Foreword

David Kay

Senior Research Analyst, Potomac Institute, Washington, D.C., and former Director, Iraq Survey Group (2003–2004)

The importance of this encyclopedia was underscored by the fact that virtually the only area of agreement in the 2004 U.S. presidential campaign between the two major candidates, President George W. Bush and Senator John F. Kerry, was that the proliferation of weapons of mass destruction poses the most serious national security threat with which the next president would have to deal.

While the prospect of chemical, biological, radiological, or nuclear weapons falling into the hands of terrorists or regimes hostile to the United States and its friends is indeed a frightening prospect, how many of us understand exactly what this means? When were such weapons first developed? Which states and scientists are leading these developments? Have these weapons actually been used in the past? How often and with what consequence—not only for the populations they were used against, but for those that used them, as well? Do these weapons really give states a decisive edge over their adversaries? How easy are they to develop and use? Does the ease of development or use of such weapons by states, like North Korea, differ from the obstacles faced by terrorist groups, like al-Qaeda? What are the tools available to the United States to halt the spread of such weapons? Have we had any success in limiting the spread of these weapons? Are there any protective measures that individuals can take to lessen their vulnerability if such weapons are used?

These are but a few of the questions that the authors of this authoritative two-volume study attempt to answer. This encyclopedia will have enduring importance as states and societies attempt to come to terms with the consequence of the collision of scientific progress with the failure to develop a reliable global security structure. The initial development of chemical, biological, and nuclear weapons, as this study makes clear, often involved scientific and engineering breakthroughs of the highest order. The paths to enriching uranium and genetically modifying pathogens are but two examples of such successes, scientific breakthroughs that have made new classes of weapons possible. But scientific progress marches at a very fast rate, leaving behind old, but still dangerous, knowledge. For example, the secrets regarding methods for enriching uranium were simply bought by the Iraqis from the U.S. Government Printing Office. That office could not imagine that there was anything important in a 40-year-old project from the dawn of the U.S. nuclear program.

In another remarkable case, uranium enrichment technology was stolen from a commercial company in Holland by A. Q. Khan—a rather ordinary Pakistani who went to Germany to earn an engineering degree. Khan subsequently used this technology to develop Pakistan's nuclear weapons and then sold the same technology to North Korea, Iran, and Libya. The techniques of gene modification, which less than 20 years ago were the stuff of Nobel prizes, are now routinely taught in American high schools and community colleges and have opened up whole new classes of biological weapons. As this study also makes clear, even the safe disposal of weapons of mass destruction following a state's decision to abandon or limit their programs presents serious challenges of preventing the weapons and associated technology from falling into the hands of terrorists. The thousands of Soviet-era nuclear weapons and the engineering talent that created them represent a clear and present danger with which the world has not yet completely dealt. The readers of this work will find numerous examples of the lowering of the barriers to the acquisition by states and terrorists of these most terrible of weapons.

But this study does not simply present the horrors of a world filled with weapons of mass destruction. It also catalogs and illuminates the various methods of attempting to control and constrain these weapons—including treaties and agreements such as the Nuclear Non-Proliferation Treaty and the Chemical Weapons Convention, as well as intrusive inspections, such as the efforts of the United Nations to hunt such weapons in Iraq after the first Gulf War. As will be clear to the reader, such endeavors have had both successes and failures. Much remains to be done to ensure that their effectiveness matches the problems posed by the proliferation of such weapons. The largest gap in effective mechanisms of control and response to the acquisition of such weapons is with regard to the efforts of terrorists groups to acquire the means of mass murder. While these volumes identify the few efforts made in this regard, it is hard not to come away with a sense of dread for the future. Most control efforts have been aimed at states, not at terrorists operating outside of the control of states. Hopefully students and policy makers using this book a few years hence will be able to record more progress toward meeting this new challenge.

The authors and editors have done an important service by pulling together such an illuminating study at exactly the point when there is a broad political consensus of the importance of the problem. One can only hope that our citizens and our political leaders take the time to explore the depth of information presented here.

Preface: Weapons of Mass Destruction

Eric A. Croddy and James J. Wirtz

The term "weapon of mass destruction" (WMD) is a relatively modern expression. It was probably first used in print media following the international uproar over Germany's aerial bombardment of the Basque city of Guernica in April 1937. (The latter event was famously depicted in Picasso's painting *Guernica y Luno.*) Only a year before, another Axis power, Italy, had begun using mustard and other chemical warfare (CW) agents in Abyssinia (modern-day Ethiopia).[1] During the anxious years leading up World War II, WMD referred to the indiscriminate killing of civilians by modern weaponry, especially aircraft. It also echoed the fear of chemical weapons that was unleashed by World War I, which had come to a conclusion just a few years earlier.

Following the development of the atomic bomb in 1945, the term "WMD" came to include nuclear and eventually biological weapons. WMD was apparently first used to describe nuclear warfare by Soviet strategists. In 1956, during the 20th Communist Party Congress in Moscow, the Soviet Minister of Defense—and "Hero of Stalingrad"—Marshal Georgy Konstantinovich Zhukov prophesied that modern warfare "will be characterized by the massive use of air forces, various rocket weapons and various means of mass destruction such as atomic, thermonuclear, chemical and bacteriological weapons."[2] In that same year, the Hungarian Minister of Defense echoed Marshal Zhukov, stating that "Under modern conditions, the decisive aspect of operational planning is the use of nuclear and other weapons of mass destruction."[3]

When the West learned of Zhukov's speech, national security strategists in the United States and elsewhere became quite concerned. By inference, they concluded that WMD—nuclear, biological, and chemical weapons—were an integral part of Soviet military doctrine. Partly in response to Zhukov's ministrations on WMD, the United States reviewed its offensive chemical and biological weapons program in 1958. The U.S. military was never particularly enamored by chemical or biological weapons and treated them as a deterrent to be used in retaliation for the use of chemical or biological weapons used by the opponent. By the early 1990s, the U.S. military had abandoned offensive use of these weapons, although it maintained a research and development program designed to produce effective equipment, procedures, medications, and inoculations to defend against chemical and biological attack.

