell normal operation can be restored (19).

There are other examples where superconducting front ends offer clear advantages over conventional ones. In Europe, the Universal Mobile Telecommunications System (UMTS) must accommodate high-power-level transmit signals adjacent to receive-only bands in WCDMA. In

Figure 19. A 3G WCDMA cell site is completely restored to its normal levels of operation after the superconducting front end is introduced. The plotted signals as a function of time in minutes are base-station interference [dBμ] (green), base-station signal: interference ratio (SIR) [dB] (yellow), and mobile transmit power [dBm] (red). (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

some regions, new WCDMA bands will be located as close as 2 MHz to the band edge of existing PCS bands. Another example is hierarchical cell structures where uplink signals of nearby microcells arrive at the macrocell (umbrella cell) at a much higher power level than do the uplink signals of remote users in the macrocell. Acceptable wireless transmission of data requires at least four orders of magnitude lower BER than what is needed for voice transmission. Superconducting front ends can provide this enhanced BER without raising the power level in the wireless network, which is a significant benefit in 3G WCDMA.

MICROWAVE SWITCHES

ROBERT H. CAVERLY
Villanova University
Villanova, Pennsylvania

1. INTRODUCTION

Modern microwave systems often require the routing of microwave signals to different locations or subsystems. This signal routing is frequently controlled electronically, and strict system requirements often require rapid signal routing. The system component used to control this flow of microwave energy is the *microwave switch*. Depending on the application, these devices must be able to rapidly switch microwave signals whose power levels range from the microwatt range in receiver applications to hundreds of kilowatts in high-power radar applications.

A common use of a microwave switch is to connect a single antenna to either a receiver or a transmitter. Figure 1 is a schematic diagram of a transmit/receive switch or *TR switch*. When switch SW_A is closed (connected) and switch SW_B is open (disconnected), the receiver is directly connected to the antenna. The transmitter is connected to antenna when SW_B is closed and SW_A is open.

2. MICROWAVE SWITCH TERMINOLOGY AND TYPES

An ideal microwave switch in the connected or ON state should exhibit no losses. These losses will absorb the microwave energy as it flows through the switch. The ideal microwave switch in the disconnected or OFF state will not allow transmission of energy. In reality, losses do occur in the ON-state switch, and these losses must be minimized through careful selection and design of the switch element. The term that microwave engineers use to describe these ON-state switch losses is switch *insertion loss*. In the OFF-state switch, some transmission of energy does occur, but can be minimized by careful selection and design. For the OFF-state switch, the measure of the level of signal transmission is termed switch *isolation*. The microwave engineer attempts to design microwave switches with low insertion loss and high isolation over the entire frequency and power range of operation. Often the engineer finds that by improving one switch property, another one is adversely affected, so engineering tradeoffs are always a part of the design process. Several design passes using computer-aided design tools and construction of actual switch prototype circuits are usually needed before the optimum microwave switch configuration is determined.

Modern microwave switch applications require the actual switching action be done electronically rather than mechanically (as in a light switch), allowing a digital computer system, for example, to control the switching operation. The utility of electronically controlled microwave switches can be shown by an example based on the TR switch shown in Fig. 1. Consider a radar transmitter sending out pulses of energy that will be reflected back to the receiver if an object is encountered. If the object is

Figure 1. Schematic diagram of a microwave TR switch.

25 km away from the radar site, the travel time for a single radar pulse to go from the transmitter to the object and back to the receiver is approximately $130\ \mu\text{s}$. The microwave switch must switch the radar antenna between the high-power radar transmitter and the receiver in this short time period (or shorter if the object is closer), and the switch must be capable of repeating this action hundreds of times each second.

Two classes of electronically controllable microwave switching elements are widely used: *solid-state switch* elements based on specialized diode and transistor elements and *ferrite switch* elements based on magnetic material that controls the direction of microwave energy flow. Solid-state devices are used in applications such as battery-operated radio systems, nuclear magnetic resonance imaging systems, and electronically steered antenna arrays. Ferrite switches are usually found only in applications such as high-power radar systems where hundreds of kilowatts of power must be controlled. A third class of electronically controllable microwave switching element is the solid-state MEMS (microelectromechanical system) switch. Although this type of switch is fabricated using processes similar to those for diode and transistor-based solid-state switches, its operation is significantly different from these other switch elements to be warrant separate discussion.

Solid-state switching devices are further divided into two types: those based on two terminal switch elements such as p-i-n diodes (fabricated using silicon or gallium arsenide semiconductors) or three-terminal switch elements such as gallium arsenide metal semiconductor field-effect transistors (MESFETs). Both types of solid-state switching elements are physically small. Microwave p-i-n diodes that are used for low power but very high frequency may be as small as $10\ \mu\text{m}$ in diameter and $25\ \mu\text{m}$ in length. Higher-power diodes can be $100\ \mu\text{m}$ in diameter and $250\ \mu\text{m}$ thick to aid in handling the additional power requirements. FET switch elements may reside on a square of semiconductor material no larger than $1000\ \mu\text{m}$ on a side. A large RF MEMS switch matrix array can be placed on a single semiconductor die since the physical size of the individual switch elements can be as small as $25\ \mu\text{m}$ on a side. The bulk of a microwave switch module can be taken up by the package used to contain the solid-state switch element, allowing the switch module to be handled by skilled circuit fabrication technicians or automated electronic fabrication machines. Ferrite switches are physically larger than their solid-state counterparts because of both the physical operation of the switch and the high power that the switch must handle.

Table 1. Characteristics of Common Microwave Switch Elements

Switch Type	Switching Energy	Switching Time	Power-Handling Range
Ferrite switch	High	Very slow ($\geq 100\ \mu\text{s}$)	Megawatts
FET elements	Very low	Very fast (10 ns)	Watts
MEMS	Very low	Slow (2–20 μs)	Watts
p-i-n diodes	Medium	Fast (10–50 ns)	Kilowatts

The amount of energy used to activate the microwave switch is also an important design specification. Ferrite and some p-i-n diode switch elements can control much higher powers than can FET and MEMS-based switches, but FET and MEMS switches require very little energy to activate, although MEMS switches require somewhat higher switching voltages than do the diode and transistor-based solid-state switching elements. The switching energy is unusually high in some ferrite switches because of the relatively high current required to generate the necessary magnetic field that governs ferrite operation. Table 1 summarizes some important microwave switch characteristics and table shows that selection of switch type is strongly dependent on the application. The designer must balance these specifications with other design specifications such as physical size, insertion loss, isolation, and cost.

3. MICROWAVE SWITCH MODELING

The primary design specification that a microwave switch designer considers is the switch circuit's insertion loss and isolation. Insertion loss (IL) and isolation (ISO) are defined as the level of microwave power present at the load after the switch is installed with respect to that present at the load before the switch is installed. This definition can be written mathematically as [1]:

$$\frac{\text{IL}}{\text{ISO}} = 10 \log \frac{P_{\text{La}}}{P_{\text{Lb}}} \text{ dB} \quad (1)$$

where $P_{\text{La(Lb)}}$ is the power available at the load after (before) the switch module is inserted into the system. Typical values of switch insertion loss range from 0.2 to 1.0 dB, with the higher values of insertion loss typical for microwave switch elements used at X band (8–12 GHz) and above. A good microwave switch will exhibit isolation greater than 20 dB. At low frequencies, microwave switch isolation can be greater than 80 dB depending on the actual switch configuration. Because of the nature of microwave switch elements, isolation and insertion loss often exhibit marked variations with frequency.

The microwave switch designer's task is simplified by use of *lumped-element switch modeling*. These switch models replace the actual switch with simple circuit elements that can be quickly and easily analyzed. Insertion loss and isolation for the various switch elements is computed by modeling each individual switch element as a

Figure 2. Simplified model for a microwave switch element, showing the ON-state resistance R_S and the OFF-state capacitance C_S .

parallel combination of an ideal switch and resistance R_S and capacitance C_S . This simple microwave switch element model is shown in Fig. 2. The utility of this model can be seen by studying the simplest microwave switch topology, the single-pole single-throw (SPST) switch. The switching elements in the SPST circuit can be placed either in series or shunt. Figure 3 shows a series connected switch element (with switch model in place), and Fig. 4 shows the shunt connected switch element. Z_0 is the source and load impedance (the so-called matched-load condition). Using the circuit diagrams shown in Figs. 3 and 4, relationships for insertion loss and isolation can be developed. For the series switch, insertion loss and isolation can be written in terms of R_S , C_S , and the operating radian frequency ω as

$$IL = 20 \log \left[1 + \frac{R_S}{2Z_0} \right] \tag{2}$$

and

$$ISO = 10 \log \left[1 + \left(\frac{1}{2\omega C_S Z_0} \right)^2 \right] \tag{3}$$

whereas for the shunt switch, insertion loss and isolation can be written as

$$IL = 10 \log [1 + (0.5\omega C_S Z_0)^2] \tag{4}$$

and

$$ISO = 20 \log \left[1 + \frac{Z_0}{2R_S} \right] \tag{5}$$

Figure 3. Series-connected SPST microwave switch showing source, load, and equivalent circuit for the switch element.

Figure 4. Shunt-connected SPST microwave switch showing source, load, and equivalent circuit for the switch element.

Insertion loss for the shunt switch is frequency-dependent because of the reactance of the shunt capacitance, whereas isolation for the series switch is the frequency-dependent parameter. Figure 5 shows the insertion loss (isolation) for the series (shunt) SPST switch as a function of resistance R_S . The data shown in Fig. 5 indicate that low insertion loss (less than 0.5 dB) occurs for resistance values of less than approximately 5Ω for the series switch. Isolation greater than 20 dB occurs for resistance values of approximately 2Ω or less for the shunt switch. Figures 6 and 7 illustrate the isolation (insertion loss) for the shunt (series) SPST 50- Ω switch as a function of frequency using the switch capacitance C_S as a parameter. Figure 6 shows that isolation of the series switch is greater than 25 dB at 1000 MHz using capacitance values less than 0.1 pF. Figure 7 indicates that a shunt switch with capacitance of 1.0 pF or less exhibits less than 0.5 dB insertion loss at 1000 MHz.

Multithrow microwave switches are designed using combinations of series and shunt elements to implement the desired switching function. The operation of a single-pole double-throw (SPDT) TR switch illustrated in Fig. 1, for example, can be predicted by replacing the two switches SW_A and SW_B by the switch element model in Fig. 2. Various applications often require more complex switch topologies, but the insertion loss and isolation of these circuits can still be estimated using the lumped-element switch model in Fig. 2. It should be noted that Fig. 2 represents

Figure 5. Insertion loss and isolation for the series and shunt SPST 50- Ω switch as a function of series resistance R_S .

Figure 6. Isolation for the series SPST 50- Ω switch as a function of frequency using the switch capacitance C_S as a parameter.

the simplest of switch element models. Switch packaging and circuit connections introduce their own undesired properties that must be included by the microwave engineer as part of the design process. Some of these undesired or *parasitic elements* are package capacitance, contact resistance, and bond wire inductance. The parasitic elements influence both microwave switch insertion loss and isolation.

When a microwave switch is in its high-impedance state, the majority of the signal voltage is dropped across the switching element. In the low-impedance state, the current flow through the switch element can be large. These maximum voltages and currents, and the corresponding peak power, must be known at the time of the design so that suitable switch elements can be selected. These specifications can vary widely depending on the application, from low-power low-voltage requirements for receive-only applications to high-voltage high-power switching devices for radar or other transmitter applications. A wide variety of switching elements have been developed over the decades in response to these differing system requirements. The choices facing the microwave switch designer are detailed in the next section.

4. MICROWAVE SWITCH ELEMENTS

Both p-i-n diodes and FETs are the primary solid-state switch elements used in modern microwave switches. p-i-n

Figure 7. Insertion loss for the shunt SPST 50- Ω switch as a function of frequency using the switch capacitance C_S as a parameter.

diodes fabricated using either silicon or gallium arsenide are used in switching applications from frequencies below 1 MHz to 50 GHz and beyond, and can switch peak microwave power into the tens of kilowatts range. p-i-n diode switching elements exhibit ON- and OFF-state characteristics that are modeled using parameters illustrated in Fig. 2.

A p-i-n diode consists of a nearly intrinsic or pure semiconductor region (i region) sandwiched between heavily doped n/p-type regions. The ON-state or forward-bias resistance R_S of the p-i-n diode is a function of the i-region width W as well as the i-region carrier lifetime τ and the DC bias current flowing through the device I_0 . In its simplest form, the ON-state resistance can be written as [2]

$$R_S = \frac{W^2}{2\mu I_0 \tau} \quad (6)$$

where μ is the ambipolar carrier mobility. The i-region carrier lifetime τ is the average time a carrier exists in the i region of the device, and can vary from 1 ns in thin gallium arsenide p-i-n diodes to 10 μ s or longer in thick silicon diodes. The i-region thickness W can vary from 1 μ m or less in low-power p-i-n diodes to 200 μ m and higher in p-i-n diodes designed for high-power high-voltage applications. Under reverse-bias conditions, a capacitance is developed across the p-i-n diode's i region. Beyond a certain reverse bias voltage, termed the *punch-through voltage*, the OFF-state or *punch-through capacitance* is constant and is modeled as C_S . Gallium arsenide p-i-n diodes and some thin silicon p-i-n diodes typically exhibit punch-through with no voltage applied (*zero-bias punch-through*).

p-i-n diode switch elements are available as either discrete devices or multithrow switching modules. Switch modules provide the microwave switch designer ease of design, whereas discrete devices provide more design flexibility. Discrete devices are usually used in very high-power operation. A wide variety of discrete p-i-n switching diodes of different electrical and physical properties are commercially available. Manufacturer's data-sheets often specify their p-i-n diode products in terms of W , τ , R_S at certain bias currents (1 or 10 mA) and frequencies (usually 100 MHz), C_S at a certain reverse bias voltage (typically -6 V) and a frequency of 1 MHz, and the diode's maximum voltage rating. p-i-n diode switching modules are specified by their multithrow switch operation, operating frequency range, minimum isolation, maximum insertion loss, diode voltage rating, and maximum power handling.

A common misconception involved in specifying p-i-n diodes is the relationship between carrier lifetime τ and p-i-n diode *switching time*. These two parameters are only weakly related, with the switching time more a function of the external driver circuitry. This driver circuit must remove the i-region *stored charge* ($Q = I_0 \tau$) to completely turn the diode off or inject the necessary charge to turn the diode on. The p-i-n diode driver circuit is seldom included in switch circuit diagrams, but is fundamental to proper switch operation. Silicon p-i-n diodes cannot be driven

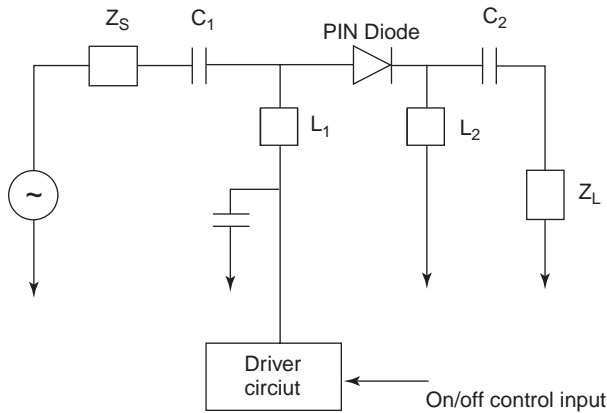

Figure 8. SPST p-i-n diode switch with driver circuit DC decoupling elements shown.

directly from digital TTL (transistor–transistor logic)-compatible signals, so a driver circuit is used to translate these digital signals into voltages and currents needed to turn the p-i-n diode on and off quickly. The driver circuit must also be AC-decoupled from the microwave switch circuit. Zero-bias punch-through diodes such as gallium arsenide p-i-n diodes can be driven directly by digital TTL-compatible signals without the need for complex driver circuitry, although AC decoupling is still required. The circuit elements used in this decoupling circuit frequently limit the usable bandwidth and switching speed of the p-i-n diode switch. Figure 8 shows an example of an SPST p-i-n diode switch circuit with driver circuit and AC decoupling elements included. Capacitors C_1 and C_2 act as DC blocks, preventing DC from reaching either the source or the load. Inductor L_1 isolates the driver circuit from the AC signal path, and inductor L_2 provides a DC return path. L_2 and C_2 may be eliminated if the load Z_L can act as the DC return path.

To improve isolation or insertion loss in p-i-n diode switch circuits, multiple diodes may be placed in series or parallel. If two shunt connected p-i-n diodes replace the one diode illustrated in Fig. 4, the effective series resistance R_S is halved, increasing the isolation by 6 dB. When two or more p-i-n diodes are used in shunt, improved switch performance can frequently be obtained by spacing the diodes a quarter-wavelength ($\lambda/4$) apart. This spacing can be obtained physically by the use of transmission lines or a lumped-element equivalent. This technique, however, can restrict the overall bandwidth of the switching module.

A significant achievement in switch module and monolithic microwave integrated circuit (MMIC) technology occurred with the development of metal semiconductor FET (MESFET) switch elements in gallium arsenide. This technology not only provides switch elements in modular form but also allows entire systems, switching included, to be fully integrated onto a single gallium arsenide integrated circuit. Modern microwave FET switches can be directly connected to their driver circuitry without the need for complex driver or decoupling circuitry since the control port of the FET, a three-terminal device, is inherently isolated from the signal ports. FETs switch faster than do p-i-n diodes since the amount of charge that must

be added or removed during switching is much less. Switching energy is lower for FET switches since only a few microamperes flow into the control line versus milliamperes in p-i-n diodes. The disadvantages of FET switches are that they are only available in switch modules and can handle power levels only in the tens of watts. Another disadvantage of FET over p-i-n diode switch modules occurs in unipolar power supply applications. Gallium arsenide FET switches require negative voltages to turn them off, so the microwave switch designer must float or DC-isolate the switch to obtain the proper voltage polarity. These DC decoupling elements complicate the switch design and can limit the switch bandwidth.

FET switch modules can operate over wider bandwidths than p-i-n diode switches. Packaged FET modules exhibit good switch performance from DC to 2 GHz. Wider bandwidths of DC to 18 GHz can be obtained using unpackaged switch chips that are directly connected (e.g., by wire bonding) to the circuit to be controlled. Gallium arsenide MESFET switch modules are specified by their multi-throw switch operation, packaging (packaged or chip form), operating frequency range, minimum isolation, maximum insertion loss, diode voltage rating, and maximum power handling. Insertion loss is usually higher and isolation usually lower for the wider-bandwidth switch modules because of engineering tradeoffs that are needed to extend the bandwidth in these devices. Gallium arsenide FET switch insertion loss typically ranges from 0.2 to 1.0 dB, with the higher values of insertion loss typical for operation at 8 GHz and above. A good MESFET switch will exhibit isolation greater than 20 dB, although isolation at lower frequencies can be greater than 80 dB.

Microwave MEMS switches utilize moving parts at the microscopic level to create the switching action. The two main MEMS switch structures are the cantilever beam and the capacitive membrane switch; the capacitive membrane switch is more widely used at microwave frequencies (Fig. 9), frequently using coplanar waveguide. Both of these switch structures rely on the application of an electrostatic force (the switch voltage, usually in the tens of volts) to overcome the force due to the spring constant of the un-deformed structure. For the capacitive membrane MEMS switch (the most common structure at microwave frequencies), the actuation voltage is a function of the switch area (A), the spring constant (k), and the gap above the actuation electrode (g) [3]:

$$V_P = \sqrt{\frac{8kg^3}{27\epsilon A}} \quad (7)$$

Using typical values of $k = 10 \text{ N/m}$, $A = 10^4 \mu\text{m}^2$, and a $2.5\text{-}\mu\text{m}$ gap yields a switch actuation voltage of approximately 23 V. Once the switch has been activated, g is reduced and the holding voltage is correspondingly less.

MEMS switches exhibit better insertion loss and isolation performance at high microwave frequencies than do their solid-state counterparts, but tend to switch at slower rates [3]. Using the typical MEMS switch values above, the membrane switch exhibits an OFF-state capacitance of approximately 35 fF (10^{-15} farads), which yields less than

Figure 9. RF MEMS capacitive membrane switch over coplanar waveguide in its open (a) and closed (b) positions.

0.1 dB insertion loss at 10 GHz when used in a shunt configuration (Fig. 9a). When the switch is activated (Fig. 9b), the gap g is substantially reduced, increasing the capacitance by a factor of 10 or more. This increases the loss of the switch, providing the isolation between the source and the load. For a gap reduction of 50 (1.7 pF), an isolation of 10 dB can be achieved.

Ferrite switch modules have been largely replaced by semiconductor switches for all except high-power applications. Ferrite switch modules are physically large and bulky. However, they provide the only method of controlling microwave power into the megawatt levels. Peak powers of more than a megawatt can be easily switched at frequencies below 8 GHz with ferrite switches with low loss (less than 0.5 dB) and isolation greater than 20 dB. Ferrite switches based on switching circulators have been used as high as 220 GHz [4].

A common ferrite switch uses a switched *ferrite circulator* as the basic switching module. The arrow in Fig. 10 shows the direction of microwave energy flow. With one magnetic field orientation, microwave energy entering port 1 leaves port 2, and energy entering port 2 leaves port 3. By reversing the magnetic field orientation, the circulation pattern (1→2→3→1) changes to (1→3→2→1), and the circulator acts as a nonreciprocal SPDT switch. Because of the nonreciprocity of the switch, energy entering port 1 leaves port 2 but energy entering port 2 leaves port 3. A reciprocal version of this SPDT switch requires one nonreciprocal switching module and two fixed circulators [5]. Ferrite switch modules are inherently narrow band. Figure 11 shows insertion loss, isolation, and VSWR of a 35-GHz latching ferrite switch module [6], illustrating the relatively narrowband properties of the module. Ferrite switches exhibit insertion losses of less than 0.5 dB at frequencies below 12 GHz, although higher losses (up to 1.0 dB) occur at higher operating frequencies. Isolation of 20 dB or greater is typical at frequencies of 94 GHz and

Figure 10. Microwave energy flow in a switching ferrite circulator [7] (copyright 1989, John Wiley and Sons, reprinted by permission of John Wiley & Sons, Inc.).

beyond. The bandwidth of a ferrite switch can be extended using special matching techniques [7].

Another drawback for the ferrite switch compared to the solid-state microwave switch is the ferrite switch's relatively slow switching speed. To change switch states, the magnetic field in the ferrite must be reversed, and phenomena such as material demagnetization and switching eddy currents combine to slow the switching speed. Switching speeds of several hundred nanoseconds have been achieved in some ferrite switch modules [6]. Relatively large currents are needed to induce the ferrite switch action, making them unsuitable for most battery or portable applications.

5. NONIDEAL MICROWAVE SWITCH ELEMENT OPERATION

The insertion loss and isolation are measures of the microwave switch's impact on the fundamental microwave signal. A side effect of using active microwave switch elements is their generation of unwanted signals based on the level of microwave signal energy. These so called

Figure 11. Insertion loss, isolation, and VSWR for a 35-GHz latching ferrite switch [6] (copyright 1966 IEEE).

nonlinear effects produce spurious signals that are harmonically related to the fundamental microwave signal, introducing *distortion* into the system. The two most widely specified microwave switch distortion products are second- and third-order *intermodulation distortion*. These distortion products are measured using the *two-tone test*, where two signals of equal amplitude but slightly different frequency (F_1 and F_2) are incident on the microwave switch. The second-order nonlinear effects in the microwave switch generate spurious signals at frequencies $2F_1$ and $2F_2$ (*harmonic distortion*) and at frequencies $F_1 \pm F_2$ (*intermodulation distortion*). The third-order nonlinear effect generates signals at frequencies $3F_1$ and $3F_2$ (*harmonic distortion*), and $2F_1 \pm F_2$ and $2F_2 \pm F_1$ (*intermodulation distortion*). The most difficult distortion terms to manage are the third-order intermodulation products ($2F_1 - F_2$ and $2F_2 - F_1$) because these frequency components can be close to the fundamental frequencies F_1 and F_2 , and hence are difficult to remove by filtering. Second- and third-order microwave switch intermodulation distortion is frequently specified using distortion intercept points IP2 and IP3. The intercept point is determined by measuring the distortion power with respect to the power in the fundamental [8]:

$$\text{IP2} = P_F + R_{ab/a} \quad (8)$$

$$\text{IP3} = P_F + 0.5R_{2ab/a} \quad (9)$$

where P_F is the fundamental power (in dBm), and $R_{ab/a}$ and $R_{2ab/a}$ are the relative second- and third-order distortion powers (in dBc), respectively. Equations (8) and (9) also show that the distortion power can be computed given the distortion intercept point and fundamental power level. Less distortion is introduced into the system by using high intercept point switches or switching elements.

For a single-series p-i-n diode switch, the ON-state (forward-biased p-i-n diode) IP2 and IP3 have been found to be a function of QF/R_S , where Q ($I_0\tau$) is the i-region stored charge, F is the operating frequency, and R_S is the series resistance. For a series connected p-i-n diode switch, IP2 and IP3 have been computed as [8]

$$\text{IP2} = 34 + 20 \log \left(\frac{Q_{nc} F_{\text{MHz}}}{R_S} \right) \text{dBm} \quad (10)$$

$$\text{IP3} = 24 + 15 \log \left(\frac{Q_{nc} F_{\text{MHz}}}{R_S} \right) \text{dBm} \quad (11)$$

where Q_{nc} is the i-region stored charge in nanocoulombs, F is the frequency in MHz, and R_S is the series resistance in ohms. This ratio can be increased by increasing the i-region stored charge (high DC bias current or large carrier lifetime) and/or lowering the series resistance. Distortion also improves as the frequency of operation increases. The underlying cause of forward-biased p-i-n diode distortion is modulation of the i-region DC stored charge by the microwave signal.

The p-i-n diode also introduces distortion in its OFF state (reverse bias) due to modulation of the reverse bias capacitance C_S by the microwave signal. Second- and

third-order distortion for the series-connected p-i-n diode switch can be estimated from the reverse-bias capacitance-voltage characteristic, specifically the first and second derivative (C'_S and C''_S , respectively) [9]:

$$\text{IP2} = \frac{1}{32(C'_S)^2 Z_0^3 (\omega_1 + \omega_2)^2} \quad (12)$$

$$\text{IP3} = \frac{1}{12(C''_S) Z_0^2 (2\omega_1 + \omega_2)} \quad (13)$$

Since multithrow switch circuits have combinations of ON- and OFF-state p-i-n diodes for each switch state, all diode distortion contributions must be included for an accurate microwave switch distortion prediction. The ON-state p-i-n diode usually contributes more distortion than do p-i-n diodes in the OFF state.

Gallium arsenide MESFET switches also introduce distortion [10]. ON-state MESFET switch distortion is caused by modulation of the conducting channel region by the applied microwave signal. In the OFF state, distortion is generated by variations in the gate-drain and gate-source capacitance (C_{GD} and C_{GS} , respectively) by the applied signal. Figure 12 shows ON-state IP2 and IP3 versus frequency for a typical $1000 \times 1\text{-}\mu\text{m}$ series-connected MESFET switch. The transition region for the distortion occurs in the vicinity of $R_B(C_{GS} + C_{GD})$, where R_B is the gate bias resistor. In the OFF state, MESFET switch distortion increases with increasing frequency. Figure 13 shows IP2 and IP3 for a gallium arsenide MESFET SPST switch. Typical IP2 (IP3) values range from 80 dBm (50 dBm) for 2-GHz SPDT gallium arsenide MESFET switch modules to 65 dBm (40 dBm) for 18-GHz switch modules. Similar to p-i-n diodes, MESFET switch ON-state distortion is usually much larger than distortion in the OFF state. Since gallium arsenide MESFET switches are typically available only in module form, IP2 and IP3 are specified only for the ON state.

The ferrite circulator will generate intermodulation distortion as well. The two main sources of nonlinearity in the ferrite circulator are due to uniform precession of the ferrite magnetization and by the presence of spin

waves [11]. Third-order intermodulation distortion has been shown to improve with increasing frequency, similar to the behavior of the p-i-n diode. However, the amount of distortion introduced by the ferrite is significantly lower than that introduced by either the p-i-n diode or MESFET switch element. Since the switching ferrite circulator is used at high power levels, the low distortion behavior of the ferrite device is an asset.

6. OTHER MICROWAVE SWITCH ELEMENTS

Semiconductor and ferrite microwave switches require direct-wired connections to control their switch state. Optical control of microwave switches has been investigated by a number of workers. The two most common types of optically controlled switches use bulk semiconductor [12] and p-i-n diodes [13,14]. Bulk semiconductor switches, or photoconductive semiconductor switches, use light energy (usually from a high-power laser) to modulate the conductivity of the material. The most common optically controlled microwave switch circuit topology has a transmission-line gap with the bulk semiconductor within the gap (Fig. 14). The transmission-line gap can range from a few micrometers in low-power applications to millimeters in high-power or high-voltage applications. During the OFF (dark) state, the high resistivity of the bulk semiconductor effectively isolates the two transmission

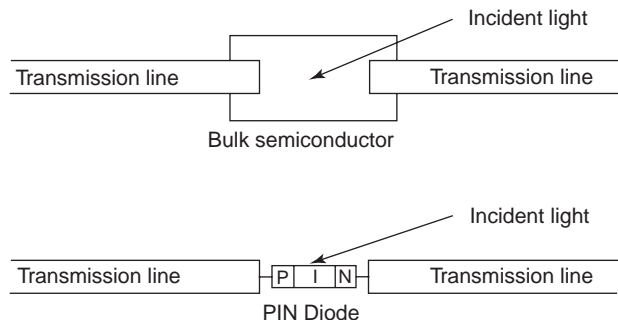

Figure 14. Optically controlled microwave switches: bulk semiconductor and reverse-biased p-i-n diode physical layouts.

lines. The switch is activated by an intense beam of photons directed on the semiconductor material, which quickly generates electron-hole pairs in the material, increasing the semiconductor’s conductivity, and providing a low loss connection between the two transmission lines. When the light source is removed, the electron-hole pairs recombine, returning the switch to its OFF state. This turnoff process is dependent on the carrier lifetime of the electron-hole pairs in the semiconductor material. Various semiconductor processing techniques such as introducing a high density of recombination centers have been developed to lower the carrier lifetime to speed the switching action.

Optically controlled p-i-n diode switches also rely on electron-hole pair generation by an incident beam of photons as well. The OFF state (high isolation) is accomplished with a reverse-biased p-i-n diode bridging the transmission line gap instead of the bulk semiconductor material (Fig. 14). The switch is turned on with a beam of photons focused on the i region, causing the generation of electron-hole pairs. The i-region conductivity dramatically increases, thereby creating a low-loss connection across the gap. Carriers swept out of the i region by the electric field are continually replenished by the optically generated carriers. This same field quickly sweeps all the electron-hole pairs out of the i region when the light source is removed, rapidly returning the microwave switch to its OFF state. These switches can be activated in less than 100 ps and turned off in several nanoseconds [13,14].

Considerable research and development has been done in developing entire microwave communications systems on a single integrated circuit [called *system on a chip* (SOC) or *single-chip radio* (SCR)]. The recent technologies of interest have been silicon because of the integrability of the high-frequency section with digital control and signal processing components. The microwave switch elements of interest in SOC research are primarily based on MOS, BiCMOS, and MEMS silicon technologies. Silicon MOSFET RF circuit topologies mimic those of their gallium arsenide counterparts, but since the current-carrying characteristics of silicon MOSFETs are poorer than gallium arsenide MESFETs, the resulting transistor sizes are larger and therefore the frequency response of these RF control elements is poorer. The silicon MOSFET also does not handle as much power as the gallium arsenide MESFET without creating large signal distortion. However, with silicon technologies approaching 100 nm (10^{-7} m) gate widths, these devices are being used in applications up to several gigahertz [15].

Microwave-switching FETs based on other technologies such as silicon germanium (SiGe) have shown promise up to 5 GHz in switching applications [16]. Higher-power microwave switch technologies based on so-called wide-band-gap semiconductors (silicon carbide and gallium nitride) have been proposed and studied and show promise in this area [17].

FURTHER READING

Several excellent publications on microwave switches are available for further reading. The classic treatment of p-i-n diode switches can be found in Ref. [2]. For gallium arsenide MESFET switches, the classic papers in the field are in Refs. [18, 19, 20]. Since ferrite switches are usually based on circulator technology, the reader is encouraged to read the sections on ferrite devices elsewhere in the encyclopedia. A good overview of the use of MEMS for microwave switches can be found in Ref. [3]. The most widely used research publications containing information on microwave switches are the *IEEE Transactions on Microwave Theory and Techniques* and the *Microwave Journal*. The *Transactions on Microwave Theory and Techniques* has cumulative indices listing the *Transactions'* publications from 1950 to 1988 [21, 22]. A digital archive of all publications from the IEEE Microwave Theory and Techniques Society from 1953 to the present is also available [23]. Application notes from suppliers of microwave switch elements and modules are also good sources of design information.

MICROWAVE TUBES

VICTOR L. GRANATSTEIN
University of Maryland
College Park, Maryland
ROBERT K. PARKER
Naval Research Laboratory
Washington, D.C.

Microwave tubes are devices that generate or amplify electromagnetic radiation in the frequency range of 0.3–300 GHz (microwave frequencies); they are based on the interaction between the electromagnetic radiation and a stream of electrons inside a vacuum envelope (the tube). Compared with solid-state microwave devices, microwave tubes operate at much higher power levels. Average output power ratings for state-of-the-art, single microwave tubes or solid-state devices are plotted versus frequency in Fig. 1 for the decades from 1950 to 1990. It can be seen that in 1990 microwave tubes were 1000 times more powerful than the most powerful solid-state devices at a frequency of 1 GHz, and 100,000 times more powerful at a frequency of 100 GHz.

Because of their compactness, solid-state devices are usually the preferred choice for low-power systems, with microwave tubes preferred in high-power systems. The breakpoint comes for system average output power of approximately 100 W. There, the greater efficiency of microwave tubes (typically, 50% vs. 25% for solid-state devices) results in a more compact overall system when a microwave tube output stage is combined with a smaller power supply.

The superior efficiency of microwaves may be understood from the fact that in vacuum the electrons do not pass through a background material that would impeded

Figure 1. Histogram of power available from a single microwave oscillator or amplifier as a function of frequency. The solid lines represent solid-state device limits. The dashed lines represent vacuum electronic device limits.

their movement. Thus, the heating of a background material is not a limiting factor of high-power operation. Also, the electron trajectories are not randomized by collisions with a background material so that after passing through the microwave generation region the energy spectrum of the spent electrons is concentrated in a relatively narrow energy range; this facilitates energy recovery from the spent electrons and high overall device efficiency.

1. PRINCIPLES OF OPERATION

Electrons that are accelerated (or decelerated) emit electromagnetic radiation. However, unless the positions of the electrons form an ordered pattern (bunching), the emitted radiation will be incoherent; that is, the phase of the electromagnetic wave emitted by an electron will be random compared with the phases of the waves emitted by the other electrons. To achieve powerful radiation the emitted waves must add up in phase (coherent radiation), and this requires bunching.

The microwave tube contains a structure (the circuit) that supports electromagnetic waves that can interact with the electronbeam to form microbunches of electrons. An unbunched electronbeam passing through the vacuum tube with axial velocity v_z is shown in Fig. 2a. The periodic axial electric field component of an electromagnetic wave (transverse magnetic mode) is also shown in this figure, and this field will exert a force on the electrons that will concentrate them into bunches as shown in Fig. 2b.

When the phase of the bunches is arranged with respect to the wave electric field as shown in Fig. 2, the electrons are decelerated. The decrease in electron energy is accompanied by an equal increase in the energy of the electromagnetic wave. This can be regarded as coherent radiation of microwaves by the electrons; the bunching is required for coherence. In order for the wave to keep extracting energy from the beam, its axial phase velocity must match the electron axial velocity; this condition is called *beam/wave synchronism*.

Figure 2. (a) An unbunched beam of electrons passing through a vacuum tube together with the periodic axial electric field of an electromagnetic wave; (b) a bunched electron beam with the bunches arranged to be decelerated by the wave field.

The bunching process results from excitation of the natural modes of an electronbeam with charge density ρ streaming with axial velocity v_z in the presence of a constant, externally applied, axial magnetic field B_0 . These modes of oscillation are of two types:

1. Space charge waves that involve the plasma frequency

$$\omega_p = \sqrt{\frac{e\rho}{m\epsilon_0}}$$

where e and m are, respectively, the charge and mass of an electron and ϵ_0 is the permittivity of free space

2. Cyclotron waves that involve the electron cyclotron frequency

$$\omega_c = \frac{eB_0}{m}$$

The propagation of a particular wave is described by its dispersion equation, which is a relationship between its frequency ω and its axial wavenumber β . The space charge waves on an electronbeam obey the dispersion equation

$$\omega = \beta v_z \pm \omega_p F \quad (1)$$

where F , the space charge reduction factor, depends on the finite transverse geometry of the waveguide; for an electronbeam filling a hollow cylindrical waveguide with conducting walls of radius a , we obtain

$$F = \left[1 + \left(\frac{2.405}{\beta a} \right)^2 \right]^{-1/2}$$

Thus, F approaches unity as βa becomes large. In Eq. (1), the plus sign refers to the fast space charge wave while the minus sign is for the slow space charge wave.

If the electrons also have a velocity component transverse to the axis v_\perp , then cyclotron waves may exist in addition to the space charge waves. The dispersion equation for the cyclotron waves is

$$\omega = \beta v_z \pm \omega_c \quad (2)$$

Figure 3. The average power capability of a single microwave tube versus frequency shown for some major types of microwave tube.

where the plus sign refers to the fast cyclotron wave and the minus sign refers to the slow cyclotron wave.

Finally in this section, we note that the microwave tube can be either an oscillator or an amplifier. Oscillators have no microwave input signal and effectively amplify noise; they are most commonly used in heating applications such as domestic cooking, industrial processing of materials, and heating of the ionized gas (plasma) in a controlled fusion reactor to the temperature required for thermonuclear ignition. Amplifiers do have a microwave input signal that is strengthened by its interaction with the electronbeam to produce an output signal that is much stronger than the input; the output signal tracks the frequency and phase of

the input signal. Amplifiers are used in communications and radar systems and in other systems that require phase control, such as high-energy particle accelerators.

2. TYPES OF MICROWAVE TUBES

A number of important types of microwave tubes differ with regard to the configuration of the circuit inside the vacuum envelope and/or with regard to the electrode configuration used for generating the electronbeam. These differing configurations lead to a variety of combinations of performance characteristics (e.g., operating frequency, power, bandwidth, oscillator or amplifier operation). The average power capability of some of the more important types of microwave tubes are plotted in Fig. 3 as a function of frequency.

In Table 1 the important features and applications of each of the major types of microwave tubes is indicated. Each tube type is identified as either an oscillator or amplifier, depending on its most usual deployment; however, we have also indicated the complementary tubes that use similar configurations. We will now describe the circuit configuration, the electronbeam configuration, the process of electron bunching, and the process of microwave amplification in each of the major tube types.

2.1. Traveling-Wave Tube (TWT) Amplifiers

The configuration of a helix TWT amplifier is sketched in Fig. 4. The Pierce electron gun ideally produces a solid cylindrical electronbeam that streams through the circuit

Table 1. Major Types of Microwave Tubes

Tube Type	Circuit	Electron Beam	Advantages	Most Common Applications	Complimentary Tube
Traveling wave tube (TWT) amplifier	Periodic waveguide; helix or coupled cavity (CC)	Solid cylindrical beam produced by Pierce electron gun	Wide bandwidth	Communications; jammers	Backward wave oscillator (BWO); wide tunability; used for spectroscopy
Klystron amplifier	Resonant, small-gap cavities separated by cutoff drift tubes	Solid cylindrical beam produced by Pierce electron gun	High gain; ^a high efficiency ^b	Radar; electron accelerators for medical applications and high-energy physics research	Reflex klystron oscillator
Magnetron oscillator	Coaxial configuration of inner cathode cylinder and outer anode that contains periodic arrangement of resonant cavities	Rotating electron-beam in annular space between cathode and anode	Rugged; low-cost	Domestic cooking; industrial heating of materials	Cross-field amplifier (CFA); used in radar
Gyrotron oscillator	Resonant cavity employing high-order transverse electric mode (e.g., TE _{15,2})	Annular beam of spiraling electrons produced by magnetron injection gun (MIG)	High average power at millimeter wavelengths (30–300 GHz)	Plasma heating in controlled thermonuclear fusion research (CTFR)	Gyroklystron amplifier; used in millimeter-wave radar (35 GHz, 94 GHz)

^aGain is the ratio of power in the output microwave signal to power in the input microwave signal.

^bEfficiency is the fraction of electron beam power that is converted to microwave output power.

Figure 4. Configuration of a helix traveling-wave tube amplifier.

along the lines of the externally applied axial magnetic field with velocity v_z and without appreciable transverse velocity. The circuit is a helix that supports the propagation of slow electromagnetic waves; that is, the phase velocity of the wave in the axial direction is less than the speed of light, c . For a helix of period p and diameter d , the axial phase velocity is

$$v_p = c \frac{p}{\sqrt{p^2 + (\pi d)^2}}$$

and if v_p is made equal to the initial value of electron velocity, v_z , beam/wave synchronism will be achieved. Bunching and deceleration of the electrons can then occur as depicted in Fig. 2; the process can be regarded as an interaction between the slow electromagnetic wave of the helix circuit and the slow space charge wave of the electronbeam. In Fig. 5, the dispersion curves of the circuit wave and of the slow space charge wave are sketched. They are seen to be approximately in synchronism (i.e., almost touching) over a wide range of frequencies (one to three octaves) with maximum value of frequency just a little smaller than $2\pi v_z \omega / a$.

Amplification may then occur over this wide range of frequencies. The amplifier linear gain in dB is given by

$$G(\text{dB}) = -9.54 + 3.75 \frac{\omega L}{v_z} \left(\frac{\omega_p}{\omega} \right)^{3/2} \quad (3)$$

Figure 5. Dispersion curves of the helix circuit wave and the slow space charge wave.

where L is the length of the helix circuit and the first term on the right-hand side is the insertion loss caused by excitation of beam modes that do not grow.

The amplification process saturates when v_z is decreased from its initial value by deceleration to such an extent that the synchronism $v_z = v_p$ is no longer maintained to an adequate degree. Single-pass efficiency is on the order of only 10%, but this may be increased to approximately 50% by the use of techniques to recover energy in the spent electronbeam, such as depressed collectors.

The helix circuit is especially capable of wide bandwidth, but it is rather delicate and will not support a very large power rating, especially as frequency rises (see Fig. 3). The coupled-cavity periodic circuit, which also supports slow waves, is much more robust and is capable of supporting larger powers; however, its bandwidth is more limited.

A miniaturized helix TWT is used as the output power stage of the 100 W continuous-wave (CW) microwave power module (MPM). The MPM is more compact overall than a system with a solid-state output stage because of the 50% efficiency of the TWT. This tube also achieves a gain of 50 dB in a length of 22 cm and covers a frequency of range of 4.5–18 GHz. Coupled cavity TWTs have a much smaller bandwidth of only a few percent, but they have achieved 700 W average power at 94 GHz.