Over the last decade, much has been written about WMD. The meaning of the term itself is somewhat controversial, although there is a formal, legalistic definition. According to U.S. Code Title 50, "War and National Defense," per the U.S. Congress, the term "weapon of mass destruction" means "any weapon or device that is intended, or has the capability, to cause death or serious bodily injury to a significant number of people through the release, dissemination, or impact of toxic or poisonous chemicals or their precursors; a disease organism; radiation or radioactivity."[4] For its part, the U.S. Department of Defense has a similar characterization of WMD, although in addition it includes "...the means to deliver [WMD]."[5] So, what makes a weapon massively destructive? Is it the type of injurious agents involved, namely radioactive, chemical, or biological, or is it that the attack itself produces significant casualties or destruction? Also what would "significant" mean in this context: ten, a hundred, or a thousand casualties? What if very few people are actually killed or hurt by at attack? In the latter respect, the U.S. Federal Bureau of Investigation has a rather unique and somewhat satisfying interpretation of the term "WMD," invoked when the U.S. government indicted Timothy McVeigh with using a WMD in his 1995 terrorist attack in Oklahoma City. In this case, although the device used was a conventional bomb (employing ammonium nitrate-fuel oil explosive), "A weapon crosses the WMD threshold when the consequences of its release overwhelm local responders."[6]

Some analysts, however, have suggested that various technical hurdles prevent chemical and even biological weapons from causing casualties on a truly massive scale. Some point to the Aum Shinrikyo sarin attack on the Tokyo subway system on March 20, 1995, which resulted in eleven deaths, as an example of the *limits* of WMD. They note that high-explosives have been used with far greater lethal effects than sarin in the annals of modern terrorism. Others are increasingly concerned about the destructive potential of even rudimentary weapons. Analysts today are worried, for instance, that terrorists might try to employ radiological dispersal devices or "dirty bombs." These weapons do not detonate with a fission reaction, but rather utilize conventional explosives to distribute radiological materials and contaminate a given area. Few deaths are likely to result from the effects of a dirty bomb, but the consequences—in terms of anxiety, clean-up, and the recognized ability of a terrorist to conduct the very act itself—would likely be far reaching.

About the Encyclopedia

The very presence of chemical, biological and nuclear weapons in international arsenals and the potential that they might fall into the hands of terrorist organizations guarantees that weapons of mass destruction will be of great policy, public, and scholarly interest for years to come. We cannot resolve the debates prompted by WMD, but we hope that we and our contributors can provide facts to help the reader sort through the controversies that are likely to emerge in the years ahead. Much that is contained in these volumes is disturbing and even frightening; it is impossible to write a cheery encyclopedia about weapons whose primary purpose is to conduct postindustrial-scale mass murder. The sad truth of the matter is that chemical, biological, radiological, and nuclear weapons reflect the willingness of humans to go to great lengths to find increasingly lethal and destructive instruments of war and violence. We are pleased to note, however, that much of what is reported in these volumes is historical in nature and that civilized people everywhere reject the use of chemical and biological weapons. International law is replete with treaties, agreements, and regimes whose purpose is to proscribe the use of these weapons, or mitigate the consequences of any such use. In particular, the world has successfully kept nuclear weapons in reserve for almost sixty years as truly deterrent weapons of last resort.

Our encyclopedia covers a wide range of topics, some historical, some drawn from today's headlines. We describe many of the pathogens, diseases, substances, and machines that can serve as weapons of mass destruction, as well as their associated delivery systems. We also describe important events and individuals that have been influential in the development of weapons of mass destruction and doctrines for their use (or control). We have encouraged our contributors to highlight ongoing controversies and contemporary concerns about WMD and current international arms control and nonproliferation efforts intended to reduce the threat they pose to world peace and security. Even a work of this length, however, cannot completely cover the history, science, and personal stories associated with a topic of this magnitude, so we have included abundant references to help readers take those initial steps for further study of the topics we survey.

Acknowledgments

Our deepest debt is to the contributors who made this volume a reality. Many of them joined the project at its inauguration several years ago and have waited a long time to see their work in print. It is impossible for just three people to be experts on all of the subjects covered in this volume, and without the hard work of our contributors, this encyclopedia would never have been completed. Thanks to our research assistants, Abraham Denmark and Laura Fontaine, who uncovered most of the key documents in both volumes and wrote a few entries for us, as well. We also want to express our appreciation to a senior government official who reviewed Volume II for accuracy and sensitive material. We owe a special debt to Jeff Larsen, our managing editor, whose help was instrumental in the success of this project. Not only did he provide editorial support to both volumes, but he displayed a keen ability to deal with the publisher and our 95 contributors, keep track of timelines, requirements, and progress, and gently push the two of us when we needed encour-

agement during this multiyear project that involved over 500 separate parts. Finally, we also want to express our appreciation to Alicia Merritt, Martha Whitt, Giulia Rossi, and the behind-the-scenes copyeditors at ABC-CLIO who worked tirelessly to help get this manuscript into print. We discovered that nothing is a trivial matter when it comes to a manuscript of this size. The commitment of our publisher to this topic, and the dedication of the production staff at ABC-CLIO, greatly facilitated the completion of these volumes.

We hope that this encyclopedia will help inform the public debate about weapons of mass destruction and international security policy, with the goal of never again seeing such weapons used in anger.

Introduction: Chemical and Biological Weapons

Eric A. Croddy

In the United States, there are various legal and academic definitions of weapons of mass destruction (WMD), although not everyone may agree on any of them. The U.S. Department of Defense (DOD) defines WMD as, "Weapons that are capable of a high order of destruction and/or of being used in such a manner as to destroy large numbers of people. Weapons of mass destruction can be high explosives or nuclear, biological, chemical, and radiological weapons, but exclude the means of transporting or propelling the weapon where such means is a separable and divisible part of the weapon."[1]

According to the DOD, conventional explosives also can be considered WMD. And this is reasonable, especially when one considers the cumulative number of deaths caused by gunpowder since its invention in the tenth century and by nitroglycerine since its invention in the nineteenth century.[2] But the underlying assumption of what makes a weapon massively destructive is the idea that these weapons can cause simultaneous mass casualties. Nuclear weapons (dealt with separately in Volume II) are an obvious category of WMD, but radiological weapons (such as so-called dirty bombs are less likely to cause mass injury or death (*see* Radiological Dispersal Device in volume II).[3]

Highly toxic chemical compounds—the nerve agents being prime candidates—could comprise WMD, for example, if delivered effectively against an urban target. Biological agents—that is, pathogens and toxins derived from plants or animals—might also constitute WMD if delivered efficiently. When compared to conventional and chemical weapons, biological agents have the greatest potential to cause mass casualties, and, theoretically, theirs could easily exceed the casualties caused by the largest nuclear weapon.

In terms of referring to nuclear, chemical—and by inference, biological—weapons, the term "weapons of mass destruction" first came into use in 1956 when it was used in a speech by Soviet Red Army Marshal Georgi Konstantinovich Zhukov. In fact, it was this speech that highlighted for U.S. policy makers the real or perceived threat from the Soviet Union, particularly in terms of the latter's presumed arsenal of chemical and biological weaponry. As such, Zhukov's speech invigorated United States Cold War research into WMD, including biological weaponry.[4] During the Cold War, the United States—and, to a much greater extent, the Soviet Union—amassed large chemical and biological weapons stockpiles. The threat posed by these stockpiles has diminished greatly since the crumbling of the Berlin wall.

Regional threats posed by state-funded militaries from chemical and biological weapons also have declined. By the end of 2003, the U.S. government had admitted that there was little evidence that Iraq had possessed large chemical or biological weapon stockpiles after the mid-1990s. This has since led both the United States and British governments to begin inquiries into the faulty prewar intelligence on Iraq that was in large part the basis for justifying Operation Iraqi Freedom in March 2003.[5]

Other regional threats, however, still remain. Among these, states such as Syria and North Korea are suspected of possessing chemical and biological weapons. Their bellicose posture regarding their immediate neighbors and regional rivals, as well as their possession of long-range delivery systems (such as Scud missiles), make these threats impossible to ignore. By contrast, Libyan leader Mohamar Qaddafi stated in early 2004 that he would renounce the possession of WMD, which demonstrates how quickly the threat of weapons of mass destruction seems to rise and fall on the global agenda.

Individuals and terrorist organizations also are reportedly interested in using chemical or biological agents in their operations. A salient example was a statement by a self-proclaimed spokesman for the terrorist organization al-Qaeda, who said in June 2002, "We have the right to kill 4 million Americans—2 million of them children—and to exile twice as many and wound and cripple hundreds of thousands. Furthermore, it is our right to fight them with chemical and biological weapons, so as to afflict them with the fatal maladies that have afflicted the Muslims because of the [Americans'] chemical and biological weapons."[6]

It is not clear as of this writing whether any individuals or groups will be able to carry out an attack using chemical or biological warfare agents, at least in a manner that could cause more deaths than the September 11, 2001, attacks on the World Trade Center (2,749 dead) and the Pentagon (184 dead). In 2001, the biological agent that causes anthrax killed five people when an unknown actor or group mailed *Bacillus anthracis* spores through the U.S. postal system. On February 3, 2004, envelopes containing ricin toxin were discovered at the office of the U.S. Senate majority leader and at a mail sorting facility for the White House. These incidents involving ricin resulted in no injuries, but justifiably caused much concern.

A Brief History of WMD

The historical record shows that mass poisonings and the occasional plot to spread disease among armies and civilian populations go back many centuries.[7] Still, chemical and biological warfare (CBW)—sometimes referred to in military parlance as "bugs and gas"—is essentially a modern phenomenon. It is modern in the sense that the science and industry required to produce these types of WMD have only existed since the early 1900s. However, there may indeed have been designs to use chemical or biological agents as a means of warfare (or possibly terrorism) before the Industrial Revolution. Before the late nineteenth century (the time of Louis Pasteur and many developments in chemistry), however, the requisite scientific knowledge and engineering capacity were insufficient to bring any such ideas to fruition. Obviously, this is no longer the case.