2.2. Magnetron

Magnetrons are the most ubiquitous of microwave tubes, used by the tens of millions in domestic microwave ovens. They also have a celebrated history, enabling high-power radar in World War II and credited for the victory of the Allies in the Battle of Britain and perhaps the entire war. The primary reason for the magnetron being the earliest radar power tube and its present widescale domestic application is the simplicity of its structure. In contrast to the TWT amplifier sketched in Fig. 4, the magnetron has no electron gun. Instead, the anode and cathode are coaxial with the annular space between them functioning as the region in which the electron stream and the electromagnetic waves interact.

A cross section of the coaxial magnetron geometry is sketched in Fig. 6. There is a DC voltage V_0 applied between the anode and cathode that produces a radial DC electric field

$$E_0 = \frac{V_0}{r \ln(b/a)} \approx \frac{V_0}{2r} \frac{b+a}{b-a} \quad (4)$$

where r is the radial coordinate and a and b are the cathode and anode radii, respectively. A DC magnetic field B_0 is applied in the axial direction. Under the influence of the crossed electric and magnetic fields, the electrons execute a cycloidal motion that can usually be decomposed into small orbit Larmor rotations at the electron cyclotron frequency and a lower azimuthal motion around the annulus with velocity

$$\vec{v}_\phi = \frac{\vec{E}_0 \times \vec{B}_0}{B_0^2} \quad (5)$$

Figure 6. Configuration of a coaxial magnetron oscillator.

Cavities that are resonant at the operating frequency are cut into the anode block and arranged periodically around the azimuth. For the π mode in which the field in adjacent cavities are 180° out of phase as shown in Fig. 6, the fringing fields at radius r in the annular space appear to rotate with phase velocity

$$v_p = \frac{2\omega r}{N} \tag{6}$$

where N is the number of cavities.

An interaction between the rotating electron cloud and the electromagnetic fields can then lead to a growing electromagnetic wave in a manner related to the process in the TWT. This requires synchronism between the electron azimuthal velocity given by Eq. (5) and the phase velocity given by Eq. (6). For electrons at the center of the annular space, that is, $r = (b + a)/2$ and with E_0 related to V_0 by Eq. (4), the synchronism condition gives

$$V_0 = B_0 \omega \frac{b^2 - a^2}{N} \tag{7}$$

This type of synchronism relationship between V_0 and B_0 is known as a *Buneman–Hartree equation*.

There is also an inequality that V_0 must satisfy to ensure that the DC electron trajectories will not strike the anode. This is known as the *Hull cutoff condition* and is

$$V_0 < \frac{1}{8} \frac{e}{m} B_0^2 \frac{(b^2 - a^2)^2}{b^2} \tag{8}$$

As the electromagnetic wave grows, energy is extracted from the rotating electron cloud. The electrons in the process are forced outward to new radial positions where their potential energy is lower. The magnetron process may therefore be viewed as converting electron potential energy to electromagnetic wave energy. The electron kinetic energy, however, remains sufficient to maintain the synchronism between v_ϕ and v_p until the electron eventually reads the anode. Because of this mechanism for maintaining a synchronous interaction, magnetrons have relatively large efficiency compared with the single-pass efficiency of TWT amplifiers.

The 2.45 GHz magnetrons used in ovens for domestic cooking typically operate at better than 50% efficiency with average output power of 600 W. Other magnetrons have been developed with efficiency as great as 85% and with average power of hundreds of kilowatts.

2.3. Klystrons

Although magnetrons are high-power and efficient microwave oscillators, they are not suitable for applications that require high-gain amplifiers; for such applications klystrons have been the devices of choice. The layout of a two-cavity klystron is sketched in Fig. 7. Interaction between the electronbeam and electromagnetic waves occurs only while the electrons are passing through narrow gaps that form the capacitive regions of the resonant cavities; the drift tube between the cavities is cut off for electromagnetic waves.

Each resonant cavity has a coaxial outer region that is inductive with inductance

$$\mathcal{L} = \frac{1}{\pi} \sqrt{\frac{\mu_0}{\epsilon_0}} \ln\left(\frac{b}{a}\right) \frac{1}{\omega} \tan\left(\frac{\omega L}{2c}\right)$$

Figure 7. Configuration of a two-cavity klystron amplifier.

where μ_0 is the permeability of free space. This inductance may be considered to be in parallel with the narrow-gap region that has capacitance

$$\mathcal{C} = \frac{\epsilon_0 \pi a^2}{d}$$

The resonant frequency of the cavity will be $\omega_r = 1/\mathcal{L}\mathcal{C}$. Each cavity will also be characterized by its unloaded quality factor

$$Q_0 = \frac{\omega_r \mathcal{C}}{G_W}$$

where G_W is the wall conductance whose nonzero value is a measure of the microwave power that is lost in heating the cavity walls.

When the electron beam passes through the gap in the first cavity, it is modulated in velocity by the microwave field in the gap. This leads to excitation of both the slow space charge wave and the fast space charge wave that grow and phase interfere in the drift tube. The interference leads to axial bunching of the electron as shown in Fig. 7, and when such a bunched beam streams through the gap in the output cavity, it excites microwave fields there that may be much stronger than the fields in the input cavity.

In the regime of small signal linear operation, gain is optimum when the distance between the gaps in the two cavities is chosen to be

$$L = \frac{\pi v_z}{2 \omega_p F}$$

Then, the linear gain is

$$G = \frac{1}{\pi^2} \left(\frac{I_0}{V_0} \right)^2 \left(\frac{\omega L}{v_z} \right)^2 \frac{G_L}{G_i(G_o + G_L)^2} \tag{9}$$

where we have assumed that the gap width d is much less than the wavelength; G_i and G_o are the G_W conductances representing wall losses in the input cavity and output cavity, respectively; G_L is the conductance representing power coupled from the output cavity into the load. The electron beam voltage and current are given by V_0 and I_0 , respectively.

While it is in general much more difficult to analyze nonlinear behavior, a nonlinear analysis of the two-cavity klystron has been carried out in the limit of small space charge effects:

$$\omega_p F \ll \frac{v_z}{L}$$

In this limit the efficiency of converting electron kinetic energy to microwave energy in the output cavity has been shown to be given by

$$\eta_E = J_1(X) \tag{10}$$

where η_E is called the electronic efficiency, J_1 is the Bessel function of the first kind of order 1, and the beam

bunching parameter is given by

$$X = \frac{1 E_i d \omega L}{\pi V_0 v_z}$$

where E_i is the magnitude of the microwave electric field developed across the gap in the input cavity. The electronic efficiency as given by Eq. (10) has a maximum value of $\eta_E = 58.2\%$ when the beam bunching parameter $X = 1.841$.

Even higher efficiency, and certainly much higher gain than is indicated by Eq. (9), is attainable in klystron amplifiers with more than two cavities. A five-cavity, 11.4 GHz klystron amplifier has been developed at the Stanford Linear Accelerator Center for driving the next generation of electron/positron accelerators for high-energy physics research. It has a gain of 50 dB with peak output power of 56 MW in 1.5 μ s-long pulses. The pulse repetition frequency is 180 pps (pulses per second), the electron beam in the klystron is focused with permanent magnets, and klystron output efficiency is 60%.

2.4. Gyrotrons

As capable as klystrons are, they do become limited in power rating as frequency rises to the millimeter-wave regime (≥ 30 GHz). This is true because their cutoff drift tubes and their resonant cavities shrink in size with the wavelength. A relatively new vacuum electronics device that has operated successfully using a highly overmoded circuit is the gyrotron. The configuration of a gyrotron oscillator is sketched in Fig. 8.

The magnetron injection gun produces an annulus of electrons that travel along the circuit spiraling around the lines of the axial DC magnetic field. An important parameter of such an electron beam is the ratio of perpendicular velocity v_\perp to axial velocity v_z . Usually v_\perp/v_z is in the range of 1.0–2.0. The low value gives greater stability against spurious oscillation, while the high value gives greater efficiency.

A cross section of the electron beam is shown schematically in Fig. 9, where the electrons are initially seen to have random phase in their electron orbits. Also shown in Fig. 9 is E_θ , the azimuthal electric field of a TE_{0n} mode of the cylindrical gyrotron cavity. An electron such as 1 (in Fig. 9) will be decelerated by the electron beam, and its mass will decrease (this is a relativistic effect) leading to an increase in its cyclotron frequency as

$$\omega_c = \frac{eB_0}{m} = \frac{eB_0}{m_0} \sqrt{1 - (v_z^2 + v_\perp^2)/c^2}$$

where m_0 is the electron rest mass. Similarly, an electron with phase like electron 2 will be accelerated by E_θ , and its cyclotron frequency will decrease.

This modulation of the cyclotron frequencies can lead to phase bunching in the cyclotron orbits as shown in Fig. 10. If the electromagnetic wave is propagating axially at the same speed as the electrons and switching its polarity at the cyclotron frequency in the beam frame ($v_z = 0$), it can continuously decelerate the electrons and extract energy from their decrease in transverse velocity.

Figure 8. Configuration of a gyrotron oscillator. The strong DC magnetic field which is required is usually provided by a superconducting solenoid.

The process of phase bunching and energy extraction may be regarded as an interaction between a fast ($v_p > c$), transverse electric (TE), electromagnetic wave, and the fast cyclotron wave of the electron beam. The dispersion curves of these two waves is plotted in Fig. 11. The point of grazing intersection, where the two curves just touch, is the usual point of operation. Simultaneous solution of the two dispersion equations plotted in Fig. 11 for the case of grazing intersection gives the following equation, which may be used to design a gyrotron oscillator. The cutoff frequency of the operative TE mode is given by

$$\omega_n^2 = \omega_c^2 \frac{c^2}{c^2 - v_z^2} \quad (11)$$

Also, the axial wavenumber is given by

$$\beta = \frac{\omega_c v_z}{c^2 - v_z^2} \quad (12)$$

For example, if the electron energy, the ratio v_\perp/v_z , and the DC magnetic field were specified, then for a given $TE_{m,n,p}$ mode, Eq. (11) could be used to determine the

cavity radius and Eq. (12) could be used to determine the cavity length.

We also note that there is a threshold value that v_\perp must exceed in order to turn on the gyrotron. This is given approximately by the inequality

$$v_\perp > \left(0.1 \frac{\bar{\omega}_p^2 \omega_c^3 v_z c^2}{\beta \omega_n^4} \right)^{1/4}$$

where $\bar{\omega}_p$ is the plasma frequency averaged over the cavity cross section.

Gyrotron oscillators are quite efficient in converting the transverse kinetic energy of the spiraling electrons into microwave energy; however, the axial electron energy is not utilized. Overall, the output efficiency of a gyrotron oscillator is typically in the range of 30–40%. This is also subject to improvement by techniques for recovering energy from the spent electron beam.

Gyrotron oscillators developed for the plasma heating application have had peak output power of 1038 kW and average output power of 198 kW at a frequency of 140 GHz. There is also an active gyrotron amplifier research-and-development program; a 94-GHz gyrokystron has been produced with an average power of 2.5 kW and a bandwidth of 0.35%; the average power rating is several

times larger than the most capable 94-GHz coupled-cavity TWT amplifier. Finally, gyroklystrons are being evaluated as drivers for high-energy electron accelerators, especially if these are operated at microwave frequency much larger than at present (say, ≥ 20 GHz); a 20-GHz gyroklystron amplifier has been demonstrated with pulsed output power of 30 MW.

3. FUTURE DIRECTIONS

There is a continuing and vigorous program of research and development of microwave tubes to meet the needs of advanced applications. The microwave power module (MPM) combines three elements: (1) a low-noise, high-gain, solid-state input amplifier; (2) a compact, high efficiency, vacuum traveling-wave tube functioning as output power booster; and (3) an integrated electronic power supply. The MPM, as mentioned previously, achieves 100 W average power levels over an extended frequency range in a package that is more compact and lighter than an all solid-state system, and it is especially attractive for deployment on platforms where weight and prime power are at a premium. Current thrusts in MPM research aim at developing a 3 octave bandwidth capability that will cover the frequency range of 2–18 GHz in a single module. Work is also under way on developing a high-frequency MPM that will cover the range of 18–40 GHz; this push to millimeter wavelengths is of special interest for satellite communications. There has also been preliminary consideration of developing an MPM-like system with 100 W CW capability in the frequency range 84–104 GHz; this module would involve a serpentine folded waveguide circuit rather than a helix circuit in order to realize the 100 W average power rating at such a short wavelength (~ 3 mm).

For applications that require higher power than TWTs but do not need such an extended bandwidth, gyrotron amplifiers are being developed. For 94-GHz radar, a four-cavity, TE₀₁ mode gyroklystron is under construction that will have 40 dB gain, 0.8% bandwidth, peak power of 80 kW, and average power of 10 kW. Gyrotron amplifier circuits with wider bandwidth capabilities (e.g., gyro-TWTs and gyrotwistrons) are being considered for future development. Also, the use of higher-order modes is being considered to increase the amplifier average power.

Klystron amplifiers at 11.4 GHz for driving electron-positron colliders in high-energy physics research are also under development. The aim is to extend the 56 MW output power already achieved to 75 MW. Improvements in efficiency are also sought since the 7000 klystrons that will be required to drive the 1-TeV NeXT collider that is being planned at the Stanford Linear Accelerator Center will represent consumption of large amounts of average power.

For electron-positron colliders at 3–10 TeV energy, a higher microwave frequency will likely be chosen. Gyro-klystrons may then be the optimum choice of amplifier. Current experimental studies at 17.1 GHz are aimed at demonstrating an output peak power of 100 MW. Efficiency could be enhanced to the 50% level by using depressed collectors in this device. Design studies have indicated that similar performance might be achievable at 34 GHz with the use of a superconducting solenoid to provide the gyroklystron magnetic field. Typically, such amplifiers for driving colliders operate with a duty factor of 3×10^{-4} so that 100 MW peak power would correspond to about 30 kW average power.

Higher average power has already been achieved in gyrotron oscillators, which have operated at 200 kW average power out to frequencies of 140 GHz. These oscillators, which are intended for plasma heating in controlled thermonuclear fusion research, are currently being developed with a goal of 1 MW average output power. Lower-power (10 kW average) gyrotron oscillators are being developed at millimeter wavelengths with an emphasis on minimizing system cost so that they may be widely adopted by industry for material processing applications.

Finally, we note that progress in materials research and in computer science are enabling rapid advances in microwave tube performance. Producing vacuum output windows that would allow for the passage of very high average power microwave and fabricating focusing magnets that are compact and lightweight are among the major technological challenges in high-power microwave electronics. Diamond windows are very promising for high-power devices. High-temperature superconductors promise to make microwave tubes that require high magnetic fields (e.g., gyrotrons) practical for an increased number of applications.

Time-dependent, multimode computer codes have been developed that have effectively been applied to modeling the operation of a variety of microwave generators and have led to improving their design. The creation of an integrated computational framework for microwave tubes for initial design to production has been initiated. Extensive software tools are incorporated including thermomechanical analysis codes and electromagnetic

computational codes. This will allow for interactive study of the performance of the microwave tube being designed.

These advances will allow not only for higher power ratings of microwave tubes at higher frequencies but also for production of microwave power systems that are less costly, lighter in weight, more compact, and more efficient. The enhanced capabilities of microwave tubes will be exploited to improve the performance of radar and communication systems, to enable new industrial processing techniques and to extend the reach of basic and applied research.

MILITARY COMMUNICATION

CHARLES C. WANG
TIEN M. NGUYEN
GARY W. GOO
The Aerospace Corporation

In general, military communication systems are different from ordinary systems in various specific security requirements, namely, robustness in hostile environments, shielding from adversaries, and immunity from unfriendly eaves-dropping.

Hostile environments to communications are radiofrequency interference (RFI), spoofing, jamming, and fading, either natural or human-made. RFI is unintentional but can significantly degrade performance. Spoofing is intentional and can cause a great deal of confusion. Jamming is also intentional and can completely shut down the entire communication. Fading can severely disrupt communications. A conventional communication system is not able to survive in such hostile environments. All spread-spectrum schemes can be utilized for counterattacking the measurements from spoofer and jammer. A good military communication system generally requires the addition of an antenna nulling technique that can isolate the effect of an intentional jammer or spoofer. Techniques such as channel interleaving can be employed to "whiten" the channel in the presence of fading to reduce their efficacy. Other schemes such as channel coding, diversity, or equal-

ization are also important to make a system robust under a jamming or a fading environment.

The requirement of shielding from adversaries refers to the ability of not being detected by enemies. In modern warfare, using electronic equipment for communication, position location, and so on, is crucial for tactical movement, combat, evasion, and rescue. However, an adversary can detect the signal that is intended for the friendly party. Consequently, the location of a soldier or a command post can be identified and life can be jeopardized. Therefore, low probability of detect (LPD) or low probability of intercept (LPI) becomes critical for designing military systems.

Eavesdropping is a technique used to surreptitiously intercept intelligence information from an enemy. This can always change the outcome of a battle or a war. Unlike detecting the existence of a signal, which can usually be achieved by using a radiometer, eavesdropping requires the right demodulator, decoder, and so on. In order to be immune to eavesdropping, in addition to sophisticated spread-spectrum techniques, such as direct sequence, frequency hopping and time hopping, a system needs a cryptography technique to ensure the secrecy of communications.

Other important areas in military communications include target recognition (classification) and navigation. Target recognition involves a great deal of data collection and processing. Optical remote sensing methods, such as optical lenses, laser or infrared light, is always a way of collecting target images. However, in poor weather conditions, it can be difficult if not impossible to obtain any image using optical equipment. In recent years, synthetic aperture radar (SAR) has been extensively utilized for remote sensing. Besides providing better quality and resolution of the image, the SAR system can be operated regardless of the weather condition.

The global positioning system (GPS) is a satellite-based navigation system with global coverage. In view of four GPS satellites, a GPS receiver can determine its three-dimensional position to an accuracy of better than 16 m. Greater accuracy of less than 1 meter can be achieved by using correction information from another GPS receiver at a known location. The Persian Gulf region, with its wide expanses of featureless desert, is the ideal combat environment in which to prove the value of GPS. Without a reliable navigation system like GPS, the U.S. forces could not have performed the maneuvers that contributed to the success of Operation Desert Storm in 1991.

1. UNINTENTIONAL INTERFERENCE

The radiofrequency interference (RFI) from another unintentional interferer can be substantial in a multiuser, multiservice communication system. RFI can penetrate the receiver from main-, side-, or backlobes of the receiving antenna, resulting in significant performance degradation. From the spectral point of view, the RFI can be located within the intended receiving bandwidth, referred to as the cochannel interference (CCI), or leaked from the

adjacent channels, referred to as the adjacent-channel interference (ACI).

The CCI can be initiated from intermodulations, leakage from spatial discriminated cochannel signals, and code-division multiple-access (CDMA) scenarios, such as direct-sequence spreading and frequency hopping (to be discussed later). In general, making use of channel coding to enhance the power efficiency of the desired signal can mitigate the CCI problem.

The ACI is caused by leakage of the signal power from adjacent channels next to the desired signal bandwidth. This leakage exists because no ideal brick-wall filter, which passes 100% of the signal power within a certain range of frequencies and also completely cuts off the power beyond this range, can be realized. Thus, portions of the power spectra of adjacent channels overlap each other, resulting in leakage. In addition to the channel coding, the mitigation technique for the ACI rejection includes the adoption of a bandwidth-efficient modulation scheme, such as Gaussian minimum shift keying (GMSK) or filtered phase shift keying (FPSK), which basically has a confined power spectrum with no sidelobes.

2. SPOOFING

Spoofing is defined as the purposeful degradation, denial, or deception to a receiver by an external source using a “look-alike” signal. Spoofing can cause greater damage than other intentional interference, such as jamming, because armed forces personnel may make a costly or deadly mistake in response to a deceived command without knowing it.

3. JAMMING

A jammer is a device that seeks to nullify a communication system by inserting energy into the target spectrum. The jammer power at the target antenna system can be represented by

$$J = P_j G_j / (4\pi R_j^2) B_{s/j} / L_j \tag{1}$$

where

- J = jammer power at target antenna
- P_j = RF power delivered to jammer antenna
- G_j = gain of jammer antenna
- R_j = range from jammer to target antenna
- $B_{s/j}$ = ratio between bandwidth overlap between energy inserted into the target spectrum and jammer’s transmitted spectrum
- L_j = losses in propagation between jammer and target antenna

To be effective, the jammer must act to lower the SNR, and hence the E_b/N_{total} , to raise the bit error rate (BER) of the communication system beyond acceptable levels:

$$E_b/N_{total} = E_b / (N_0 + J_0) = [(1/E_b/N_0) + (1/E_b/J_0)]^{-1} \tag{2}$$

where E_b is the signal energy per bit, J_0 is the jamming energy per bit, and N_0 is the one-sided power spectral density of the received additive white Gaussian noise (AWGN).

A measure of jammer power versus signal power is

$$J/S = (P_j G_j) / (P_t G_t) (B_{s/j}) (R_t / R_j)^2 (L_a / L_j) \tag{3}$$

where

- S = signal power at antenna
- P_t = power delivered to transmit antenna
- G_t = gain of the transmit antenna
- R_t = range from transmit to receive antenna
- L_a = losses in propagation between transmit and receive antenna

If there are differences in range between the communications transmitter and jammer from the receive antenna, a standoff distance can be computed for a known J/S value where the jammer becomes ineffective:

$$\begin{aligned} \text{Standoff distance} &= R_t [(P_j G_j) / (P_t G_t) \\ &\times (S/J) (B_{s/j}) (L_a / L_j)]^{1/2} \end{aligned} \tag{4}$$

The jammer nominally attempts to disrupt communications with minimal resource use; that is, for a given total power it will maximize jamming energy at the detector. The jammer can use several waveform strategies to maximize its effectiveness and reduce E_b/J_0 .

3.1. Broadband Noise Jamming

A broadband noise jammer, as shown in Fig. 1, employs a noise source of bandwidth B_j that covers the entire allocated spectrum B_s of the communication system under attack. The noise density is

$$\text{Noise density} = J/B_j = J_0 \quad (B_j = B_s) \tag{5}$$

3.2. Partial-Band Noise Jamming

A partial-band noise jammer (PBNJ), as shown in Fig. 2, employs a noise source that covers some fraction α of the allocated spectrum of the communication systems under attack. For given jammer power J , this raises the noise density over that part of the band:

$$\text{Noise density} = J/B_j = J / (\alpha B_s) = J_0 \quad (B_j < B_s) \tag{6}$$

Figure 1. Spectrum of a broadband noise jammer.

Figure 2. Spectrum of a partial-band jammer.

Figure 4. A pulsed jammer in time domain.

3.3. Worst-Case Partial-Band Jamming

A worst-case partial band jammer (WCPBJ) is employed against a system whose instantaneous bandwidth is less than allocated spectrum, $B_j = \beta B_s$. One must compute the joint probability of likely coincidence, ρ_0 , with the waveform and noncoincidence, $(1 - \rho_0)$, to obtain statistics of BER. The WCPBJ would attempt to vary the value of ρ_0 , the fraction of bandwidth occupied, to maximize BER in the joint probability computation.

3.4. Multitone Jamming

A multitone jammer, as shown in Fig. 3, employs sets of sinusoids instead of noise sources to cover the jamming band. Generally these are generated by a harmonic source, resulting in frequency spacings that are equidistant. The power per tone for the equal-amplitude amplitude case is

$$P_j = J/N \tag{7}$$

where N is the number of tones. For the case of equidistant frequency tones, the total jamming bandwidth occupied is

$$B_j = f_s(N - 1) \tag{8}$$

where f_s is the frequency spacing.

3.5. Pulsed Jamming

A pulsed jammer, as shown in Fig. 4, seeks to obtain a high instantaneous power output by reducing its duty cycle; that is, the power production is for a fraction of time. Some microwave tubes have the ability to produce large amounts of instantaneous but not continuous power. The source waveform for small duty cycles is generally rectangular—that is, a pulse, which is rich in harmonics and can cover a wide instantaneous bandwidth.

3.6. Smart Jammers

The category of smart jammers includes the frequency follower, the store and forward, and frequency chirp jammers. The frequency follower and the store-and-forward class of jammers is nominally frequency-agile and captures or senses the victim signal and mimics the carrier frequency and perhaps the modulated waveform. These

Figure 3. Spectrum of a multitone jammer.

jammers are effective against stationary or slow frequency hoppers where the signal stays at frequency long enough for the jammer to copy and transmit to the victim in one frequency hop period.

The frequency chirp jammer, as its name implies, frequency sweeps or chirps the intended jamming band to put energy into the victim receiving system. These jammers would be employed if certain aspects of the victim system are known and can be exploited by a nonstationary signal.

4. ANTISPOOFING AND ANTIJAMMING TECHNIQUES

To make a system robust in hostile environments, antispoofting and antijamming techniques need to be implemented. Different techniques should be adopted to counterattack different types of jamming. They can be based on the concepts of power, frequency, time, and spatial discriminations. In most cases, a hybrid system that includes more than one antijamming technique is implemented. All techniques described here can be used for antispoofting purposes as well without being particularly specified in the context.

4.1. Direct Sequence

Direct sequence (DS) is a spread-spectrum technique that is usually used with the phase shift keying (PSK) signaling. A pseudorandom number (PN) binary sequence whose elements have values of $+1$ or -1 are generated by a PN sequence generator N_c times faster than the data rate. Conventionally, the unit of each element of a PN sequence is called a “chip.” Therefore, the chip time T_c equals T_d/N_c , where T_d is the data bit duration. Practically, the N can be between 100 and 10^6 or higher, depending on the capability of antijamming (antispoofting) and/or the spread bandwidth of the system. Let $d(t)$ and $c(t)$ be denoted as the original data and PN sequence, respectively. Then

$$d(t) = \sum_{k=-\infty}^{\infty} d_k p_d(t) \tag{9}$$

and

$$c(t) = \sum_{k=-\infty}^{\infty} c_k p_c(t) \tag{10}$$

where d_k and c_k are either $+1$ or -1 , and $p_d(t)$ and $p_c(t)$ are unit pulse functions with duration T_d and T_c , respectively. In the DS spread PSK system, the modulating signal is the multiplication of $d(t)$ and $c(t)$. Figure 5 illustrates the waveforms of $d(t)$, $c(t)$ and $d(t)c(t)$.

Figure 5. Waveforms of data $d(t)$, PN sequence $c(t)$, and modulating signal $d(t)c(t)$.

The DS spread binary PSK (DS/BPSK) signal can be expressed as

$$x(t) = \sqrt{2S}d(t)c(t) \cos \omega_c t = c(t)s(t) \quad (11)$$

where

$$s(t) = \sqrt{2S}d(t) \cos \omega_c t \quad (12)$$

is the ordinary BPSK signaling. Since $c(t)$ changes its polarity N_c times faster than $d(t)$, the bandwidth of $x(t)$, denoted by W_{DS} , is N_c times wider than that of $d(t)$, which is $R_d (= 1/T_d)$. The processing gain of this DS/BPSK system is simply

$$PG = \frac{W_{DS}}{R_d} = N_c \quad (13)$$

In the presence of jamming signal $J(t)$, the received signal at the receiver can be represented by

$$r(t) = x(t) + J(t) \quad (14)$$

The receiver multiplies the received signal $r(t)$ by a duplicate of the PN signal $c(t)$ to obtain

$$z(t) = c(t)(x(t) + J(t)) = s(t) + c(t)J(t) \quad (15)$$

since $c^2(t) = 1$. Therefore, the effective noise component at the input to the BPSK demodulator becomes $n(t) = c(t)J(t)$. Again, for the case that jammer's bandwidth B_J is much smaller than $R_c = 1/T_c$, the bandwidth of $n(t)$ will be approximately $N_J (= R_c/B_J)$ times wider than that of $J(t)$. For a fixed amount of jammer power J , the value of the power spectrum density function of $n(t)$ at the carrier frequency ω_0 is approximately $1/N_J$ that of $J(t)$. As a result of this, after the signal $z(t)$ passes through the front-end filter of the BPSK demodulator, which is approximately R_d , the effective noise component contributed to the decision rule is significantly reduced. Hence, this technique essentially enhances the effective SNR input to the demodulator. This implies that the direct-sequence spread-spectrum approach is based on the concept of power discrimination.

It has been shown [1] that the BPSK data modulation with QPSK direct sequence spreading is a robust antijamming system to combat either continuous-wave (tone) or random (partial-band) jammer.

It is worthwhile to mention that the DS technique can be also used for the purpose of multiple access. The multiple access scheme that adopts the DS technique is called code division multiple access (CDMA). Other types of multiple access include frequency division multiple access (FDMA) and time division multiple access (TDMA). In a CDMA system, users each have their own unique code ID. The same idea of using process gain stated early in this section is the concept used to discriminate the unwanted user from the desired one.

4.2. Frequency Hopping

A frequency hopping (FH) system is driven by a frequency synthesizer that responds to a PN sequence from a PN code generator. The most commonly used modulation schemes when the FH technique is adopted are M -ary frequency shift keying (MFSK) modulations. Based on the output sequence from a PN code generator, the frequency hopper outputs a continuous sinusoidal waveform that frequency jumps from one value to another. These frequencies are, in turn, used as the carrier frequencies of a MFSK signal.

Depending on the hopping rate that the frequency changes, the FH system can be categorized into slow frequency hopping (SFH) and fast frequency hopping (FFH).

- *Slow Frequency Hop.* The hopping rate is slower than or equal to the data rate, which implies that there are one or more data bits in each hop, as shown in Fig. 6a.

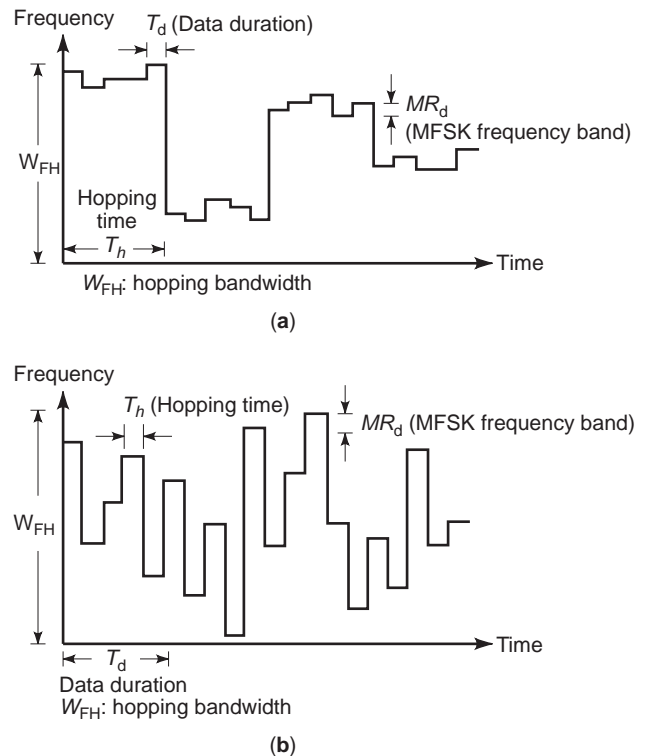

Figure 6. (a) Slow frequency hopping; (b) fast frequency hopping.

- *Fast Frequency Hop.* The hopping rate is faster than the data rate, which implies that there are multiple hops within each data bit duration, as shown in Fig. 6b.

Note that the FH/MFSK system has a much wider range of frequencies than the ordinary MFSK system. For a fixed jammer power J , the broadband jammer needs to spread its power over the entire FH bandwidth W_{FH} . Hence, the effective corrupting power fallen into a single MFSK band is J/PG , where PG is the processing gain of the FH/MFSK system and is defined as

$$PG = \frac{W_{FH}}{MR_d} \quad (16)$$

Because the PG is usually very large, the FH/MFSK is very effective in counterattacking broadband jamming.

For a stationary partial-band or multitone jammer, an FH system is also considered to be robust. This is due to the fact that the signal is lost for only a small portion of time when the hopping frequency falls into the fixed jamming band. For a majority of time, the signal is free of jamming. This implies that the FH is based on the concept of frequency discrimination.

Unfortunately, the partial-band or multitone jammer is intelligent enough to be able to detect the transmitted FH/MFSK signal, follow the hopping pattern, and concentrate its total power J to jam the full band of M MFSK carriers. Therefore, the FH/MFSK system becomes vulnerable to the intelligent partial-band and multitone jammers. To solve this problem, an FFH must be adopted so that the jammer is not able to follow the hopping pattern. In addition, the coding and time diversity becomes desirable in this scenario.

4.3. Time Hopping

Like FH, time hopping (TH) is also driven by a PN sequence generated by a PN code generator. Instead of hopping the carrier frequencies in a much wider frequency band, the time hopper controls the time stamps for turning on and off the signal transmission in the time domain. This technique is effective only to the pulsed jamming. A TH system can force a jammer to stay on at all times in order to be effective. Under the constraint of a fixed energy, the jammer needs to reduce its transmitting power, resulting in less interference. Obviously, the TH system is based on the concept of time discrimination [2].

4.4. Time Diversity

Time diversity is a technique in which each information bit is subdivided into multiple equally spaced subbits before entering the modulator. It is usually implemented in the FFH system to counterattack the partial-band or multitone jamming. To make the counterattack more effective, the hop duration has to be equal to or less than the subbit duration. Therefore, if one subbit is jammed, other subbits of the same bit may be hopped to a frequency outside the jamming band and detected without errors. This

antijamming technique is also based on the concept of time discrimination.

4.5. Antenna Nulling

A spatial discriminating technique for antispoofing and antijamming is antenna nulling or sidelobe cancellation [3]. In order to provide a nulling capability, the antenna system needs to be equipped with an array of element antennas and associated electronics for beamforming. At least two spot beam element antennas, each of which can be pointed and controlled independently, are needed. The received signals from all element antennas are phase-shifted and amplitude-attenuated independently and individually, and then combined to form a single signal. The combination of this array of element antennas is called *phased-array antenna*.

First, the antenna system tries to sense the presence of a spoofer or jammer within the antenna field of view by sampling the received signal from each element antenna and determining whether there is significant energy outside the expected bandwidth. After the spoofer or jammer is detected, a nuller algorithm processor decides and adjusts accordingly to the phases and attenuation weights of all element antennas. As a result, a null is generated at the direction to the spoofer or jammer so that the interference attack becomes completely ineffective. Figure 7 illustrates a conceptual diagram of forming an antenna null. In most military communications systems, such as the military satellite communications (MILSATCOM) systems, the antenna nulling scheme is required to be implemented on spacecraft.

4.6. Forward Error Correcting Code

In general, using a forward error correcting (FEC) code to improve the power efficiency can be also considered as an anti-spoofing or antijamming technique. Various coding schemes have been included in various systems for this purpose. The $(7, \frac{1}{2})$ convolutional code with Viterbi decoding has been widely used because of its good FEC capability [4]. The Reed–Solomon code has been shown to be powerful for correcting burst errors [5]. Concatenated code structure with $(7, \frac{1}{2})$ convolutional code as the inner code and Reed–Solomon code as the outer code has been known

Figure 7. A conceptual antenna pattern of nulling.

to have a significant anti-corruption capability [6]. Recently, a newly invented turbo code has demonstrated its ability to provide a near-Shannon-limit coding gain [7].

5. PROPAGATION CHANNEL CHARACTERISTICS

The term *fading channel* is used when the physical medium affects radiowave propagation such that the received signal appears to have amplitude fading and/or phase jitter. Three principal fading phenomena are (1) multipath, (2) ionospheric effects, and (3) nuclear-blast-induced plasma.

5.1. Multipath Fading

Multipath fading is usually associated with terrestrial communications or low-elevation-angle satellite communications where the transmit and receive signals are subject to reflection from terrain and objects, fixed or moving. Measurement data have been provided from NASA missions [8,9], and Brayer of MITRE also performed several investigations in this area [10,11]. In multipath fading, the signal is a composite of the line-of-sight wave and reflections, from the earth's surface, that occur along the propagation channel. Fade condition is dependent on the terrain encountered, such as mountainous, smooth, lake, or oceanic. The received signal is a composite of constructive and destructive interference of the primary and coherent reflections to induce the scintillation behavior. It is convenient to define the single-frequency case after Bullington [12] for the primary and echo without modulation:

$$v = 1 + Re^{i(\theta + (n-1)\pi)} = Le^{-i\gamma} \tag{17}$$

with

$$\tan \gamma = \frac{R \sin \theta}{1 - R \cos \theta} \tag{18}$$

where R is the instantaneous amplitude and θ is the instantaneous phase of the "composite echo." Experiments have shown that both fades and their duration would be proportional to the combined amplitude L as

$$\text{Prob}[(L_{\min}/L) \leq X] = X, \quad \text{where } 0 \leq X \leq 1 \tag{19}$$

Figure 8 illustrates a relationship between fade duration and percent of fades for an example of multipath fading at 4 GHz.

5.2. Ionospheric Effects

Fading or scintillation occurs in the ionosphere because of the influence of electron densities in the propagation medium. Ionospheric scintillation can be a major factor for satellite communications depending on carrier frequency, satellite to terminal locations, time of day, season, and magnetic activity. Figure 9 indicates the change of ionospheric scintillation as the frequency changes [13].

Equatorial scintillation is caused by electron gradients at altitudes of several hundred kilometers. High-latitude

Figure 8. Duration of fading at 4 GHz on a 30-mi path.

scintillation occurs from the visible aurora region (regions D and E) and from the polar cap to the aurora [14]. The electron densities in the ionosphere tend to align with the earth's magnetic field lines. This causes the fading characteristics to be highly geometry-dependent, particularly at high latitudes and at the poles. Figure 10 shows the geographic distribution of the ionospheric scintillation [15], in which the darker the region, the severer the fade.

5.3. Nuclear-Blast-Induced Plasma

Nuclear-induced scintillation is postulated when such ordinance is detonated in the upper atmosphere to cut off communications, particularly via satellite. Corroboration of such characteristics were conducted by the "Starfish" experiments in the 1950s and by the STRESS test, in which barium clouds were set up in the upper atmosphere through which radiowave propagation was studied.

The generalized power spectrum $\Gamma(f, \tau)$ of the scintillation fading can be characterized by the scintillation

Figure 9. Frequency dependence of ionospheric scintillation fading.

Figure 10. Geographic distribution ionospheric scintillation. The depth of scintillation fading is proportional to the density of cross-hatching.

decorrelation time τ_0 and the frequency-selective bandwidth f_0 [16]

$$\Gamma(f, \tau) = \frac{1.864\tau_0\delta(\tau)}{[1 + 8.572(\tau_0f)^2]^2} \quad (20)$$

for $f_0 \cdot T > 1$, where T is the minimum symbol time, and δ is the Dirac delta function. For frequency-selective fades ($f_0T < 1$), we have

$$\begin{aligned} \Gamma(f, \tau) &= 2.981 \frac{f'\tau_0}{C_1^{1/2}} \exp \\ &\times \left\{ -\frac{1}{2C_1^2} [(\pi\tau_0f)^2 - 2\pi f'\tau]^2 - (\pi\tau_0f)^2 \right\} \\ &\times \int_{-\infty}^{\infty} \exp\{-x^4 - 2x^2 \\ &\times \left[\frac{C_1}{2^{1/2}} \left(1 + \frac{1}{C_1^2} ((\pi\tau_0f)^2 - 2\pi f'\tau) \right) \right]\} dx \end{aligned} \quad (21)$$

where

$$\begin{aligned} f' &= f_0(1 + C_1^2)^{1/2} \\ C_1 &= \text{delay parameter } (\approx 0.25) \end{aligned} \quad (22)$$

For both Eqs. (20) and (21), we have

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \Gamma(f, \tau) df d\tau = 1 \quad (23)$$

In scintillation, there are random time-varying components of the electron density. If the random component is zero mean and normally distributed, Wittwer [16] has

given the variance of this component $g(f)$ as

$$\begin{aligned} &\overline{g * (f)g(f')} \\ &= \begin{cases} \delta(f - f') \frac{\tau_0(f_c/r_0c)^2}{[a^2 + (2\pi f\tau_0)^2]^{3/2}} & \text{for } f \leq f_r \\ 0 & \text{for } f > f_r \end{cases} \end{aligned} \quad (24)$$

where

$$\begin{aligned} g(-f) &= g^*(f) \\ a^2 &= (r_0 \cdot c \cdot N_L(t)/f_c)^{-2} \\ r_0 &= \text{classical electron radius } (2.82 \times 10^{-5} \text{ m}) \\ c &= \text{light speed } (3 \times 10^8 \text{ m/s}) \\ N_L(t) &= \text{large scale (slow component of electron density)} \\ f_c &= \text{carrier frequency} \\ f_r &= 1/(2\pi\sigma\tau_0) \\ \sigma &= \text{Rayleigh phase variance, Rayleigh scintillations} \\ &= 0 \text{ phase-only scintillation} \end{aligned}$$

6. FADING MITIGATION TECHNIQUES

There are five major techniques that can be employed to specifically combat the effects of fading: (1) frequency band selection and diversity, (2) spatial diversity, (3) time diversity (interleaving), (4) polarization, and (5) equalization. In addition, coding and frequency hopping (with or without chirp combined), where the hop rate is faster than the data rate, also mitigate fading.

6.1. Frequency Band Selection and Diversity

Scattering and scintillation are two major factors that cause fading in communication systems. As was shown in the previous section, the effectiveness of these two factors depends on the operating frequency. Therefore, properly selecting a frequency band for a satellite system to operate becomes very important. Furthermore, transmitting the signal on multiple carriers and employing a diversity combiner is also an effective way to combat the fading loss.

6.2. Spatial Diversity

Due to link geometry, the effects of the fading phenomena are spatially selective as well. Fading is more sensitive to spacing with vertical than with horizontal distance by about an order of magnitude. Spacing the transmit/receive apertures to decorrelate fading provides immunity. Providing multiple receptions by utilizing more than one ground station and then combining the received signals can build up a robust system in fading environments.

6.3. Polarization

Polarization is the orientation of the plane on which the electric field vibrates when an electromagnetic wave propagates through the medium. The wave can be linearly, elliptically, or circularly polarized. Jordan suggested that multipath effects can be limited by use of circular rather

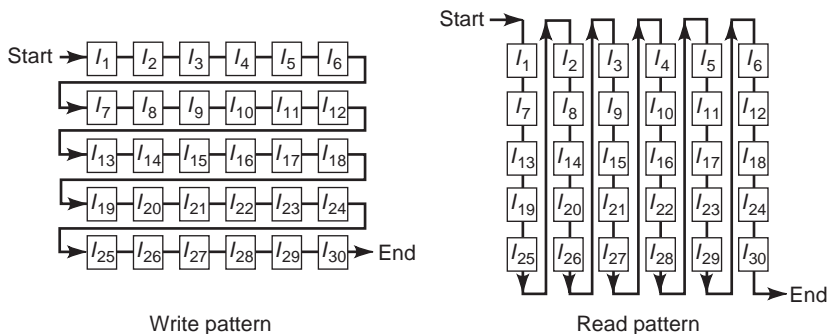

Figure 11. A 5 × 6 block interleaver.

than linear polarization [17]. This is due to the nature of the wave propagation and multipath reflections. Therefore, in a fading environment, circular polarization is preferable.