Many books and articles that discuss CBW often introduce the subject by bringing up past examples of chemical or biological warfare. In an excellent introduction to chemical weapons, a short book published by the Chinese People's Liberation Army discusses a case of CW (chemical warfare) from China's early history: In the *Zuochuan,* it is written that in the sixth century to about the fifth century B.C.E., "An official of the noble princes of the Xia, came from the Jin to attack the [forces of] Qin, and poisoned the Jing River, killing more than a division of men." Another case is cited: "In the year 1000 [C.E.], there was one named Tangfu, who made poison fire grenades and gave them to the Chao court of the Song dynasty. The poisonous smoke ball, containing arsenic oxide (As_2O_3) and a type of poison derived from crotonaldehyde (see the Arsenicals listing), looked a bit like a precursor to a chemical gas grenade. After alighting, this weapon would issue forth smoke to poison the enemy and thus weaken their ability to fight."[8]

These same authors also point out that this is a far cry from what one expects in modern times, for back then chemical warfare "was just in its infancy, and not only were its methods crude but its utility in actually killing people was limited. Because of this, chemical weapons were regarded as a method to generally assist in conducting warfare, and at the time did not draw any particular attention. Coming into the recent era, as the developments in technology continued, chemical weapons then really began to demonstrate their real menace."[9]

Another premodern military tactic that is often described as a form of BW (biological warfare) is the siege of Kaffa (1346 C.E.), in modern Feodosia, Ukraine. During a campaign by Mongol forces to defeat a heavily defended city of mostly Genoese merchants, bubonic plague struck the area: "The Tartars died as soon as the signs of disease appeared on their bodies: swellings in the armpit or groin caused by coagulating humors, followed by a putrid fever. The dying Tartars, stunned and stupefied by the immensity of the disaster brought about by the disease, and realizing that they had no hope of escape, lost interest in the siege. But they ordered corpses to be placed in catapults and lobbed into the city in the hope that the intolerable stench would kill everyone inside. . . ."[10] We note here that "stench" was considered in the pre-germ theory era to be responsible for disease. Thus, miasmas, "noxious effluvia," or "corrupt vapors" (*febres pestilentiales*) were synonymous with the spread of deadly epidemics—plague (causative organism: *Yersinia pestis*) being among the most notorious.[11]

The suggestion later made by historians that the Mongols were in fact able to spread bubonic plague by hurling disease-ridden corpses over the fortress walls is an intriguing one. During the fourteenth century, however, a germ theory of disease did not exist. How would the people of that era have known exactly how the disease could spread? What they could not have known is that bubonic plague is spread by fleas, which collect the bacteria *Yersinia pestis* (the causative organism of plague) through feeding upon infected rats. Fleas do not linger near the body once the temperature of the host (be it rodent or human) cools following death, making it rather unlikely that the cadavers would have done much to spread the plague. In the end, it was not the use of projectile cadavers, but more likely the exceptionally large rat population around the Black Sea that led to a pandemic throughout the region (and indeed much of Europe). One could probably conclude, however, that the Mongols did have the intent to spread disease among their enemy, and at least in this respect they conducted an early form of BW.

CBW in the Modern Era

The stunningly high rate of casualties that occurred in World War I had much do with the machine gun and rapid-fire artillery, but it also was caused in large part by the great number of men that were brought to the battlefields. World War I marks the emergence of "gas warfare:" the use of chlorine, phosgene, and other toxic chemicals. For the most part, these were used in vain attempts to achieve a breakthrough against well-defended armies in trenches. Later, chemical warfare agents such as sulfur mustard entered the scene when previous compounds were found to be less effective on the battlefield. Unlike chemicals used during the early stages of the conflict, mustard is not gaseous, but an oily liquid. It did not kill large numbers of troops, but it caused debilitating injury by irritating the skin, eyes, and upper airways. First used in 1917, it was responsible for the most injuries caused by chemical weapons during World War I.

Japan conducted CBW against China from 1937 to 1945. It is unknown whether the use of chemicals against Chinese soldiers gave the Japanese army a significant advantage on the battlefield. It is certain, however, that horrific BW experiments were conducted upon Chinese civilians and prisoners of war.[12] It is possible that some Allied soldiers, including American and British personnel, were experimented upon by Ishii Shiro (see the Sino-Japanese War listing) and his scientists, but this has not been confirmed. Apart from the East Asian theater of operations, however, no offensive use of CBW was conducted in World War II. Suggestions that the Soviet Red Army used tularemia (caused by the bacterium *Francisella tularensis*) against invading Nazi forces at the Stalingrad front are not supported by the available evidence.[13] German and Allied military scientists did pursue the manufacture of CW agents in very large quantities, but these never were used in conflict.

In the Korean War (1950–1953), Chinese officials, during armistice negotiations, accused the United States of using biological weapons. Although there is evidence that at least some of the communist Chinese leaders truly believed the allegations concerning BW in Korea[14], there is no evidence that the U.S. military used chemical or biological weapons during the conflict.[15]

During the Cold War, chemical agents became even deadlier. The United States and the Soviet Union stockpiled the German G-series nerve agents (sarin and soman), as well as the newer V-agents. Perhaps more dangerous was the development of weaponized biological agents. The United States and its allies during World War II had pursued a rudimentary offensive and defensive BW program. Later, work continued using a variety of infectious agents, including the causative organisms of anthrax, tularemia, and less deadly—but highly efficient—microbes such as Venezuelan equine encephalitis.

The controversy over the potential use of CBW grew increasingly protracted during the Vietnam War, particularly when the U.S. military used herbicides (such as Agent Orange) against Viet Cong-controlled areas. In a variety of instances, riot control agents (RCAs or tear gas) were used against the Viet Cong and Viet Minh regular army. Although such forms of weaponry were not intended to cause death, their use in an unpopular war heightened the sensitivity of the U.S. government to public perceptions of its CBW policies. As a consequence of Vietnam and high-profile incidents involving nerve agents at storage facilities in Utah and Okinawa, President Richard Nixon ended most U.S. chemical and biological programs in 1969.

When President Nixon renounced offensive BW and the United States stopped the production of biological weapons, the Soviet Union was only getting started. In 1979, a mysterious outbreak of anthrax in Sverdlovsk, Siberia (now Yekaterinberg) was suspected by Western intelligence to have been caused by a BW-related accident. (After many years of denials, Russia admitted in the 1990s that the Sverdlovsk outbreak was caused by Soviet military work with BW agents.) By the late 1980s, the Soviet BW apparatus (Biopreparat) had assembled the world's largest infrastructure devoted to the development of biological weapons. The Soviet arsenal included the standard agents, anthrax, tularemia, and a particularly virulent form of plague. But it had also weaponized smallpox, placing it in a liquid form to be delivered by intercontinental ballistic missiles.[16] Boris Yeltsin formally ended the program in 1992.[17]

Iraq had already used large amounts of chemical (but not biological) weapons against Iranian troops and Kurdish populations during its 1980–1988 conflict with Iran. After the first Gulf War (1990–1991), subsequent inspections conducted by United Nations personnel revealed that Iraq had undertaken a serious effort to develop chemical, biological, nuclear, and possibly radiological weapons. In 1995, the western world was particularly alarmed by the scope of the Iraqi BW program. Suspecting that Iraq had maintained at least a remnant of its WMD programs, including CBW agents and missile delivery systems, the United States led a war against Iraq beginning in 2003 that toppled the Iraqi regime. No caches of CBW agents have yet been found in Iraq by coalition forces since their occupation of Iraq.

The Chemical and Biological Threat Today

The world after September 11, 2001 has certainly changed, but even before then experts such as Michael Osterholm, Jessica Stern, and Jonathan Tucker had worried about the prospect that terrorists might obtain and use WMD. In 1993, Ramzi Yousef made the first attempt to destroy the World Trade Center. Yousef and his cohorts might have hoped that the towers would fall over in domino fashion, killing upwards of 250,000 people. Instead, the bomb they planted killed six people and injured more than 1,000. The attack failed to achieve the intended level of death and destruction, but it caused significant structural damage. Yousef reportedly considered the use of cyanide—a toxic "blood agent"—during the 1993 bombing. However, technical difficulties and other unknown factors prevented Yousef from designing such a device.[18]

There was another "wake-up call" to the threat of WMD, this time in Tokyo, Japan, when a guru named Shoko Asahara instructed followers to use nerve agents (sarin) against his real or perceived enemies. In 1995, Shoko Asahara's cult (Aum Shinrikyo) struck at the Tokyo authorities by releasing a nerve agent on the subway system. The death toll was 12, with thousands injured. The end result of the Tokyo subway attack was less than many experts expected from a WMD attack. Still, it made a tremendous impact, not only on Japanese society but also on how governments around the world reevaluated the CBW terrorist threat.

Improvised devices made by Palestinian terrorists using toxic chemicals have been a particular concern to Israel. But death and injury caused by shrapnel (ball bearings, nails, bolts, etc. made into projectiles by an exploding device) comprise the largest portion of the casualties inflicted by Palestinian suicide bombers. In 2002, however, it was reported that Israeli intelligence believed Palestinian homicide bombers to have put rat poison in their explosive devices. According to this assessment, terrorists put an anticoagulant type of rodenticide on shrapnel. Following bombings that occurred in 2002, Israeli doctors made note of excessive bleeding in certain bombing victims. This type of poison (warfarin) acts very slowly in mammals, making its utility and effect somewhat doubtful.[19] There is other evidence that Palestinian terrorists have been attempting to use other types of toxic chemicals in improvised explosive devices.[20]

Now that Saddam Hussein's Baath Party has lost control of Iraq and Libya has offered to abandon its WMD programs, there is a lower risk of seeing CBW on the battlefield among national armies. Syria and North Korea still retain a significant chemical weapons capability. But even skeptics of arms control treaties such as the 1993 Chemical Weapons Convention (CWC), the 1972 Biological and Toxin Weapons Convention (BTWC), and informal arrangements such as the Australia Group must concede that some progress has recently been made on the nonproliferation front. It is increasingly apparent that the world community has sustained the recent momentum toward the elimination of chemical and biological weapons, despite some notable setbacks.

Although the United States and other developed countries seem to be headed toward complete (if slow) chemical and biological disarmament, they continue to prepare their militaries for CBW defense in terms of materials and training. This is prudent, but one could make the argument that modern militaries are not likely to encounter chemical or biological weapons in organized combat. The more likely threat is from terrorists using toxic chemicals or infectious agents. This is unnerving, but terrorists have thus far made little effective use of these types of unconventional weapons. And yet, despite recent gains in the war against international terrorism, WMD will continue to pose a threat to society. It is difficult to conceive of a worse scenario than the effective use of chemical or biological weapons by terrorists who act with little or no restraint. By fostering an understanding of CBW agents, weapons, and their potential role in conflict, it is hoped that this volume will increase awareness—and vigilance—to defeat these threats.