6.4. Equalization

Equalization attempts to compensate for the time dispersion effect in the fading channel. The effects of the multipath channel has the effect of time smearing the signal introducing intersymbol interference (ISI). A common equalizer structure is the mean-square error (MSE), where the sum of the squares of ISI and noise power is minimized. Lee and Messerschitt [18], Widrow and Stearns [19], and Orfanidis [20] discussed the concept of equalization and adaptive signal processing. A synchronization sequence must be transmitted to aid the adaptation process.

6.5. Coding

Using an effective FEC code is an important antifading scheme. Because fading is usually on and off so that the received signal is corrupted only in a small portion of a duty cycle, the errors generally come in bursts. Reed–Solomon code is known to be good for burst error correction. However, in a severe fading environment where the fade duration is long, the concatenated code structure, with a convolutional or turbo code as the inner code and a Reed–Solomon code as the outer code, incorporated with interleaving is required.

6.6. Interleaving/Deinterleaving

Interleaving is essentially a permutation among the transmitted channel symbols. Thus, when an interleaving technique is adopted, the continuous data need to be subdivided into blocks. In addition, it generally comes with an FEC code. In the transmitter, the modulated symbols at the output of modulator are permuted before entering the channel. The channel symbols are corrupted in bursts in a fading environment. At the receiver, a deinterleaver re-scrambles channel symbols using a reverse permutation pattern so that the order of the originally modulated symbols is preserved. Due to the process of deinterleaving, the burst channel symbol errors are broken into scattered random errors that will be, in turn, easily corrected by an FEC decoder. In order to ensure the randomness of the channel symbol errors after deinterleaving, the inter-

leaving depth should be linearly increased as the fade duration increases.

It should be pointed out that interleaving/deinterleaving results in a delay that depends on the interleaving depth and type. Theoretically, the interleaving pattern can be any format of permutation. Block and convolutional interleavings are the two most commonly used patterns.

- *Block Interleaver.* As shown in Fig. 11, a block interleaver is a regular interleaver in that the input symbols are written in rows and read in columns. For a 5 × 6 block interleaver, if $I_1, I_2, I_3, I_4, \dots$ are the input symbols, the outputs are $I_1, I_7, I_{13}, I_{19}, I_{25}, I_2, I_8, I_{14}, \dots$. It can be seen that the permutation cannot take place until the entire block is filled up with the input symbols. Therefore, a block interleaver of size N suffers a delay of N symbol intervals.
- *Convolutional Interleaver.* Figure 12 illustrates the structure of a convolutional interleaver. For the same input symbols $I_1, I_2, I_3, I_4, \dots$, the outputs become $I_1, X, X, X, X, X, I_7, I_2, X, X, X, X, I_{13}, I_8, I_3, X, X, X, I_{19}, I_{14}, I_9, I_4, X, X, I_{25}, I_{20}, I_{15}, I_{10}, I_5, X, \dots$, where X is a dummy symbol. It can be seen that the convolutional interleaver reads out the symbols on diagonals. So, the convolutional interleaver can start its output without having the entire block filled up. As a result, the delay is one-half of the interleaver depth.

7. LOW PROBABILITY OF DETECT/LOW PROBABILITY OF INTERCEPT (LPD/LPI)

In electronic warfare, radio signals from transmitters can be detected by adversaries. As a result, the location of soldiers and command posts can be identified, jeopardizing human lives and success of operations. In order to prevent signals from being intercepted, receivers are designed

Figure 12. A convolutional interleaver of depth 6.

with good capability of low probability of detect (LPD) or low probability of intercept (LPI).

7.1. Detection of Signals in the Presence of Noise

In communication systems, the most commonly used theory is the detection theory. This refers to the technique of making a decision as to whether a radio signal is received in the presence of noise. It is possible that the receiver misdetects a radio signal when it thinks that only the noise is received. On the other hand, the receiver may present a false alarm by declaring that a radio signal is present when no signal actually exists. Hypothesis testing is one of the most important statistical tools for making such decisions [21]. The hypotheses are statements of the possible decisions that are being considered. For example, in a radar detection problem we might select two hypotheses—a target is present (H_1) or no target is present (H_0).

The total power radiometer is a commonly used device that detects the existence of a radio signal in the presence of noise. It operates as a square-law device that outputs the average power of the input signal within a certain bandwidth and over a certain period of time T_0 . Figure 13 shows the block diagram of a total power radiometer.

The input $x(t)$ to the radiometer includes the signal component $s(t)$ of power P_s and the noise component $n(t)$, which is white with power spectrum N_0 . The test statistic z out of the radiometer can be expressed as

$$z = \frac{1}{T_0} \int_{t_0}^{t_0+T_0} (s(t) + n^*(t))^2 dt \quad (25)$$

where t_0 is a particular time instant for starting the observation, T_0 is the observation period, and $n^*(t)$ is the band-limited noise component. Let the likelihood function, $p_0(z)$ and $p_1(z)$, be defined as the probability of observable being at z given conditions of H_0 and H_1 , respectively. It can be shown [22] that $p_0(z)$ and $p_1(z)$ can be approximated by Gaussian probability density functions with mean values, m_0 and m_1 , and variances, σ_0^2 and σ_1^2 , respectively, given by

$$\begin{aligned} m_0 &= P_s + N_0 B \\ m_1 &= N_0 B \\ \sigma_0^2 &= (2P_s + N_0 B)N_0/T_0 \\ \sigma_1^2 &= N_0^2 B/T_0 \end{aligned} \quad (26)$$

where B is the bandwidth of the input filter of the radiometer, assuming that an ideal filter is used.

It should be pointed out that the design of the front-end filter bandwidth of a receiver is based on the requirement of adjacent-channel interference (ACI). For example, a system may require the ACI at the edge of the input filter bandwidth to be at least -20 dB of the center carrier

power so that the system can provide a good link quality to the customer. In this case, the bandwidth of the input filter, assuming to be ideal, has to be at least 1.8 times the R_s for QPSK signaling [23], where R_s is the channel symbol rate. On the other hand, if the receiver is used simply to detect the presence of a radio signal, the bandwidth of the input filter can merely match the 3 dB bandwidth of the power spectrum of the signal. In this section, we assume that the input filter bandwidth of the radiometer is equal to R_s of the $s(t)$, which is close to the 3 dB bandwidth.

When a single fixed-length packet is transmitted with a packet duration less than the observation time T_0 , we will replace the above P_s by μP_s , where μ is the duty cycle of the packet within T_0 , assuming that the entire packet is to be observed within the observation period T_0 . This is a practical assumption as long as T_0 is much larger than the packet duration.

To decide whether it is H_0 or H_1 , the observable z is compared against a threshold. The signal is declared to be present if z is above or equal to the threshold, and absent if z is below the threshold. Let us define the probability of detection P_d as the probability that the signal is declared to be present (z is above or equal to the threshold) when the signal indeed exists, while the probability of false alarm P_{fa} is defined as the probability that the signal is declared to be present when no signal is actually transmitted. It can be seen that the sensitivity of the detection (interception) depends on the threshold set. If it is set too low, although the signal will not likely be missed, the P_{fa} will be high, which is not desirable. To the contrary, if the threshold is set too high, the radiometer will not be able to effectively detect the presence of a signal. Therefore, for any specified values of P_{fa} and P_d there is a corresponding threshold. In this type of detection problem, the Neyman-Pearson criterion [21], which maximizes the likelihood ratio $p_1(z)/p_0(z)$ for a given P_{fa} is generally adopted for setting up the threshold.

In order to be effective, a channelized total power radiometer is used, in that a bank of filters and integrate-and-dump circuits are implemented, each of which matches with the frequency band of each channel so that the radiometer can detect the entire transmitted frequency band. Because different communication systems may allocate different bandwidths for the entire system, for the sake of fairness, the LPD/LPI capabilities for different systems should be compared based on the same length of observation period T_0 and the same specification of false-alarm rate (FAR). FAR is defined as the number of false-alarm declarations within a unit of time and for a unit of bandwidth. Hence, P_{fa} (for each channel) = T_0 [FAR] [channel bandwidth]. For example, for a FAR = 1/h/MHz and $T_0 = 1$ s, P_{fa} (for each channel) = (channel bandwidth in MHz)/3600.

Let us consider a case where the threshold of the radiometer is set such that the probability of correctly detecting a radio signal P_d exceeds 50% (with FAR = 1/h/MHz). Based on the Neyman-Pearson criterion, the normalized threshold, defined as

$$\eta = \frac{\text{mean difference}}{\text{standard deviation}} \quad (27)$$

Figure 13. Block diagram of a total power radiometer.

is such that

$$P_{fa} = \frac{1}{\sqrt{2\pi}} \int_{\eta}^{\infty} \exp\left(-\frac{x^2}{2}\right) dx \quad (28)$$

Thus, the threshold η depends on only P_{fa} , which may vary for different systems. From Eq. (26), it can be seen that

$$\eta = \frac{\mu P_s}{N_0} \sqrt{\frac{T_0}{B}} \quad (29)$$

Using this threshold and the fact that $B = R_s$, the received signal-to-noise ratio (SNR), defined as P_s/N_0B , required for this detection is

$$\text{SNR}_{\text{detection}} = \frac{\eta}{\mu \sqrt{R_s T_0}} \quad (30)$$

When a very sensitive detection device is implemented so that the radiometer can detect the signal given a very small amount of energy, a much finer integration time can be used for detection. As a result, this so-called intelligent radiometer is able to pinpoint the time at which each received packet starts and ends. In this case, the total observation time can essentially match with the actual packet duration. Therefore, the duty cycle is always 1. Accordingly, the $\text{SNR}_{\text{detection}}$ used in the intelligent radiometer will be different under the same specifications of P_d and P_{fa} .

7.2. Range of Vulnerability

The range of vulnerability, which is defined as the range from the adversary within which a radio can be detected, is used to quantify the capability of the LPI/LPD of a system. From above, it was shown that the sensitivity of detect (intercept) of a radiometer depends on the threshold set. This implies that the range of vulnerability is dependent on the level of threshold. The lower the threshold, the longer the range for a radio not being detected. Thus, the range of vulnerability is meaningful only under specified values of P_{fa} and P_d .

It is well known [24] that the received power of a radio signal at the receiver can be represented by

$$P_r = P_t G_t G_r / L \quad (31)$$

where P_t is the transmitting power, G_t is the transmit antenna gain, G_r is the receive antenna gain, and L is the loss during propagation. The received noise power can be represented by

$$N = N_0 B = kTB \quad (32)$$

where k is Boltzmann's constant ($= 1.379 \times 10^{-23}$ J/K), T is the receiver system temperature in kelvin, and B is the bandwidth of the input filter in hertz. Combining Eqs. (31)

and (32), the receiving SNR at the radiometer can be expressed as

$$\text{SNR} = (\text{EIRP})(G_r/T)/(LkB) \quad (33)$$

where $\text{EIRP} (= P_t G_t)$ is the transmitted equivalent isotropic radiated power from a radio and G_r/T is defined as the figure of merit of the receiving antenna.

The range of vulnerability can be studied under two categories, ground collection and airborne collection. The ground vulnerability range is associated with an adversarial radiometer, which is on or near the ground. In this case, the dominant loss of the radiowave power is due to the reflection from the terrain. The airborne vulnerability range is associated with radiometer placed on the aircraft, in which case the free space loss is only considered in determining the received radio power.

7.2.1. Ground Collection. Blake showed that when a radiowave is reflected from the ground, the received signal is subject to a loss of $L = R^4/(h_t^2 h_r^2)$, where R is the distance between a radio and the radiometer, h_t is the radio's transmit antenna height (from ground), and h_r is the radiometer antenna height [24]. Therefore, from Eq. (33), the vulnerability range for the ground collection can be expressed as

$$R = [(\text{EIRP})(h_t^2 h_r^2)(G_r/T)/(kR_s)/\text{SNR}_{\text{detection}}]^{1/4} \quad (34)$$

7.2.2. Airborne Collection. For airborne collection, L is simply the free-space loss that is equal to $(4\pi R/\lambda)^2$, where λ is the wavelength of the carrier. Therefore, the vulnerability range becomes

$$R = [(\text{EIRP})(\lambda/4\pi)^2(G_r/T)/(kR_s)/\text{SNR}_{\text{detection}}]^{1/2} \quad (35)$$

Plugging Eq. (30) into both Eq. (34) and Eq. (35), it can be illustrated that

$$R \propto \left(\frac{\text{EIRP} \cdot \mu}{\eta} \sqrt{\frac{T_0}{R_s}} \right)^e \quad (36)$$

where $e = 1/4$ for ground collection and $1/2$ for air collection.

From Eq. (36), it can be seen that a radio with higher channel symbol rate R_s is less vulnerable to the radiometer detection. That is why the LPI/LPD capability is significantly improved when a CDMA system is utilized. Note that adopting TDMA in a system will reduce the duty cycle μ and increase the R_s by the same factor of γ , resulting in a reduction of range of vulnerability by a factor of $\gamma^{3/2}$. This implies that a TDMA system also has a good LPI/LPD property. Furthermore, Eq. (36) also explains why the radio is more vulnerable to an intelligent radiometer than a basic radiometer. This is due to the fact that when an intelligent radiometer is used, the observation time is reduced by a factor of $1/\mu$ (T_0 becomes μT_0 ; $\mu < 1$) and the μ in Eq. (36) is replaced by 1, resulting in an

increase of vulnerability range R by a factor of $\sqrt{1/\mu}$. Thus, a TDMA system becomes vulnerable when an intelligent radiometer is utilized.

8. CRYPTOGRAPHY

One of the more important elements that differentiates military communications from commercial communications is secrecy. Without appropriate safeguards, the transmitted data are susceptible to unauthorized interception, deletion, addition, and modification. Such unwanted exposure of data may jeopardize national security. Cryptography is a practical method of protecting transmitted information from being intercepted.

8.1. Classical Cryptology

When a transmitter generates a plaintext or unenciphered message to be communicated over an insecure channel to a legitimate receiver, an eavesdropper can easily intercept it. In order to prevent the eavesdropper from learning it, in the classic cryptography system, the transmitter operates on the plaintext with an invertible transformation to produce a ciphertext or cryptogram. The inverse transformation (or called "key") is either already known by or transmitted via a secure channel to the legitimate receiver. Therefore, the receiver can decipher the received ciphertext by applying the key and recover the original plaintext. This system requires exchanges of the secret keys among communicators.

8.2. Public Key Cryptosystems

The public key cryptosystem is the first secrecy system that does not rely on exchanges of secret keys to obtain its security from cryptanalysis [25]. This system employs a public directory in that each subscriber places a key to be used by other subscribers for encrypting their transmitted messages addressed to each recipient. All subscribers keep secret their corresponding decryption keys for decrypting their received messages.

8.3. Methods of Encryption

In any cryptosystem, the most important thing is to design a means of encryption so that it is practically impossible for cryptanalysis to break it. Wang developed an algorithm of generating a significantly long pseudo-random number (PN) sequence using exponentiation in finite fields [26]. This PN sequence can be used as an encryption/decryption code that is applied to the plaintext by the same way as in the direct-sequence (DS) spread-spectrum system. Diffie and Hellman used the finite field exponentiation as the operation for encipher or decipher [25]. Merkle and Hellman designed a so-called trapdoor knapsack n -vector as the public encryption key [27]. McEliece suggested using a linear error correcting code, Goppa code, for the encryption algorithm [28].

9. TARGET RECOGNITION OR CLASSIFICATION

Identifying a target in a sense with object distortions and background clutter present is a challenging problem for military applications. Two basic mechanisms, optics and electronics, can be adopted for target image collection. Lens, laser, and infrared light are commonly used for optical sensing, while the classic radar and synthetic aperture radar (SAR) [29] are used for electronic sensing.

After the image is collected, an extensive amount of processing is required. In general, there are five levels of processing required to complete a target recognition: (1) detection, (2) image enhancement, (3) segmentation, (4) feature extraction, and (5) identification.

9.1. Detection

Detection is the most computationally demanding stage. It must handle every pixel in the input scene, accommodate target distortions, reject clutter, and locate all candidate regions of interest (RoIs). It does not attempt to recognize the object from the background; it merely attempts to locate RoIs. Because it conceivably must process every pixel in every image, it must contain simple and fast algorithms to avoid long processing time. Various types of correlator (detection filter), such as hit/miss (H/M) and rank order H/M, were developed [30].

9.2. Image Enhancement

Once RoIs have been located, each RoI must be further enhanced to reduce background noises, and fill in holes and sharp edges. These processes will help remove false alarms and achieve identification. Optical morphology [31] is a technique used to enhance the optically collected images.

9.3. Segmentation

Segmentation refers to the inference about objects within each RoI and includes rejection of clutter, omission of false alarms, and identification of macroclass (large-sized) target. Early rule-based inference systems such as MYCIN used certainty factors and developed a simple calculus to compute an overall certainty factor for a hypothesis [32]. More recently the Dempster-Shafer theory of evidence was developed and refined to address the evidence accumulation issue in target recognition [33,34]. Currently, a popular approach to evidence accumulation is via Bayes nets [35]. Bayes nets are graphs, primarily tree-structured but not necessarily so, that use Bayes' rule to lay out all of the conditional probability relationships in assessing the probability that a given hypothesis is true.

9.4. Feature Extraction

The next step for target recognition is to examine the RoI and extract features that would support the inference. In optical sensing systems, computer generated hologram filters can be used [36]. In SAR, the extracted features might be the locations of scattering centers, the shape of the diffuse return of the object, or the location of shadows. The concept is that appropriate features be detected, located,

and characterized so that they can be matched against predicted features in the final stage, identification.

9.5. Identification

The K nearest neighbor (K -NN) is a classic algorithm for target identification or classification [37]. The problems of this method are selecting the threshold and requiring the number of classes that were known a priori. This process is also slow since it uses a feedforward unsupervised learning method [38]. More recently, feedforward neural networks have been used for target identification [39]. This algorithm is fast, less noisy, and more accurate. It can also classify multitarget and multibackground images [40].

10. GLOBAL POSITIONING SYSTEM

In military applications, ranging and navigation are essential. To achieve them, a space-based navigation system, global positioning system (GPS), has been developed and launched [41]. The objective of GPS is to provide accurate, continuous position location information in three dimensions anywhere on or near Earth in all weather conditions. The concept involves measuring the times of arrival of radio signals transmitted from satellites whose positions are precisely known. This gives the ranges to the known satellites, which, in turn, establishes the user's position. To be effective, atomic clocks are installed onboard each satellite, which must be synchronized with a master system clock. Transmission frequencies are selected to minimize timing errors caused by Earth's ionosphere and to be unaffected by rain and weather. By measuring the distance to four GPS satellites, it is possible to establish the three coordinates of a user's position (latitude, longitude, and altitude), as well as GPS time.

10.1. Space Segment

The complete GPS space segment consists of 24 satellites. The satellites travel in 12 h circular orbits 11,000 nautical miles above Earth. They occupy six orbital planes, inclined 55° , with four operational satellites in each plane. The satellites are positioned so that six are observable nearly 100% of the time from any point on the earth. Each is equipped with a combination of rubidium or cesium atomic clocks, which are accurate to within 10 ns. By 1994, the GPS had already completed its full 24-satellite constellation.

10.2. Control Segment

The worldwide GPS ground control segment includes monitor stations, ground antennas, and a master control station. Receivers at the monitor stations track the GPS satellites, record their positions and status, and relay information to the master control station. There the data are processed to establish the satellites' clock correction factors and current orbital elements for transmission back to the satellites via the ground antennas. Currently, the master station is at Falcon Air Force Base, Colorado. The GPS monitor stations are located in Kwajalein,

Hawaii, Diego Garcia, Ascension Island, and Colorado. Ground antennas are located at Kwajalein, Diego Garcia, Ascension Island, and Cape Canaveral.

10.3. User Segment

GPS receiver equipment, unique to each application, can be placed onboard aircraft, ships, submarines, trains, cars, trucks, or other vehicles, or it can be hand-carried. The receivers detect, decode, and process the GPS satellite signals. GPS can determine a user's position with an accuracy of better than 16 m. Greater accuracy, less than 1 m, can be obtained by using corrections sent from another GPS receiver at a known location, and used as a reference.

Today, there are more than 100 different receiver models in use for a wide variety of military and civilian applications. The typical handheld receiver is about the size of a cellular phone, and is getting smaller. The hand-held units distributed to U.S. armed forces personnel during the Persian Gulf war weighed only 28 ounces.

11. MILITARY SATELLITE COMMUNICATION SYSTEMS

Military satellite communication systems of the United States have been developed to support communication beyond line of sight and to provide global dispersed forces and global power protection [42–44]. The system can also support polar regions and oceans. The systems have been designed to have both interoperability and compatibility features so that they can support users of all types of platforms such as land, ship, shore, submarine, air, transportable, and mobile. The choice of frequency bands is critical in designing the MILSATCOM systems. Three basic frequency bands, namely, ultrahigh frequency (UHF), superhigh frequency (SHF), and extremely high frequency (EHF), are available and each provides different advantages. UHF with frequency ranging from 300 to 3000 MHz is suitable for mobile systems, which can work in bad weather conditions and dense foliage. Moreover, UHF systems are inexpensive. Since the operating frequencies for SHF systems range from 3 to 30 GHz, they can support higher data rates and hence provide more jam resistance than UHF (because we spread the signals wider than UHF). EHF frequency bands provide the highest data rates and are the most jam-resistant of the three bands because the operating frequencies are allocated in the range of 30–300 GHz. Designed systems are also required to provide maximum flexibility for situations such as unpredictable conflicts in location, time, and operation duration and intensity. The systems are able to support voice, text, data, imagery, and video. Figure 14 shows a typical MILSATCOM system.

In the following section we will briefly describe the current MILSATCOM systems and Milstar architecture.

11.1. Current MILSATCOM Systems

Based on the frequency bands allocated to the MILSATCOM systems, one can classify the current systems into three categories, namely UHF, SHF, and EHF systems.

Figure 14. MILSATCOM system.

11.1.1. UHF Systems. UHF systems consist of two types of satellites:

- *FLTSATCOM and AFSATCOM.* The FLTSAT serves Navy surface ships, submarines, aircraft, and shore stations. The AFSAT serves Air Force strategic aircraft, airborne command posts, and ground terminals. The two systems share a set of eight satellites in synchronous equatorial orbits. The Air Force also has communications payload on several satellites in high inclination orbits to provide coverage of the north polar region, which is not visible from the equatorial satellites. These satellites were built by TRW with a design life of 5 years and a weight of 1860 kg at launch. The satellites operate in the frequency ranges of 240–400 MHz with onboard signal processing for SHF uplink. The FLTSATs 7 and 8 have fleet EHF packages.
- *UFO.* UFO stands for UHF follow-on satellites, which are built to replace the FLTSAT. The program is managed by the Navy as a lead service with a plan for 10 satellites, with two satellites in each of five coverage areas. These satellites are built by Hughes Aircraft Company with a 14-year design life. These satellites also have EHF onboard signal processing packages.

11.1.2. SHF Systems. The Defense Satellite Communication System (DSCS) has been developed to provide the Department of Defense (DoD), other government agencies, and U.S. allies with global communications services. DSCS provides required national security and maintains thorough communications during crisis and conflict. The DSCS provides services that cannot be provided by other media. The services are provided for both stressed and unstressed environments. Stressed environments contain jamming, nuclear scintillation, and tactical antijam (AJ).

Unstressed environments include ATM, dedicated voice and data, high-speed computer to computer, wideband and high capacity during peace and precrisis. These satellites are built by TRW for Air Force Space Systems Division with a design life of 5 years and operating frequency ranging from 7200 to 8400 MHz.

11.1.3. EHF Systems. EHF systems can be classified into two systems:

- *Milstar.* This system, which is the latest addition to and the most advanced in the MILSATCOM architecture, provides service for mobile users for both strategic and tactical missions. The tactical missions are command and control using a low-data-rate (LDR) communication mode, tactical intelligence dissemination using both LDR and medium-data-rate (MDR) modes, Army mobile subscriber equipment using an MDR mode, and Navy task force connectivity also using an MDR mode. The strategic missions include strategic intelligence relay, tactical warning/attack assessment data relay, force management, and force report back.

The Milstar system and satellites are built to be survivable throughout all levels of conflict. The satellites are hardened to resist the effects of nuclear radiation. The Milstar communication links have high threat mitigation features such as LPI, LPD, exploitation, antijam, and antiscintillation capabilities. Other salient features associated with Milstar include LDR and MDR communication services using robust signal waveform, flexible network configuration, and interoperable terminal base.

Milstar is a joint MILSATCOM program consisting of a six-satellite constellation operating at UHF (225–400 MHz), SHF (20.2–21.2 GHz), and EHF (43.5–45.5 GHz). Milstar satellites can provide

narrow coverage spot beams and MDR nulling antenna capabilities.

- *UFO/E*. This is the ultrahigh frequency follow-on/EHF with operating frequencies in the range of 43.5–45.5 GHz for the uplink and 20.2–21.2 GHz for the downlink. The UFO/E does not support the cross-links, and it provides LDR capability only. However, UFO/E provides high-speed fleet broadcast capability.

11.2. Milstar Architecture

The Milstar system consists of three segments and the support facilities. The three segments are space, mission control, and terminal segments.

11.2.1. Space Segment. The space segment includes orbiting satellites with satellite bus, LDR and MDR payloads, and cross links. Milstar satellites are placed in geosynchronous orbits that can provide coverage up to $\pm 65^\circ$ latitude. Satellites use EHF and SHF for the uplink and downlink, respectively. There are two Milstar I satellites in orbit today with the LDR payload only. The first Milstar II was expected to be launched in early 1999.

- *LDR Payload*. This provides UHF uplink with 2 GHz bandwidth and SHF downlink with 1 GHz bandwidth. It also provides fleet broadcast services. The payload has onboard signal processing, and routing provides interconnections from EHF/SHF links to UHF uplinks and downlinks. The following are some of the features associated with the LDR payload:
 - Data rate: 75–2400 bps.
 - Frequency hopping with either low hop rate (LHR) or high hop rate (HHR).
 - Multiplexing: TDM/FDM on the uplink and TDM on the downlink.
 - Modulation: FSK on the uplink and DPSK/FSK on the downlink.
- *MDR Payload*. This supports EHF uplink with 2 GHz bandwidth and SHF downlink with 1 GHz bandwidth. It provides crosslink processing of MDR data. The payload has onboard signal processing and resource control. The following are some of the features associated with the MDR payload:
 - Data rate: 4.8 kbps–1.544 Mbps.
 - Multiplexing: TDM (up to 70 channels)/FDM (32 channels) on the uplink and single TDM on the downlink.
 - Modulation: Filter symmetric DPSK on the uplink and DPSK on the downlink.
 - Capacity: Maximum throughput of about 45 Mbps.
- *Crosslink Payload*. This simultaneously allows LDR and MDR communication data transmissions and reception between satellites. The crosslink payload also allows for command and telemetry to and from all satellites from a single ground station.

11.2.2. Mission Control Segment. The mission control segment consists of satellite control subsystem and three mission elements, namely, mission support, mission development, and mission planning elements.

- *Satellite Control Subsystem*. This provides distributed command and control via multiple satellite mission control subsystems (SMCS) and preplanned response to satellite. This subsystem uses LDR terminal EHF/SHF communications to control Milstar satellites.
- *Mission Support Element (MSE)*. This provides software and databases to control Milstar satellites. This element also supports launch, satellite initialization, and resolution of complex satellite anomalies.
- *Mission Development Element*. This provides a software tool for building SMCS and MSE database, and system simulation supports training and software/database validation.
- *Mission Planning Element*. This provides communications planning software and generates satellite and terminal database information. This element also supports communication resource apportionment, conflict resolution, contingency planning, and detailed communications network planning.

11.2.3. Terminal Segment. The terminal designs and communications protocols are required to provide for interoperable communications among Army-, Navy-, and Air Force–developed terminals. LDR terminals provide survivable tactical and strategic user communications, voice, teletype, and data. LDR terminals also provide force direction/report back, tactical command and control, and emergency message dissemination. MDR terminals can provide all of the features that LDR can provide, including imagery, targeting updates, and mobile subscriber equipment range extension. There are three basic types of terminals: Air Force Milstar, Navy, and Army terminals.

- *Air Force Milstar Terminals*. This include EHF/UHF command post-ground and transportable, as well as UHF force element (also referred to as AFSATCOM dual modem upgrade II).
- *Navy Terminals*. These include ship, shore, submarine, and MDR upgrade program.
- *Army Terminals*. These include secure mobile anti-jam reliable tactical terminal (SMART-T) and single/multiple channel anti-jam portable terminal (SCAMP) Block I and II.

11.2.4. Support Facilities. The two basic support facilities are Milstar auxiliary support center and on-orbit test facility.

MILLIMETER-WAVE INTEGRATED CIRCUITS

HUEI WANG
 KUN-YOU LIN
 REN-CHIEH LIU
 HONG-YEH CHANG
 National Taiwan University
 Taipei, Taiwan

Millimeter-wave (MMW) components are becoming more available and affordable because of advances in the design, processing, testing, and packaging technology. MMW circuits have become smaller, highly integrated, and low-cost, and are being applied in instrumentation, electronic

warfare, satellite communications, and other applications. As a result, many MMW systems are being developed and deployed that provide new and unique capabilities such as more information transfer (wider bandwidth), enhanced precision (higher resolution), and all-weather operation (through fog, dust, and smoke), for both military and commercial applications. Monolithic MMW integrated circuits (MMICs¹) are crucial to meet the requirements for the MMW systems and play an important role in the MMW components. This article describes the current status of MMW monolithic integrated circuits, including the MMIC technologies, representative designs, and performance for various integrated circuits.

1. MMIC TECHNOLOGIES IN MMW REGIME

For MMW electronics, a large number of different semiconductor materials such as Si, SiGe, GaAs, InP, and other III–V compounds, as well as wide-bandgap materials, have been employed [1]. Various types of microwave transistors exist, including metal semiconductor field-effect transistors (MESFETs), metal-oxide-semiconductor field-effect transistors (MOSFETs), high-electron-mobility transistors (HEMTs), and heterojunction bipolar transistors (HBTs). MMW transistors are the backbone of all the MMW systems. They have also undergone an impressive evolution. Continuous efforts in research of traditional GaAs FETs and HBTs have been improved. New classes of microwave transistors, such as wide-bandgap FETs and metamorphic GaAs HEMTs, have been introduced. Furthermore, Si saw a renaissance in microwave electronics. SiGe HBTs are now available commercially [2]. In addition, Si MOSFETs, which formerly were considered slow devices not suited for MMW operation, have progressed rapidly and demonstrated the applications in MMW MMICs.

1.1. High-Electron-Mobility Transistor (HEMT)

HEMT is a field-effect transistor whose conduction carriers are separated from the donor impurities that supply the electrons. Other names include two-dimensional electron gas FET (TEGFET), modulation-doped FET (MODFET), heterostructure FET (HFET), and selectively doped heterostructure transistor (SDHT), which focus on different aspects of the device. Since no impurities are present in the channel as scatterers, the electron mobility increases, which means that HEMT has higher operating frequency, and lower noise figure than do those of the MESFET counterparts [3]. A typical layer structure of a HEMT device is shown in Fig. 1. MESFET, on the other hand, has a structure similar to that of MOSFET, except that in a MESFET, the gate is isolated from the drain and source by the Schottky junction instead of an actual oxide layer.

Several families of HEMTs currently exist, categorized by their substrate and composition of their channels. The

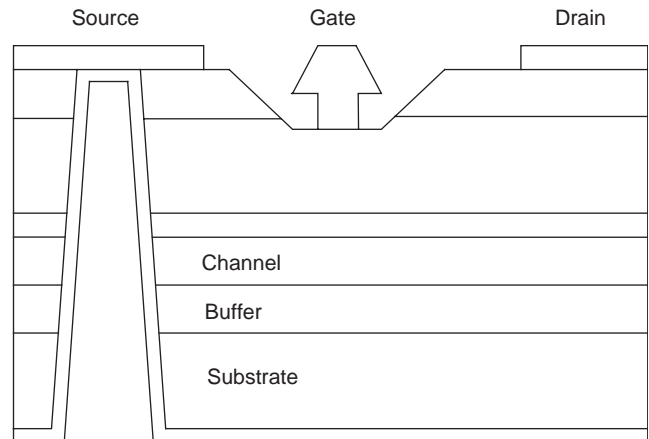

Figure 1. Cross section of a HEMT structure. Electrons travel in the undoped channel layer, which are provided by the layers adjacent to the channel; in MESFETs, the channel is n-doped GaAs, and the doping reduces the electron mobility of the material and therefore yields a poorer performance compared to that of HEMT.

earliest HEMT devices were lattice-matched HEMTs [4]. In lattice-matched HEMT, the electron gas is located on the undoped GaAs in the AlGaAs/GaAs junction. With addition of indium to the channel, the electron mobility can be increased. Pseudomorphic HEMTs (PHEMT), InP HEMT, and metamorphic HEMTs (MHEMT) were developed by adding different concentrations of indium in the electron gas channel. The performance of these devices has superseded that of lattice-matched HEMTs; therefore lattice-matched HEMTs on GaAs are rarely seen nowadays. PHEMT on GaAs substrate is currently the most popular type of HEMT available; a thin-strained $\text{In}_x\text{Ga}_{1-x}\text{As}$ ($x = 0.15\text{--}0.35$) layer is grown at the site where the two-dimensional electron gas is located, and this strained layer, while maintaining lattice integrity, is responsible for the term “pseudomorphic” for this device. InP HEMTs use InP as the substrate, and $\text{In}_x\text{Ga}_{1-x}\text{As}$ ($x = 0.53$) as a channel, which is lattice-matched to the InP substrate. InP PHEMT consists of $\text{InAlAs}/\text{In}_x\text{Ga}_{1-x}\text{As}$ ($x > 0.53$) on InP substrate. InP PHEMTs have exhibited the best performance in noise and operating frequency to date, but the substrate is very brittle and difficult to fabricate. To circumvent the disadvantages of InP substrate and still retain the performance of InP HEMTs, MHEMT grown on GaAs substrate has been developed. In MHEMTs, a buffer layer is grown to provide good lattice match between the GaAs substrate and the GaInAs channel. Another HEMT device, namely, GaN HEMT, which has wide bandgap (3.4 eV) and moderate electron mobility, is extremely attractive for power amplifier designs. Presently, the lack of a GaN substrate poses a disadvantage for mass production, but its electrical properties still make GaN HEMT a potential contender in power applications at microwave frequency. The characteristics and performance of each type of HEMT will be introduced in the following text.

1.1.1. GaAs pseudomorphic HEMT. GaAs PHEMT is currently most popular because of its early development and mature fabrication. Many commercial MMIC foundries are

¹The acronym MMIC usually stands for monolithic microwave and/or MMW integrated circuit. In this article, we use it for monolithic MMW integrated circuit in particular.

available, including the most advanced 6-in. GaAs wafer processes. A lot of information can be found in the literature on the subject of GaAs PHEMTs, such as a brief summary and comparison of various PHEMT devices and InP HEMT devices [5]. Depending on gate length and periphery, GaAs PHEMTs can operate from 2 to 120 GHz, with output RF power up to 1 W at 44 GHz [6].

Traditional PHEMTs are AlGaAs/InGaAs/GaAs structures. However, this structure has several disadvantages, mostly in the area of fabrication control and thermal stress. More recent research on GaAs PHEMT has focused on InGaP/InGaAs/GaAs structure. InGaP has several advantages over AlGaAs: higher bandgap (1.92 eV), higher valence band discontinuity, no deep-complex center, excellent etching selectivity between InGaAs, and good thermal stability [7]. InGaP contains no aluminum, which makes the device more inert in atmosphere, adding to the stability of the device. These advantages translate to lower noise, higher associated gain, constant threshold voltage, and lower $1/f$ noise. Huang et al. have shown a 0.25- μm InGaP/InGaAs/GaAs HEMT with an f_T of 85 GHz, f_{max} of 160 GHz, and a minimum noise figure of 0.46 dB at 12 GHz [7].

1.1.2. InP HEMT. In GaAs PHEMTs, the two-dimensional electron gas is at the strained $\text{In}_x\text{Ga}_{1-x}\text{As}$ ($x = 0.15\text{--}0.35$) layer. It is possible to increase the speed of the electrons in the channel by increasing the mole fraction of indium. However, higher indium composition will excessively distort the lattice making the device incapable of being manufactured on GaAs substrate. Because InP has a lattice constant closer to that of InGaAs, channels that are InGaAs (where indium has the higher mole fraction) are fabricated on InP substrates. HEMTs on InP substrate can also be fabricated into pseudomorphic HEMTs, but the distinction between InP lattice-matched HEMT and PHEMT is seldom emphasized.

InP HEMTs have a significantly better speed/frequency response ratio compared to that of GaAs PHEMTs. Several reports demonstrated f_T over 300 GHz [8–10], and a device with 400-GHz f_T has been reported [11]. An f_{max} of >600 GHz has also been reported [12,13]. InP HEMTs also have the lowest noise figure of any room-temperature receiver technology, and are often further exploited by cryogenic freezing to achieve ultra-low-noise amplifications. Grundbacher et al. demonstrated a W-band cryogenic MMIC LNA operating at 20 K that shows over 23 dB gain with a noise temperature of 30–40 K (0.45–0.6 dB noise figure) over the band of 80–105 GHz [14].

1.1.3. GaAs metamorphic HEMT. MHEMT combines the affordability of GaAs process and the performance of InP HEMTs by growing the active layers on a strain-relaxed, compositionally graded metamorphic buffer layer. This buffer layer can be adjusted to accommodate any indium content channel desired (30–80%), which allows device designers an additional degree of freedom to optimize the transistor performance. GaAs MHEMTs outperform GaAs PHEMTs in terms of noise and efficiency, and rival InP HEMTs.

The indium content of MHEMTs can be adjusted over a wide range. MHEMTs with intermediate indium content

(25–45%) can offer high breakdown voltages, large power densities, and better noise performance than PHEMTs. Whelan et al. [15] demonstrated the performance of MHEMT at 25 GHz with an NF_{min} (minimum noise figure) of 1.18 dB and associated gain of 10.7 dB; a GaAs PHEMTs with the same periphery has 0.4 dB higher NF_{min} and 3 dB less associated gain. The power density of MHEMT at 35 GHz is 830 mW/mm and a PAE (Power-added efficiency) of over 40%, which beats (outperforms) the same PHEMT by 130 mW/mm. A V-band MHEMT MMIC power amplifier with high efficiency has also been demonstrated with an output power of 23 dBm and PAE of 39–43% from 56 to 63 GHz [16].

1.1.4. GaN HEMT. Most power devices have a low input impedance (under 10 Ω), which makes matching network design very difficult. The higher power density of GaN HEMT translates to a smaller device periphery, which offers an input impedance much higher than that of other power devices. High operation voltages make GaN HEMTs compatible with 28-V systems (standard wireless base stations), which offer higher efficiency and simplified cooling [17]. Because of the lack of native substrates, GaN HEMTs are usually fabricated on SiC or sapphire. GaN HEMTs on Si substrate were also demonstrated, but suffered a loss of power density.

The highest power density of GaN HEMTs reported to date has been fabricated on SiC substrate [18]. At a frequency of 10 GHz, a 1.5-mm device has an output power of 13.8 W (power density of 9.2 W/mm), and PAE of 33%. At a frequency of 20 GHz, a power density of 6.4 W/mm and PAE of 16% was demonstrated [19]. The noise performance of GaN HEMTs on SiC substrate was also reported with a minimum noise figure of 1.5 dB at 26 GHz [20]. GaN HEMTs on sapphire substrates demonstrate a power density of 3.6–4.2 W/mm at 8–10 GHz [21,22]. GaN HEMTs on Si substrate usually has a power density of under 2 W/mm, but a GaN HEMT on resistive Si has demonstrated a power density of 6.6 W/mm at 2 GHz [23].

Several commercial HEMT processes are available. Lattice-matched HEMTs are virtually nonexistent nowadays. Velocium provides several GaAs PHEMT and InP HEMT processes [204], and its performance is recognized as state of the art. Their 0.15- μm GaAs PHEMT process has an f_T of 80 GHz and f_{max} of 200 GHz and 0.10- μm GaAs PHEMT process has an f_T of 120 GHz and f_{max} of 250 GHz; the 0.10- μm InP HEMT process has an f_T of 180 GHz and f_{max} of 350 GHz. Raytheon RF Components (now part of Fairchild RF) offers the best commercial MHEMT process; their standard low noise 0.10- μm MHEMT process has an f_{max} of over 260 GHz [204] and ultralow noise of 0.24 dB NF_{min} at 12 GHz [205]. There has been no commercial GaN HEMT process until now; most reports have been in academia or R&D; however, many online resources give up-to-date news on the latest developments of GaN technology [206,207].

1.2. Heterojunction Bipolar Transistor (HBT)

The heterojunction bipolar transistor (HBT) is an improved type of conventional bipolar transistor (BJT).

Figure 2. Cross section of HBT structure.

HBT has the same vertical structure as that of BJT, as shown in Fig. 2. This emitter material has a wider energy bandgap than does base material, and therefore the term “heterojunction” applies for this device. With wider bandgap, the base doping density can be increased without decreasing the current gain. Increasing base doping thus reduces base resistance and improves the maximum oscillating frequency (f_{max}). This significantly improves the operating frequency of the HBT [1].

In comparison to bipolar transistors, HBT can be optimized for a higher f_T , a higher Early voltage (high output resistance), a lower base-emitter capacitance, a reduced base resistance, or a higher voltage-handling capability. Compared with GaAs- or InP-based HEMT, HBT offers a higher transconductance, a higher current density, a lower flicker noise ($1/f$ noise), and better threshold voltage uniformity.

Several families of HBTs currently exist, which can be categorized by their substrates and layer materials. HBT on GaAs substrate is most popular now. In GaAs-based HBT, GaAs and AlAs both have the zincblende structure with a lattice constant of about 5.65 Å. Since GaAs and AlAs have similar lattice constants, one can choose the composition x of the ternary compound $Al_xGa_{1-x}As$ as the layer material to fit the particular device requirement. InP HBTs use InP as substrate and InGaAs as layer material. Because GaAs and InAs do not have the same lattice constant with InP, the ratio of In and Ga in InGaAs should be selected carefully. One can choose $In_{0.53}Ga_{0.47}As$ to grow a lattice-matched layer to InP substrate. SiGe HBTs use Si as the substrate and SiGe as the layer material. The materials used to produce HBTs can be classified according to substrate materials, as shown in Table 1.

Table 1. Range of HBT Materials Currently in Use

Substrate	Emitter	Base	Collector
GaAs	AlGaAs	GaAs orAlGaAs	GaAs orAlGaAs
	GaInP	GaAs orAlGaAs	GaAs orGaInP
InP	InP	InGaAs	GaAs orGaInP
	AllnAs	InGaAs	InGaAs orGaInP
Si	Si/poly-Si	SiGe	Si
Sapphire	AlGaN	GaN	GaN

Source: Ref. 24.