2. Joseph Needham, *Science and Civilisation in China,* vol. 5, pt. 7: *Military Technology: The Gunpowder Epic* (New York: Cambridge University Press, 1986), p. 9. As a British diplomat (and to his death a committed Marxist), Needham was among the first to alert the world to Japan's use of chemical weapons against China during World War II.
3. A radiological dispersal device (RDD) or "dirty bomb" employs a high explosive (such as dynamite) to disperse radiological materials (such as cobalt–60, cesium–137, or strontium–90) across a large area. This would not result in a massive radiological hazard as no fission takes place. Rather, the contaminated area would likely remain off limits to people until it was fully cleared of radiating materials—a time-consuming and expensive process. The immediate effects of the explosion itself might of course cause death and injury, but few casualties would be expected from the radiological sources themselves. Nonetheless, the disproportionate (if somewhat justified) fear of "radiation" by the general public would no doubt cause great anxiety at the very least, perhaps even panic. Thus, RDDs are sometimes referred to as "weapons of mass disruption," as opposed to WMD.

Chronology: Chemical and Biological Weapons

Incidents of chemical or biological warfare (CBW) in history are of great interest, but they are also quite problematic—at least until we arrive at modern times (the post–World War I era). We say problematic because until the twentieth century, science had not sufficiently explained the roles of toxic chemicals or infectious disease in order to effectively utilize them in warfare. Nor had industry been developed in like fashion to exploit chemistry or biology for the purpose of waging battle. When it comes to chemical weaponry in particular, Augustin Prentiss put it quite well:

> History records numerous earlier but abortive attempts to utilize the powers of chemistry for military ends . . . .With the exception of Greek fire [use of petroleum-based incendiaries, ca. 7th century C.E.], none of them produced important results and none permanently challenged the supremacy of existing weapons. They are of interest to us only as indicating man's eagerness to experiment with any means that promise to promote his fortunes in battle and his final dependence upon technical knowledge to produce such means. (Prentiss, p. xvi)

Quite the same can be said of biological weaponry. In either case of chemical or biological weapons, the basic knowledge to understand the scientific disciplines behind them was inadequate until the nineteenth century, when significant advances were made in fields such as organic chemistry and microbiology. Still, it then took the latter stages of the Industrial Revolution for nations to develop the capacity for mass production of chemicals that would play a noteworthy—albeit overall insignificant—role in World War I (1914–1918).

Another criterion to consider is the scope of the purported attack. Was this a poisoning of a few individuals, or a whole army? Keeping in context with a weapon of mass destruction (WMD), that is, a device causing mass casualties, certainly not all events would necessarily qualify.

This will not stop us from trying to delineate a chronology of examples that are relevant to CBW. Here are listed a selection of historical events, with an effort to describe them by category: either chemical or biological weaponry.

Sixth Century B.C.	Assyrians reportedly used ergot fungus (*Claviceps purpurea*) to poison their enemy's water wells
431–404 B.C.	Spartan armies use sulfur and toxic arsenic smoke during Peloponnesian War
Fourth Century B.C.	Chinese engineers use arsenic against underground sappers.
Circa 200 B.C.	Officers in Hannibal's army adulterate the wine of African rebels with mandrake, which contains belladonna alkaloids causing hallucinations.
187 B.C.	Ambraciots (Greece) employ irritating smoke against Roman soldiers
7th Century C.E.	The Byzantine architect, Callinicus ("Kallinikos"), reportedly invents the first

	liquid incendiary—"Greek Fire."
Circa 1040	Scottish king poisons wine using a belladonna-like ("sleepy nightshade") herb and gives to Norwegian enemies as "provisions" under pretense of surrender. Scots then slaughter the incapacitated Norwegians.
1347	Mongolians lay siege to Kaffa (in modern Ukraine) and throw corpses over city walls to spread bubonic plague. May have contributed to Black Death, which killed approximately 50 million people through the fourteenth century.
1672	Bishop of Münster attempted the use of atropine-like drug in grenades in siege against city of Groningen. Attack backfires.
1767	British plot to supply cloths from a smallpox hospital ward to American Indian tribes in hopes of spreading disease. Unknown if this strategy was ultimately successful.
1855	Sir Lyon Playfair suggests using cyanide-containing chemicals against Russian troops during Crimean War, but this tactic never found approval by the British High Command.
29 July 1899	First Hague Convention signed, prohibiting "the use of projectiles the sole object of which is the diffusion of asphyxiating or deleterious gases." (Mauroni, p. 81)
1914	French troops use tear gas grenades against German positions in World War I
22 April 1915	German military uses barrage of chlorine gas against Allied trenches in Ypres, Belgium.
12 July 1917	Germany uses mustard agent against Allied troops at Ypres, Belgium.
1916–1918	German agents infect beasts of burden—including horses bound for use by Allies in Europe—using glanders and anthrax.
1919	In midst of the Russian civil war, British troops use adamsite (diphenylaminearsine, DM) against Bolsheviks.
1922	The U.S. delegates at the Washington Arms Conference table a proposal to abolish chemical warfare, but France ultimately rejects the treaty because of stipulations regarding submarines.
17 June 1925	Geneva Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous or other gases, and of Bacteriological Methods of Warfare is signed by nearly thirty countries.
1936	German chemists synthesize first nerve agents to be weaponized, including tabun (GA).