1.2.1. GaAs HBT. AlGaAs was the first material used for emitter material of GaAs HBT. Because GaAs and AlAs have similar lattice constants and AlGaAs has a wider bandgap than does GaAs, one can arbitrarily choose the concentration of Al in AlGaAs to produce the emitter, or even a grading emitter. However, Al suffers from the incorporation with oxygen; that is, Al_2O_3 will increase the recombination current and thus decrease the current gain. InGaP is found to be more appropriate for manufacturing because of the selective etching solution. To etch GaAs using H_2O_2 to adjust with NH_4OH automatically stops at InGaP, while using HCl to etch InGaP also stops at GaAs [25]. In addition, InGaP will not suffer from the oxidation as the AlGaAs does. However, it is difficult to use InGaP to produce grading emitter because the lattice constant is different from that of GaAs. The f_T and f_{max} of GaAs HBT are generally higher than 100 GHz. In 2001, an InGaP/GaAs HBT with an f_T of 156 GHz and f_{max} of 255 GHz, with a collector-emitter breakdown voltage of 9.6 V was reported [26]. This means that GaAs HBTs have the potential to operate at frequencies higher than 200 GHz.

Several commercial foundries provide GaAs HBT processes. WIN Semiconductors provides 2- μm HBT with 35-GHz f_T and 100-GHz f_{max} , together with 1- μm HBT of 65-GHz f_T and 80-GHz f_{max} [208]. Velocium has GaAs HBT with 42-GHz f_T and 72-GHz f_{max} [209]. TriQuint Semiconductor provides 3- μm InGaP HBT with 28-GHz f_T and 46-GHz f_{max} [210]. Global Communication Technology Corporation (GCTC) provides 2- μm HBT with 35-GHz f_T and 60-GHz f_{max} [211]. GCS provides high-power process with 45-GHz f_T and 55-GHz f_{max} , while a high-speed process is available with 65-GHz f_T and 70-GHz f_{max} [212].

1.2.2. InP HBT. InP has higher electron mobility than does GaAs, and thus it can operate at higher frequency. It has the best potential for high-speed operation, with f_T and f_{max} usually higher than 150 GHz. InP HBT is also suitable for very high speed applications. The f_T and f_{max} of InP-based HBT have also been demonstrated to exceed 300 GHz [27,28], with the DHBT (double heterojunction bipolar transistor) structure, which means that the base-emitter and base-collector junctions are all heterojunctions. This makes InP HBT the highest-speed transistor at present.

There are a couple of commercial InP HBT foundry services. Velocium provides InP HBT with 150-GHz f_T and 180-GHz f_{max} [209]. Global Communication Semiconductors, Inc. (GCS) also has InP HBT with 150-GHz f_T and 180-GHz f_{max} [212].

1.2.3. SiGe HBT. SiGe HBT has received a much attention lately because it can be easily adopted to the highly matured Si-based CMOS process and thus is potentially lower cost compared with the III-V material-based HBTs (GaAs- or InP-based HBTs). SiGe HBT technology is rapidly advancing at present. Besides the potential of low cost, since SiGe HBT is also fabricated on silicon substrate, it can easily be integrated with CMOS technology. However, it has the disadvantage of lower breakdown

voltage and poorer power handling than the GaAs- and InP-based HBTs.

At present, SiGe HBTs with f_T and f_{max} greater than 150 GHz were reported. In 2001, a 0.18- μm -emitter-width HBT with 180-GHz f_{max} and 210-GHz f_T was reported [29]. The breakdown voltages of collector-emitter and collector-base are 3.3 and 5.5 V, respectively. Although the operating frequency of the SiGe HBT is comparable to that of GaAs HBT, the breakdown voltage is usually lower. There are still some challenges to improve the breakdown voltage and thus enhance the power performance.

The companies that provide SiGe HBT foundry service are as follows. Taiwan Semiconductor Manufacturing Company Ltd. (TSMC) provides 0.35- μm SiGe HBT with 62-GHz f_T and 70-GHz f_{max} [213]. IBM has provided 0.18- μm SiGe HBT with 120-GHz f_T and 100-GHz f_{max} , together with 0.25- μm , 0.35- μm , and 0.5- μm HBT [214]. Atmel provides 0.3- μm SiGe HBT with 50-GHz f_T and 90-GHz f_{max} , as well as 0.5- μm HBT with 30-GHz f_T and 50-GHz f_{max} [215].

1.2.4. Applications. In digital applications, high-speed digital circuits using emitter-coupled logic (ECL) or current-mode logic (CML) are implemented by HBTs. With high operating frequency of HBT, ECL of up to several tens of GHz can be designed. For example, a 47–48-GHz frequency divider was reported using GaAs HBT ECL and CML [30]. On the other hand, for analog applications, HBTs cover a range of applications, including linear amplifiers, wideband amplifiers, power amplifiers, low-phase-noise oscillators, and mixers. Among these, the power amplifier is most important for current wireless communication applications. HBTs have advantages for power amplifier design due to their high breakdown voltage and high current density. Many commercial power amplifier products are fabricated using HBTs. Another important application for HBT is low-phase-noise oscillators due to the low flicker noise characteristics of the HBT. HBTs were also used to design wideband amplifiers. Using the Darlington pair, a compact wideband InP HBT amplifier operating up to 85 GHz was reported in 2000 [31]. The device has an f_T of 120 GHz and f_{max} of 150 GHz.

1.3. CMOS/BiCMOS

Since the late 1970s, the metal oxide semiconductor field-effect transistor (MOSFET) has been extremely popular. Most very-large-scale integrated circuits (VLSI), such as digital logic, memory, and analog functions, are fabricated using MOS technology at the present time. RF integrated circuits (RFICs) are also preferably designed using complementary MOS (CMOS) transistors, due to the low cost of Si process and integration capability with baseband circuits. Owing to the rapid development of the deep-submicrometer CMOS technologies, many CMOS MMW circuits have been demonstrated [32–36].

In most MOSFETs, the gate is one plate of a capacitor separated by a thin dielectric from the bulk. With no voltage applied to the gate, the transistor is essentially non-conductive between the source and drain terminals. When a voltage of sufficient magnitude is applied to the gate,

charge of opposite polarity is induced in the semiconductor, thereby enhancing the conductivity.

1.3.1. CMOS. A p-channel enhancement-type MOSFET (PMOS) is fabricated on an n-type substrate with p^+ regions for the drain and source, with holes as charge carriers. In contrast, an NMOS is formed on a p-type substrate with n^+ regions for the drain and source, and electrons as charge carriers. PMOS was originally the dominant technology. However, since the electron mobility is higher than the hole mobility, the speed and the current-driving capability of NMOS devices are much better than those of the PMOS devices. NMOS technology has eventually replaced PMOS. Complementary MOS (CMOS) RF ICs are designed using complementary MOS (CMOS) technology employs both PMOS and NMOS transistors and enables various aspects of circuit design. Therefore, CMOS is most popular among all the MOS IC technologies at the present time.

A cutoff frequency of 125 GHz for a 70-nm gate bulk Si MOSFET [37] and 245 GHz f_T [38] for an 80-nm CMOS were reported in 1997 and 2001, respectively. For a long time, MOSFETs suffered from relatively low power gains at high frequencies and low f_{max} . The main reasons for this were the high specific resistance of the gate material (polysilicon) and the fact that the mushroom gates generally used in HEMT were not yet available in standard Si CMOS processes. A lot of efforts have been spent to reduce the gate resistance by depositing silicides or metal on top of the polysilicon and by employing metal gates. These effects finally led to improved power gain and f_{max} behavior. A 0.18- μm gate bulk MOSFET with an f_{max} of 150 GHz has been reported [39]. A standard commercial process featuring 0.25-, 0.18-, 0.13- and 90-nm CMOS mixed-signal (MS) and RF technologies has been reported [2]. The traditionally limited f_T and f_{max} in CMOS have been improved through the shrinkage of gate oxide thickness and device dimension. The f_T increases from 33 GHz in 0.25- μm technology with 50 Å of gate oxide to 110 GHz in 90-nm technology with 17 Å of gate oxide. Meanwhile, f_{max} of the 90-nm technology is improved to approximately 90 GHz from the f_{max} of 30 GHz for 0.25- μm technology.

1.3.2. SoI/SoS technologies. SoI (Silicon on Insulator) CMOS devices are placed on the insulator, namely, the silicon dioxide. Each SoI CMOS device is completely separated from the silicon substrate. The SoI CMOS is advantageous over bulk CMOS because of the elimination of area junction capacitance, the lack of reverse body effect in stacked circuits, and the fact that the SoI body is slightly forward-biased under most operating conditions. A 0.13- μm SoI CMOS has been used to implement a 40-GHz VCO with 9–15% tuning range [40]. A 40-nm gate SoI MOSFET with a record f_{max} of 193 GHz [41] and a 80-nm gate SoI MOSFET with a record f_{max} of 185 GHz [42] have been reported. Silicon-on-sapphire (SoS) CMOS technology is also attractive for RF applications because of its reduced parasitic capacitance and reduced minimal capacitive substrate loss. Fabricated 250-nm T-gated devices can achieve 105-GHz f_T and 50-GHz f_{max} for n-channel operation [43]. However, both

Table 2. State-of-the-Art LNA above 30 GHz

Technology	Frequency (GHz)	Gain (dB)	NF (dB)	Ref.

SoI and SoS CMOS technologies are mostly in the R&D phase and are not widely being used for production.

1.3.3. SiGe HBT and BiCMOS. There is clear trend to shift the research efforts to HBTs for higher frequencies, especially for MMW applications. SiGe HBT can be fabricated with the existing Si CMOS technology with only a few more steps added [2]. A 60-GHz SiGe bipolar transceiver circuit including an LNA, a direct downconverter, a PA, and a VCO has been reported [219]. On the other hand, BiCMOS technology development began in the early 1980s as a way of significantly enhancing digital performance. This technology combines bipolar and CMOS transistors on the same IC chip and therefore is attractive for high-level integrations, and even system-on-chip (SoC) applications. The low frequency and broadband noise characteristics of SiGe HBT are superior to those of CMOS. The high transconductance of the BJT and HBT leads to lower optimum source reflection coefficient and noise resistance, simplifying lower-power noise matching. The resulting circuits retain the characteristics of low power, high input impedance, and wide noise margin of CMOS and the high current-driving capability and high speed of operation of bipolar transistor [44].

2. MILLIMETER-WAVE MMICs

2.1. Amplifiers

2.1.1. Low-Noise Amplifiers. A low-noise amplifier (LNA) is usually the first component in a receiver, due to the signal-to-noise ratio (SNR) consideration. The gain and noise figure are the two most important parameters in the design. For a MMW LNA, although the design principle is similar to that in the microwave range, as documented in many textbooks [17], there are some special

considerations. The appropriate technology must be selected before the circuit design. GaAs PHEMT and InP-based HEMT are typically the choices for low noise and high gain. MHEMT has received attention and demonstrated comparable performance as InP HEMT. The device size needs to be carefully selected to fulfill the design goals based on an accurate device model or measured small-signal scattering (S) parameters and noise-parameters. Both microstrip-line and coplanar waveguide (CPW) designs were found in the literature. Either way, the layout design tends to be simple, especially for those designs above 100 GHz in order to avoid the uncertainties of the passive-element models. The substrate thickness is also a concern in the microstrip-line design for single-mode operation, such as 3-mil or thinner is typically used for circuits above 100 GHz. EM simulation, nevertheless, is critical in high-frequency LNA design. The layout, EM, and circuit simulation will need to be performed iteratively to attain the desired targets. The stability issue also requires thorough investigations; one needs to ensure that the circuit is free of oscillation from very low frequency until it has no gain.

The state-of-the-art LNAs above 40 GHz are listed in Table 2. It is observed that the HEMT technology still demonstrates low noise and high gain performance in MMW regime and InP HEMT produces best results above 100 GHz. The highest-frequency LNA to be reported as of 1999 [45] had 17 dB gain at 215 GHz with six stages, and the layout is shown in Fig. 3.

Regarding silicon-based devices, CMOS and SiGe HBT have also evolved rapidly. The unity-gain frequency (f_T) values of CMOS and SiGe HBT have been reported to be about 95 and 90 GHz, respectively [46,47], indicating the potential for high-frequency application of silicon technology. Currently there are MMIC LNAs above 20 GHz using CMOS and SiGe HBT [47,48]. It is expected that MMW LNA using Si-based device will be reported in the near future.

2.1.2. Power Amplifiers. A power amplifier (PA) is typically used at the front end in a transmitter and is required to provide sufficient gain and output power to transmit the signal. In the MMW regime, traveling-wave tube amplifiers (TWTAs) have been used for very-high-power applications up to 140 kW level [58]. More recently, solid-state power amplifiers (SSPAs) and MMIC PAs for medium-power-level applications of several watts have been developed [59]. In addition to the output power, linearity is usually another important design consideration in many communication systems.

Figure 3. Layout of the six-stage amplifier including WR-5 coupling probes (© 1999 IEEE) [45].

Figure 4. The Ka-band prematch structure (©1993 IEEE) [60].

The design principle of a MMW PA is also similar to that in the microwave regime. However, it is still not easy to obtain accurate optimal load impedance of a power transistor from load-pull testing since such a transistor usually has a large size and thus very low input and output impedances. Instead, the prematch approach was proposed, and an example can be found in Ref. 60. The combined transistors with a total gate periphery of $1600\ \mu\text{m}$ were used to form a pre-matched structure as shown in Fig. 4, and thus the very low input/output impedances were transformed to desired values that can be measured and characterized. A two-stage Ka-band 1.6-W amplifier was developed using a single prematched structure to drive four prematched structures [60]. The MMIC PAs with higher power and gain requirements can then be designed on the basis of a similar structure in the next iteration. On the other hand, the more recent advancement of nonlinear modeling techniques and CAD tools is no doubt beneficial to predict the power contour of a transistor, even at high frequencies.

The MMW MMIC PAs are currently dominated by III-V compound HEMT (GaAs- or InP-based) devices, due to high gain characteristics at high frequencies. A few low-medium-power amplifiers designed for high linearity using HBTs were also reported at Q band [61]. For thermal concerns of PA design, the thin-substrate (≤ 2 mil) MMIC technology has been emphasized [62]. The thin substrate not only enhances the thermal conductivity but also benefits the PA design with a number of features: (1) the ground via holes can be made smaller so that they can be placed under the HEMTs for a more compact device layout; (2) the via hole inductance, which directly translates to the source inductance of the common source HEMT, is drastically reduced and thus enhances the gain performance at MMW frequencies; and (3) the low impedance microstrip lines on a thinner substrate are narrower and thus make the whole PA layout more compact. All these

features will improve the output power, power gain, and power-added efficiency (PAE) of a PA. In fact, most of state-of-the-art MMW MMIC PA results to date were obtained using 2-mil technologies. A Q-band 3-W PA is realized with 2-mil $0.15\text{-}\mu\text{m}$ GaAs PHEMT process [63], and a 62.5-GHz PA using the same technology has demonstrated 564 mW and achieved 21% PAE [64]. A set of PA MMIC chips reported by Wang et al. [65] covers 70–113 GHz using 2-mil, $0.1\text{-}\mu\text{m}$ GaAs PHEMTs.

The power-combining technique is often used to build a high-power module with multiple MMIC PA chips. Since the combining structures usually occupy large areas, they can be implemented using low loss and less expensive substrates, such as Al_2O_3 , or quartz. A Ka-band power module demonstrated 6-W output power, 24% PAE, and 21.5 dB associated power gain using an eight-way binary Wilkinson combiner realized on Al_2O_3 substrate, as illustrated in Fig. 5 [59]. A V-band power module design utilizing an eight-way radial combiner consisting of eight basic units, with each basic unit containing three-way planar combiners and three power amplifiers, has been reported [66]. It achieved 3.8 W output power and 31 dB power gain. A 0.35-W, 94-GHz PA module was also reported [67].

A number of amplifiers with medium output power and/or wide bandwidth were also reported using InP-based devices, such as a 85-GHz 16.2-dBm common-base amplifier and a 90-GHz 14 dBm cascode amplifier, fabricated using InP DHBT [68], and also a 60–145-GHz amplifier with 24 mW output power using $0.1\text{-}\mu\text{m}$ InP HEMTs [69].

2.1.3. Broadband Amplifiers

2.1.3.1. Distributed Amplifiers. Distributed amplifiers (DAs), also commonly referred to as *traveling-wave amplifiers* (TWAs), are broadband circuits whose gain-bandwidth product substantially exceeds the transistor unity-gain frequency f_T because the input and output capacitances of the active devices can be absorbed in the distributed structures. Figure 6 shows the schematic of a conventional DA designed with FETs. It consists of input and output transmission lines coupled by the transconductances of the FETs. The transmission lines are formed by using lumped inductors and are referred to as the *gate* and *drain lines*. The gate line is periodically loaded by the FET gate-source capacitance and is terminated in its characteristic impedance at the end. As the RF signal travels on the gate line, each transistor is excited by the traveling voltage wave and transfers the signal to the

Figure 5. Photograph of a 6-W power module (© 1997 IEEE) [59].

Figure 6. Schematic of the conventional distributed amplifier designed using FETs.

drain line through its transconductance. If the phase velocities on the gate line and drain line are identical, the in-phase signals on the drain line will add up along the forward direction as they arrive at the output. The out-of-phase wave traveling in the reverse direction will be absorbed by the drain-line termination.

A GaAs HEMT distributed amplifier, shown in Fig. 7, demonstrated 20 dBm output power at 1–50 GHz [70]. To improve the output power, a cascade broadband driver distributed PHEMT amplifier with a high-output-power output stage and a bandwidth of 17–40 GHz with an output power of 22.5 dBm has been proposed [71].

2.1.3.2. Cascode Distributed Amplifier. In addition to the common-source topology DAs [72,73], the cascode configuration is generally used to improve the gain-bandwidth product of MMW DAs. The cascode configuration, known for its high maximum available gain, wide bandwidth, improved input-output isolation, and variable gain control capability, has been utilized in many applications such as mixers, frequency multipliers, and distributed amplifiers. The DAs using InP-based HEMTs demonstrated 1–112 GHz bandwidth with 7 dB gain and 1–157 GHz bandwidth with 5 dB gain, and Fig. 8 shows the schematic and chip photo [74]. These amplifiers were designed using cascode cell and gate-line capacitive division to achieve high cutoff frequency.

2.1.3.3. Matrix Distributed Amplifier. The matrix DA has the advantages of additive and multiplicative amplification and provides higher gain as well as better reverse isolation over a wide frequency range. The matrix DA was

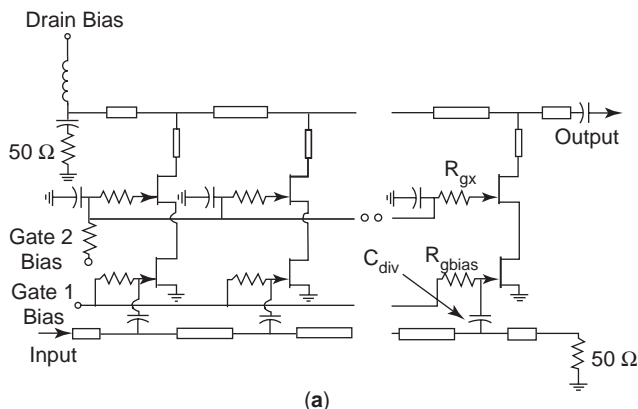

Figure 7. Photograph of the 1–50-GHz power amplifier [70].

(a)

(b)

Figure 8. (a) Schematic, and (b) chip photo of the cascode capacitive-division distributed amplifier (© 1998 IEEE) [74].

formed by adding a new dimension to the distributed amplifier with one or more rows of transistors [75], as shown in the schematic of Fig. 9. A matrix DA using GaAs HEMT technology demonstrated 9 dB gain at 2–52 GHz [76].

2.1.3.4. Cascaded Single-Stage Distributed Amplifier. The cascaded single-stage DA CSSDA shows excellent performance with high gain, good gain flatness, lower input/output VSWRs, flat group delays, and a low noise figure. Using the concept as for traveling-wave gain stages to maintain the DA broadband performance, the cascaded single-stage distributed amplifiers (CSSDA) [76,77] can be

Figure 9. Schematic of a matrix distributed amplifier.

Figure 10. Chip photo of the amplifier combines a conventional DA and a CSSDA (© 2003 IEEE) [78].

used for broadband gain stages. By adopting this topology in the DA design, the high gain and wide bandwidth could be obtained simultaneously. With the combination of a conventional DA and a CSSDA, an amplifier demonstrated 22-dB small-signal gain from 0.1 to 40 GHz with a chip size of $1.5 \times 2 \text{ mm}^2$, as shown in Fig. 10 [78].

2.1.3.5. DA Using Si-Based Transistors. DAs using CMOS and SiGe HBT processes also evolve rapidly. The reported unity-gain frequency (f_T) values of CMOS and SiGe HBT were 95 and 90 GHz, respectively [75,79], indicating the potential of the high-frequency application of silicon technology. In fact, a MMIC DA using SiGe HBT demonstrated 50 GHz bandwidth with a gain of 5–9 dB [80]; another SiGe differential distributed amplifier has a single-ended gain of 7 dB with a 3 dB bandwidth of 81 GHz [218]. There is also a MMIC DA reported to operate from 0.6 to 22 GHz using the CMOS process [81]. It is expected that MMW DAs using CMOS processes will appear in the near future.

2.1.3.6. Transimpedance Amplifiers. Transimpedance amplifiers (TIAs) are also typical broadband amplifiers covering the MMW regime. TIAs are most widely used as preamplifiers in the receivers of optical communication systems because of high dynamic range, wide bandwidth, and relatively high output voltage (high transimpedance gain). TIAs convert and amplify the current from the photodiode to voltage. The *gain* is defined as the output

voltage over the input current ($\delta V_{\text{out}}/\delta I_{\text{in}}$), which has the same unit (Ω), as that of a resistor, and thus is called “transimpedance gain.”

Table 3 summarizes the most recently reported TIAs with operation frequencies up to the MMW regime [82–88]. A TIA using InP HBT demonstrated a transimpedance gain of $3.6 \text{ k}\Omega$ (71 dB· Ω) with a bandwidth of 60 GHz. This TIA benchmarks the best gain–bandwidth product (GBP) of 1.9 THz, which is the highest transimpedance–bandwidth product (TZBWP) of $216\Omega \cdot \text{THz}$ and the highest TZ-BWP per DC power efficiency of 797 $\Omega \cdot \text{GHz/mW}$ for a 40-Gbps transimpedance amplifier [82].

2.2. Mixers

Mixers play the role of frequency conversion in a wireless communication system and directly affect the integrity of the signal transmitted or received [89]. A mixer in a receiver (downconverting mixer) is often placed after the LNA because of the system noise consideration. On the other hand, an upconverting mixer is used in a transmitter and usually feeds the output signal to a PA and then to the antenna.

MMIC mixers can be classified as active mixers and passive mixers, depending on the bias conditions of mixing devices. Passive mixers use diodes or transistors in passive mode. An active mixer utilizes transistors or diodes operated in active region to perform frequency mixing, and has the advantage of conversion gain or low conversion loss, with a lower local oscillator (LO) power requirement. Mixers with special functions, such as for modulation applications and broad bandwidth, are also described in this section.

2.2.1. Passive Mixers

2.2.1.1. Diode mixers. The diode mixer is the most common MMW mixer, and a Schottky diode is usually used for its fast switching speed.

The most primitive mixer is the single-device mixer. Although it is simple and easy to implement, it requires filters at each I/O port to separate different frequencies and thus attain good port-to-port isolation. Balanced configurations are most frequently adopted to achieve port-to-port isolations, which use a coupler (or hybrid) to split one input signal into two with different phase (90° or 180°), and then perform frequency mixing at the devices, finally combining the mixed signals at the output port. Take the downconverting mixer, for example; the preprocessed

Table 3. TIAs with Operation Frequency to MMW Regime

Technology	Bandwidth (GHz)	Gain dB· Ω	Input Noise ^a (pA/ $\sqrt{\text{Hz}}$)	P_{DC} (mW)	Ref.
InP HBT	60	71	20	797	82
InP HBT	40	62.3	—	165	83

InP HEMT	52	52	—	520	88

^aEquivalent input noise current spectral density.

input (RF or LO) signals with opposite phases will cancel out at the output terminal (IF), and thus a satisfactory isolation will be achieved. The isolation between the RF and LO ports is determined by the hybrid under matched conditions. Another advantage of the balanced mixer is the suppression of certain spurious signals.

2.2.1.2. Singly Balanced Diode Mixers. The singly balanced mixer can be implemented with a 90° or 180° hybrid. A 90° hybrid singly balanced mixer is seldom adopted, since the LO-to-RF isolation is poor. The 180° hybrid singly balanced mixer is more frequently used, where one signal (either RF or LO) is applied at the devices in phase and the other is applied out of phase. If LO is applied out of phase, the LO power, along with AM noise and spurious signals on the LO, would cancel out. For a balanced diode mixer, the conversion loss is determined by the diode ON-state resistance, while the bandwidth is determined by the hybrid. A diode mixer with a wideband hybrid could have octave bandwidth. A CPW rat-race mixer using $0.18\text{-}\mu\text{m}$ GaAs MESFET process achieves a conversion loss of 14.7 dB at 3.5 dBm LO power [90].

2.2.1.3. Doubly Balanced Diode Mixers. For a doubly balanced mixer, both RF and LO signals are applied in opposite phase and would cancel out at IF. They possess numerous advantages, such as good isolation between all terminals and low-order spurious signal rejection. Nevertheless, they suffer low conversion gain (high conversion loss) and high LO power requirement. There exist “ring” and “star” configurations for doubly balanced mixers. The schematic of a ring mixer is shown in Fig. 11. Four diodes are connected as a ring, and LO, RF are applied at each node between diodes through a balance to unbalance transformer, or simply denoted as “balun,” which is indeed an 180° hybrid. Figure 12 shows the schematic of a star mixer. As the star mixer has no IF return inductors, it has lower series inductance at IF port and can demonstrate wider IF bandwidth [91].

2.2.1.4. Subharmonically Pumped (SHP) Mixers. In the MMW regime, it is sometimes expensive to use a fundamental frequency LO for a mixer. Furthermore, monolithic signal sources at such high frequencies may suffer from high phase noises and limited power level. A mixer using the harmonic signals of LO source in mixing is called a

Figure 12. Schematic of a doubly balanced star diode mixer (© 1993 IEEE) [91].

subharmonically pumped (SHP) mixer. For a SHP mixer, all the mixing frequencies are usually distant from each other and can be separated easily so that good isolation can be achieved. Balanced and subharmonically pumped configurations can be applied simultaneously to enhance performance. The output signal of a SHP mixer is produced by mixing the RF signal and high-order harmonics of a LO signal. A 94-GHz SHP mixer using antiparallel diode pair (APDP) has been reported. This mixer demonstrated a minimum conversion loss of 11.4 dB at a RF frequency of 94 GHz and a LO frequency of 23.5 GHz [92].

2.2.1.5. Resistive FET mixers. The resistive mixer is popular in the MMW regime [93]. The transistor is operated in passive mode as a variable resistor. Compared with the diode mixer, a resistive mixer demonstrates a compatible noise figure, conversion loss, and similar LO power requirement, with higher linearity and lower distortion [94,95]. Besides, no drain DC current is present, so less $1/f$ noise is generated and thus the noise performance is usually better than that of its active counterparts [96]. Singly balanced resistive mixers in different frequency bands have been reported [93]. RF signal is fed in the devices through two coupled-line filters to achieve low insertion loss and IF rejection. The capacitors and the transmission lines form a lowpass filter to ensure LO-to-IF and RF-to-IF rejection. The resistive mixers attained wide bandwidth with moderate conversion loss for a high-IF system, as summarized in Table 4 and Table 5.

2.2.2. Active FET (HEMT) mixers

2.2.2.1. Gate Mixer. The LO power is applied at gate to achieve a time-varying transconductance (g_m) at LO frequency. The RF signal is applied as small-signal voltage input at gate, and the resulting IF signal can be derived at drain. A W-band GaAs HEMT gate mixer has been reported [8]. The device is biased near pinchoff so that g_m can be maximized. Radial stubs are inserted as short circuits at RF/LO frequencies. With careful design, this method has achieved conversion gain with 2 dBm LO power.

2.2.2.2. Drain Mixer. The transistor is biased at the knee region of the DC IV curves, and a LO signal is

Figure 11. Schematic of a doubly balanced ring diode mixer (© 1993 IEEE) [91].

Table 4. Comparisons of Balanced Diode Mixers

	LO-to-RF Isolation	LO Power Requirement	IP3	Spur. Rejection
Single device	Filter dependent	Low	Low	None
Single balanced (180° hybrid)	Good	Moderate	Moderate	Good
Single balanced (90° hybrid)	Poor	Moderate	Moderate	Moderate
Doubly balanced	Good	High	High	Great

Source: Ref. 89.

applied at drain. A 60-GHz drain mixer using InGaP/InGaAs HEMT demonstrated a good noise performance of 3.16 dB at 58.5 GHz [103]. The mixer implemented the image rejection function with a 90° hybrid and a Wilkinson in-phase power divider. The complete downconverter, which consists of a four-stage LNA and the drain mixer, achieved a maximum conversion gain of 22.9 dB at RF of 61 GHz, and a minimum noise figure of 3.16 dB at RF of 58.5 GHz, with an LO power of 5 dBm.

2.2.2.3. Dual-Gate Mixer. A dual-gate mixer can be considered as a special gate mixer. The dual-gate device has two separate gates, and thus good LO-to-RF isolation can be achieved without extra couplers compared with the single-gate mixers [104,105]. Design of a dual-gate mixer beyond microwave frequency is rarely considered because of this mixer's notorious noise figure and the difficulty of device modeling. However, a MMW dual-gate mixer utilizing a GaAs HEMT process was reported [105]. The LO power is applied at the first gate (G1) so that the transconductance and output impedance of the second gate (G2) are modulated. The upper gate also operates as an IF amplifier. Since RF and LO are separated properly, the matching for each end (RF and LO) is easier. A compact die size can be achieved without the requirement of a coupler. This circuit showed a conversion gain of 3 dB with 5 dBm LO power and good RF return loss of better than 10 dB from 87 to 100 GHz. The RF-to-LO isolation is better than 17 dB.

2.2.3. Mixer for Modulator Application. The balanced mixers can be used for amplitude modulation (AM), binary phase shift keying (BPSK) modulation, and IQ modulation, due to their superior spur performance, linearity, and port-to-port isolation [97,98]. Most of them are composed of doubly balanced mixers or singly balanced mixers due to the isolation between LO and RF ports. This is important since an unwanted (spurious) carrier signal could

degrade modulation quality at high-level amplification, and also increase difficulty in demodulation.

Modulators based on the Gilbert cell or resistive ring architectures have been reported in the literature [99,100]. They featured good amplitude/phase match and LO rejection; however, most of them operated below 10 GHz. For MMW applications, the modulators can be based on a double-balanced diode mixer structure and show good amplitude/phase balance. However, they usually need a high LO drive power [97,98]. On the other hand, a balanced reflection-type phase shifter [9] can be used for the BPSK modulator, which utilized a Lange coupler as a 90° hybrid and two shunt cold-mode devices for switching. The cold-mode devices can be either HEMT [101] or HBT [102] devices, and can be operated to 110 GHz with good amplitude/phase match.

2.2.4. Wideband mixers

2.2.4.1. Gilbert Cell Mixer. Gilbert-cell active mixers basically consist of the RF differential transconductance pair and four-quadrant switching devices. An RF signal is transferred by the transconductance pair into switching devices and mixed via switching devices driven by the LO signal. Filters and/or matching networks could lead to the IF output port to enhance the mixer performance. Because of the differential LO/RF input and symmetry of transconductance pair, the Gilbert cell mixer has excellent LO/RF, LO/IF, and RF/IF isolation. Besides, owing to the RF transconductance amplification and IF restrengthening property, Gilbert cell mixers can achieve conversion gain in some frequency range. These advantages and compact chip size make Gilbert cell mixers very popular in wireless communication applications [106,107].

Gilbert cell mixers (Fig. 13) were not popular at high frequencies because of transistor parasitic capacitance and gain degradation. With the advanced device technologies and design techniques, there are a few examples have been reported in the MMW regime. A Gilbert cell mixer could have good conversion efficiency in the MMW

Table 5. Summary of the Reported Resistive Mixer

RF Frequency (GHz)	Conversion Loss (dB)	IF Frequency (GHz)	Spurious Signal Rejection	$P_{1\text{ dB}}$ (dBm)
Q band (42–56 GHz)	11.7	11	–35	4 (RF = 50 GHz)
V band (56–72 GHz)	12.8	18	–35	2 (RF = 60 GHz)
W band (72–84 GHz)	10.6	30	–30	–2 (RF = 77 GHz)

Figure 13. Basic Gilbert cell mixer structure.

range with proper RF matching, and it can also achieve very wide bandwidth (from DC to millimeter wave) with a lossy matching technique. The Gilbert cell configuration can also be used to design an analog multiplier; a 1–17-GHz Gilbert cell mixer and a multiplier have achieved a conversion gain of 9.3 dB [108]. Another distributed Gilbert cell analog multiplier using InP HEMT has –5 dB conversion gain from DC to 38 GHz [106].

2.2.4.2. Distributed Mixer. Wideband mixers can also be implemented using distributed configurations [109–111]. A 3–33-GHz distributed mixer using GaAs HEMT has been reported [109]. The RF and LO signals are applied at the gate and drain lines, respectively, and the IF signal is extracted via a lowpass filter. The mixer demonstrated a conversion loss of better than 4 dB from 3 to 33 GHz.

2.3. MMW Oscillators and Frequency Sources

A millimeter-wave (MMW) source is a key component in a transceiver system, especially for the applications of communication, radar, image, and remote sensing [112]. The typical requirements of a MMW oscillator are high reliability, low phase noise, and low cost. The frequency sources can be implemented via either simply designing fundamental oscillators or using lower-frequency oscillators with frequency multipliers. Applying the multiple-push approach is also an alternative for MMW frequency sources.

2.3.1. Design Considerations

2.3.1.1. Noise in Oscillators. There are three sources of noise in an oscillator: AM noise due to amplitude modulation, FM noise due to frequency modulation, and PM noise due to phase modulation by the noise sources. These noise modulations cause spectrum spread and degrade the phase noise performance of an oscillator. The primary noise sources in a MMIC oscillator are the $1/f$ noise and thermal noise.

Phase noise theory has been investigated [113,114]. In order to minimize the phase noise of an oscillator, the following should be considered in the design:

1. Maximize the unloaded Q factor of the resonator.
2. Select an active device with low noise figure and low flicker noise.
3. Use a low LC ratio and maximize the reactive energy.
4. Minimize the phase perturbation for the circuit design.

Off-chip high- Q components are usually applied to enhance phase noise performance, such as dielectric resonators (DRs) and varactors. Dielectric resonator oscillators (DROs) in the MMW regime exhibit excellent phase noise performance and temperature stability because of the extremely high Q factor and good temperature coefficient of DR.

2.3.1.2. Fundamental Oscillators. The fundamental frequency oscillator is the simplest approach for the MMW frequency source, but has drawbacks of low Q factor and insufficient device gain at the MMW regime. The oscillation frequency is limited by the figure of merit f_{max} of the transistor.

2.3.1.3. Oscillator and Frequency Multiplier Chain. An MMW source can be composed of a lower-frequency oscillator and frequency multipliers to obtain desired frequencies. There are several advantages to this approach. It is easier to achieve low phase noise for an oscillator operating at lower frequency. Also, a wider bandwidth can be achieved because of the frequency multiplication. Several MMW frequency sources have been reported using MMIC technology, including lower-frequency fundamental oscillators and frequency multipliers [115,116]. Figure 14

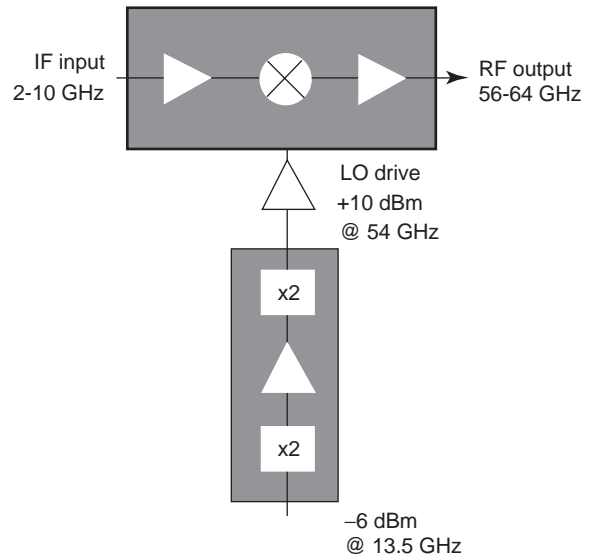

Figure 14. Block diagram of the V-band up-converter with the LO chain consisting of lower-frequency fundamental oscillator and frequency multipliers (© 1994 IEEE) [115].

shows a block diagram of the V-band up-converter with the LO chain consisting of lower-frequency fundamental oscillator and frequency multipliers.

2.3.1.4. Multiple-Push Oscillator. A push–push (or double-push) oscillator design consists of two fundamental frequency oscillators operating at half of the desired output frequency. Also, the higher- Q -factor resonator and sufficient device gain are easily obtained at half of the output frequency. The push–push oscillators have been reported in MMW range [117,118], with phase noises of -88 and -109 dBc/Hz achieved at 1- and 10-MHz offsets, respectively. A novel coupling method for push–push DRO, although it is a hybrid circuit, demonstrated excellent spectral purity at 40 GHz, output power, and phase noise of about -100 dBc/Hz at 100-kHz offset [119].

The triple-push oscillator approach, extending from the push–push oscillator, has been proposed [121]. Figure 15 shows the chip photo of a 28.4-GHz HBT MMIC triple-push oscillator. It consists of three identical fundamental oscillators with a phase shift of 120° among three odd-mode fundamental signals. The fundamental and the second-harmonic signals cancel out altogether, and the desired third harmonic signals combine in phase. Consequently, a triple-push oscillator can extend the usable frequency range and obtain high- Q -factor resonance more easily than can a push–push oscillator. Multiple-push ($n > 3$) oscillators can operate with a similar principle [120]. Ka- and Q-band MMIC triple- and quadruple-push oscillators have also been reported [121–124].

2.3.2. Device Technologies for Oscillators. HEMT has dominated the MMW MMIC designs because of its high f_T and f_{max} , as well as superior low noise figure. The MMIC fundamental frequency oscillator implemented using GaAs-based PHEMTs demonstrated W-band (~ 90 GHz) oscillations with phase noise of -90 dBc/Hz at 1-MHz offset [125]. Monolithic oscillators using InP-based HEMTs were also reported above 100 GHz [126,127].

Figure 15. Chip photo of the 28.4-GHz HBT MMIC triple-push oscillator (© 2001 IEEE) [121].

Figure 16. Schematic of the 150-GHz SiGe HBT push–push oscillator (© 2003 IEEE) [135].

For low-phase-noise applications, HBT is the preferred because of its superior $1/f$ noise characteristics. To date, the highest-frequency oscillator using GaAs HBT was reported by Uchida et al. [128] with 106 GHz output and -88 dBc/Hz phase noise at 1-MHz offset. On the other hand, InP-based HBTs exhibit even lower $1/f$ noise than do GaAs HBTs because of the lower surface recombination velocity in InP-based materials and the absence of DX center in the emitter. InP-based HBT VCOs demonstrated impressive high-frequency performance [116,129], with -65 dBc/Hz phase noise at 1-MHz offset of 150 GHz operation frequency [116]. Also, a superior phase noise of -95 dBc/Hz for 1-MHz offset at 104 GHz oscillation has been reported [130].

As for silicon-based (CMOS and SiGe HBT) technologies, the fundamental frequency CMOS VCOs were achieved to 50 GHz with a phase noise of -85 dBc/Hz at 1-MHz offset [131,132]. Using push–push topology, a CMOS VCO achieved a measured output power of -4 dBm, a tuning range of 2.5 GHz, and a phase noise of -85 dBc/Hz at 1-MHz offset without any output amplifier in a commercial $0.25\text{-}\mu\text{m}$ CMOS process [216]. Fully integrated MMW MMIC oscillators using SiGe HBTs were also reported operated at 50 GHz with phase noise between -103 and -110 dBc/Hz at 1-MHz offset [133,134]. A SiGe push–push VCO with a phase noise of -85 dBc/Hz at 1-MHz offset and operating up to 150 GHz has been reported [135]. The schematic is shown in Fig. 16.

2.4. Frequency Multipliers

A frequency multiplier is a component used to generate the harmonic signal of the input signal. The conversion loss, which is the power ratio of the desired output harmonic signal to the input fundamental signal, reveals the efficiency of the multiplier. Beside the conversion loss, the

Table 6. Features and Performance of Reported Passive and Active Multipliers

^aA—active mode; P—passive mode.

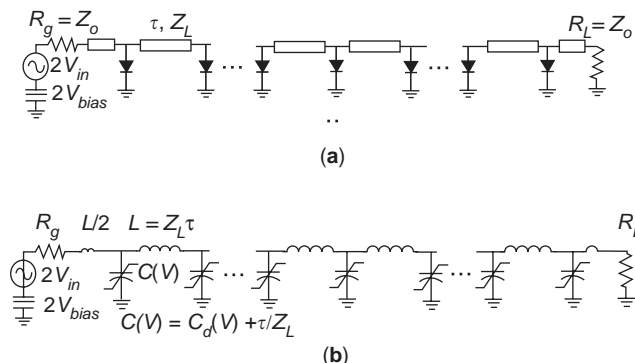

Figure 17. (a) Schematic and (b) LC ladder network equivalent circuit of the nonlinear transmission line (© 1996 IEEE) [145].

port return losses and harmonic rejections are also important design considerations. All the frequency multipliers degrade the phase noise by at least $20 \log(n)$ dB, where n is the multiple number [136].

Doublers and triplers are mostly used. Higher-harmonic multipliers are seldom found because of the low power level of harmonic signals. Although there exist quadruplers and higher-order multipliers using single transistor, the multipliers are often composed of two cascaded doublers or triplers with buffer amplifiers [137–139].

In designing multipliers, the type of device determines the performance of the multiplier. Basically, active multipliers feature better conversion loss and even better ability to achieve conversion gain, while passive multipliers, although lossy, can be made very broadband, such as the multipliers using Schottky barrier diodes. As shown in Table 6, while passive multipliers achieve broadband performance, active ones yield conversion gains within narrowband frequency.

Passive multipliers are probably the most practical in modern microwave and RF systems because of their bandwidth [140–142]. Popular structures for passive doublers are single-ended and balanced configurations. The passive triplers are usually implemented by using an antiparallel

diode pair (APDP) due to the odd harmonics, which are combined in phase while the even harmonics are canceled out [141,142].

Multipliers utilizing nonlinear transmission lines (NLTLs) and distributed varactors feature broad bandwidth. Figure 17 shows the schematic and LC ladder network equivalent circuit of the nonlinear transmission line. The NLTL doubler demonstrates 6.6 dB conversion loss in the 3 dB bandwidth 52–63.1 GHz, and a NLTL tripler with 11.2 dB conversion loss in the 3 dB bandwidth at 81–109 GHz [145].

As mentioned, active multipliers can yield conversion gain within a narrow band. Most of them have the conversion loss of better than 5 dB [143,144,146–150]. Broad bandwidth can also be achieved with the tradeoff of conversion gain. Table 7 lists the features and performance of reported active broadband multipliers.

The most practical way to design an active multiplier is with the balanced structure, providing good fundamental and odd-harmonic rejections. It contains two FETs and an input balun or a 180° hybrid. Basically, it can be used only for even-harmonic multipliers and is most suitable for doublers. However, a modified balanced structure using Lange couplers for the tripler as shown in Fig. 18 has been reported [154]. The third-harmonic signal will add in phase at the output port with suppression of the unwanted harmonics. Also, broadband active multipliers can be implemented using distributed configurations [155]. Single-device structure is generally used for a compact chip size and features good efficiencies, although fundamental-frequency leakage can be a problem [143,144].

2.5. RF Switches

Switches are important components that control the signal flow in communication systems. Transmit/receive (TR) switches are components directly connected the low-noise amplifiers and power amplifiers in the TR modules. Two major design parameters for a switch are minimum insertion loss in the ON state and maximum isolation in the OFF

Table 7. Features and Performance of Reported Active Broadband Multipliers

Multiplier	Frequency (GHz)	Process	Approach	Conversion Loss (dB)	Ref.
Doubler	V band	GaAs	Balanced	8.5–11.38	151
Doubler	2–40	—	Balanced	10 ± 1.5	152
Doubler	50–68	GaAs	Balanced	5.5 ± 2.5	153
Tripler	42–51	GaAs	Balanced	11.1–17.6	154

state. Power-handling capability is another important design consideration.

2.5.1. MEMS switch. Microelectromechanical system (MEMS) switches are operated by using mechanical movement to achieve a short circuit or an open circuit. The force required for mechanical movement is obtained by electrostatic means. MEMS switches have demonstrated excellent switching performance in MMW frequency range due to very small parasitic effect [156–159]. The DC power consumption of the MEMS switch is almost zero, but a high drive voltage (20–80 V) is required. Few MEMS switches can handle power more than 20–50 mW. MEMS switches need to be packaged in inert atmospheres (nitrogen, argon) and low humidity, so the packaging costs are very high [160]. Most of the reported MEMS switches are of single-pole single-throw (SPST) configuration and have demonstrated isolation of better than 30 dB [157–159].

2.5.2. Pin Diode Switch. The p-type-insulator-n type (pin) diode is widely used for MMW switch design because of its low insertion loss, high isolation, and high power-handling capability [161–165]. Because pin diodes will consume DC current when the diodes are in the ON state, pin diode switches require DC blocking capacitors and biased network, such as RF choke or quarter-wavelength short stub. Compared with MEMS switches and passive FET switches, pin diode switches have demonstrated the best power-handling capability. For example, the SPDT (single-pole double-throw) switch provided by Skyworks Inc. achieves watt-level power-handling capability [165].

2.5.3. Passive HEMT Switch. Since the pin diode and MEMS processes are not compatible with the HEMT MMIC process, the passive HEMT (or FET) switches are still very popular because of their integrability with other major building blocks in a MMW TR module, which are fabricated mostly using the HEMT MMIC process. For frequencies of 20 GHz or lower, series and/or shunt configurations of passive FET can readily serve as very good switches with excellent isolation and insertion loss results demonstrated in two studies [166,167]. However, at higher frequencies, the parasitic capacitor will significantly

degrade the isolation performance of a series switch and the insertion loss of a shunt switch. Several methods to improve switching characteristics of the passive FET switches were reported [168–173].

2.5.3.1. Parallel Resonant Technique. Because the parasitic drain-to-source capacitor degrades the switch performance significantly in the high-frequency range, the parallel-inductor resonant technique is widely used to compensate the parasitic capacitor of OFF-state FET. Because the impedance of OFF-state capacitors become low in high frequency, a small inductor is placed between the drain and the source of the transistor to resonate out the OFF-state capacitor. In general, the small inductor is implemented by a high-impedance transmission line. The OFF-state FET and the parallel inductor are used to form a parallel resonator, and this resonator represents high impedance around the resonant frequency. The ON-state FET with a parallel inductor still represents low impedance. The parallel resonant technique can improve the isolation of the series switches and insertion loss of the shunt switches. A W-band SPST series switch employing the parallel resonant inductor demonstrated 1.6 dB insertion loss and 22.5 dB isolation at 94 GHz [168].

2.5.3.2. Impedance Transformation. This method utilizes impedance transformation to compensate the drain-to-source capacitance of the OFF-state passive HEMT switches. As shown in Fig. 19, the ON- and OFF-state impedances of the passive HEMT are transformed to near open circuit and near short circuit simultaneously by an impedance transformation. By using this concept, a Q-band SPDT switch demonstrated a measured isolation better than 30 dB and 2 dB insertion loss from 38 to 45 GHz, while a V-band switch has a measured isolation better than 30 dB and 4 dB insertion loss from 53 to 61 GHz [169].

2.5.3.3. Traveling-Wave (Distributed) Concept. The traveling-wave concept was also proposed for wide band

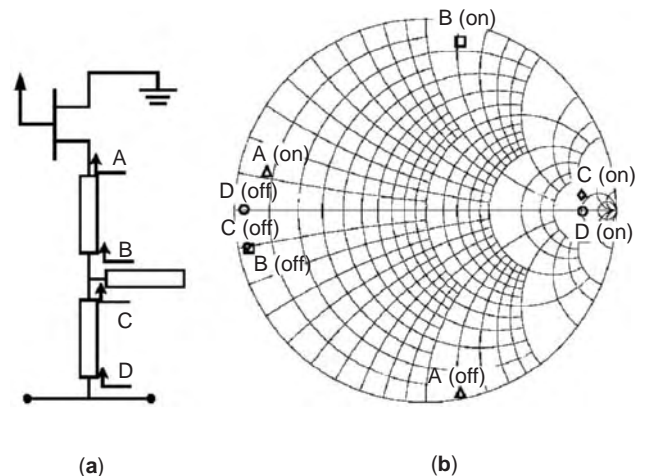

Figure 19. (a) Schematic of a FET connected in series with the impedance transformation network; (b) input impedances looking into points A, B, C, D of the passive switch with impedance transformation network.

Figure 20. Schematic of the SPST traveling-wave switch.

switch design. A traveling-wave switch consists of a finite numbers of series inductors and shunt FETs as shown in Fig. 20. The series inductors are usually implemented with high-impedance transmission lines, and the OFF-state transistors can be simplified as a small capacitor. The complete traveling-wave switch represents as a 50- Ω artificial transmission line while the FETs are at OFF state. The switches using the traveling-wave concept manifest broadband characteristics. A DC–40-GHz SPDT switch demonstrated 3 dB insertion loss and 23 dB isolation [170], and a 15–80-GHz SPDT switch using a quarter-wavelength transformer has an insertion of lower than 3.6 dB and an isolation of better than 25 dB [171].

2.5.3.4. Special Process. By employing the ohmic electrode-sharing technology (OEST), no interconnect lines are needed between the FETs because an ohmic electrode is shared by the source of one FET and the drain of another FET. The DC–40 GHz SPDT switches demonstrated 3.5 dB insertion loss and 25.5 dB isolation at 40 GHz, while the SPST switch has an insertion loss of better than 1.64 dB and an isolation of better than 20.6 dB from DC to 60 GHz [172].

The distributed FET has a single gate, with input/output ports connected to the drain electrode of the FET, and the source terminal connected to several via holes. The structure of an SPST switch using distributed FET is shown in Fig. 21. The small-signal characteristics of this switch were expressed by a lossless transmission-line model while the FET is pinched off, and a lossy transmission-line model while the FET is in ON state. A DC–110-GHz SPST switch using the distributed FET has shown an insertion loss of lower than 2.55 dB and an isolation of better than 22.2 dB [173].

2.6. Phase Shifter

A phase shifter is a device that changes the phase of a signal. Classified by the type of phase control, phase shifters can be divided into groups of analog and digital phase

Figure 21. Structure of SPST switch using distributed FET (© 2000 IEEE) [173].

shifters, in which the phase shifts are, respectively, continuous and discrete. The most essential design parameter of a phase shifter is the shift of the phase, that is, the difference between the phases of the output signal and the input signal. Insertion loss is also important for passive shifters. For a digital phase shifter, limits must also be imposed on its phase error, which is a measure of the extent to which the actual phase shift deviates from the desired or ideal phase shift.

The analog phase shifter has the advantage of continuous phase shift and thus can be adjusted to achieve precise phase shift. The reflective-type phase shifter (RTPS), which contains a 3-dB 90° coupler and varactor diodes (or MEMS capacitors), often has low insertion loss and low sensitivity on temperature and process variation [174]. Another kind of phase shifter employs the concept of vector sum as shown in Fig. 22 [175], which does not depend on varactor diodes in its phase shift mechanism and therefore its shift range will not be limited by the tuning range of the varactor diodes. A vector sum phase shifter may utilize either variable attenuators or variable-gain amplifiers for its gain control. The distributed phase shifter utilizing a varactor-tuned transmission line is also a popular approach. The phase shift is achieved by changing the phase velocity of the varactor-tuned transmission line. The varactor can be implemented by either diodes [176] or MEMS capacitors [177], and thus the phase shift is achieved. There still exist other design concepts such as tunable phase shifter [178], but they are rarely found.

Digital phase shifters use binary-represented control signals. An n -bit digitally controlled phase shifter has n phase shift blocks and 2^n states; thus the phase shift precision is $360^\circ/2^n$. There are two paths in a phase shift unit. A switching mechanism is applied to determine the direction in which the way the signal will pass, while the relative phase difference between the two paths is the phase shift of that phase shift unit. The phase-shifting path may be implemented with either filters [179] or delay lines [180], depending on the operating frequency of the circuits. The vector sum concept has also been applied to the design of a digitally controlled phase shifter [181]. There is also a digital RTPS, in which the termination is discretely tuned. Figure 23 shows a schematic and chip photo [182].

Combination of analog-controlled and digitally controlled phase shifters has been attempted [181]. The phase shift is first roughly achieved by a digitally controlled phase shifter and then fine-tuned by an analog-controlled phase shifter. This architecture alleviates the difficulty of designing analog phase shifter with a large phase shift. It has been shown to significantly reduce the required phase shift of an analog-controlled phase shifter while still achieving 360° of phase control. The drawback is large chip size when all the components are integrated into a single chip.

In the MMW regime, a DC–60-GHz distributed MEMS phase shifter has demonstrated a capability of a 360° phase shifter with an insertion loss of 5.1 dB at 40 GHz and 4 dB at 60 GHz, respectively [183]. Also, a 60–110-GHz MEMS phase shifter features a figure of merit of the ratio for tuning phase range over an insertion loss of 70°/dB

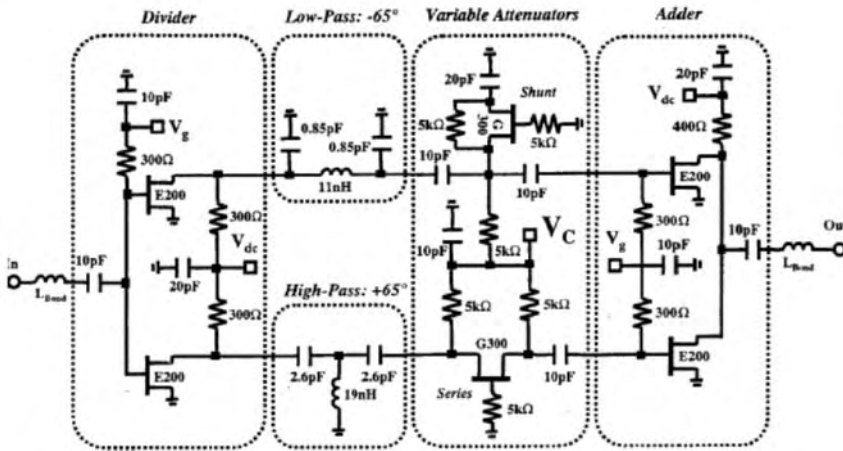

Figure 22. Schematic of the vector modulator-based phase shifter (© 2002 IEEE) [175].

from 60 to 110 GHz [184]. Monolithic phase shifters have been operated up to 100 GHz with switching times well under 1 μs [185]. The RTPS can also be implemented in the MMW regime with broadband couplers. The HEMT-based monolithic RTPS were reported in Ref. 186, while the HBT-based can be found in Ref. 187.

2.7. Multifunction MMICs and System Applications

The advancement of MMIC technology not only improves the existing system performance but also enables new system applications. A multifunction MMIC incorporates several single-function circuits onto a single chip. Although many individual components can be integrated onto a single chip, the level of integration heavily depends on the maturity of MMIC process and circuit design. A typical example is a transceiver chip, which usually includes a LNA and a downconverting mixer for the receiving end and an upconverting mixer, and a PA for the transmitting end. Sometimes the VCO and frequency multipliers could also be included as the LO chain. Since there are too many configurations for multifunction MMICs, we introduce only a few examples for MMW applications in this article.

2.7.1. Single-Chip Radar Transceiver for Automotive Radar Application.

The forward collision warning (FCW) and autonomous intelligent cruise control (AICC) radars are forward-looking automotive radars (FLARs) that require a sensor range of about 100 m. The FCW radar will detect potential forward collision situations and provide a warning to the driver, while the AICC will operate in an autonomous control loop to maintain a continuous safe following distance.

Cost and hardware size are two dominant factors, in addition to the performance requirement for all-weather conditions that drive the technology for automotive radars. MMW radars have the advantages of small hardware size and high range resolution over the microwave radars. They can also be operated in the so-called all-weather conditions, such as in rains and fogs, thus outperforming the infrared systems. Low cost is the key factor for consumers in accepting the radar as an affordable safety component of their vehicles. The size constraint is also essential for integration of the radar onto the vehicle without major impact on vehicle design and performance. Several W-band TR MMICs, including single multifunction chips and chipsets, were developed for FLAR and/or other automotive applications [188–192].

As an example, the block diagram of the single-chip W-band FMCW transceiver is shown in Fig. 24 [188]. This transceiver chip consists of a VCO, a PA, a mixer, and an LNA. Transmit and receive channels used separate

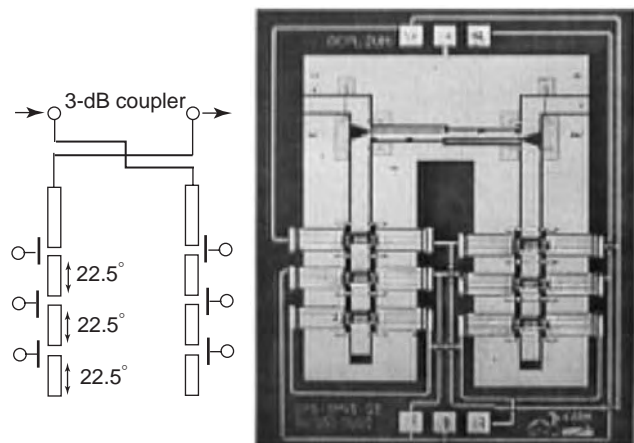

Figure 23. Schematic and photograph of 2-bit reflection-type MEMS phase shifter (© 2002 IEEE) [182].

Figure 24. Block diagram of the single chip W-band FMCW transceiver (© 1995 IEEE) [188].

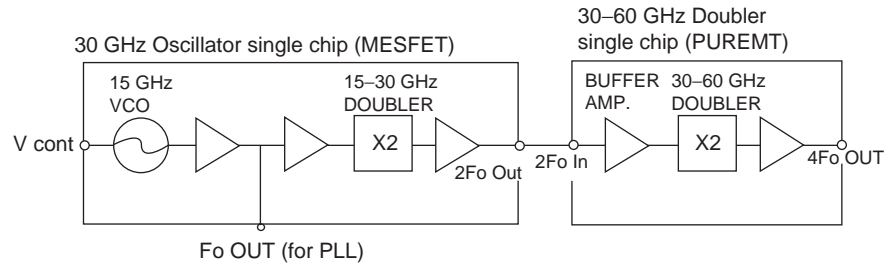

Figure 25. Block diagram of the MMIC LO chipset [196].

antennas for better isolation. An FCW signal was generated from the VCO and fed to the transmit amplifiers. A portion of the transmit power was coupled back to the receiving channel and used as an LO source for the mixer. The transmitter had more than 10 dBm output power with a tuning range of 500 MHz around 92.5 GHz. The receiving chain had a conversion gain of 9 dB. However, the receiving noise figure was higher than 20 dB for IF less than 10 MHz because of the flicker noise of the gate-HEMT diode mixer. This might impact the system sensitivity for the homodyne FCW operation for an object at a long range. A number of W-band transceiver architectures have been investigated to improve the sensitivity [191,192].

2.7.2. Passive Imaging Application. The interest in MMW imaging is due primarily to its capability of imaging through fog, cloud, smoke, sandstorms, and darkness. Owing to lack of MMW components, MMW imaging arrays typically were previously based on the heterodyne approach and relied on a front-end mixer to convert an incoming signal to low frequency for signal processing. This approach not only suffers from high conversion loss and high noise figure but also requires complicated LO signal generation and distribution. The LO problem is aggravated as imaging array size increases. An alternative approach is to employ a direct-detection architecture, which requires a high gain LNA and a detector circuit. This approach has the advantages of no LO requirement, low DC power consumption, fewer parts, and low cost. These advantages become even more pronounced in focal plane staring array systems. Owing to advances in MMW MMIC technology, the direct-detection imaging receiver was developed because of the enabling MMIC components, in particular, the high-gain LNA, and thus the simple direct-detection approach became feasible. A W-band monolithic integrated seven-stage LNA and detector on a single chip was developed [193]. The LNA has a linear gain of 34 dB from 92 to 96 GHz with a noise figure of 4 dB. The complete monolithic chip was tested via on-wafer probing with a W-band noise source as the input signal and showed a net output of 10 mV between the noise source in ON and OFF states. This chip has been successfully implemented in a real-time MMW imaging system to facilitate aircraft landing in inclement weather [194,195].

2.7.3. MMIC Chipset for a V-Band Phase-Locked Local Oscillator. A local oscillator is essential in all microwave and MMW communication systems for frequency conversion. Many systems also require a voltage-controlled oscillator for precise and fast frequency synthesis. As

demand increases for higher data transmission speeds, the radiofrequency must be increased and the MMW local oscillator will be more important.

A V-band fully monolithic voltage controlled LO chipset has been developed to realize a MMW synthesizer [196]. The chipset is composed of a highly integrated multifunction MMIC for 15 GHz voltage-controlled oscillation and 15–30-GHz frequency doubling, and a 30–60-GHz frequency doubler. A block diagram of the MMIC LO chipset is shown in Fig. 25. The 30-GHz oscillator chip was fabricated with a 0.3- μm ion-planted MESFET process. The chip includes a 15-GHz VCO, a 15–30-GHz balanced frequency doubler, and an output amplifier. Output of the 15-GHz VCO is amplified by a dual-output amplifier. One of the two amplifier outputs is for a phase-locked loop (PLL), and the other is fed to a 15–30-GHz frequency doubler. The other chip, a 30–60-GHz doubler, was fabricated with the 0.1- μm pseudomorphic AlGaAs/InGaAs/GaAs HEMT process. It includes a buffer amplifier, a 30–60-GHz frequency doubler, and a 60-GHz amplifier. The buffer amplifier is essential since the output impedance of the frequency doubler changes significantly with the frequency of the input signal. Each circuit is greatly reduced in size by using the uniplanar structure. Output power of 3.5 ± 1.5 dBm and tuning performance of 55.6–60.3 GHz with SSB phase noise of less than -80 dBc/Hz at 1-MHz offset were achieved. The chip set allows a small and simple MMW synthesizer to be realized.

2.7.4. Ka-Band Transceiver for BCIS System. The objective of the battlefield combat identification system (BCIS) is to provide quick and positive target identification, either friendly or unknown, without any additional impact to the platform operators [197]. The shooter platforms would be equipped with an interrogator/transponder set, while the armored personnel carrier would only have the transponder unit. The BCIS is initiated by the shooter platform by simply pointing the interrogator antenna and transmitting a Ka-band spread-spectrum signal to the potential target. If the potential target is also equipped with the BCIS set, it would then receive the interrogation signal and respond to the query with the requester's and its own identification through the transponder unit. The shooter platform validates the returned transponder message and determines whether it is friendly or unknown. The entire query-response process takes less than one second.

The Ka-band transceiver unit is the key unit in the BCIS equipment set. The transceiver module was developed using a total of 13 GaAs MMIC chips [197]. Later

Figure 26. Schematic of the quasioptical integrated antenna-receiver front end (© 2003 IEEE) [217].

most of the HEMT chips were replaced by multifunction transceiver chips [198,199].

2.7.5. HEMT and HBT MMIC Integration. Monolithic integration of HEMT and HBT is attractive since it allows circuit designers to take the advantages of the features of each device. Both GaAs- and InP-based HEMT-HBT integration using selective regrowth of HEMT islands on patterned and etched HBT materials have been reported [200,201]. A few examples of MMW multifunction MMICs based on the InP HEMT-HBT integration process have been demonstrated. One of them is a single-chip 94-GHz frequency source, which includes a 23.5-GHz HBT VCO and a buffer amplifier, followed by a 23.5–94-GHz HEMT quadrupler composed of a 23.5–47-GHz doubler, a 47-GHz buffer amplifier, and a 47–94-GHz doubler [202]. The other is a 94-GHz HEMT low-noise amplifier with HBT bias regulation [203].

2.7.6. V-Band Integrated Antenna-Receiver Front End. A V-band GaAs HEMT monolithic integrated antenna-receiver front end has been developed [217]. This chip consists of a folded-slot antenna integrated with a singly balanced diode mixer, a voltage-controlled oscillator, a CPW-to-slotline transition, and a lowpass filter. Figure 26 shows the complete schematic of the quasioptical integrated antenna-receiver front end. It demonstrates a 15 dB single-sideband isotropic conversion loss.

Acknowledgement

The authors would like to thank Chia-Chi Chang, Shih-Fone Chao, Po-An Chen, Kuo-Liang Deng, Jia-Shiang Fu, Ping-Chen Huang, Ming-Fong Lei, Chin-Shen Lin, Chong-Liang Lin, Zhi-Wei Ling, Shih-Chieh Shin, Zou-Min Tsai, Chi-Hsueh Wang, and Mei-Chao Yeh of National Taiwan University for their help in the literature survey. Thanks also go to Professors Liang-Hung Lu, Shey-Shi Lu, Tian-Wei Huang of the Department of Electrical Engineering, National Taiwan University for their discussions and suggestions.

The millimeter-wavelength spectral band covers the frequency range 30 GHz ($\lambda = 10$ mm) to 300 GHz ($\lambda = 1$ mm). In the larger view, it can include a part of the submillimeter band: the extended range up to 1 THz ($\lambda = 0.3$ mm), which represents one of the least explored portions of the electromagnetic spectrum. The frontier between the millimeter–submillimeter region and the far-infrared region is arbitrary and variable. The distinction comes mainly from the detection techniques employed (coherent or incoherent detection). The millimeter spectrum is presented in Fig. 1.

In the microwave domain, the atmosphere is transparent to frequencies up to 40 GHz except for a weak water vapor absorption line at 22 GHz. However, in the millimeter domain, there are several strong absorption lines: (1) a large and complex set of oxygen lines around 55–60 GHz, (2) a single oxygen line around 119 GHz, and (3) a water vapor line around 183 GHz. Above 300 GHz, several absorption lines exist, mainly due to the water vapor. The spectral region located in between these lines, currently called “windows,” is decreasingly transparent when the frequency increases.

Millimeter waves offer a solution to the increasing demand in frequency allocation due to the low-frequency-band saturation and the requirement for higher data rates. Moreover, a high directivity can be obtained with small antennas associated with small-sized circuits that become more easily integrable. Applications are numerous, ranging from mobile communications, local-area

The millimeter-wavelength spectral band covers the frequency range 30 GHz ($\lambda = 10$ mm) to 300 GHz ($\lambda = 1$ mm). In the larger view, it can include a part of the submillimeter band: the extended range up to 1 THz ($\lambda = 0.3$ mm), which represents one of the least explored portions of the electromagnetic spectrum. The frontier between the millimeter–submillimeter region and the far-infrared region is arbitrary and variable. The distinction comes mainly from the detection techniques employed (coherent or incoherent detection). The millimeter spectrum is presented in Fig. 1.

In the microwave domain, the atmosphere is transparent to frequencies up to 40 GHz except for a weak water vapor absorption line at 22 GHz. However, in the millimeter domain, there are several strong absorption lines: (1) a large and complex set of oxygen lines around 55–60 GHz, (2) a single oxygen line around 119 GHz, and (3) a water vapor line around 183 GHz. Above 300 GHz, several absorption lines exist, mainly due to the water vapor. The spectral region located in between these lines, currently called “windows,” is decreasingly transparent when the frequency increases.

Millimeter waves offer a solution to the increasing demand in frequency allocation due to the low-frequency-band saturation and the requirement for higher data rates. Moreover, a high directivity can be obtained with small antennas associated with small-sized circuits that become more easily integrable. Applications are numerous, ranging from mobile communications, local-area

Figure 1. Atmospheric transmission in the millimeter domain.

networks, and collision avoidance radars to satellite communications, radio astronomy, radio altimetry, and robotics.

In the millimeter-wave range up to 100 GHz, the equipment and methods of measurement have been extended from the microwave domain. The major problems in the millimeter field are due to the small size of the devices and the transmission line losses. Above 100 GHz, as an alternative, other equipment and methods of measurement, using a quasi-optic setup, have been developed or adapted from far-infrared techniques (dielectric waveguide cavity resonator, free-space methods).

1. MILLIMETER-WAVE AUTOMATIC NETWORK ANALYZER

As all other types of automatic network analyzer (ANA), the millimeter-wave automatic network analyzer (MWANA) measures magnitudes and phases of scattering parameters (S parameters) of the device under test (DUT).

1.1. Main Types of MWANA

1.1.1. Broadband Coaxial Systems. In this group, single or multiple synthesized sweeper network analyzers are commercially available [1]. The single synthesized source systems perform S -parameter measurements up to 50 GHz using 2.4 mm coaxial accessories, and up to 67 GHz using 1.85 mm coaxial elements (V connectors). The multiple synthesized sources system may cover the 40 MHz to 110 GHz frequency range using 1 mm coaxial elements (W connectors).

1.1.2. Rectangular Waveguide Systems. These network analyzers perform S -parameter measurements in Q (33–50 GHz), U (40–60 GHz), V (50–75 GHz), and W (75 “to” 110 GHz) frequency ranges; the rectangular waveguide standards are WR-22, WR-19, WR-15, and WR-10, respectively.

In the multiple-source network analyzer, one synthesized source provides the radiofrequency (RF) (stimulus) signal and the second provides the local-oscillator (LO) signal. Figure 2 shows a simplified block diagram of this system common to all waveguide bands. This system consists of a conventional network analyzer, two microwave sources (RF and LO), and a pair of band-dependent millimeter-wave test set modules covering the frequency bands given above. The RF signal after amplification is routed to the port 1 test set module for forward measurements (S_{11} and S_{21}) or to the port 2 test set module for reverse measurements (S_{22} and S_{12}). Components in the millimeter-wave test set module provide frequency multiplication, signal separation to sample incident, reflected and transmitted signals, and the harmonic mixers to accomplish the intermediate frequency (IF) conversion (generally first IF) to some MHz (e.g., 20 MHz). The second source provides the LO for the four harmonic mixers. This LO source is set such that the millimeter-wave RF test signal frequency and the appropriate LO harmonic are offset by exactly the IF (e.g., 20 MHz). For instance, in the case of the HP8510C MWANA [1] with V-band millimeter-wave test set modules, the frequency of the two microwave sources (RF and LO) can be expressed as follows

$$\text{RF} = \frac{F_{\text{op}}}{4} \quad \text{and} \quad \text{LO} = \frac{(F_{\text{op}} + 20 \text{ MHz})}{14}$$

where F_{op} is the operating frequency.

As compared with a single-source network analyzer (coaxial), the rectangular waveguide system has inherent drawbacks. Indeed the power of the RF signal injected to the DUT cannot be controlled due to the frequency multiplication. This power may be close to 0 dBm (1 mW on 50-W system) and may be more dependent on the frequency band. This feature may induce nonlinear phenomena (compression, distortion) when the DUT is an active device (transistor, amplifier, etc.). Moreover, reactive impedance of a rectangular waveguide below its cutoff frequency may allow instability of the active DUT.

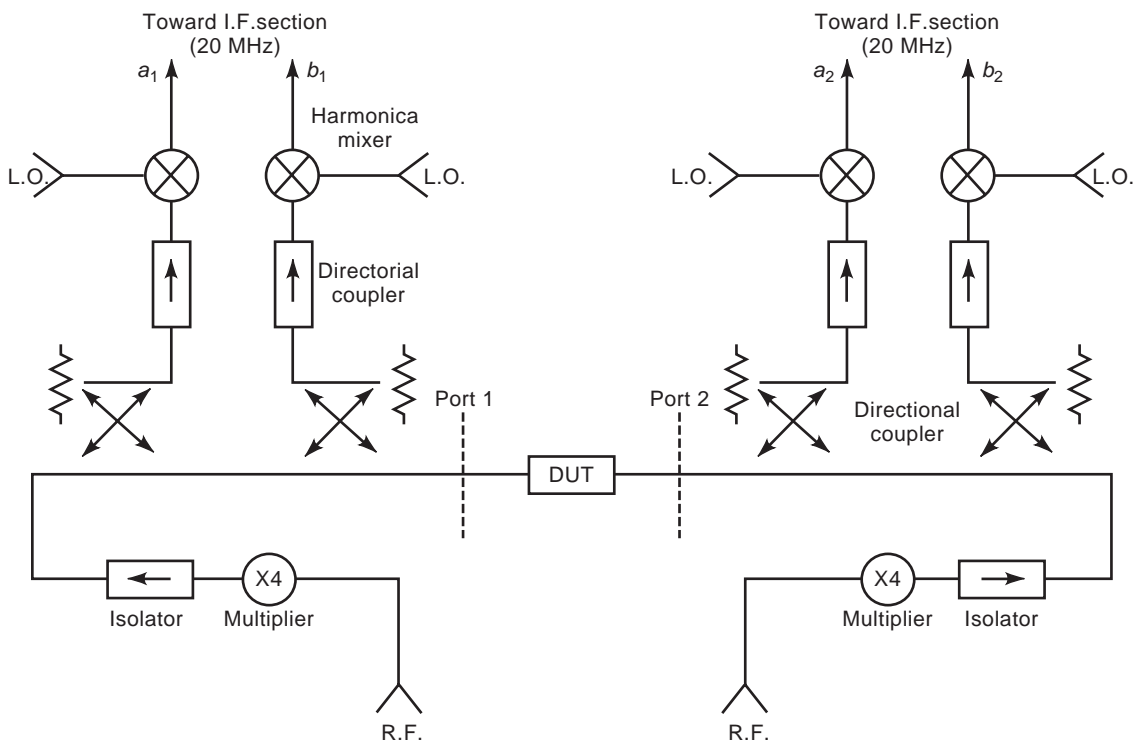

Figure 2. Simplified synopsis of a MWANA test set, for an HP85106D V-band system (50–75 GHz).

1.2. Dynamic Range of Millimeter-Wave Automatic Network Analyzer

Dynamic range, which is the key consideration in most measurement systems, relates to the ability of a receiver to accurately detect a signal over a large amplitude range. The largest input signal is usually limited by compression in the input receiver, while the smallest ones that can be detected are limited by the noise floor and other undesirable signals. Dynamic range can be improved by increasing the number of measurement averages and changing video IF bandwidth. Table 1 summarizes the dynamic range of HP8510C for transmission measurements as function of the frequency band.

1.3. On-Wafer Probing System

Commercially available coplanar probes cover the full millimeter-wave band [2]. On-wafer probing in millimeter-wave measurement is by far the most precise technique, due to (1) better positioning and (2) better contact

repeatability. For millimeter-wave measurement, only ground–signal–ground (G–S–G) topology is useful, since fundamental modes must only be excited at the probe tip. There are mainly two types of coplanar probes: coaxial-to-coplanar probe tips and wave-guide-to-coplanar probe tips. The former one uses the internal MWANA test set bias tee, while the latter one may include a direct-current (DC) bias tee inside the probe (Fig. 3). Typical values for return loss and insertion loss are, respectively, within 10–15 dB and 1–2 dB [2]. The connection between the probe and the test set port must be kept as short as possible, and the millimeter-wave coaxial cable may easily add several decibels to the insertion loss.

1.4. Specific On-Wafer Calibration Technique

High-precision measurement relies on careful reference plane definition and on-chip parasitic access determination [4]. Reference plane definition strongly correlates with the calibration used. For SOLT (short, open, load, and through standards) calibration, the reference plane is

Table 1. Dynamic Range of HP8510C for Transmission Measurements as a Function of the Frequency Band

Frequency range (GHz)	38–50	40–60	50–75	75–110
Maximum power measured at port 2, nominal value	+12 dBm	+10 dBm	+10 dBm	0 dBm
Reference power at port 1, nominal value	0 dBm	0 dBm	0 dBm	–3 dBm
Minimum power measured at port 2	–87 dBm	–87 dBm	–75 dBm	–79 dBm
Receiver dynamic range ^a	99 dB	97 dB	85 dB	79 dB
System dynamic range ^b	87 dB	87 dB	75 dB	75 dB

^a“Receiver dynamic range” is defined as the ratio of the maximum signal level at port 2 for 0.1 dB compression to the system noise floor.

^b“System dynamic range” is defined to the ratio of the maximum signal at port 1 and the system noise floor.

Figure 3. Mechanical structure of the waveguide-coaxial transition and the coaxial probe. (From Ref. 3.)

defined by the coherent values declared for “short” and “open.” Through losses must be kept low, and delay declaration must be coherent with reference plane positioning. Any inconsistency will lead to poor measurement. For TRL (through, reflect, line standards) or LRM (line, reflects, match standards) calibration, the reference plane is always located in the center of the through, but may be moved to some other convenient place after calibration. When using on-chip standards, some or all of the on-chip access parasitics may be included in the calibration, while use of specific standards (on alumina substrate) implies subsequent determination (deembedding) of the access parasitics. In the latter case, the reference plane is usually located under the probe tip. The main error sources are (1) bad calibration and (2) bad access parasitic determination. Advanced calibration techniques have been devised for improving calibration while use of specific on-wafer elements may improve deembedding of the access parasitic.

1.4.1. Advanced Calibration Technique. This technique uses more standards in order to (1) obtain better standards definition (SOLT calibration) and (2) perform vector errors correction (LRM calibration and TRL calibration). None of these techniques are implemented in ANA hardware, so specific computer programs are needed.

1.4.1.1. SOLT Enhancement. The reference plane is solely determined by the short declaration (usually 0 pF). An open-ended long line measurement is performed with an incorrect open declaration and an error model to allow finding for each frequency the open declaration error, thus leading to a better frequency dependent open declaration [5]. This allows precise measurement with SOLT up to 110 GHz.

1.4.1.2. LRRM Calibration. A standard LRM calibration is performed, a new reflect is measured (a short if the calibration reflect was an open), and a new set of error vectors is calculated [6]. This allows us to correct for

a small probe misplacement in addition to true load deviation.

1.4.1.3. NIST Multiline Calibration. The TRL calibration technique is based only on the accurate knowledge of the characteristic impedance of transmission line standards. One of the main drawbacks of TRL is its relatively narrow operating frequency range. To perform a very broadband (up to 110 GHz) TRL calibration, a multiline calibration technique has been proposed by the National Institute of Standards and Technology (NIST) [7].

1.5. Deembedding of the Access Parasitic

The use of an on-chip-specific design may allow precise determination of all access parasitics between a reference plane and a DUT port. This is an alternative to techniques based on frequency dependence of Y and Z parameters, which allow parasitic determination for transistor measurement [8]. The deembedding uses direct S -parameter correction or correction through precise parasitic modeling using a specially designed on-chip test device.

1.5.1. Direct S -Parameter Correction. The measurement of open and short placed at the DUT port position allows direct S -parameter correction, using S -to- Y transformation:

$$Y_{\text{device}} = ((Y_{\text{meas}} - Y_{\text{open}})^{-1} - (Y_{\text{short}} - Y_{\text{open}})^{-1})^{-1}$$

This technique is frequently used for microwave measurement on silicon devices but is also interesting in millimeter-wave measurement. However, extreme care must be taken to compensate for open capacitance (fringing field) and short inductance (ground access) when designing the specific open and short device.

1.5.2. Precise Parasitic Modeling. This usually uses several short, open, and through devices. A careful modeling of all these elements allows us to find out the true access parasitic and the intrinsic device parasitic. Once the access parasitic models are known, correction of the DUT measurement are obtained through the use of a linear simulator.

1.6. Specific Characterizations of Transistors in Millimeter Wave

In view of the increasing number of applications in the centimeter-wave range, the millimeter-wave range is now largely used. MVDS (40.5–42.5 GHz), wireless local area networks (60 GHz WLAN), and automotive radar (77 GHz) are among the most focused millimeter-wave applications today. In addition, advanced technologies are now available for manufacturing integrated circuits used in this range. The main challenge is to design this integrated circuit accurately. To this end, reliable broadband transistor models are needed for designing a millimeter-wave integrated circuit. Linear models (or equivalent circuit) including high-frequency noise sources are usually deduced from S parameter and noise parameter on-wafer

measurements. The accuracy of each element of such models depends on the measurement accuracy. The determination of equivalent circuit elements may be difficult and inaccurate in the millimeter-wave range. The key considerations in designing a reliable equivalent circuit of transistors in the millimeter-wave range are as follows:

1. The choice of calibration technique as a function of the topology of the transistor and the nature of the substrate,
2. The choice of the equivalent circuit topology including parasitic elements.

Another solution consists in establishing an equivalent circuit of transistors from S parameters and noise parameters performed in a relatively lower frequency range (for instance, up to 50 GHz). The main advantage is that the accuracy of measurement in this frequency range is better controlled than that in the millimeter-wave range. To validate the reliability of such an equivalent circuit, we calculate the S parameters and noise parameters from the elements of the equivalent circuit and we compare these calculated data with measured ones in the millimeter-wave range.

1.7. Millimeter-Wave Cryogenic On-Wafer Measurement

There are basically two different solutions depending on the temperature range. For measurements down to 200 K, the setup is similar to that of the system used for high temperature measurement. The system works at ambient pressure, only the chuck is cold, and a local overpressure of drier air or nitrogen is used to prevent icing of wafer or probe tips. In this case, the temperature gradient is mainly located on the probe itself, so cable length at low temperatures is kept minimal. The calibration substrate may be kept at room temperature.

For measurements down to a few kelvin, the device and probes are kept under vacuum in a nitrogen or helium flow cryostat. Probe displacement under vacuum is obtained through the use of a bellow, cable length is significant, and calibration and measurement must be made at the same temperature.

2. VOLTAGE AND POWER RATIO TECHNIQUES: SIX-PORT NETWORK ANALYZER

The voltage and power ratio techniques and the six-port network analyzer (SPNA) are based on direct detection of the millimeter-wave. The hardware configuration of these measurement systems is simple because it is composed of diode or thermal detectors and of directional couplers or probes. In contrast, heterodyne detection systems involve multiple frequency conversions requiring local oscillators. The complexity of the measurement system makes random and systematic errors more difficult to estimate. That is why direct detection techniques provide much of the basis for precision microwave metrology. This article deals with the measurement of the scattering parameters S_{ij} of n -port millimeter devices using a slotted line, a (tuned) reflectometer, and an SPNA.

2.1. Slotted Line

This is the oldest method for measuring the reflection coefficient S_{11} of an impedance. In the millimeter frequency range, the slotted line is realized using a piece of metallic rectangular waveguide with a slot located at the center of the broad wall of the guide. The electric field inside the guide is sampled with a wire antenna connected to a Schottky diode detector. The magnitude of S_{11} is given by the voltage standing-wave ratio (VSWR). The phase of S_{11} is given by the position of the antenna for which the detected voltage is minimum. This technique has been largely replaced by an automated method.

2.2. The Tuned Reflectometer

A simple reflectometer requires one or two directional couplers and power detectors in order to measure the magnitude of S_{11} . These techniques suffer from low directivity of the couplers and from the mismatches of the source and the measurement port Γ_0 . A tuned reflectometer includes tuners in order to overcome these difficulties. The measurement system is composed of a millimeter-wave source, one coupler of directivity D , one power detector, and two tuners. The detected power P may be written as follows:

$$P = K \left| \frac{S_{11} + D}{1 - S_{11}\Gamma_0} \right|^2$$

where K is a constant characterizing the measurement system.

The measurement procedure consists of successively connecting a sliding load and a sliding short in order to null D and Γ_0 using the tuners. Thereafter, the magnitude of S_{11} is given by the power ratio

$$|S_{11}| = \frac{P}{P_{cc}}$$

where P_{cc} is the power measurement when a short circuit takes place at the DUT. For a frequency equal to 110 GHz, the uncertainty measurement (defined at 2σ) of $|S_{11}|$ using the tuned reflectometer is in the range of 0.005–0.06 when $|S_{11}|$ varies from 0.01 to 0.5. In metrological labs, transmission measurements (S_{21}) are performed using an IF attenuator (IF substitution method).

2.3. Six-Port Network Analyzer

The term “six-port” is due to the six-port millimeter-wave junction (Fig. 4). At its four output ports it provides power readings P_3 to P_6 , which are a weighted addition of the incident a_2 and reflected b_2 waves. The complex value of S_{11} (b_2/a_2) derives from the six-port equations:

$$\frac{P_i}{P_3} = K_i \left| \frac{\alpha_i a_2 + \beta_i b_2}{\alpha_3 a_2} \right|^2, \quad i = 4, 5, 6$$

where α_i and β_i are the weighted factor of the waves a_2 and b_2 at the i th port and K_i is a constant of the power detector.

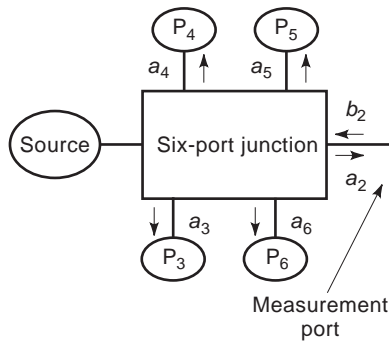

Figure 4. Six-port measurement system. It provides the complex value of the reflection coefficient S_{11} of the load connected at the measurement port. The power detector, connected at each output port, measures the power of b_i , where $i = 3-6$.

The four scattering parameters may be obtained by the connection of two SPNAs at the two ports of the DUT or one SPNA in the reflection or transmission mode.