1937–1942	During Sino-Japanese War, Japan employs chemical and biological weapons against Chinese troops and civilians.
1939	Japanese attempt to poison water with *Salmonella enterica* Typhi (causative agent in typhoid) in the so-called Nomonhon Incident in a biological attack on Soviet troops, but apparently is unsuccessful.
1935	Italian troops under Benito Mussolini begin using chemical weapons (mustard agent) against Ethiopians.
1942	United States undertakes study of biological warfare (BW) agents, including defensive and offensive preparations.
December 1943	German Luftwaffe attacks Allied ships carrying sulfur mustard in Bari, Italy, leading to more than 600 casualties.
1956	Soviet Marshal and Defense Minister Georgy Zhukov mentions the use of "various means of mass destruction, such as atomic, thermonuclear, chemical and bacteriological weapons," stirring great interest and anxiety in the West. (Mauroni, p. 85)
1962	The U.S. military begins herbicide operations in Vietnam War, including the use of Agent Orange.
1965	As the war in Vietnam escalates, the United States employs riot control agents—chiefly CS—in certain military operations, creating controversy, especially for war critics at home and abroad.
1967	With possible support from the Soviet Union, Egyptian forces use chemical weapons, including mustard agent and some kind of organophosphate (nerve agent) against Yemeni royalists.
25 November 1969	U.S. president Richard M. Nixon renounces the offensive use of biological weapons, ordering that the U.S. program be dismantled.
10 April 1972	Great Britain, the Soviet Union, and the United States sign the Biological and Toxin Weapons Convention.
1973	Following the Yom Kippur War (fought between Israel and Arab countries), U.S. military analysts discover that Egypt possessed armored vehicles equipped with protection against nuclear, chemical, and biological (NBC) warfare. This leads to concern that Warsaw Pact forces, supported by the Soviet Union, were prepared to use NBC weapons.
1973–1974	The Soviet Union initiates and establishes Biopreparat, a civilian organization devoted to producing biological warfare agents.

26 March 1975	The Biological and Toxin Weapons Convention enters into force.
1979	Anthrax (*Bacillus anthracis*) spores are accidentally released from a biological weapons facility in Sverdlovsk, Russia; at least 64 people died from inhalation anthrax.
1983	Iraq begins using chemical warfare agents, including mustard, in the Iran-Iraq War (1980–1988).
January–March 1991	A United States–led coalition invades Iraq in Operation Desert Storm. The goal is to force Iraqi compliance with United Nations resolutions calling for its withdrawal from Kuwait and elimination of its weapons of mass destruction (WMD) programs. A newly formed United Nations Special Commission on Iraq (UNSCOM) searches for WMD and oversees the destruction of known chemical and biological weapons arsenals and production facilities until 1998, when Iraq defies international mandates and forces UNSCOM inspectors to leave the country.
13 January 1993	The Chemical Weapons Convention (CWC) is open for signature.
26 February 1993	On 26 February 1993, a small group of men from the Middle East with suspected links to the terrorist organization al-Qaeda detonate 1,500 pounds of explosive in the basement of the World Trade Center in New York. The attack does not destroy the buildings, but kills six people and injures more than one thousand. Concerns arise over the possibility that the terrorists laced the high explosives with chemical weapons in order to increase the number of casualties.
27 June 1994	Aum Shinrikyo, a new religious cult in Japan, uses sarin nerve agent in an assassination attempt on three judges in Matsumoto, killing seven people and injuring over 200.
20 March 1995	Aum Shinrikyo releases sarin nerve agent on the Tokyo subway, killing 12 people and injuring about 1,000. Japanese police discover nerve agent precursors at the cult's home base near Mt. Fuji and also learn that Aum attempted to produce biological weapons.
19 April 1995	Timothy McVeigh detonates a 4,000-pound ammonium nitrate fuel oil (ANFO) explosive device in a rented truck, destroying the Alfred P. Murrah Federal Building in Oklahoma City, Oklahoma and killing 168 people.
29 April 1997	The CWC enters into force.

October 2001	A still unknown perpetrator mails four letters containing anthrax spores to unsuspecting victims in Florida, New York, and two U.S. senators in Washington, D.C. Five people eventually die of inhalation anthrax, while seventeen others—having contracted either inhalation or cutaneous forms of the disease—are treated successfully.	
March–April 2003	Led by the United States, coalition forces undertake Operation Iraqi Freedom, with the stated goal of ridding Iraq of its weapons of mass destruction (WMD) programs.

A

ABERDEEN PROVING GROUND

Established in October 1917, Aberdeen Proving Ground in Maryland is the oldest active location in the United States for the design and testing of munitions and protective military equipment. During World War I, Edgewood Arsenal, the northern area of the proving ground, was the primary location in the United States for chemical weapons research, development, production, and testing. Aberdeen Proving Ground was also the center of United States offensive chemical weapons operations until production of chemical warfare (CW) agents in the United States ended in 1968.

Among the chemical agents the Edgewood facility produced (in ton quantities) were the choking agents phosgene and chloropicrin, the blister agent mustard, and the nerve agent sarin (*see* Choking Agents, Mustard [military code: HD, for mustard, "H," distilled, "D"], Sarin [GB, for "German" nerve agent type, "B," second in series]). Throughout the decades of the U.S. chemical weapons program, Aberdeen Proving Ground also has been central to defensive chemical activities. Aberdeen is home to the U.S. Army Soldier and Biological Chemical Command (SBCCOM), the Program Manager for Chemical Demilitarization, and the U.S. Army Medical Research Institute of Chemical Defense (USAMRICD). Finally, the Aberdeen Chemical Agent Disposal Facility will dispose of 5 percent of the original stockpile of United States chemical weapons, which is currently being stored at Edgewood, by 2006–2007 (*see* Demilitarization of Chemical and Biological Agents).