2.4. Practical SPNA Junctions

Six-port theory is, in principle, applicable to arbitrary design. However, for better accuracy assessment, design objectives should be obtained:

- At one output port, the wave is proportional (α_3) to the incident wave a_2
- At the three remaining ports we have $|q_i| = 1.5$ and $\arg(q_i - q_j) = 120^\circ$, where $q_i = -\alpha_i / \beta_i$ for $i, j = 4, 5, 6$.

A simple six-port junction consists of one directional coupler and three voltage probes (as used in the slotted line) separated by about $\lambda/6$. A similar junction replaces the probes by a waveguide coupling structure [9]. This structure contains two *E*-plane T junctions at the upper broad wall of the main R320 (26.5–40 GHz) waveguide and

one *E*-plane T junction at the lower broadwall. The distances between the T junctions are about $\lambda/6$.

Figure 5 shows a six-port junction using techniques [10] at submillimeter wave (300 GHz). Similar quasioptical techniques have been applied in optic domains for a wavelength of $0.633 \mu\text{m}$ [11]. The beamsplitter may be replaced by directional couplers using a metallic waveguide or dielectric waveguide structure (94 GHz) [12].

A more wideband system [13] (75–110 GHz) has been realized by means of connecting five 3-dB 90° hybrid couplers. It can be shown that the q_i points are frequency-independent and are equal to $(-j, 1+j, -1+j)$ assuming identical and symmetrical couplers with a coupling factor of 3 dB. This feature is interesting in the millimeter-wave range because the phase property of commercial couplers are usually unknown.

Another technique is the multistate reflectometer. It consists of two directional couplers. The internal matched termination on the fourth arm of one coupler has been replaced by a phase shifter. Three states of the phase shifter provide the three equivalent power ratios of the six-port technique. Currently, this system permits on-wafer measurement at a frequency of 140 GHz [14].

2.5. Experimental Results

Table 2 shows S_{11} measurement results obtained with different systems. The measurement results labeled “SPNA,” “HP8510,” or “AB millimeter” can be compared with the values labeled “LCIE” given by the calibration center of LCIE (Laboratoire Central des Industries Electriques en France), which are considered arbitrarily to be the references. In this case, the magnitude of S_{11} was determined with a tuned reflectometer while the phase is obtained with a slotted line. The mean standard deviation is equal to 0.01 for the magnitude and 4° for the phase. The small differences may be due to temperature effects or the non-repeatability of the connections.

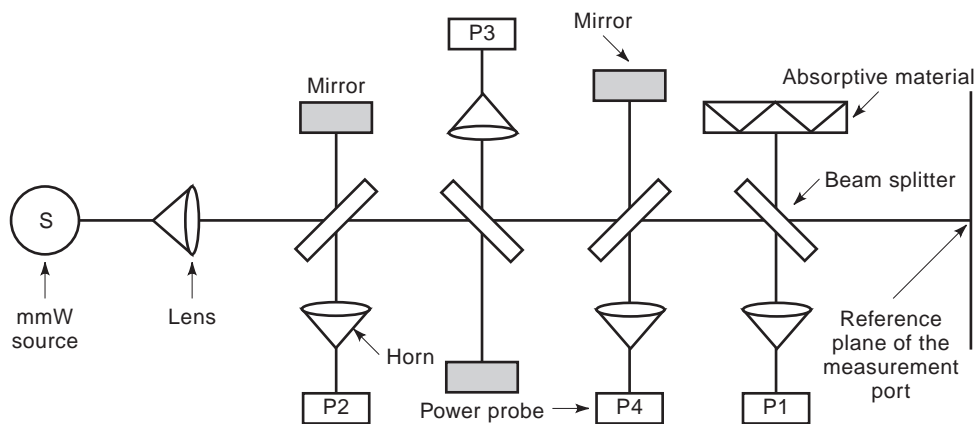

Figure 5. Six-port millimeter-wave junction using quasioptical techniques. It comprises five horns and four dielectric sheets. Each of the dielectric sheets is a beamsplitter. A metallic mirror is placed on the fourth branch of each beamsplitter except the one which involves the measurement of the source signal. The distance between the mirror and the dielectric sheet gives the weight of the added signals.

Table 2. Measurement Comparison Among Network Analyzers

Network Analyzer	93 GHz	94 GHz	95 GHz	96 GHz
LCIE	0.415 −100.8°	0.447 174.8°	0.479 91.4°	0.515 13°
SPNA	0.01 −0.1°	−0.013 +0.2°	0.012 −0.8°	−0.013 7°
HP8510	0.005 5°	0.002 3°	0.01 5°	0.002 3°
AB millimeter	0.006 0.1°	−0.007 −4°	0.02 −3°	0.01 −1°

2.6. Future Trends

The six-port junction may be realized using a microwave monolithic integrated circuit (MMIC). The MMIC chips can be used as a sensor in an antenna array or integrated inside the tips of a probe station. In the latter case, the series of losses of the probe tips and the line connection do not decrease the measurement accuracy of the wafer probe station.

3. SOURCE-PULL AND LOAD-PULL TECHNIQUES

Large-signal millimeter-wave measurements of representative samples of semiconductor devices are of prime importance for two main reasons: (1) accuracy and consistency check of nonlinear transistor models for CAD and (2) experimental optimization of transistor optimum operating conditions without the use of any model.

Nonlinear devices demonstrate different aspects of their behavior depending on the source and load match. Therefore, large-signal measurement systems use either computer-controlled tuners or active loads to change source and load impedances of the DUT to reach the optimum matching conditions under large-signal operation (load-pull system).

Tuner systems operating up to the W band are commercially available. They are widely used for the design of low-noise amplifiers [15], power amplifiers and oscillators [16], and mixers [17]. However, such systems do not allow synthesis of impedances close to the edge of the Smith chart. This main drawback becomes more and more crucial if the operating frequency increases (millimeter wave) or if on-wafer measurements are performed. For these reasons the active source and load-pull technique has emerged. Going further in the large-signal characterization, novel measurement systems allowing the extraction of voltage/current waveforms at the DUT's ports have been developed.

3.1. Basic Considerations on the Source and Load-Pull Techniques

The principle of the large-signal characterization of any non-linear two-port is sketched in Fig. 6. If a single-tone power source is used, the four power waves are expressed

**Figure 6.** Source- and load-pull techniques: principle.

as follows:

$$a_1(t) = \sum_n A_{1n} \cos(n\omega t + \varphi_{1n}),$$

$$b_1(t) = \sum_n B_{1n} \cos(n\omega t + \theta_{1n})$$

$$a_2(t) = \sum_n A_{2n} \cos(n\omega t + \varphi_{2n}),$$

$$b_2(t) = \sum_n B_{2n} \cos(n\omega t + \theta_{2n})$$

A vector network analyzer (VNA) or six-port reflectometer provides the measurements of the magnitudes $|A_{in}|$, $|B_{jn}|$ ($i, j = 1, 2$) and the power wave ratios at the same frequency. From this information, powers, impedances and gains can be calculated. Unfortunately, classical VNAs do not allow the measurements of absolute phases φ_{in} and θ_{in} . As a consequence, time-domain waveforms cannot be extracted. A novel system allowing the measurements of time-domain waveforms will be described later.

First a conventional source and load-pull system (measurements of impedances and powers) is considered. Referring to Fig. 6, a systematic approach for performing large-signal characterization of a DUT is as follows:

1. Impose desired DC voltages or currents.
2. Tune the source and load networks.
3. Sweep the power level of the input source and measure powers, efficiency, and gain.

Then the same procedure can be repeated for different operating conditions. This implies the use of a fully automated measurement system.

3.2. Multiharmonic Active Source and Load-Pull System

Multiharmonic source and load-pull systems are very useful in designing optimized nonlinear microwave circuits. Both source and load impedances have a great influence on the performances of DUTs in terms of efficiency and linearity. The load-pull characterization has also become a key step in the whole modeling process of semiconductor devices.

3.2.1. Load Pull [18]. The block diagram of a multiharmonic load-pull system is shown in Fig. 7. The measurements of absolute powers and power wave ratios are performed by using a VNA (receiver operation mode) calibrated with a TRL procedure. The synthesis of load

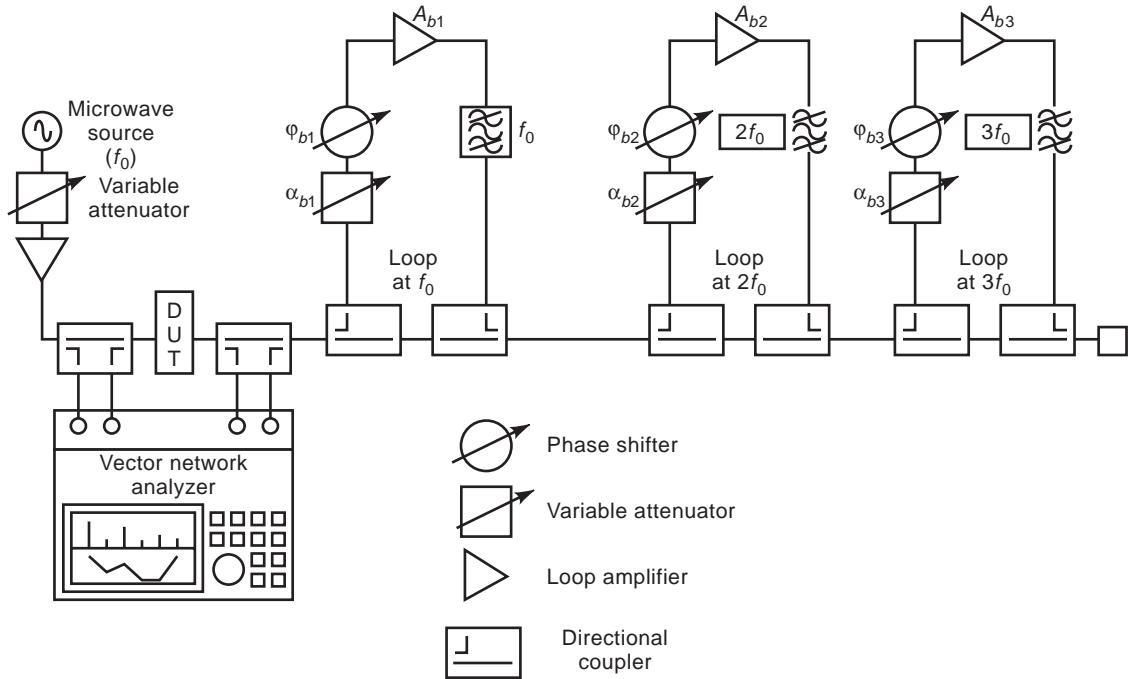

Figure 7. Multiharmonic load-pull system block diagram.

impedances at the first three harmonics coming out of the DUT is performed by using active loops and monitoring the complex gain of each loop with attenuators and phase shifters. Once the gains are fixed, a power sweep at the input of the DUT is performed and input/output power characteristics of the DUT are measured.

3.2.2. Source Pull [19]. Figure 8 shows a measurement system based on the use of six-port reflectometers. This system integrates both input and output active loops to perform source and load-pull measurements. Depending

on the position of switch 1, the input six-port measures either the input reflection coefficient of the DUT or the reflection coefficient of the source load presented to the DUT. For both cases the error terms found by a classical calibration procedure are valid.

3.3. Time-Domain Waveform Measurement System [20]

As mentioned previously, conventional VNAs do not allow the measurements of absolute phases of harmonically related signals. As a consequence, time-domain waveforms cannot be extracted. Therefore, different institutes have

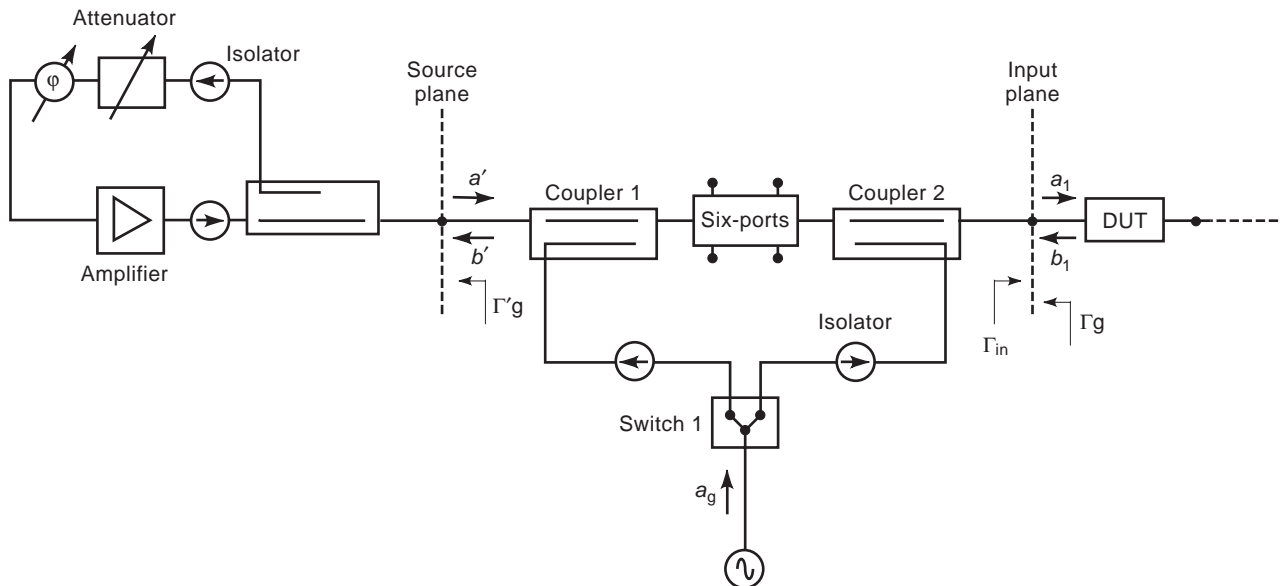

Figure 8. Source-pull implementation with a millimeter-wave six-port junction.

developed measurement systems to extract time waveforms in one or another way usually based on the HP microwave transition analyzer. The potential of the combination of the nonlinear network measurement system (NNMS) with active source and load-pull techniques is under study.

This NNMS is mainly composed of a four-channel broadband downconverter followed by digitizers. It uses the harmonic mixing principle to convert RF fundamental and harmonics into IF fundamental and harmonics. This instrument takes the place of the VNA in the system previously presented.

The calibration of the system is performed in three main steps:

1. Classical TRL calibration
2. Power calibration calibration
3. Phase calibration

During the last step, a reference generator (step recovery diode) is connected instead of the DUT [21]. The reference generator is calibrated using the nose-to-nose calibration procedure [22].

4. DIELECTRIC WAVEGUIDE CAVITY RESONATOR

As millimeter waves, resonators are useful for a large number of applications in communication systems and measurements of dielectric properties. In the millimeter-wave and submillimeter-wave ranges, difficulties arise from wavelengths which are very short, and devices are difficult to machine with a large degree of accuracy. So the problem is to achieve high circuit Q for volumic or hybrid millimeter-wave integrated circuits.

Different resonator structures are used. Some of them are derived from low-frequency application, like a cylindrical metallic cavity, but other devices have been developed specially for millimeter-wave measurement. In the following subsections we present mainly the devices given in Fig. 9, which are often used.

4.1. Cylindrical Metallic Cavity

This structure presented in Fig. 9a is composed of a cylindrical metallic waveguide closed at the top and the bottom by a metallic plane. The resonant frequency depends on the dimensions of the cavity (diameter and height) and

the mode that is excited in the structures. These modes are chosen to be TE_{01n} or TM_{01n} modes and depend on excitation line position. The unloaded Q factor of these resonators increases with the axial number n . But it is difficult to use axial numbers greater than five, because a lot of modes are excited in a frequency band and it is difficult to obtain good frequency isolation. Typically, at room temperature and with copper to realize the cavity, values of unloaded Q factor are equal to 12,000 at 30 GHz and 7000 at 100 GHz on the TE_{013} modes.

4.2. Open Resonators

The most popular of this type of resonator is the Fabry–Perot, which is presented in Fig. 9b [23,24]. These resonators are used from the short microwave to the optical domains [25]. The basic device is composed of two reflectors of arbitrary radius of curvature separated by a length d . At low frequencies, the dimensions of the mirror will be very large, so for this reason these devices are used essentially at very high frequencies. TEM_{plq} mode is excited in these structures, where p , l , and q are, respectively, radial, azimuthal, and axial variations of the energy which is localized in the center between the two mirrors. In a great number of applications, the TEM_{00q} mode is used and resonant frequency of these modes are periodic along the q parameter. As in metallic cavities, the unloaded Q factor increases with the number of axial variations, and values of the Q factor greater than 10^6 are possible in millimeter-wave measurement.

4.3. Dielectric Resonators

For high frequencies the dimension of resonators excited on conventional modes becomes impractically small. A solution consists of using dielectric resonators excited on whispering-gallery modes (WGMs), which are higher-order modes. The first advantage of this solution is the dimension of the resonators, which is approximately 10 times bigger than resonator excited on conventional modes. The geometry of the resonators is a disk with a diameter greater than thickness, as shown in Fig. 9c [26,27]. So these resonators are easy to integrate in planar circuits.

Moreover, acting on these modes, energy is confined at the periphery of the dielectric resonator, and radiation losses are negligible. Thus, unloaded Q factors are very large and only limited by dielectric losses of the material used to realize the resonators.

Figure 9. Example of millimeter-wave resonators: (a) cylindrical metallic cavity; (b) open resonators; (c) whispering-gallery dielectric resonators.

At room temperature and using quartz material, a measured Q factor of 30,000 has been obtained at 100 GHz. Placed in a metallic cavity and at 77 K, a Q factor of 30,000,000 has been measured at 7 GHz with sapphire.

4.4. Applications to Millimeter Devices

In millimeter-wave devices, a large number of applications use resonator circuits. These elements are used in devices such as filters or oscillators, or for material measurements to determine complex permittivity and permeability. In both cases, it is very interesting to have a high Q factor of the resonance modes.

4.4.1. Filtering. Insertion losses and rejection depend on Q factor of the resonators. To realize these circuits, cylindrical metallic cavity or WGM dielectric resonators are suitable because association of several resonators is possible. At high frequencies, topologies of these structures are the same as for low-frequency devices.

4.4.2. Oscillator. Frequency stabilization and phase noise need a high Q value of the resonant device. For millimeter-waves, dielectric resonators excited on WGM give good results and are easy to integrate in the devices. With these modes, the original topology of oscillators can be realized by using the wave propagation effect at the periphery of the resonators, which is another property of these modes.

4.4.3. Dielectric Material Measurement. These resonator devices are currently used because they permit good accuracy with regard to the complex permittivity of the material. For metallic cavities or open resonators, the method consists of comparing the resonant frequency and the unloaded Q factor of the empty and loaded resonators. This method is convenient if the thickness of the material under test is smaller than the wavelength. For material with a large thickness, methods using WGM are suitable. In this case, measurements of resonance frequency and Q factor are compared with results obtained by electromagnetic simulator. These methods can be used for anisotropic dielectric or magnetic material [28].

4.5. Future Trends

The performance of millimeter-wave resonator devices is limited by the difficulty of integration of resonators in devices (in particular, for cavity or open resonators) or by losses of metallic or dielectric materials. Since the late 1980s, with the development of new dielectric materials like sapphire in the microwave domain, performances have been improved with regard to the unloaded Q factors. Unfortunately, characteristics of these materials change with temperature, and frequency stabilization is difficult to obtain without using regulating temperature devices. In the future, with technology development, we can hope to obtain material with optimum characteristics.

5. FREE-SPACE METHODS: INTERFEROMETRY

Waveguide loss becomes important for millimeter waves; free-space transmission has lower loss and is good for low-noise applications as well as for high-power applications (in addition, larger area of beams spread produces a lower power density). Free-space measurement is required when contact is not possible. Such is the case in radiometry for measurement of temperature and chemical composition, as well as in interferometry and in radar detection for measurement of distance, velocity, and position.

Very often for millimeter waves, the beam diameter is a relatively small number of wavelengths; thus, diffraction must be considered. A wide variety of components and systems have been developed using quasioptical techniques, either similar to waveguide devices or derived from infrared and optical techniques [29,30].

5.1. Quasioptical Techniques

5.1.1. Gaussian Beams. Paraxial propagation of a beam in free space is relatively simple to analyze if the transverse electric field amplitude variation has a Gaussian form

$$E(r)/E(0) = \exp[-(r/w)^2]$$

where r is the distance from the axis of propagation and w is called a "beam radius." A Gaussian beam is produced with, or focused to, a minimum size; this minimum beam radius w_0 called a "beam waist."

The feedhorn is the best coupling device between the Gaussian beam and the guided wave (Fig. 10). The best coupling (98%) is obtained with a scalar feedhorn pattern. Several types of planar antennas (patch, bowtie, traveling-wave slot) can also be used. An associated lens is used to obtain reasonable coupling efficiency. Several types of planar antennas (patch, bowtie, traveling-wave slot) can be used. An associated lens allows us to reduce the beam size and increase the coupling efficiency.

5.1.2. Quasioptical Components Used in Millimeter-Wave Measurement. Quasioptical components provide a wide variety of functions used for millimeter measurements:

- Beam transformations require focusing elements such as parabolic or ellipsoidal mirrors and lenses. To minimize the absorptive loss of lenses, low-loss dielectrics must be selected (PTEE, alumina, fused silica, etc.); and to obtain low reflection loss, a matching layer or grooves are essential, except for low-index materials.
- High- Q -factor ($\gg 10,000$) resonant cavities can be formed with two spherical mirrors or one spherical and one plane mirror.
- Signal filtering can be achieved by interferometers (see below) and by plate filters: Perforated conductive plates or arrays of resonant patterns are printed on a dielectric substrate.
- Polarizing grids are usual in quasioptical systems, often used as beamsplitters for a polarized signal.

Figure 10. Devices for millimeter-wave and sub-millimeter-wave beam production (horn and open-structure examples).

These grids can be formed with freestanding wires or with dielectric-supported conducting strips. Dielectric plates are also used as beamsplitters and can function as hybrids (90° phase shift between reflected and transmitted beams).

- Different types of interferometers are developed from beamsplitters and reflective devices: dual-beam interferometers or Fabry-Perot interferometers.

5.1.3. Quasioptical Bench. The purpose of the quasioptical bench is to create a “beam waveguide” including a sufficient measurement area. Figure 11 shows a basic bench, in which the measurement area is located between a signal generator and a detector equipped with free-space coupling devices (horns and lenses). The relative positions must be finely adjustable (in three rectangular directions and two or three rotating angles) while staying extremely

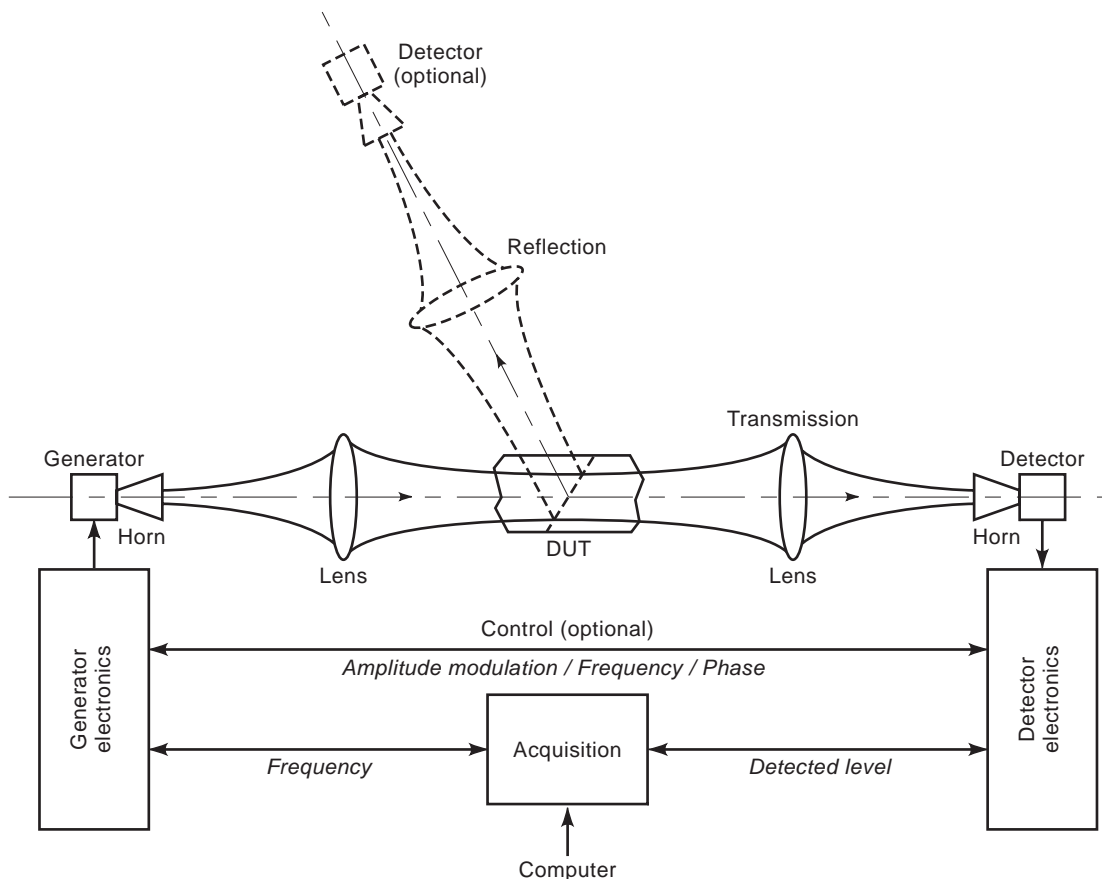

Figure 11. Quasioptical bench.

stable. As in coaxial or waveguide measurements, generators and detectors can use frequency multipliers and heterodyne and phase-locked systems to increase the sensitivity and stability.

Free-space measurements may use a device for analog-to-coaxial calibration set parts. The methods are identical, but special care is required to (1) decrease the multiple reflections by using absorbing shields and anechoic rooms, (2) take VSWR into account, and (3) manage external (or internal, electromagnetic interferences. Another source of error and instability is atmospheric absorption, when the measuring frequency band comes over the absorption bands of an atmospheric molecule.

5.2. Free-Space Antenna Measurement

The antenna characteristics that have to be measured in the millimetric range are mainly radiation patterns in co- and cross-polarization. Phase center measurements of primary feeds, as well as beam efficiency, also have a great importance for reflector antenna design. Measurement techniques are much the same as at lower frequencies, but with specific difficulties and requirements [31]. (See also RADIOMETRY, ELECTROMAGNETIC FIELD MEASUREMENT.)

5.2.1. Radiation Pattern Measurements. Far-field measurements must be performed outdoors if antenna dimensions are large compared with the wavelength, which generally is the case for reflector antennas at millimetric frequencies. However, atmospheric attenuation and geographic implementation become prohibitive when the far field exceeds 1 km. Compact antenna test ranges (CATRs) remedy this problem for medium-to-large reflector antennas in the millimetric range.

For antennas of moderate (cm) dimensions, far-field measurements can be performed indoors. Horns and printed antennas are tested in anechoic chambers. In CATRs, a local plane wave is created in a zone called the “quiet zone,” by way of one or several reflectors used to collimate the beam of a smaller source. Various designs exist, ranging from the basic one with a single offset reflector to triple reflector systems, according to the required cross-polarization and spillover levels and the size of the antennas under test. Diffraction at the edges of the reflectors is less critical than in the microwave range, but reflector surfaces requirements are more stringent because the root-mean-square (rms) surface error should be better than $\frac{1}{100}$ wavelength to obtain good precision on the plane wave phase. Corrugated or special multimode horns are used as sources.

Hologram CATRs are being developed. Reflectors are replaced by a hologram, with a surface accuracy requirement divided by 10. This technique is thus less expensive, but it is still very new and faces problems concerning the size of the required holograms as well as frequency bandwidth limitations (20–30%) and polarization difficulties.

In the near-field scanning technique, fields are measured close to the antenna under test, on either a planar, cylindrical, or spherical surface. This technique requires both amplitude and phase measurements,

because the sampled fields are used to calculate the radiated far-field through a near-field to far-field transformation. In the millimeter-wave domain, this technique encounters problems of time consumption and precision phase measurement.

5.2.2. Other Antenna Performance Measurement. The “beam efficiency measurement” is performed by measuring the power radiated within the mainbeam of the antenna. It is especially important for radiometer antennas, which must have very low sidelobes. It requires both radiation pattern measurements, although not with wide-angle scanning, and absolute power measurements. The “phase center position measurement” is useful only for horns used as primary sources in reflector antennas. It is performed by positioning the center of phase patterns in different planes along the axis of the horn. It requires precise phase measurements and mechanical positioners.

5.3. Quasioptical Measurement

5.3.1. Power Measurement. Most of the power detectors used in the microwave measurement (Schottky diodes for instance) still work in the millimeter-wave frequency range. Moreover, bolometers and the calorimeters also operate in this range. These devices mounted in a waveguide structure can be associated with a horn to make up a beam detector. To increase the sensitivity, synchronous detection and heterodyne conversion may be used. Absolute calibration must be performed with photoacoustic detectors (used at Brewster angle and through amplitude modulation).

5.3.2. Quasioptical Device Characteristics Measurement. A basic quasioptical bench allows us to measure the main of millimeter-wave characteristics of a DUT inserted in the optical path: transmittance, loss and scattering by insertion, and reflection by comparison with a good reflector. Much attention must be paid to (1) the radial size of the DUT compared with the usable beam size, (2) the compensation for phase differences, and (3) the VSWR (which can be reduced by choosing an incidence angle other than zero).

For low losses, noise measurements provide a better accuracy. The equivalent noise temperature T_1 is increased to T_2 by the insertion of a DUT at the front of a low noise receiver. Giving the DUT physical temperature T_d , the loss factor L is obtained from

$$T_2 = T_d(L - 1) + LT_1(1 + \Gamma^2)$$

with $\Gamma^2 = [(VSWR - 1)/(VSWR + 1)]^2$.

5.3.3. Noise Measurement. In addition to classic noise measurement using a noise source (diode, gas tube) associated in this case with a horn, the common noise measurement uses two absorbing targets with two different radiant temperatures. The target with the higher temperature T_h , the “hot load,” takes the place of the target with the lower temperature T_c , the “cold load,” in front of the

DUT. The respective output powers are P_h and P_c . With ideal targets the equivalent noise temperature of the DUT is

$$T_x = (T_h \cdot P_c - T_c \cdot P_h) / (P_h - P_c)$$

Radiometer systems must be extremely stable over long periods and linear over the whole level range. The target size must be enough to cover the whole beam. Temperature and absorption coefficients must be homogeneous over the target surface. At millimeter wavelengths, $h\nu < kT$, the brightness temperature is very near the physical temperature. Measurement uncertainties come from variations of the effective emissivity of the target and from the mismatch with the receiver. In addition, as a result of the standing-wave effect, the total noise entering the receiver becomes frequency-dependent.

The standard ferrite-loaded foam absorbers may be used as calibration targets in the lower frequency range, but for higher frequencies the reflected power unfortunately reaches -20 dB, depending on the polarization angle. For a single polarization and when the configuration is fixed, a specially developed ridged absorber or dielectric surface at the Brewster angle acts as a quasi-perfect absorber.

To achieve good precision ($<1\%$), a lot of specific targets have been developed from the principle of a conical hole with an angle of $<10^\circ$ to increase the number of reflections.

5.3.4. Other Quasioptical Measurements. The frequency measurement may use a downconversion by means of a millimeter mixer coupled with a local oscillator by a quasioptical coupler (an interferometer or a simple dielectric plate). The local oscillator and the low frequency counter are phase/frequency locked on a reference ultrastable oscillator. On the other hand, wavemeters may use very-high- Q -factor cavities in quasioptical techniques.

The measurement of the polarization of a signal usually takes advantage of the sensitivity of the detector for one electromagnetic field direction (detection diodes and rectangular waveguide mounts). To increase the accuracy or to use a non-polarized detector, a polarized plate (grid) may be inserted (with an incident angle to decrease a possible VSWR effect). This method requires us to rotate the whole receiver or to insert a waveguide twist behind the horn (causing a calibration problem). The other solution is to use a quasioptical polarization rotator on the optical path. This device uses three grids in transmission [32] or one grid and one reflector [33]. In this way the mechanical rotation is limited to one light device, and the transition time may be very short (<10 ms). Circular polarization may be measured with a particular disposition of Martin-Puplett interferometer.

The knowledge of the insertion effects (loss and phase variations) allows us to compute the complex dielectric constant of a material. Other methods for material characteristics measurement use modifications of a cavity resonator's Q factor.

5.4. Interferometry

The resolution of an antenna has a diffraction limit of $\approx \lambda/D$, and an interferometer increases the resolution according to the area covered by two or several connected antennas. More generally, an interferometer can be used to measure the Fourier components of a brightness distribution. Since Ryle and Hewish [34] have formulated the principle of aperture synthesis, many interferometers have been built or are in progress (mainly for radio astronomy). The aperture may be synthesized by multiplication, physically moving of elements, or by using the rotation of the earth. As baselines are increased, the major problem in millimeter-wave measurement is the maintenance of phase stability of local oscillators; for very-long-baseline interferometry (VLBI), the local oscillators are independent and need very accurate frequency standards.

1. INTRODUCTION

Wireless data services have grown rapidly both for micro- and macrocellular systems,¹ and high- and low-mobility applications. This is due to the various technological breakthroughs recorded in wireless applications such as: mobile computing, mobile and high-speed internet access, mobile multimedia, and a host of personal communications (PC) services. The demands for ubiquitous access to these services are ever increasing, and necessitating continued additions of new techniques to provide more services.

Wireless channels suffer from severe distortions caused mainly by multipath² fading. The severity of these distortions often makes it impossible for the mobile receiver to make a correct detection of the transmitted symbols, unless some less attenuated replicas of the transmitted signal are provided to the receiver. This is referred to as *diversity*. Diversity techniques are based on the notion that errors occur in reception when the channel is in deep fade—a phenomenon that is more pronounced in mobile communications, due to the mobility of the transmitter, the receiver, or both of them. Therefore, if the receiver is supplied with several replicas, say, L , of the same information signal transmitted over independently fading channels, the probability that all the L independently fading replicas fade below a critical value is P^L (where P is the probability that any one signal will fade below the critical value). The error rate performance of the system is thus improved without increasing the transmitted power. Most of these diversity solutions, however, have traditionally focused on the receiver diversity considerations. Examples of diversity technique for wireless applications can be found in Refs. 1–4.

Another powerful fading combatant that has been used for wireless channels is the *coding technique*. While diversity system introduces spatial redundancies in the received signals, coding technique on the other hand introduces the redundancies in the temporal sense. In the coding technique, an encoder takes as input n information bits at any time instant and adds error correcting bits (or redundancies) to produce at its output m bits ($m > n$) of information bearing code, known as *codeword*, and this is transmitted over the wireless channel. The

¹In mobile cellular system, cell sizes (range within which a user can be served by a nearby base station before being transferred to another base station) may vary from large macrocells to small microcells. Macrocells provide services to high speed mobiles, while microcells provide services to low-mobility applications.

²Signals emanating from the transmitter arrive at the receiver via different paths, with different delays and phase. These are referred to as multipaths (see Section 1.1).

ratio of the input–output bitlength of the encoder, n/m is known as the code rate and is a measure of the amount of information contained in one data bit after the encoding operation. At the receiving end, an event of error due to corruption in the wireless channel will be detected and corrected by the decoder using its knowledge of the valid codewords for the coding techniques employed, as long as the numbers of bits in error are not greater than the error correcting capability of the code. This process is known traditionally as *channel coding*. Thus the temporal redundancies added to the transmitted bits by the encoder are used to achieve link quality improvement. Examples of coding techniques for wireless applications can be found in Refs. 5 and 6.

A combined coding–diversity scheme, known as *space-time codes*, promising dramatically high data rates as well as reliable communication over the wireless channels was proposed in [7]. This scheme employs coding techniques appropriate to multiple transmit antennas to achieve a combined coding and diversity gains that enables higher data rates, without prejudice to error rate performance. Age-long approach to achieve higher data rates is to expand the signal constellation and use powerful coding and modulation techniques. However, this approach falls short of the goal of achieving truly high-speed data services because of the substantial SNR penalty paid for increasing the signal constellation size. In addressing this problem, the deployment of wireless systems employing multiple transmit antenna (transmit diversity) were first proposed in the context of signal processing in several publications [4,8–10] using the concept of delay transmit diversity. In the delay transmit diversity scheme, replicas of the information signal are transmitted through multiple antennas at different times, and necessary signal processing techniques are employed at the receiver to retrieve the original information signal. The delay transmit diversity scheme was shown to achieve significant performance boost to the wireless channel compared to the conventional system with single transmit antenna.

Tarokh et al. [7] then adapted a coding perspective to this scheme, and proposed the spacetime coding employing multiple transmit–multiple receive antennas. The multiple transmit antennas are used to send different encoded signals in parallel at the transmitter, and multiple antennas are employed at the receiver for signal detection. An appropriate code is employed such that the number of codewords at the output of the encoder matches the number of the transmit antennas. Spacetime codes achieve much more significant performance improvement over the conventional wireless system than does the delay diversity transmission [7]. This celebrated result has therefore spurred a host of research works aimed at increasing the

wireless channel capacity through the spacetime processing [11–18].

Alamouti [15] designed a simple but elegant MIMO system exploiting transmitter diversity to obtain system performance similar to a maximum ratio combining (MRC) receiver diversity. In his scheme, a pair of symbol is transmitted using two antennas at first, and the transformed version of the same pair is transmitted in the next time slot, to obtain the MRC-like diversity gain. Space-time block codes were later designed, using orthogonal structure, and were shown to generalize the Alamouti scheme for various MIMO configurations [13]. Several variants of the MIMO signal processing techniques have since been exploited. These include the spatial multiplexing system [19] and MIMO maximum ratio combining (MIMO-MRC) [14], among others. System performance and information capacity of the wireless communication system employing these MIMO technologies have been demonstrated to increase dramatically over those of the conventional wireless systems [16,19–23].

1.1. Basic Baseband MIMO Channel Model

This section illustrates a basic baseband model for the MIMO wireless communication system. Throughout the article, we assume a MIMO system with N transmitting antennas at the transmitter, and L receiving antennas at the receiver. We use the notation h_{ij} to denote the sampled complex channel gain from transmit antenna j to receive antenna i at discrete time k , where $i = 1, 2, \dots, L$ and $j = 1, 2, \dots, N$. Therefore, we express the $L \times N$ complex MIMO channel matrix at time k as

$$\mathbf{H}(k) = \begin{bmatrix} h_{11}(k) & h_{12}(k) & \cdots & h_{1N}(k) \\ h_{21}(k) & h_{22}(k) & \cdots & h_{2N}(k) \\ \vdots & \vdots & \ddots & \vdots \\ h_{L1}(k) & h_{L2}(k) & \cdots & h_{LN}(k) \end{bmatrix}$$

Figure 1 illustrates a general block diagram for MIMO communication systems. The system equation describing the input–output behavior of the MIMO system can be expressed, for a flat fading channel as

$$\mathbf{y}(k) = \mathbf{H}(k) \mathbf{c}(k) + \mathbf{n}(k) \quad (1)$$

where $\mathbf{y}(k) = [y_1(k), y_2(k), \dots, y_L(k)]^T$ denotes the $L \times 1$ complex received signal vector, $\mathbf{c}(k) = [c_1(k), c_2(k), \dots, c_N(k)]^T$ denotes the $N \times 1$ complex signal vector transmitted from the N transmit antennas, and k is the time index. $\mathbf{n}(k) = [n_1(k), n_2(k), \dots, n_L(k)]^T$ is the $L \times 1$ complex channel noise [additive white Gaussian noise (AWGN)] vector.

Figure 1. MIMO communication systems.

Here it is assumed that the AWGN is spatially and temporally white [i.e., $\mathbf{n}(k)$ is a zero-mean complex Gaussian vector with covariance matrix $\sigma_n^2 \mathbf{I}$].

1.2. Channel Effect in Mobile Wireless Communications

Channel effects in mobile wireless communication systems arise from multipath propagation and user mobility, besides the regular propagation loss and fading (attenuation) on wireless links. The multipath effect is a feature associated with the fact that the signal transmitted from a mobile unit undergoes scattering, reflections, or diffraction before reaching the base station, where it arrives from different paths, each with its own fading, propagation delay, and angle of arrival. Multipath scattering may arise from scatterers local to the mobile unit, remote scatterers, or scatterers local to the base station, or all of them. The signal received at the base station is a summation of these multipaths signals. Figure 2 displays a typical mobile wireless propagation environment.

The combined effect of these features leads to the characterization of mobile wireless channels as time-varying fading channels, as well as frequency-selective fading channels.

The equation describing the input–output behavior of the MIMO system can be expressed for frequency-selective fading channel as

$$\tilde{\mathbf{y}}(k) = \sum_{l=0}^{m-1} \mathbf{H}(k; l) \mathbf{c}(k-l) + \mathbf{n}(k) \quad (2)$$

where $\mathbf{H}(k; l) (l=0, 1, 2, \dots, m-1)$ is the $L \times N$ MIMO channel matrix representing the l th tap of the mobile channel matrix response with $\mathbf{c}(k)$ as the input and $\mathbf{y}(k)$ as the output at time instant k . The parameter m denotes the memory length of the impulse response of the mobile channel. To simplify the exposition hereafter, we drop the time index k in the system equations where necessary.

1.3. Capacity of MIMO Systems

For a given channel and a given transmitter input power P_T , Shannon definition of capacity for the single transmit–single receive antenna, or single input–single output

(SISO), system can be expressed as

$$C = \log_2 \left(1 + \frac{P_T}{\sigma_n^2} \right) \text{ bps/Hz} \quad (3)$$

where σ_n^2 is the noise variance and bps is bits per second.

For the case of MIMO transmission, assuming that the channel state information (CSI) is unknown at the transmitter, and that the transmitted power is divided equally among the transmit antennas, then the capacity formula can be written for a deterministic MIMO channel as [24–27]

$$C_{L < N} = \log_2 \det \left(\mathbf{I}_L + \frac{P_T}{N\sigma_n^2} \mathbf{H} \mathbf{H}^H \right) \text{ bps/Hz} \quad (4)$$

and

$$C_{L \geq N} = \log_2 \det \left(\mathbf{I}_N + \frac{P_T}{N\sigma_n^2} \mathbf{H}^H \mathbf{H} \right) \text{ bps/Hz} \quad (5)$$

where $C_{L < N}$ denotes the capacity for the case when the number of receive antennas L is less than the number of transmit antennas N , while $C_{L \geq N}$ denotes the capacity for the case when the number of receive antennas is greater than or equal to the number of transmit antennas.

The ergodic capacity for fading MIMO channel is obtained by taking the expectation of the capacity expression above with respect to the random channel. Assuming that the MIMO channel is spatially white (i.e., uncorrelated), and consider that $N=L=K$, then for arbitrarily large number of transmit and receive antennas, it can be shown using the strong law of large numbers that the MIMO channel capacity in the absence of channel knowledge at the transmitter approaches [28–31]

$$C \rightarrow K \log_2 \left(1 + \frac{P_T}{\sigma_n^2} \right) \text{ bps/Hz} \quad (6)$$

Comparing Eq. (3) and (6), we can observed that the capacity of MIMO channel increases linearly with the number of antennas K , when K is very large. Therefore, the bandwidth efficiency growth for MIMO transmission is linear with the number of antennas. Figure 3 illustrates the MIMO capacity presented by Paulraj et al. [28] for various MIMO configurations. In this figure, the number

Figure 2. Mobile radio propagation environment.

Figure 3. Ergodic capacity for various MIMO antenna configurations.

of transmit antennas is denoted as $N = M_T$ and the number of receive antennas is denoted as $N = M_R$. The capacity increase of the MIMO system over the SISO system (the case $N = 1, L = 1$) is clearly depicted in the figure.

2. MIMO COMMUNICATION SYSTEM DESIGNS

MIMO communication system design can be broadly categorized into two groups:

1. *Spatial multiplexing (SM)* methods exploiting capacity increase from the multiple antenna system
2. *Diversity* methods exploiting link quality improvements from the multiple antenna system

Figure 1 displays a general block diagram for both methods. In the former, incoming data bits are partitioned into multiple substreams and each substream is transmitted, simultaneously, on a different antenna, thereby increasing the link capacity [19]. The multiple antennas at the receiver are then expended in separating these substreams and therefore diversity against fading is rarely provided in SM—at least in the initial design known as V-BLAST (vertical Bell Labs layered spacetime codes).

In the diversity method, approaches include those exploiting both diversity and coding gains from the MIMO

processing block shown in Fig. 1, known as *spacetime coding systems* [7], and those exploiting only the diversity gain, known as *MIMO-MRC systems* [14]. In spacetime codes, coding techniques appropriate to multiple transmit antennas are incorporated in the MIMO signal processing block, in addition to the external channel codes, thereby achieving combined coding and diversity gains from this block. In the MIMO-MRC system, only channel codes external to the MIMO signal processing block are employed. The transmit–receive multiple antennas are utilized purely for diversity gains, with each transmit antenna allocated a weighted fraction of the total transmitted power. The transmit weighting vector is usually matched to the channel in a way to maximize the postprocessing SNR at the output of the channel [14]. MIMO-MRC systems have specific advantage of simplicity of implementations because the scheme employs MRC-like detection at the receiver—which is typically less complex than maximum-likelihood detection (MLD) used in spacetime coding. A detailed comparison among the performances of these methods can be found in Ref. 21.

2.1. MIMO-MRC

Figure 4 displays the model for a MIMO-MRC system consisting of N antennas at the transmitting station and L antennas at the receiving station. The symbol c to be

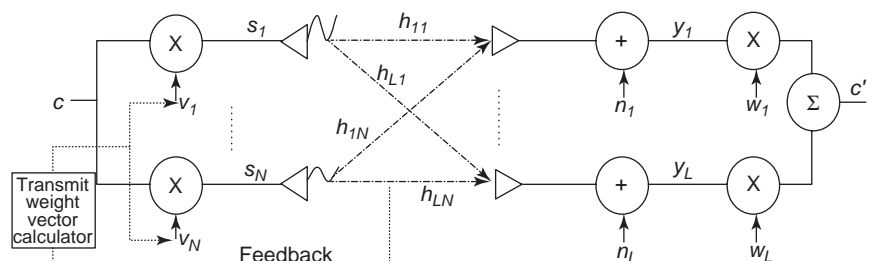

Figure 4. MIMO-MRC model.

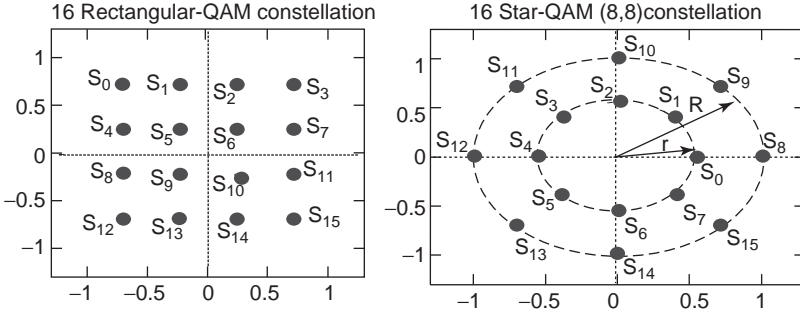

Figure 5. 16 rectangular QAM signal constellations and 16 star-QAM (8,8) signal constellations.

transmitted is weighted with a transmit weighting vector $\mathbf{v} = [v_1 \dots v_N]^T$ to obtain the transmitted signal vector:

$$\mathbf{s} = [s_1 \dots s_N]^T = c \sqrt{E_{av}} [v_1 \dots v_N]^T \quad (7)$$

where E_{av} is the average signal energy at each antenna. The transmit weight vector \mathbf{v} is chosen as [14,32–34]:

$$\mathbf{v} = [v_1 \dots v_N]^T = \mathbf{H}^H \mathbf{w} / \|\mathbf{H}^H \mathbf{w}\| \quad (8)$$

where $\mathbf{w} = [w_1 \dots w_L]^T$ is the weight vector at the receiver. For i.i.d. (independent, identically distributed) channel coefficients, the condition on \mathbf{w} to achieve maximum post-processing SNR is $|w_1| = |w_2| = \dots = |w_L|$ [14]. Without loss of generality, \mathbf{w} can be a unit vector. The received signal vector is therefore characterized as

$$\mathbf{y} = \mathbf{H}\mathbf{s} + \mathbf{n} \quad (9)$$

where \mathbf{H} is the $L \times N$ MIMO channel matrix and \mathbf{n} is the additive white Gaussian noise (AWGN) vector. The decision variable for detecting the transmitted symbol c is obtained in an MRC-like processing by taking the dot product of \mathbf{w} and \mathbf{y} , which can be expressed from Eqs. (7)–(9) as:

$$\mathbf{w}^H \mathbf{y} = c \sqrt{E_{av}} \|\mathbf{H}^H \mathbf{w}\| + \mathbf{w}^H \mathbf{n} \quad (10)$$

The output SNR from the MIMO-MRC receiver γ_{MIMO} is therefore given by

$$\gamma_{\text{MIMO}} = \frac{E_{av}}{N_0} \|\mathbf{H}^H \mathbf{w}\|^2 / \|\mathbf{w}\|^2 \quad (11)$$

where N_0 is the noise power.

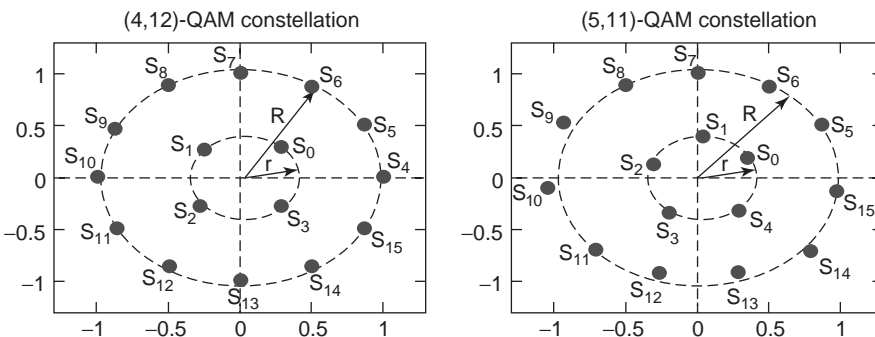

Figure 6. (4,12)-QAM signal constellations and (5,11)-QAM signal constellations.

2.1.1. Performance Results. In this section, we present some results to illustrate the performance of MIMO-MRC system for several quadrature amplitude modulation (QAM) constellations, both circular and rectangular formats. Four QAM constellations have been considered in this illustration: rectangular 16-QAM, star-QAM (8,8), (4,12), and (5,11) constellations (Figs. 5 and 6). For the circular QAM formats [star-QAM, (4,12)-QAM, and (5,11)-QAM], note that the signals in the constellations are arranged on inner and outer circles. The ratio between the radius of the outer and inner circles of a constellation is known as the *ring ratio*, $\alpha = R/r$.

Figure 7 compares the symbol error probability (SEP) of rectangular 16-QAM, star-QAM, (4,12), and (5,11) QAM constellations in MIMO channels, for various fading scenarios and various MIMO configurations. All the results presented in this figure for the circular constellations have been computed using the respective asymptotic optimum value of the ring ratio [35]. It is observed from the results that rectangular 16-QAM has similar performance with (5,11) format, with the latter having slightly better SEP performance at high MIMO order. Similarly, star-QAM and (4,12) have close SEP performance, with (4,12) having better SEP performance than star-QAM. Rectangular and (5,11) constellations both have better SEP performance than (4,12) and star-QAM constellations in all the MIMO configurations considered. For all these constellations however, dramatic improvements in the SEP performance of the MIMO system is observed as the MIMO dimension is increased (from $N=2, L=2$ to $N=4, L=4$ in this figure). This is an illustration of the link quality improvement achieved through the multiple antenna transmission.

Figure 7. SEP of rectangular and circular 16-QAM signals in MIMO channels. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

2.2. Spacetime Coding

Spacetime codes make smart use of the multiple antenna system by combining modulation, coding, and diversity transmission in one function and then use the multiple transmit antennas to transmit different codewords simultaneously at each time instant. The system utilizes both coding and diversity gains to realize significant performance improvements (higher capacity) over the single antenna system. The code construction is done in a way to ensure that both the coding and diversity gains at the receiver are maximized. A celebrated pioneer work on spacetime codes [7] presents the details of the system design criteria and code constructions.

Consider a spacetime coding system, with N transmitting and L receiving antennas, over a wireless communication channel illustrated in Fig. 8. At any time instant k , let the information-bearing signals, $d(k)$, be encoded by the spacetime encoder as $N \times 1$ code vector $\mathbf{c}(k) = [c_1(k) \ c_2(k) \ \dots \ c_N(k)]^T$, and each code symbol is transmitted simultaneously from a different antenna. All N transmitted signals have the same transmission period. At the receiver side, signals arriving at the different receive antennas undergo independent fading. The received signal is a linear combination of the transmitted signal and the MIMO channel coefficients h_{ij} , ($i = 1, \dots, N$), ($j = 1, \dots, L$), corrupted by additive noise. The received signal vector at the k th transmission period is therefore given by Eq. (1).

Figure 8. Spacetime coding system.

An appropriate signal processing operation is used to extract an estimate of the information stream from the noisy superposition of the faded version of the N transmitted signals, received by each of the antennas, which is then passed on to the detector. The main techniques proposed for this purpose include and minimum mean square error (MMSE), maximum-likelihood detection (MLD), and singular value decomposition (SVD). While some of these techniques (e.g., MLD) perform MIMO signal processing only at the receiver, others (e.g., SVD) perform MIMO processing both at the transmitter and receiver [36]. Among these detection techniques, MLD is optimum in terms of minimizing the overall error probability [37]. In the following therefore, we focus only on MLD. Assuming that maximum likelihood decoding of the transmitted data $\mathbf{c}(k)$ from the received signal sequences is carried out at the receiver, and assuming that l consecutive code vectors, $\{\mathbf{c}(k)\}_{k=1}^l$, have been transmitted. The maximum likelihood (ML) decoder can be realized using the Viterbi algorithm with the ML metric given, in the form of minimum Euclidian distance, as

$$\begin{aligned} \hat{\mathbf{c}} &= \arg \min_{\{\hat{\mathbf{c}}(1), \hat{\mathbf{c}}(2), \dots, \hat{\mathbf{c}}(l)\}} \|\mathbf{y}(1), \mathbf{y}(2), \dots, \mathbf{y}(l) \\ &\quad - (\hat{\mathbf{H}}(1) \mathbf{c}(1), \hat{\mathbf{H}}(2) \mathbf{c}(2), \dots, \hat{\mathbf{H}}(l) \mathbf{c}(l))\|^2 \quad (12) \\ &= \arg \min_{\{\hat{\mathbf{c}}(1), \hat{\mathbf{c}}(2), \dots, \hat{\mathbf{c}}(l)\}} \sum_{k=1}^l \|\mathbf{y}(k) - \hat{\mathbf{H}}(k) \hat{\mathbf{c}}(k)\|^2 \end{aligned}$$

where $\hat{\mathbf{H}}(k)$ is the MIMO channel estimate at the receiver at time instant k .

2.2.1. Spacetime Trellis Codes. For the case when the underlying code is trellis-coded modulation, an expression for upper bound on the pairwise error probability (PWE) of the resulting spacetime trellis code (STTC) is given [7] as

$$P(\mathbf{c} \rightarrow \hat{\mathbf{c}}) \leq \left(\prod_{i=1}^r \lambda_i \right)^{-L} \cdot \left(\frac{E_s}{4N_0} \right)^{-rL} \quad (13)$$

where r is the rank of the error matrix between the transmitted (true) codeword and the received (possibly erroneous) codeword [7]. $\lambda_i, i = 1, \dots, r$ are the nonzero eigenvalues of this error matrix, while E_s/N_0 is the average signal-to-noise power ratio (SNR). The first term $\delta_r = \prod_{i=1}^r \lambda_i$ represents the coding gain achieved by the spacetime code, and the second term $(E_s/4N_0)^{-rL}$ represents a diversity gain of rL achieved from the use of multiple antennas. Hence, in designing a spacetime trellis code, the rank of the error matrix r should be maximized (thereby maximizing the diversity gain) and at the same time, δ_r should be also maximized (thereby maximizing the coding gain).

An example of a four-state STTC code constructed for 4-PSK signal [7] is shown in Fig. 9. This code is designed for systems with two transmit antennas. The label ij refers to the transition between the states i and j in the trellis, and each symbol pairs in a given row labels the transition out of a given state.

Figure 9. Trellis diagram for four-state spacetime code for 4-PSK signals. (This figure is available in full color at <http://www.mrw.interscience.wiley.com/erfme>.)

2.2.2. Spacetime Block Codes. Alamouti [15] proposed an ingenious spacetime block coding scheme for transmission with two antennas. In this scheme, input symbols are grouped in pairs and transmitted at time instant k , and a transformed version of the symbols is transmitted at time $k + 1$. Let the symbols c_1 and c_2 be transmitted at time k from the first and second antennas, respectively. Then at time $k + 1$, symbol $-c_2^*$ is transmitted from the first antenna and symbol c_1^* is transmitted from the second antenna, where $(\cdot)^*$ denotes the complex conjugate. The received signals at the j th receive antenna are therefore given by

$$\begin{aligned} y_j^1 &= h_{j1}c_1 + h_{j2}c_2 + n_1 \quad j = 1, \dots, L \\ y_j^2 &= -h_{j1}c_2^* + h_{j2}c_1^* + n_2 \quad j = 1, \dots, L \end{aligned} \quad (14)$$

where we have assumed that the channel is fixed for the two transmission periods.

Alamouti's spacetime block codes have been adopted in several wireless standards such as wideband code-division multiple access (W-CDMA) and CDMA 2000 [38]. The code has the following attractive features: (1) it achieves full diversity at full transmission rate for any real or complex signal constellation and (2) the code does not require knowledge of CSI at the transmitter. Third, maximum likelihood decoding of the code involves only linear processing at the receiver, which reduces the decoding complexity significantly. The Alamouti code has been extended to the case of more than two transmit antennas [13] using the theory of orthogonal designs.

2.3. Spatial Multiplexing

Figure 10 illustrates the principle of spatial multiplexing. As shown in the figure, the input (information bearing) bitstream is first demultiplexed into p substreams and each substream is mapped to a predetermined digital modulation [e.g., phase shift keying (PSK) or QAM]. The p substreams are then transmitted simultaneously over the channel using N ($N \geq p$) independent transmit antennas [19]. The same modulation constellation with size Q is used for each substream. Therefore, $\log_2(Q)$ information bits are mapped into one Q -ary symbol. At the receiving end, the signals received by L ($L \geq p$) antennas are processed (using any of the techniques mentioned in Section 2.2) to recover the original bit-stream. Spatial

Figure 10. Spatial multiplexing.

multiplexing achieves high data rate through the transmission of parallel bitstreams.

3. RECEIVER SIGNAL PROCESSING FOR MIMO TRANSMISSIONS OVER MOBILE CHANNELS

The combined effect of the features of mobile radio propagation environment (discussed in Section 1.1) leads to the characterization of mobile wireless channels as time-varying fading channels, as well as frequency-selective fading channels. For the time-varying fading problem, the channel strengths may have significant variation within a transmission block (rapid fading) or from one block to another (quasistatic fading). In either case, channel tracking can be employed [39,40] to estimate the amount of attenuation in the wireless link, and this information [or channel state information (CSI)] is then used in the detection of the transmitted signals. The frequency selectivity problem on the other hand, results in the introduction of intersymbol interference (ISI) among successive symbols transmitted over mobile radio channels, causing severe performance degradation unless corrective measure known as *equalization* is employed.

3.1. MIMO Channel Equalization

For MIMO transmission over frequency-selective (mobile radio) channels, the channel output is given by the expression in Eq. (2) and has the Z transform given by

$$\mathbf{y}(z) = \tilde{\mathbf{H}}(z)\mathbf{c}(z) + \mathbf{n}(z) \tag{15}$$

where $\tilde{\mathbf{H}}(z) = \sum_{l=0}^{m-1} \mathbf{H}(k; l)z^{-l}$

The function of an adaptive equalizer employed at the MIMO receiver is to carry out a reverse operation of the frequency-selective MIMO channel actions in Eq. (15) in order to recover the original information bits from the noisy observation $\mathbf{y}(z)$.

If we assume perfect knowledge of the MIMO channel coefficients at the receiver, then the optimum receiver is a maximum-likelihood sequence estimator (MLSE). For transmission over frequency-selective MIMO channel, therefore, the best performance in terms of error rate, can be achieved through trellis equalization of the space-time codes based on MLSE or symbol-by-symbol maximum a posteriori probability (MAP) estimation [41]. However, it is well known that the complexity of these methods is proportional to the number of states of the trellis, which grows exponentially with the product of the channel memory and the number of transmit antennas. The complexity of the algorithm therefore becomes somewhat impractical when the channel memory becomes large and high-order constellations are used. In address-

ing this problem, some suboptimum, reduced-complexity, equalization methods have been developed. In the next section, we review two families of such suboptimum equalizers achieving a good performance-complexity tradeoff, which have been employed in MIMO channels. The first of these is the family of the block linear and Decision-Feedback equalizers, and the second is the family of the list-type equalizers.

3.2. Block Linear and Decision Feedback Equalizers

Block linear and decision feedback equalizers are by nature optimized for block transmission systems [42]; therefore these equalizers are easily adapted for MIMO systems.

3.2.1. Block Linear Equalizers. The expression for the signal estimate at the output of ZF-BLE can be written in the form

$$\hat{\mathbf{d}}_{\text{ZF-BLE}} = \mathbf{d} + \mathfrak{N}\mathbf{n} \tag{16}$$

where \mathbf{d} is the $Nl \times 1$ vector that stacks the transmitted symbols (from the N transmit antennas) during the transmission of a block of length l . The matrix \mathfrak{N} is an amplification factor that represents noise enhancements due to the zero-forcing operation, and \mathbf{n} is the noise vector.

A similar expression for the MMSE-BLE can be written as

$$\hat{\mathbf{d}}_{\text{MMSE-BLE}} = \mathbf{W}\hat{\mathbf{d}}_{\text{ZF-BLE}} \tag{17}$$

where the elements of \mathbf{W} can be seen as coefficients of a Wiener filter. The estimate from an MMSE-BLE can then be interpreted as the output of the ZF-BLE followed by a Wiener filter. The Wiener filter reduces the performance degradation caused by noise enhancement in ZF-BLE. Therefore, the SNR at the output of the MMSE-BLE per symbol is, in general, larger than that of the ZF-BLE.

3.2.2. Block Decision Feedback Equalizers. Figure 11 shows the block diagram of a block decision feedback equalizer employed in a MIMO setup. At any time instant, k , the received signal vector $\mathbf{y}(k)$ is filtered by the equalizer's feedforward filter (FFF), with coefficients $\mathbf{W}(k)$, to obtain the filtered signal vector $\mathbf{y}'(k)$. Previously obtained data estimates are processed through a feedback filter (FBF), with coefficients $\mathbf{B}(k)$, and subtracted from $\mathbf{y}'(k)$. The resultant signals are then fed into threshold detectors from where estimates of the transmitted data $\hat{\mathbf{c}}(k - \Delta)$, are obtained, where Δ is the delay in the equalizer, and $\hat{\mathbf{c}}(k - \Delta)$ corresponds to the input signals at time $k - \Delta$.

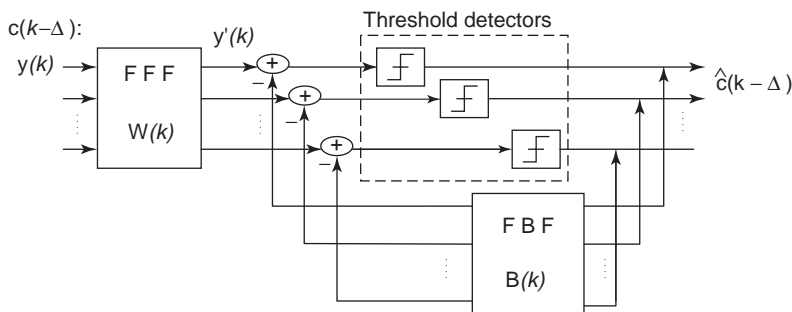

Figure 11. MIMO DFE block diagram.

Similar comparative analysis for the MMSE-BDFE and ZF-BDFE [41] shows that the SNR at the output of MMSE-BDFE is in general larger than the SNR at the output of the counterpart ZF-BDFE. Therefore, both block linear and block decision feedback equalization of MIMO channel based on MMSE criterion will yield better performance than will their counterpart zero-forcing schemes. This conclusion is consistent with what is known for the SISO channel case.

3.3. List-Type Equalizers

The list-type equalizer is another reduced complexity suboptimum equalization method. It employs a state reduction algorithm in the Viterbi or MAP equalizer, using the concept of per survivor processing (PSP) [43], to achieve a reduced complexity. The equalizers consider a reduced number of taps of the channel to construct the trellis, leading to a reduced number of states, and an adaptive equalization of the channel is carried out on the basis of the reduced states. To ensure that the best suboptimum performance is achieved, a receiver filter that concentrates the channel energy on the first few taps chosen for the trellis construction is used. This ensures that the chosen taps have the strongest energy. In the MIMO channel case, this is achieved using a multidimensional whitened matched filter (WMF) as a prefilter for the equalizer.

Comparing the performances of the block equalizers and the prefiltered list-type MAP equalizers in MIMO channel [41], it is observed that the prefiltered list-type MAP equalizer achieves better performance than the block equalizer. However, the list-type MAP equalizer is much more complex to implement. Hence, the regular tradeoff between performance and complexity has to be part of the criteria for selecting any of these structures for MIMO applications.

4. CONCLUSION

This article has presented a survey of the most popular MIMO signal processing techniques used in wireless communications. We have discussed in particular the spatial multiplexing, spacetime code, and MIMO-MRC systems. The capacity increase achieved through the spacetime MIMO transmission is also illustrated and shown to improve dramatically over the conventional wireless communication system as the number of transmit–receive antennas increase. Equalization techniques employed in

MIMO receivers for transmissions over frequency-selective, mobile communication, channels are then reviewed.

MINIATURIZED PACKAGED (EMBEDDED) ANTENNAS FOR PORTABLE WIRELESS DEVICES

M. ALI
University of South Carolina
Columbia, South Carolina

1. INTRODUCTION

With the rapid growth of wireless communications there has been an ever-increasing demand for small, wideband/multiband packaged or embedded antennas for mobile phones, wireless PDAs, pagers, GPS receivers, implantable wireless devices, and RFID tags [1–3]. The application list is not exhaustive and may also include many other scenarios, such as “man-pack” devices for the land-warrior and smart multifunctional wireless device for law enforcement personnel. When an embedded antenna is concerned one thing is common, the antenna is packaged within the housing of the device. In some cases the antenna is

printed directly on the device PCB, its housing, or an onboard chip.

This problem, however, is not very easy to solve. Depending on the specific application, there is always a set of requirements that must be fulfilled before a useful antenna can be designed. These requirements can vary widely from mobile phone application to Bluetooth to GPS. Nevertheless, the key challenges that we need to confront are bandwidth, gain, radiation pattern, polarization, and SAR (specific absorption rate). When an antenna is packaged or embedded within a device it suffers degradation in some or all of these performance characteristics. This happens because the antenna (1) needs to be miniaturized to be accommodated within a device and (2) operates in close proximity to other metallic and/or dielectric objects in its vicinity. Thus a careful evaluation of antenna performance is required. Unfortunately, since the antenna is very platform-dependent, any change in the platform or embedding medium requires full characterization and optimization. Albeit phenomenal progress has been made in electromagnetic analysis using the finite-element method or method of moments (MoM) or the finite-difference time-domain method the results obtained there from can serve as guidelines only. The actual performance predictor is an antenna prototype built and tested in the laboratory. Thus simulations must be conducted to get a broad knowledge and an overall understanding of the antenna design. In circumstances where the simulation model can replicate the exact CAD environment of the wireless device, very realistic results are obtainable. The efficacy of the simulation tools lies in their rapid prediction capabilities, which save a significant amount of time from the concept to production phase of an embedded antenna. Thus modeling and measurement must proceed hand in hand to get a functioning antenna in an embedded environment.

Note that as the development phase of the product progresses more and more variables start to add up. Thus a significant number of measurements need to be conducted to ascertain that performance criteria are met. As a simple example, consider a mobile phone antenna. It starts with a simple model of the antenna on a blank printed circuit board. Then the board gets populated with components, the mechanical components begin to add, the radio starts functioning, the audio works, and so on. Thus the antenna needs to be measured and tuned accordingly in free space, in the presence of a phantom in various talk positions, and for SAR every step of the way.

2. ANTENNAS FOR MOBILE PHONES

Before discussing antennas for mobile phones, it is worthwhile to mention the frequency bands of interest. For instance, for the AMPS (Advanced Mobile Phone Systems) system the frequency bands are 824–859 MHz for transmit (Tx) and 869–894 MHz (Rx) for receive (see Table 1). From an antenna design perspective, the two frequency bands are fairly close to each other. Thus usually a single antenna is designed to support the entire 824–894-MHz band. Respective transmit and receive frequency bands for the GSM, DCS, and PCS systems are listed in Table 1 [4].

Table 1. Frequency Bands of Different Mobile Telephone Systems

System	Transmit Frequency Band (Tx) (MHz)	Receive Frequency Band (Rx) (MHz)	Antenna Operational Band (MHz)
AMPS	824–859	869–894	824–894
GSM	880–915	925–960	880–960
DCS	1,710–1,785	1,805–1,880	1,710–1,880
PCS/GSM 1900	1,850–1,910	1,930–1,990	1,850–1,990

Lately almost all phones are at least dual-band (one low-frequency band and the other high-frequency band). Interest is growing to develop triple or quad-band phones also which will enable a user to use the same phone in different geographic locations with different air interface standards. One example is a dual-mode AMPS/GSM phone that can be easily triple band. Clearly it is greatly desirable to support all three bands by just one antenna. Thus there is demand for triple- and quad-band antennas.

A mobile phone antenna has to satisfy various performance and regulatory requirements. Among these are bandwidth, gain, radiation pattern, and SAR (specific absorption rate). The antenna must have good VSWR bandwidth (usually within a maximum VSWR of 2.5–1). Even though a VSWR limit of 2–1 is preferred, it is difficult to achieve that with a small embedded antenna. The antenna must also have reasonable peak and average gain in free space and in talk position. The gain in the talk position is extremely critical to ensure proper operation. The peak gain provides a good basis point to determine the EIRP (effective isotropic radiated power). While there are near-field chambers to measure complete three-dimensional patterns and the antenna efficiency thereof, a generally acceptable representation is obtainable by measuring the principal plane cuts. If average gain data is required it can be obtained from the total three-dimensional field distribution. The amount of head blockage (pattern shadowed by or energy absorbed by the user head) varies from antenna to antenna and from phone to phone. Thus proper electromagnetic modeling or measurement is necessary to predict the antenna average gain for each design. Antenna gain in talk position is generally measured with the aid of a phantom head consisting of brain simulating fluid.

After the phone is manufactured, radiated live tests are conducted and EIRP and receiver sensitivity are measured at different channels to obtain a complete picture of the phone performance. This is done before the product and test data are sent to the respective regulatory agencies for compliance. In the United States the Federal Communications Commission (FCC) has a set of requirements that must be met before a mobile phone can be sold in the market. These include the EIRP, out-of-band emission, and most importantly, SAR (specific absorption rate).

2.1. External Antennas

Until around 2000 most mobile phone antennas were external. In the earlier days end-fed sleeve dipoles were used

to achieve a figure-eight radiation pattern [1]. Such patterns are most common with half-wave dipole antennas. Albeit a dipole antenna works better than a monopole (ground plane independent and suffers from less head blockage) its larger size, and the requirement for a balun (when coaxial line feed is used) forced design engineers to explore and utilize the monopole geometry. In the latter case the cellular phone PCB (printed-circuit board) along with its housing (if metallic) acts as the monopole ground plane (counterpoise).

For example, at 900 MHz a resonant thin-wire monopole antenna should be about 78 mm long. This length will vary to some extent based on the wire radius and the position of the antenna with respect to the device housing. Since a conventional monopole operates on a large ground plane (several wavelengths in diameter for a circular ground plane) its radiation pattern is restricted to the upper hemisphere only with the peak of the beam directed toward the horizon. The directivity in such a case is 5.1 dBi, which is 3 dB higher than the directivity of a half-wave dipole [5]. Such a large ground plane is completely impractical for a mobile phone. Because the mobile phone ground plane is much smaller, there is a significant amount of current flow on it and the ground plane generally dominates the radiation pattern. If a phone measures $110 \times 40 \times 25$ mm, the 78-mm-long antenna and the phone housing ensemble represents an asymmetric dipole where the longer and wider ground plane dominates over the small monopole antenna. Thus the radiation pattern has a butterfly shape and is directed to Earth for a vertically oriented phone [6]. The maximum field strength is not directed toward the horizon.

External antennas have also evolved a great deal over the years primarily due to the need for miniaturization. Engineers have focused on reducing the antenna size by inductive loading. This is achieved either by employing a helical, meander, or zigzag geometry. Such an antenna can, in general, have a three-dimensional shape. In case of a meander or zigzag configuration it can also be planar. Examples of small helical or meander stub antennas as small as 35–40 mm are everywhere. Some phones come with a retractable geometry where ordinarily the antenna is a small stub which when extended can be much longer in size. As apparent a small stub will be more susceptible to performance degradation when placed close to a user's head than a 78-mm-long monopole antenna. The smaller stub is simply shadowed much more than a longer antenna. However, experience has shown that a small stub still provides reasonable performance for most cases. For dual- or triple-band operation branches are created to excite separate current flow paths. Usually the branch having a longer current flow path is responsible for the low-frequency band of operation while the shorter current flow path is responsible for the high-frequency band of operation.

2.2. Packaged (Embedded) Planar Inverted-F Antennas

2.2.1. Background. There has been a surge of interest in planar inverted-F antennas (PIFAs) for mobile phone applications [7–19]. Such antennas are smaller than

Figure 1. Half-wave microstrip patch.

resonant half-wavelength-long microstrip patches and can be easily placed internally within the housing of a mobile phone. For mobile phone applications the PIFA is usually placed under the back cover of the phone right above the battery line.

The PIFA evolved from a shorted quarter-wave microstrip patch antenna. A conventional microstrip patch is a half-wavelength (0.5λ) long (guided wavelength), including the edge effects and dielectric loading (see Fig. 1). A quarter-wave patch has a short circuit along one of its edges (Fig. 2). The short circuit is positioned along one of the patch edge and has a width of W and depth of h as indicated in Fig. 2. Thus the length L determines the operating frequency (0.25λ minus the effect of dielectric and the edge effect).

In contrast, a PIFA (see Fig. 3) consists of a shorting pin instead of a large plate as it is for a quarter-wave patch. The shorting pin diameter can be the same as the probe feed or can be different. Since only one shorting pin is present the antenna resonant length is approximately determined by $L + W$, which is about a quarter-wavelength ($\sim 0.25\lambda$) at the operating frequency. However, for mobile phone applications the positioning of the PIFA is generally at one of the edges of the PCB for convenience and better utilization of space. The PIFA performance is determined largely by the antenna parameters L, W, h and the spacing between the feed and shorting pin S . The size of the PCB also plays a dominant role in antenna performance, particularly at the low-900-MHz frequency band. As an example, if $L = 50$ mm, $W = 23$ mm, $h = 6$ mm, and the feed–shorting pin spacing is 6 mm, the PIFA will operate at 890 MHz with a bandwidth of 100 MHz within 2.5–1 VSWR. Ground-plane size is 110×50 mm.

In designing a PIFA the primary challenge is to achieve the necessary operating bandwidth, which requires that the PIFA height be about 8–12 mm from the ground plane. This large antenna height makes the phone thicker even

Figure 2. Quarter-wave microstrip patch.

Figure 3. PIFA on a mobile phone PCB.

though the battery is very thin. It will be greatly advantageous if PIFAs with much smaller heights can be designed. However, bandwidth becomes extremely narrow as antenna height is reduced.

It has been reported [20–22] that the bandwidth of a PIFA also depends on the size of the ground plane. For instance, for optimal bandwidth in the 900-MHz band the combined dimensions of the length and width of the ground plane should be 0.5λ [21]. Ground planes that are smaller than that provide much narrower bandwidth. As an example, a PIFA ($h = 4$ mm) on a 90×35 mm ground plane has 2.5% bandwidth while that on a 130×35 mm ground plane has 9.5% bandwidth. Conversely, it can be inferred that for a fixed bandwidth, a much thinner antenna can be designed if a larger ground plane is utilized.

Based on this concept, a slotted meandered ground plane was proposed in [16] that can effectively reduce the heights of PIFAs by more than 50%. The meander-line configuration proposed in [16] can be viewed as a slow-wave structure where the phase velocity of the propagating wave is smaller than the velocity of light. This makes a slotted meandered ground plane appear electrically longer, even though its physical size is unchanged, and hence helps achieve much thinner PIFA design.

2.2.2. Dual-band PIFA on Conventional and Modified Ground Planes. An example of a dual-band PIFA is shown in Fig. 4. The antenna consists of two radiating elements joined near the feedpoint. The larger element has a longer current flow path from the feed and hence is responsible for low band while the smaller element, which is close to the feed, is responsible for the high band. However, the two elements are not completely independent from each other as it pertains to overall performance characteristics. Both elements are at a height h from the PCB and the

feed–shorting pin (ground) spacing is s . All antenna parameters can be adjusted to vary the resonant frequency, bandwidth, and pattern. Typically, a design will start with a full-wave three-dimensional electromagnetic model development using the method of moments (MoM) or finite-element method (FEM), or finite-difference time-domain (FDTD) method. Concurrently or afterward antenna prototypes must be developed and tested. The prototype development and testing continues for each phase of the phone development and each degree of complexity and sophistication in the phone may require the engineer to evaluate and redesign the antenna over time.

As mentioned earlier, the typical dual-band PIFA shown in Fig. 4 depends heavily on the antenna height from the ground plane. Larger heights are usually required to satisfy the bandwidth requirements. To alleviate this problem, an alternative scheme has been proposed [16]. This scheme is shown in Fig. 5. Using this slotted meandered ground plane, PIFA heights can be reduced by more than 50%. The meanderline configuration proposed in Ref. 16 can be viewed as a slow-wave structure where the phase velocity of the propagating wave is smaller than the velocity of light. This makes a slotted meandered ground plane appear electrically longer, even though its physical size is unchanged, and hence helps achieve much thinner PIFA design.

Figure 6 shows the computed and measured VSWR data for the dual-band designs. As apparent, a significant improvement in bandwidth can be achieved with the proposed new ground plane for both the low- and high-frequency bands. In the low-frequency band, computed bandwidth for antennas on conventional and modified ground planes are 2.1% and 7.8%, respectively. Measured bandwidth for the PIFA on the modified ground plane is 7.6%.

In the high-frequency band, bandwidth of antennas on conventional and modified ground planes are 3.1% and 8.8%, respectively, whereas measured bandwidth on the modified ground plane is 7.1%.

2.3. Packaged (Embedded) Monopole-Type Antennas

Apart from PIFAs monopole-type radiators are also of interest for embedded applications. In that case the antenna can be considered as a volume lying at a height adjacent to

Figure 7. A monopole-type embedded antenna.

the ground plane. In general there cannot be any metal below the antenna. In addition, there should be additional clearance area kept in between the antenna and the ground plane (d in Fig. 7). The antenna should have a specific height h from the ground plane.

By developing antenna geometries of various different shapes and sizes, operation in single or multiple frequency bands can be achieved. Such an antenna has been described in [23,24], consisting of a driven meanderline element and two parasitic coupled elements. The geometric configuration, size, and proximity of the driven and parasitic elements help materialize the desired multiband operation. The complete antenna assembly is internal to the handset. The antenna can be tuned to operate in either the (1) 824–894-, 880–960-, and 1850–1990-MHz bands or (2) 824–894-, 880–960-, and 1710–1880-MHz bands. The size of the antenna is $50 \times 10 \times 6$ mm (3 cm^3) or less.

The geometry of the antenna and its associated printed-circuit board (PCB) is shown in Fig. 8. As can be seen, there are two metal layers. The bottom layer (layer 2) consists of a PCB and two parasitic metallic strips. The meanderline element is on the top layer at a height h from the PCB. The antenna volume is $50 \times 10 \times h$ mm. The distance d is a small separation between one of the parasite

Figure 8. Antenna and PCB geometry with associated parameters (dimensions in mm). [© 2004 IEEE. Reprinted, with permission, from M. Ali, G. J. Hayes, H.-S. Hwang, and R. A. Sadler, Design of a multi-band internal antenna for third generation mobile phone handsets, *IEEE Trans. Anten. Propag.* **51**(7):1452–1461 (July 2003).]

and the PCB that can be minimized when PCB space is critical. The parasites are directly connected to the PCB ground. The antenna is on the upper layer at a height h from the PCB. The antenna is fed using a connector pin from a RF signal pad on the PCB (not shown).

The double-meander geometry for the antenna has been chosen for two reasons: (1) to shorten the length of the antenna and make it the same size as the width of the PCB (50 mm) and (2) to achieve wideband characteristics [25]. The length of the antenna can be further reduced (current length = 50 mm) by increasing the width (antenna width = 10 mm). Note that the length of a resonant quarter-wave monopole operating at 900 MHz is about 78 mm. The double meandering reduces the antenna length to 50 mm, so that it can be enclosed within the device housing.

Computed VSWR as function of antenna height h is shown in Fig. 9, where $l = 26.5$ mm, $S = 6$ mm, $d = 4$ mm, and $w = 2$ mm. It is apparent that the antenna has two resonances at around 900 and 1920 MHz. The first resonance is due to the meander antenna, while the second is due to the parasites attached to the PCB [25,26]. The antenna VSWR changes as h varies, which has two effects: (1) a shift in the resonance frequency (as h is reduced, the resonant frequencies move higher as expected) and (2) the overall level of the minimum VSWR. It is also clear that for $h = 6$ mm, the antenna is well suited for triple-band operation. In the low-band the bandwidth is 250 MHz (27.8%) within a VSWR of 2.5–1. This is far greater than the required bandwidth for AMPS 800 and GSM 900 combined (15.25%). In the high-band the antenna bandwidth is 9.4%. The bandwidth required for TDMA/GSM 1900 is 1850–1990 MHz or 7.3%. For practical purposes VSWR of 2.5–1 as an upper limit has been generally found to be acceptable for mobile handsets, which creates only ~ 0.4 dB of loss as the VSWR changes from 2–1 to 2.5–1.

Figure 9. Computed VSWR versus frequency with antenna height h (mm) as parameter $d = 4$ mm, $l = 26.5$ mm. [© 2004 IEEE. Reprinted, with permission, from M. Ali, G. J. Hayes, H.-S. Hwang, and R. A. Sadler, Design of a multi-band internal antenna for third generation mobile phone handsets, *IEEE Trans. Anten. Propag.* **51**(7):1452–1461 (July 2003).]

A prototype antenna was fabricated and tested (see Fig. 10). Computed and measured VSWR data are compared in Fig. 11. The resonant frequencies of the antenna for both the computed and measured cases are about the same. The measured bandwidths in each band (low and high) are also in good agreement with the computed bandwidths within 2.5–1 VSWR. It is clear from Fig. 11 that the antenna operates in the AMPS 800 and GSM 900 band within 2–1 VSWR and the GSM 1900 band within VSWR of 2.3–1. Antenna radiation patterns and gain were measured with reference to two standard gain antennas (the gain values of which were known from the manufacturer's

datasheet). A logperiodic dipole antenna and a rectangular horn antenna were used for the 900 and 1900 MHz bands, respectively. Measured gain for the two principal plane patterns are listed in Table 2. The free-space peak gain at 900 MHz is between 0 and -0.5 dBi, while that at 1900 MHz is between 2.3 and 2.5 dBi. This is expected since the antenna is more directional in the high band.

Measured normalized radiation patterns for the proposed antenna are shown in Fig. 12. The azimuth (xy -plane) patterns at 900 and 1900 MHz are shown in Figs. 12a and 12b. At 900 MHz the vertical component is the dominant one and its variation is nearly uniform. The front-to-back ratio is about 3 dB. At 1900 MHz the vertical field component is fairly directional, front-to-back ratio is about 8 dB. Although the vertical component is not uniform, fairly good angular coverage can still be obtained when both vertical and horizontal components are combined.

The angular region where coverage is between -8 and -10 dB is limited between the angular region of 60 – 120° . This region will be blocked by the operator head. The directionality in the high band can be considered as an advantage since less energy is being deposited in the operator head. Also to note is the significance of total field rather than just one component. In a mobile environment polarization purity is absent. Thus when both components exist and are comparable they need to be combined to get the total field.

3. ANTENNAS FOR BLUETOOTH/WLAN APPLICATIONS

Bluetooth [27] is a consortium pioneered by Ericsson in the late 1990s and later on adopted by a large number of companies. This is an air interface standard proposed to support short-distance communication between devices,

Figure 10. Laboratory prototype of the proposed antenna. The antenna is placed on a thin transparency film to show all parameters in one picture. In actual measurement a foam ($\epsilon_r \approx 1.0$) substrate 6 mm thick was used to support the antenna. [© 2004 IEEE. Reprinted, with permission, from M. Ali, G. J. Hayes, H.-S. Hwang, and R. A. Sadler, Design of a multi-band internal antenna for third generation mobile phone handsets, *IEEE Trans. Anten. Propag.* **51**(7):1452–1461 (July 2003).]

Figure 11. Computed and measured VSWR versus frequency; $d = 4$ mm, $s = 6$ mm, and $l = 26.5$ mm. [© 2004 IEEE. Reprinted, with permission, from M. Ali, G. J. Hayes, H.-S. Hwang, and R.A. Sadler, Design of a multi-band internal antenna for third generation mobile phone handsets, *IEEE Trans. Anten. Propag.* **51**(7):1452–1461 (July 2003).]

such as mobile phones, laptops, desktops, and PDAs. The frequency band of operation in the United States is 2.4–2.485 GHz. This band also coincides with the IEEE 802.11b standard. For more detailed information on Bluetooth, please see Ref. 27. Typically the transmitter has 0 dBm of output power, which can provide a link of up to 10 m, which can be extended to up to 100 m by increasing the output power to 20 dBm. In addition to Bluetooth, there are the WLAN protocols based on several IEEE standards, such as the IEEE 802.11a,b,e,g. There is also Hyperlan in Europe. For high-speed directional WLAN links, one must resort to directional high-gain antennas, which are not practical for embedding within the device. Thus most if not all embedded Bluetooth and WLAN antennas are essentially nondirectional.

3.1. Surface Mount PIFAs

The most popular among embedded antennas for these types of applications is the surface mount PIFA as depicted in Fig. 13. This antenna is essentially a planar inverted-F antenna (PIFA) fabricated on a dielectric

Table 2. Measured Peak Gain Data for Proposed Antenna (Free-Space) at 5.25 and 5.78 GHz^a

Frequency (GHz)	Peak Gain (dBi), yz Plane	Peak Gain (dBi), xy Plane
5.25	1.8 at $\theta = 0^\circ$	-0.5 at $\theta = 210^\circ$
5.78	0.8 dBi at $\theta = 140^\circ$	0.6 dBi at $\theta = 190^\circ$

^aFor pattern characteristics and beam peak locations for yz and xy planes, see Fig. 6.

substrate, such as FR4. Typical antenna size can be about $25 \times 4 \times 4$ mm (length, width, height). As indicated, the antenna has a feed and shorting pin that are connected to the respective pads on the PCB when surface-mounted. The antenna size can be further reduced by either modifying the geometry or using higher dielectric constant substrates (ceramics). Geometry modification usually occurs in the form of employing a meanderline configuration. This can be utilized either on the top surface or on the top as well as the side surfaces. Whether it is geometry modification or high dielectric substrate antenna size reduction will result in bandwidth and gain degradation. Thus clearly one must focus on the required bandwidth (e.g., for Bluetooth it is 2.4–2.485 GHz). Once a surface mount PIFA is fabricated it must be embedded within the device PCB and housing and its characteristics evaluated. Since in most circumstances the PIFA has to reside on the same PCB as the mobile phone antenna adequate isolation between them must be ensured (typically 10 dB or better). Usually this is achieved by employing spatial separation between the two antennas.

3.2. Integrated IFAs

3.2.1. Board-Mounted IFA. As indicated, surface mount PIFAs are fabricated separately from the wireless device PCB and hence they need to be assembled on the PCB later on. After the placement of the antenna its characteristics is then evaluated and if performance deficiency is noted the design is changed accordingly. A superior and alternative solution was proposed by Ali et al. [11,15]. In their proposal the Bluetooth/WLAN antenna is an integrated inverted-F antenna (IFA) rather than a PIFA. The IFA is directly printed on the wireless device PCB, and hence no assembly is required. Testing is conducted as soon as the board is released. The antenna requires that

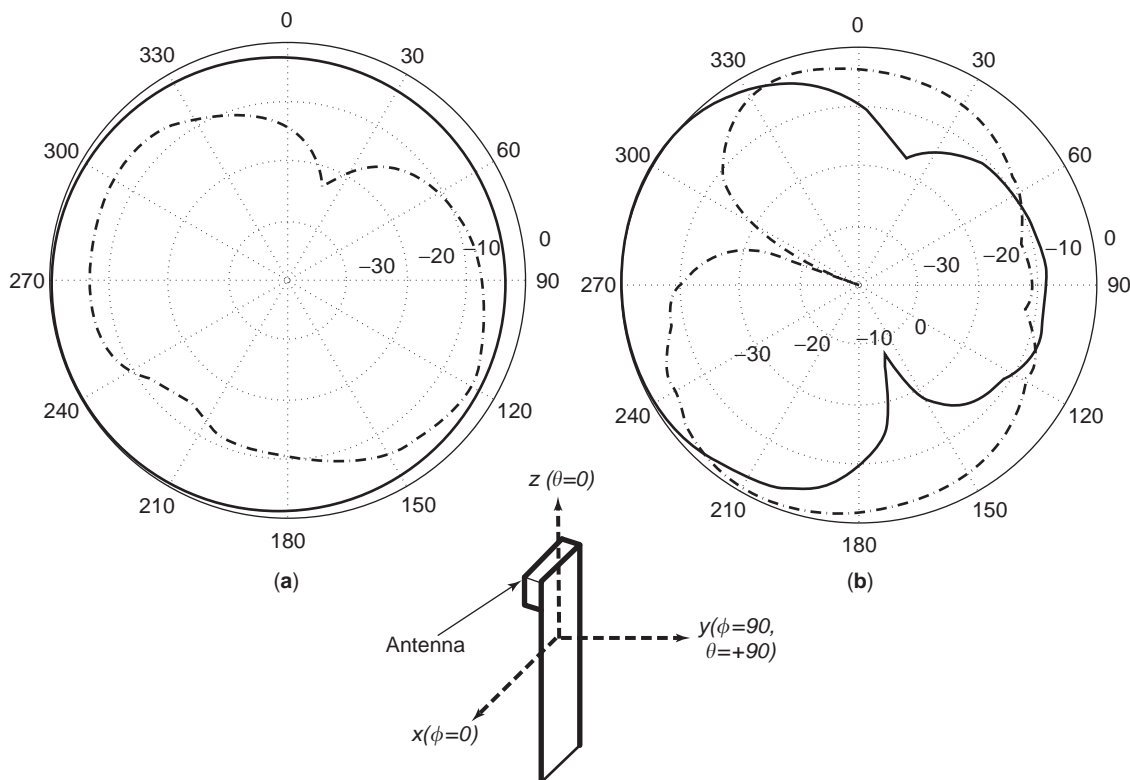

Figure 12. Measured normalized azimuth plane patterns: (a) xy plane (900 MHz); (b) xy plane (1900 MHz). Solid line—vertical component; dashed line—horizontal component; $d = 4$ mm, $s = 6$ mm, and $l = 26.5$ mm. [© 2004 IEEE. Reprinted, with permission, from M. Ali, G. J. Hayes, H.-S. Hwang, and R. A. Sadler, Design of a multi-band internal antenna for third generation mobile phone handsets, *IEEE Trans. Anten. Propag.* **51**(7):1452–1461 (July 2003).]

Figure 13. Surface-mount PIFA.

there be an opening on both sides of the PCB so that it can radiate (see Fig. 14). The antenna is directly printed on the substrate material. In Fig. 14, dielectric material has been shown as removed from the region to help visualize the antenna. In reality, dielectric material will be present

and the antenna will be printed on it. Note that the antenna consists of a trace, a feed (that brings the signal through a transmission line, usually a microstrip or strip-line), a via (through hole), and a shorting pin just adjacent to the feed. The transmission line and via are not shown in the figure. In the window where the antenna is located there is no metal on the top or bottom part of the PCB except the antenna, its feed, and the shorting pin. In addition, when the PCB is placed inside a device housing, there cannot be any metal shadowing the antenna.

In Fig. 15 measured VSWR is plotted against the frequency response for the proposed antenna. Note that the antenna works under 2–1 VSWR throughout the entire Bluetooth band. Finally, we show measured elevation

Figure 14. Integrated inverted-F antenna (IFA) [15].

plane pattern data for a typical Bluetooth PIFA on a PC board (Fig. 15). For comparison the pattern of a half-wave dipole on a PC board is also shown. The dipole is twice as long as the PIFA. Note that the peak gain of the PIFA is slightly smaller. The PIFA pattern is much broader and does not have sharp nulls as the dipole. Patterns in other orthogonal planes also show comparable performance.

3.2.2. Flexible Film-Type Antenna. Ali et al. [14] presented a small internal inverted-F antenna printed on the

inside surface of the stylus holder of a PDA (Fig. 16). The antenna can be printed on a flexible film substrate and bonded to the plastic with an adhesive. The proposed antenna operated with or without the stylus considering that the stylus and the stylus holder both were made of plastic material.

Input impedance data for the proposed antenna with and without a dielectric insert are shown in Fig. 17. It is evident that the impedance locus for each case is very close to the center of the Smith chart, especially within the

Figure 15. Measured VSWR and radiation patterns [15].

Figure 16. A uniquely packaged inverted-F antenna for Bluetooth or WLAN. [© 2004 IEEE. Reprinted, with permission, from M. Ali, R. A. Sadler, and G. J. Hayes, A uniquely packaged internal inverted-F antenna for Bluetooth or wireless LAN application, *IEEE Anten. Wireless Propag. Lett.* 1(1):5-7 (2002).]

frequency range of 2.4–2.485 GHz. The center frequency is 2.45 GHz, and the bandwidth is 11%. The antenna operates within 1.5–1 VSWR throughout the entire Bluetooth band (2.4–2.485 GHz).

The yz-plane pattern is shown in Fig. 18. This is the most important pattern that provides clear understanding about the angular coverage that the antenna can provide.

3.3. Monopole-Type Radiators

In Fig. 19 a monopole type embedded antenna is shown for wideband WLAN application in the 5–6-GHz bands [28,29]. This antenna can support the IEEE 802.11a wireless local-area network bands (5.15–5.35 GHz and 5.725–5.825 GHz). The configuration is similar to the ones presented in Refs. 30 and 31. In Ref. 30, only a single-band folded design was presented for Bluetooth application (2.4–2.485 GHz, 3.5% bandwidth). No method of wideband/dual-band operation was described. The proposed packaged design can either be used as a wideband antenna, which can provide bandwidths in excess of 10% within 2–1 VSWR, or it can be used for dual-band operation, where the bands are separated by 500–700 MHz in the 5–6 GHz band. This latter property has been exploited to present a design that satisfies the IEEE 802.11a WLAN 5.15–5.35-GHz and 5.725–5.825-GHz bands. The antenna design presented here is packaged within the housing of a personal digital assistant (PDA) and has the maximum dimensions of $28 \times 9 \times 3$ mm. The wideband/dual-band operation has been achieved through proximity parasitic

Figure 18. yz -plane pattern. [© 2004 IEEE. Reprinted, with permission, from M. Ali, R. A. Sadler, and G. J. Hayes, A uniquely packaged internal inverted-F antenna for Bluetooth or wireless LAN application, *IEEE Anten. Wireless Propag. Lett.* 1(1):5–7 (2002).]

coupling between a folded radiator and an extended PCB ground plane. The dimensions of the extended PCB ground plane have been appropriately adjusted to ensure the desired coupling.

The proposed antenna can also be manufactured to operate in air. In such a case manufacturing the antenna should be much simpler and easier. Computed VSWR data for antenna on FR4 and in air are shown in Fig. 20.

Bandwidth obtained is 15.5% with 3 mm antenna height and 18.0% with 4 mm antenna height (within VSWR of 2–1). In contrast bandwidth obtained with FR4 was 10% with 3 mm antenna height (within VSWR of 2–1). Thus wider bandwidth can be obtained by replacing FR4 with air. However, the dimensions of the antenna in air are about $50 \times 22 \times 3$ mm, while that on FR4 are $28 \times 9 \times 3$ mm. A laboratory prototype of the proposed antenna

Figure 19. Antenna and PCB geometry. [© 2004 IEEE. Reprinted, with permission, from M. Ali, T. Sittironnarit, H.-S. Hwang, R. A. Sadler, and G. J. Hayes, Wideband/dual-band packaged antenna for 5–6 GHz WLAN application, *IEEE Trans. Anten. Propag.* 52(2): 610–615 (Feb. 2004).]

Figure 20. VSWR characteristics. [© 2004 IEEE. Reprinted, with permission, from M. Ali, T. Sittironnarit, H.-S. Hwang, R. A. Sadler, and G. J. Hayes, Wideband/dual-band packaged antenna for 5–6 GHz WLAN application, *IEEE Trans. Anten. Propag.* **52**(2): 610–615 (Feb. 2004).]

(on FR4) was built and tested for VSWR. Measured and computed VSWR data are compared in Fig. 20. The agreement between the measured and computed data is quite good. Computed and measured resonant frequencies are about the same. The measured bandwidths in both bands are also in good agreement with the computed bandwidths within 2–1 VSWR. It is clear that the antenna satisfies the bandwidth requirements for the IEEE 802.11a LAN (5.15–5.35 GHz and 5.725–5.825 GHz). The midband VSWR is only as high as 2.7–1. Antenna radiation pattern and gain were measured inside an anechoic chamber. Measured gain for the two principal plane patterns are listed in Table 2. The free-space peak gain at 5.25 GHz is 1.8 dBi, while that at 5.78 GHz is 0.8 dBi.

4. ELECTRICALLY SMALL ANTENNAS, DIELECTRIC LOADING, AND BANDWIDTH

As defined by Wheller [32], an electrically small antenna has its maximum dimension contained within a sphere with radius $\lambda/2\pi$. Thus, clearly, if a linear antenna such as a straight thin-wire dipole is constructed, it needs to be λ/π or smaller to fall within this category. A comprehensive study on the minimum achievable antenna quality factor (Q) is available in the literature [32–36]. These references are extremely useful if one intends to explore the fundamental limits on small antennas. Since most embedded or packaged antennas for mobile phones utilize these platforms, it is unlikely that these antennas will fall within the category of electrically small antennas. However, antennas for wireless radios or small antennas for VHF and other UHF applications may belong to the class of electrically small antennas. Primarily the antenna bandwidth diminishes with extreme miniaturization, and specifically for an electrically small antenna, the spherical volume

needs to be utilized properly to achieve the lowest possible Q . A thin-wire dipole represents a rather poor utilization of the radian sphere, a normal-mode helical antenna, most commonly used in police radios (scanners) and mobile phones, represents a better utilization of the same axial dimension, while the disk-loaded monopole or the Gobou antenna represents even better utilization of the small antenna volume. There has been some effort in terms of genetically optimizing electrically small antennas [37].

Apart from geometric modification, electrically small antennas can also be developed using dielectric loading. This invariably results in narrower antenna bandwidth and lower antenna gain. For instance, a small GPS patch using ceramic dielectric can be easily fabricated. Also since for GPS, bandwidth required is extremely small (only to satisfy tolerance), a small antenna size can be readily achieved. However, comparing a 25-mm² patch with a 12-mm² patch shows that the peak right-hand circularly polarized gain can fall from 6.5 to –2 dBi. A good discussion on dielectric loading of antennas can be found in Ref. 38. A more recent example of a dielectric loaded antenna can be found in Ref. 39.

5. DISCUSSION AND FUTURE TRENDS

Research will continue on antenna miniaturization and broadbanding. Miniaturization will be achieved primarily by utilizing the available antenna volume rather than a planar surface. Thus designers will increasingly utilize a three-dimensional space. Antenna geometric modification will also occur in the form of employing meander, zigzag, and fractal-type elements.

While electromagnetic bandgap (EBG) materials have shown tremendous progress in improving the gain of microstrip patch antennas by reducing the surface waves,

such structures have not been very useful for small mobile antenna applications. This is due partly to the fact that mobile antennas are so dependent on their counterpoise. There have already been some research activities in terms of small, low-profile antenna development using novel materials [40–46]. Nevertheless, in future negative reflection coefficient materials, negative transmission-line materials and EBG materials may find some useful role in packaged (embedded) antenna development.

Fractal geometries have been considered to design small resonant antennas because of their unique space filling properties. The usefulness of a Hilbert wire antenna in order to lower the antenna resonant frequency has been studied [47–49]. Zhu et al. [48] conducted a parametric study on a matched Hilbert antenna to understand its bandwidth and cross-polarization level. A printed Hilbert antenna was proposed [49] for operation in the UHF band. More recently we have proposed a miniaturized Hilbert shaped PIFA for dual-band applications (900 and 1900 MHz) [50]. The proposed antenna occupied a volume of only $40 \times 10.65 \times 10$ mm (4.3 cm^3). In contrast, a conventional dual-band PIFA made of polygonal plates occupies a volume of $40 \times 22.6 \times 10$ mm (8.4 cm^3). Thus, a 50% saving in antenna volume was readily achieved with our proposed design.

Apart from wire or printed dipole/monopole type antennas, miniaturized slot antennas are also drawing interests. Some examples can be found in Refs. 51–54. As wireless devices shrink in size and more and more functionalities are added (phone, WLAN, GPS for E-911), the need for reconfigurable/multifunctional antennas will also grow. Such antennas must be researched and developed within the embedding platform. MEMs switches can play a dominant role in that area.

As evidenced from numerous publications, smart antennas are becoming increasingly popular to increase system capacity in a mobile communication system. Currently researchers are focusing mostly on arrays for base-station application that can scan the beam in space in an adaptive fashion and track the mobile user. This way a much larger antenna gain can be achieved with little or no interference in any other angular direction. Introducing smart antennas in mobile portable or handheld terminals will require significant progress since array elements have to be placed in very close proximity to each other.

MISSILE GUIDANCE

ARMANDO A. RODRIGUEZ
Arizona State University
Tempe, Arizona

1. A BRIEF HISTORY: FROM 1944 TO THE PRESENT

1.1. The Missile Age

Even prior to World War I—when powered flight was in its first decade—forward-thinking individuals from several countries advocated the use of unmanned vehicles to deliver high-explosive weapons from afar. Although the earliest efforts to develop a practical flying bomb were undertaken in the United States and Great Britain, it was in Germany that a workable concept finally emerged. After 14 years of intense research, the Germans ushered in the missile age during World War II with their Vengeance

weapons: the Luftwaffe-developed V-1 buzz bomb, and the Army-developed V-2 rocket [1].

1.1.1. Lark Guided Missile. Because of the lack of success of anti-aircraft artillery in stopping Kamikaze aircraft attacks against naval vessels, the U.S. Navy initiated the development of the Lark guided missile in 1944. The first successful intercept of an unmanned aircraft occurred 6 years later on December 2, 1950. An account of this, as well as the development of other missiles (e.g. Sparrow, Hawk), is provided in Ref. 2.

1.1.2. The First Ballistic Missiles. The first long-range ballistic missile, deployed in 1944, was the German V-2. After World War II, significant improvements in inertial guidance system technology led to the Redstone missile—the first short-range U.S. ballistic missile with a highly accurate inertial guidance system. Additional progress was made with the medium-range U.S. Jupiter missile [3].

1.1.3. Intercontinental Ballistic Missiles (ICBMs). Further advancements in the area of nuclear warhead design, inertial guidance system, and booster engine technology led to the development of the intercontinental ballistic missile (ICBM). The first U.S. ICBM—the Atlas—was tested in 1959. The Atlas would be used to launch satellites into orbit, launch probes to the (Earth's) Moon and other planets, and to launch the Mercury spacecraft into orbit around Earth. The Atlas was followed by the Titan one year later. Both Atlas and Titan were liquid-fueled multistage rockets that required fueling immediately prior to launch. In 1961, the Minuteman ICBM was put into service. Located within dispersed hardened silos, the Minuteman used a solid propellant stored within the missile. The LGM-30 Minuteman III was deployed in 1970. This system was designed such that specially configured EC-135 airborne launch control aircraft could automatically assume command and control of an isolated missile or missiles in the event that command capability is lost between the launch control center and the remote missile launch facilities. In 1986, the LGM-118A Peacekeeper was deployed. This three-stage solid propellant system permits 10 warheads to be carried via multiple independent (independently targeted) reentry vehicles (MIRVs). At the peak of the cold war, the Soviet Union possessed nearly 8000 nuclear warheads on ICBMs. During the cold war, the United States built up its strategic defense arsenal, focusing on a nuclear triad consisting of (1) long-range bombers (B-52 bombers and KC-135 tankers) with nuclear air-to-surface missiles, (2) USA-based ICBMs, and (3) submarine-launched ballistic missiles (SLBMs) launched from nuclear-powered submarines (<http://www.chinfo.navy.mil/navpalib/factfile/ships/ship-ssbn.html>). To complement the ground-based leg of the triad, the U.S. Navy would develop the submarine-launched Polaris, Poseidon, and Trident ICBMs (<http://www.chinfo.navy.mil/navpalib/factfile/missiles/wep-d5.html>). Trident I and II were deployed in 1979 and 1990, respectively. Both accommodate nuclear MIRVs and are deployed in Ohio-class

(Trident) submarines, each carrying 24 missiles (eight 100 kiloton warheads per missile).

1.2. Treaties and Programs

1.2.1. Nuclear Proliferation Treaties: SALT and MAD. Because of the large number of Soviet nuclear warheads during the cold war, some felt that U.S. ICBM fields were threatened. On March 14, 1969, President Nixon announced his decision to deploy a missile defense system (called *Safeguard*) to protect U.S. ICBM fields from attack by Soviet missiles. This initiated intense strategic arms negotiations between the United States and the Soviet Union. The Strategic Arms Limitation Talks (SALT), between the United States and the Soviet Union led to a 1971 agreement fixing the number of ICBMs that could be deployed by the two nations. The Anti-ballistic Missile (ABM) Treaty—signed by the United States and the Soviet Union on May 26, 1972—was designed to implement the doctrine of *mutually assured destruction* (MAD). MAD was intended to discourage the launching of a first strike by the certainty of being destroyed by retaliation. The treaty prohibits deployment of sea-, air-, and space-based missiles and limits deployment of sea-, air-, and space-based sensors. The impetus behind these arguments was to perpetuate the existing balance of power and avoid the economic chaos that would result from a full-scale arms race. In 1976, the U.S. Congress ordered the closing of Safeguard—only 4 months after it was operational. In 2001, the ABM treaty came under attack in the U.S. Congress as the United States and Russia (the former Soviet Union) discussed how to differentiate between theater and strategic missile defenses.

1.2.2. BMD and SDI. In 1983, President Reagan initiated the Ballistic Missile Defense (BMD) program under the Strategic Defense Initiative (SDI). SDI would focus on space-based defense research. Because SDI deployment would contravene the ABM treaty, many critics felt SDI, with its potential offensive use, would escalate the arms race. In 1984, the Strategic Defense Initiative Organization (SDIO) was formed. In 1987, Judge Abraham D. Sofaer, State Department Legal Advisor, concluded that the ABM treaty did not preclude testing of space-based missile defense systems, including directed energy weapons; SDI research would continue. With the breakup of the Soviet Union in 1991, the need for great nuclear arsenals came into question. In 1993, the Ballistic Missile Defense Organization (BMDO) was formed, replacing the SDIO, and SDI was abandoned for ground-based anti-missile systems.

1.2.3. Strategic Arms Reduction Treaties. In November 1994, the Strategic Arms Reduction Treaty I (START I) became effective, with the United States, Russia, Belarus, Kazakhstan, and Ukraine agreeing to reduce nuclear warheads by 25%. In appreciation for the ratification, the United States appropriated \$1.5 billion for assistance in dismantling nuclear weapons, properly storing weapons grade materials, and turning military factories into civilian buildings. The 2004 Treaty of Moscow promises to reduce the number of warheads from 6000 to 2200 by 2012.

1.3. Missile Warning Systems

Although the United States has no active ABM defense system in place, an extensive warning system has been in place for many years. Air and space defense is delegated to the North American Aerospace Defense Command (NORAD)—a joint U.S.-Canadian organization. A Ballistic Missile Early Warning System (BMEWS) consisting of warning and tracking radars in Alaska, Greenland, and the United Kingdom can detect missiles 4800 km (~3000 mi) away and provides a 15-min warning of an attack on North America. The Perimeter Acquisition Radar Characterization System (PARCS), operating within the United States interior, tracks incoming warheads and determines impact areas. Phased-array radar antennas along the U.S. Atlantic, Pacific, Alaskan, and Gulf coasts provide warning of SLBM launches.

1.4. Persian Gulf War

In January 1991, the role of air power in modern warfare was dramatically demonstrated during the Persian Gulf War. Initial attacks by the United States–led multinational coalition were designed to suppress Iraqi air defenses. These attacks included Tomahawk cruise missiles launched from warships in the Persian Gulf, F-117A Stealth fighter-bombers armed with laser-guided smart bombs, and F-4G Wild Weasel aircraft carrying high-speed antiradiation missiles (HARMs). These attacks permitted F-14, F-15, F-16, and F/A-18 fighter bombers to achieve air superiority and to drop TV- and laser-guided precision bombs. During the ground war, A-10 Thunderbolts with armor-piercing heat-seeking or optically guided AGM-65 Maverick missiles, provided support for ground units. The AH-64 Apache and AH-1 Cobra helicopters fired laser-guided Hellfire missiles, guided to tanks by ground observers or scout helicopters. The E-3A airborne warning and control system (AWACS), a flying radar system, provided targeting information to coalition members.

1.5. Missile Defense

While most weapon systems performed superbly during the Gulf War, little could be done to stop the Iraqi Scuds launched against Saudi Arabia and Israel. However, a Patriot surface-to-air missile (SAM) system was brought in to repel Scud attacks. Although the Patriot system had been used in 1987 to destroy another Patriot during a demonstration flight, the system was originally designed as an anti-aircraft defense system. Thus, its effectiveness against the Scuds was limited, because intercepts often did not take place at sufficiently high altitudes. Part of the problem was attributed to the fact that the Patriot relied on proximity detonation rather than a “hit to kill”. This would often cause the incoming Scud to break up, leaving a free-falling warhead to detonate on the civilian population below. The many Patriot–Scud engagements were televised to a world audience and demonstrated the need for a high altitude air defense system that could intercept (tactical) ballistic missiles far from critical military assets and civilian population centers. For this reason much research shifted toward the development of hit-to-kill thea-

ter high-altitude air defense (THAAD) systems. In his January 1991 State of the Union address, President George H.W. Bush formally announced a shift in SDI to a concept of global protection against limited strikes (GPALS), and by December, he signed into law the Missile Defense Act of 1991. On January 24, 1997, a Standard Missile 2 (SM-2) Block IVA successfully intercepted and destroyed a Lance missile at the White Sands Missile Range in New Mexico. During the test, the SM-2 successfully transitioned from radar midcourse guidance to its heat-seeking endgame/terminal guidance system prior to destroying the target with its blast fragmentation warhead. On February 7, 1997, BMDO carried out a test in which a Patriot Advanced Capability-2 (PAC-2) missile successfully intercepted a theater ballistic target missile over the Pacific Ocean. In April 1997, BMDO established the Joint Program Office (JPO) for the National Missile Defense (NMD). On June 24, 1997, the first NMD flight test was successfully completed. During this test an exo-atmospheric kill vehicle (EKV) sensor was used to identify and track objects in space. To appreciate the formidable problems associated with developing a THAAD system, it is necessary to understand issues associated with the design of missile guidance systems.

2. MISSILE GUIDANCE, NAVIGATION, AND CONTROL SUBSYSTEMS

We begin our technical discussion by describing the subsystems that make up a missile system. In addition to a warhead, a missile contains several key supporting subsystems. These subsystems may include a target-sensing system, a missile-navigation system, a guidance system, an autopilot or control system, and the physical missile (including airframe and actuation subsystem) (see Fig. 1).

2.1. Target Sensing System

The target sensing system provides target “information” to the missile guidance system, including relative position, velocity, line-of-sight (LOS) angle and rate. Target sensing systems may be based on a number of sensors, such as radar, laser, heat, acoustic, or optical sensors. Optical sensors, for example, may be as simple as a camera for a weapons systems officer (WSO) to visualize the target from a remote location. They may be a sophisticated imaging system (see text below). For some applications, target coordinates are known a priori (e.g., via satellite intelligence) and a target sensor becomes irrelevant. In

Figure 1. Information flow for missile–target engagements.

such a case, the navigation system provides the required information.

2.2. Navigation System

A navigation system provides information to the missile guidance system about the missile position in space relative to some inertial frame of reference, such as a flat-Earth constant-gravity model for short-range flights and a rotating Earth variable-gravity model for long-range flights. To do so, it may use information obtained from a variety of sensors. These may include simple sensors such as accelerometers or a radar altimeter. It may include more sophisticated sensors such as a global positioning system (GPS) receiver or an optical terrain sensor that relies on comparisons between an image of the terrain below with a stored image and a stored desired trajectory. Optical stellar sensors rely on comparisons between an image of the stars above with a stored image and a stored desired trajectory.

2.3. Guidance System

Target and missile information is used by the guidance system to compute updated guidance commands, which, when issued to the missile autopilot, should ideally guide (or steer) the missile toward the target [4,5]. When target coordinates are known a priori, missile coordinates provided by the navigation system (e.g., GPS-based) are periodically compared with the (preprogrammed) target coordinates to compute appropriate guidance corrections. In general, the quality of the computed guidance commands depends on the quality of the sensor data gathered and the fidelity of the models used for the missile and target. Targets may be stationary, mobile, or highly maneuverable (e.g., silo, ship, fighter aircraft). Physically, guidance commands may represent quantities such as desired thrust, desired (pitch/yaw) acceleration, desired speed, desired flight path or roll angle, and desired altitude. Guidance commands issued by the guidance system to the missile autopilot are analogous to the speed commands issued by automobile drivers to the cruise control systems in their cars. In this sense, the missile guidance system is like the automobile driver and the missile autopilot is like the automobile cruise control system. Missile guidance commands are computed in accordance with a guidance algorithm. Guidance algorithms and navigational aids will be discussed below.

2.4. Autopilot

The primary function of the autopilot—sometimes referred to as the *flight control system* (FCS) or attitude control system (ACS)—is to ensure (1) missile attitude stability and (2) that commands issued by the guidance system are followed as closely as possible [4]. The autopilot accomplishes this command-following objective by computing and issuing appropriate control commands to the missile's actuators. These actuators may include, for example, rocket thrusters, ramjets, or servomotors that

move aerodynamic control surfaces. More specifically, the autopilot compares commands issued by the guidance system with real-time measurements (e.g., acceleration, attitude and attitude rate, altitude) obtained from on-board sensors (e.g., accelerometers, gyroscopes, radar altimeters) and/or external tracking systems. This comparison, essentially a subtraction of signals, produces a feedback error signal, which is then used to compute control commands for the missile actuators. This computation may be based on a very complex mathematical model that captures the following: missile airframe, aerodynamics (depending on speed, dynamic pressure, angle of attack, side-slip angle, etc.), actuators, sensors, flexible modes, and uncertainty descriptions (e.g., dynamic uncertainty, parametric uncertainty [6,7], disturbance/noise bounds). It should be noted that commands that are issued by the guidance system to the autopilot cannot always be followed exactly because of the presence of multiple sources of uncertainty. Sources of uncertainty may include disturbances acting on the missile, sensor noise, unmodeled or uncertain missile airframe, actuator, and sensor dynamics.

2.5. Flight Phases

The flight of a missile can be broken into three phases: (1) a launch, separation, or boost phase; (2) a midcourse or cruise phase; and (3) an endgame or terminal phase. During each phase, a missile may use distinct guidance, navigation, and control systems, specifically designed to accommodate the requirements during that phase of the flight. During each phase, the missile may very well use different sets of sensors, actuators, and power sources.

2.6. Guidance System Performance Terminology

To describe the function and performance of a guidance system, some terminology is essential. The imaginary line that connects a missile center of gravity (c.g.) to the target c.g. is referred to as the *line of sight* (LOS) [8]. The length of this line is called the *range*. The associated vector from missile to target is referred to as the *range vector*. The time derivative of the range vector is called the *closing velocity*. The most important measure of performance for any missile guidance system is the so-called miss distance. "Miss distance" is defined to be the missile-target range at that instant when the two are closest to one another [8, p. 27]. The objective of most guidance systems is to minimize the miss distance within an allotted time period. For some applications (e.g., hit to kill), zero miss distance is essential. For some applications (e.g., to minimize collateral damage), it is essential to impact the target at a specific angle. Because miss distance is sensitive to many variables and small variations from missile to missile, other quantities are used to measure performance. One of the most common measures used is circular error probability (CEP). The CEP for a missile attempts to provide an average miss distance for a class of missile-target engagements. If a missile has a CEP of 10 m, then most of the time, say, 68% of the time, it will detonate within 10 m of the target.

3. CLASSIFICATION OF MISSILES, TARGETS, GUIDANCE SYSTEMS, NAVIGATION METHODS, AND TARGET SENSING METHODS

The guidance system used by a missile depends on the intended use of the missile. Missiles are classified according to many categories. The most commonly used classifications are as follows: strategic, tactical, exoatmospheric, endoatmospheric, aerodynamic, ballistic, surface-to-surface, surface-to-air, air-to-surface, air-to-air, inertially guided, terrain guided, stellar guided, satellite guided, passive; active, homing, command-guided, radar-guided, laser-guided, heat seeking, fire-and-forget, line-of-sight guided, radar terrain-guided, TV guided, cruise, skid-to-turn (STD), and bank-to-turn (BTT). Each category is now briefly discussed.

3.1. Missile Types

3.1.1. Strategic Missiles. Strategic missiles are used primarily against strategic targets, that is, resources that permit an enemy to conduct large-scale military operations (e.g., battle management/command, control, and communication centers, industrial/weapons manufacturing centers). Such targets are usually located far behind the battle line. As such, strategic missiles are typically designed for long-range missions. While such missiles are usually launched from naval vessels or from missile silos situated below ground, they are sometimes launched from aircraft (e.g., strategic bombers). Because such missiles are intended to eliminate the most significant military targets, they typically carry nuclear warheads rather than conventional warheads. Strategic missiles typically operate at orbital speeds (~ 5 mi/s), outside the atmosphere, over intercontinental distances. They use rockets/thrusters/fuel and require very precise instrumentation for critical midcourse guidance. GPS has made such systems very accurate.

3.1.2. Tactical Missiles. Tactical missiles are used primarily against tactical targets, that is, resources that permit an enemy to conduct small-scale military operations (a ship, an airfield, a munitions bunker, etc.). Such targets are usually located near the battle line. As such, tactical missiles are typically designed for short- or medium-range missions. Such missiles carry conventional explosive warheads, the size of which depends on the designated target. Tactical missiles sometimes carry nuclear warheads in an effort to deter the use of tactical nuclear/chemical/biological weapons and to engage the most hardened targets (e.g., enemy nuclear strategic missile silos). Tactical missiles typically operate at lower speeds (< 1 mi/s), inside the atmosphere, and over short to medium distances (e.g., 150 mi). They typically use aerodynamic control surfaces (discussed below) and require adequate instrumentation for midcourse and terminal guidance. A target sensor (e.g., radar seeker) permits such missiles to engage mobile and highly maneuverable targets.

3.1.3. Exoatmospheric Missiles. Exoatmospheric missiles fly their missions mostly outside Earth's atmosphere.

Such missiles are used against long-range strategic targets. Because they fly outside the atmosphere, thrusters are required to change direction. Such thrusters use onboard fuel. In order to maximize warhead size, and because missile weight grows exponentially with fuel weight, it is important that guidance and control systems for long-range missiles (e.g., strategic, exoatmospheric) provide for minimum fuel consumption.

3.1.4. Endoatmospheric Missiles. Endoatmospheric missiles fly their missions inside Earth's atmosphere. Such missiles are used against strategic and tactical targets. In contrast to exoatmospheric missiles, endoatmospheric missiles may use movable control surfaces such as fins (called *aerodynamic control surfaces*), which deflect airflow in order to alter the missile flight path. In such a case, the missile is called an *aerodynamic missile*. Endoatmospheric missiles may, in some cases, rely entirely on rocket power. In such a case, they are not aerodynamic. Exoatmospheric missiles that fly outside Earth's atmosphere rely on rocket power and thrusters. These are not aerodynamic. Examples of aerodynamic missiles are the Sidewinder and Patriot.

3.1.5. Ballistic Missiles. Ballistic missiles assume a free-falling (unpowered) trajectory after an internally guided, self-powered (boost and midcourse) ascent. Such missiles are usually used against long-range strategic targets. ICBMs, for example, are usually exoatmospheric strategic missiles that were developed for use against strategic targets, and are typically launched from underground missile silos and submarines. Modern ICBMs contain multiple independently targeted nuclear warheads deployed via MIRVs. Examples of ICBMs are the Atlas, Titan, Minuteman, and Polaris. The Iraqi Scud, used in the Persian Gulf War, is another ballistic missile.

3.1.6. Surface-to-Surface Missiles (SSMs). SSMs are typically launched from the ground, beneath the ground (e.g., from a missile silo), or from naval platforms against ground targets (e.g., tank, munitions depot, missile silo) or naval targets (e.g., battleship, submarine). ICBMs are typically SSMs. SSMs may carry nuclear, biological, chemical, or conventional warheads. Examples of SSMs are the antiship Silkworm and the Tomahawk.

3.1.7. Surface-to-Air Missiles (SAMs). SAMs are typically launched from the ground, beneath the ground (e.g., from a missile silo), or from naval platforms against aircraft and missiles. SAMs were developed to defend surface targets from air attacks, especially from high-altitude bombers flying well above the range of conventional anti-aircraft artillery (AAA). Most air defense SAMs employ separate radars to acquire (detect) and track enemy air threats. The separate radar is also used to guide the SAM toward the hostile target; endgame guidance may be accomplished by the missile's onboard guidance system. SSMs are typically heavier and carry larger warheads than SAMs because they are usually intended to penetrate hardened targets. Shoulder-launched SAMs (e.g., Stinger)

have become a major concern given increased terrorist activities.

3.1.8. Air-to-Surface Missiles (ASMs). ASMs are launched from aircraft against ground targets (e.g., a bridge, airfield) or naval targets. While ASMs are typically intended for tactical targets, they are used by both strategic and tactical bombers. Equipping strategic bombers with long-range ASMs extends their range, significantly reducing the range that they need to travel toward the intended target. Examples of ASMs are the antitank Hawk and Hellfire, the antiradar AGM-88 HARM, the antiship Exocet and AGM-84D Harpoon, and the antiarmored vehicle AGM-65 Maverick (<http://www.af.mil/factsheets/>). Other ASM systems include the advanced medium-range air-to-air missile (AIM-120 AMRAAM) and the airborne laser (ABL) system being developed by several defense contractors. The ABL system has been considered for boost-phase intercepts during which the launched missile has the largest signature and is traveling at its slowest speed.

3.1.9. Air-to-Air Missiles (AAMs). AAMs are launched from aircraft against aircraft, ballistic missiles, and most recently against tactical missiles. Such missiles are typically light, highly maneuverable, tactical weapons. AAMs are generally smaller, lighter, and faster than ASMs since ASMs are typically directed at hardened, less mobile, targets. Some SAMs and ASMs are used as AAMs and vice versa. Examples of AAMs are the AIM-7 Sparrow, AIM-9 Sidewinder, AIM-54 Phoenix, and the AIM-120A AMRAAM.

3.2. Guidance Methods: Fixed Targets with Known Fixed Positions

A missile may be guided toward a target, having a known fixed position, using a variety of guidance methods and/or navigational aids, such as inertial, terrain, stellar, and satellite guidance and navigation.

3.2.1. Inertially Guided Missiles. Inertially guided missiles use missile spatial navigation information relative to some inertial frame of reference to guide a missile to its designated target. For short-range missions, one may use a flat-Earth constant-gravity inertial frame of reference. This is not appropriate for long-range missions, approaching intercontinental distances, for which Earth may not be treated as flat. For such missions, the sun or stars provide an inertial frame of reference. One can also use an Earth-centered variable-gravity frame. Position information is typically obtained by integrating acceleration information obtained from accelerometers or by pattern matching algorithms exploiting imaging systems. Because accelerometers are sensitive to gravity, they must be mounted in a fixed position with respect to gravity. Typically, accelerometers are mounted on platforms that are stabilized by gyroscopes or star tracking telescopes. Terrain and stellar navigation systems are examples of imaging systems. Satellite navigated missiles use satellites for navigation. Some satellite guided missiles use the Navstar

Global Positioning System (GPS)—a constellation of orbiting navigation satellites—to navigate and guide the missile to its target. GPS has increased precision significantly.

3.3. Guidance Methods: Mobile Targets with Unknown Positions

If the target position is not known a priori, the forementioned methods and aids may be used in part but other real-time target acquisition, tracking, navigation, and guidance mechanisms are required. The most commonly used classifications for the guidance system in such cases are as follows: passive, active, and semiactive. These are now discussed.

3.3.1. Passive Missiles. Passive missiles are missiles that have a target sensor sensitive to target energy emissions (e.g., radar and thermal energy) and a guidance system that uses received target emission signals to guide the missile toward the target. Such missiles are said to have a passive guidance system. While such systems are, in principle, simple to implement, it should be noted that they rely on a “cooperative target”: targets that radiate energy at appreciable (detectable) power levels. Such systems are also susceptible to decoys.

3.3.2. Active Missiles. Active missiles use an energy-emitting transmitter combined with a reflection-detection receiver (e.g., an active seeker) to acquire targets and guide the missile toward the target. Such missiles are said to have an active guidance system. For such systems, great care is taken to ensure that transmitted and received signals are isolated from one another. Stealthy targets are those that absorb or scatter (misdirect) the transmitted energy. Receivers can consist of a gimballed (movable) seeker antenna. Such mechanically directed antennas are slow and have a limited field of view. Fixed phase array antennas—operating on interferometric principles—offer rapid electronic scanning capability as well as a broad field of view.

3.3.3. Semiactive Missiles. Semiactive missiles use a reflection-sensitive receiver to guide the missile to the target. The reflected energy may be provided by a ground-based, ship-based, or aircraft-based energy emission (e.g., radar or laser) system or by such a system aboard the launching platform. In either case, a human operator (e.g., WSO) illuminates the target with a radar or laser beacon and the missile automatically steers toward the source of the reflected energy. Such missiles are said to possess semiactive guidance systems. For such implementations, the illuminating power can be large.

Passive systems, of course, are stealthier than semiactive or active systems as they do not intentionally emit energy toward the target. Anti-radar missiles typically use passive guidance systems since radars are constantly emitting energy. As an antiradar missile approaches the intended radar, radar operators typically shut down the radar. This causes the missile to lose its critical guidance signal. In such a case, an active guidance system must

take over. Active systems require more instrumentation than passive systems and hence are heavier and more expensive.

Guidance system performance is limited by various noise sources. For active systems, there is range dependent noise that is proportional to the square of the distance from the missile to the target. For semiactive systems, there is range dependent noise that is proportional to the distance from the missile to the target. For either system, the noise is wideband, may be modeled as white, and goes to zero at intercept. For either system, there are random fluctuations due to the target radar return. This source of noise is referred to as glint noise. It depends directly on the physical dimensions of the target and is typically highly correlated [8].

3.4. Other Guidance Methods and Missile Types

3.4.1. Homing Missiles. Homing missiles, like homing pigeons, home in on a target by steering toward energy emitted by or reflected from the target. If the missile homes in on energy emitted by the target, then it uses a passive guidance system. If the missile transmits a signal and homes in on the reflected energy, its guidance system is active. In principle, sensor information and homing improve as the missile gets closer to the target.