The Chemical Warfare Service (CWS) was created in 1918 to oversee all United States chemical weapons activities; during World War I, Edgewood Arsenal was the home of offensive weapons production by CWS that comprised four production plants and four munitions-filling plants. In the interwar years, almost all CWS activities were transferred to Edgewood, where the emphasis shifted from agent production to defensive research and development and chemical defense training for troops. During World War II, President Franklin Roosevelt condemned Japan's use of chemical weapons in China, but he reserved the right to respond in kind if such an attack were launched on the Allies. This resulted in a military requirement spurring more chemical weapons activity at Edgewood. But with the exception of Japanese chemical weapons used in China (1937–1943), and possible use of cyanide grenades against Allied soldiers in the Pacific, no other actor in World War II utilized chemical weapons on the battlefield. The only U.S. chemical casualties suffered during World War II were accidental (*see* Bari Incident).

Following World War II, Edgewood continued to be the center for U.S. chemical weapons research, serving as the site for pilot production of the nerve agent sarin. In 1969, however, President Richard Nixon stopped U.S. chemical weapons production, and on November 25 he announced that he would resubmit the 1925 Geneva Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous, or Other Gases, and of Bacteriological Methods of Warfare to the Senate for ratification (it had been rejected in 1926). The U.S. Senate, however, did not ratify the Geneva Protocol until the subsequent Ford administration (1975).

Throughout its history, Edgewood has played a key role in defensive chemical weapons efforts, from development and testing of gas masks and other protective equipment, to researching and developing medical treatments for chemical weapons casualties. When destruction of the U.S. chemical weapons stockpile began in earnest by the 1990s, Edgewood became home to both the Program Manager for Chemical Demilitarization (the office overseeing U.S. destruction efforts), and the Chemical Demilitarization Training Facility, where personnel responsible for operating destruction facilities are trained. Destruction of 1,818 one-ton containers of mustard will take place at the Aberdeen Chemical Agent Disposal Facility beginning in 2004. This disposal will be conducted by first using chemicals to neutralize the agent. Afterward, the hazardous waste products generated will be detoxified by sewage treatment bacteria at an off-site commercial facility.

ABRIN

Abrin is a highly toxic protein that can be used as a poison. But like ricin (a toxin found in the castor bean plant, *Ricinus communis*), abrin is more likely to be used as a poison for murder or for assassinating certain targets than as a component in a weapon of mass destruction (WMD).

Abrin can be extracted from the seeds of the *Abrus precatorius* plant, the beans of which are known as Rosary peas, precatory beans, crab's eye, or the jequirity bean. Provided the bean is well masticated, one such seed from this plant can be enough to kill a human adult. Both abrin and ricin (another plant lectin) share similar structures, toxicological properties, and approximately the same molecular weight (60,000 and 65,000, respectively). Research conducted in the 1970s demonstrated that abrin was approximately 2.5 times more toxic than ricin when administered to mice. Due to the much larger market for castor beans (as a source for vegetable oil and for use in lubricants), the worldwide availability of jequirity seeds is relatively small. As a consequence, and despite the disparity in their toxicities, ricin probably remains a greater overall threat.

The abrin toxin itself consists of a large protein chain. Like ricin toxin, the abrin protein attaches itself to a cell with its B portion, and the A segment inserts itself into the ribosome, stopping protein synthesis. This leads to cell death and causes nausea, vomiting, and shock. If abrin particles are inhaled, abrin can cause the death of tissue in the lungs and airways, leading to severe inflammation and edema. Death from abrin poisoning would likely occur many hours after exposure.

In a military manual published by members of the al-Qaeda terrorist organization (circa 2000), the reader is instructed that precatory beans ("red or black and used in prayer beads") could be used to extract abrin for assassination purposes. The recipe described in the manual was probably derived from *The Poisoner's Handbook,* an underground pamphlet published in the 1980s.

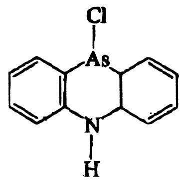
ADAMSITE (DM, DIPHENYLAMINO-CHLORARSINE)

The chemical agent adamsite falls between the categories of moderately toxic chemical warfare (CW) agent and riot control agent (RCA). For adamsite to be used as a WMD, large quantities would be required, and such a scenario seems implausible. In enclosed spaces, however, many people could be affected by a release of adamsite. According to a Chinese military book on chemical weaponry, the United States used adamsite in the Korean War (1950–1953), probably a reference to the use of tear gas—which included adamsite at the time—used to control rioting Chinese and North Korean POWs. Today, no known modern military stocks significant amounts of this chemical. Still, large quantities may remain (most likely in Russia) in existence, awaiting destruction as an old chemical weapon (produced prior to 1946).

Figure A-1: Adamsite



Adamsite (DM)

The German chemist Heinrich Wieland is credited with having synthesized diphenylaminochlorarsine in 1915. Three years later in the United States, Major Roger Adams also synthesized this compound while conducting his own independent research. Thereafter, the U.S. military referred to this chemical as adamsite. During the early twentieth century, rapid advances in organic chemistry—including the mass production of dye-base precursors such as diphenylamine—made adamsite relatively easy to manufacture in large quantities. Reportedly, in 1919, the British employed adamsite against Bolshevik forces during the Russian Civil War. During its war against China in World War II, Japan used large quantities of related compounds such as diphenylcyanoarsine, and Japan may also have used adamsite.

Adamsite is a yellowish, crystalline solid that can be delivered by means of generating smoke with high heat. Adamsite can also be delivered in the form of a liquid (dissolved in solvent) or fine powder. As the term *vomiting agent* suggests, adamsite has been known to cause severe nausea, although it is not entirely clear why it has this effect in humans. Adamsite also has been referred to as a sneeze gas (sternutator) and an irritant smoke. Unlike other types of RCAs, the effects of adamsite—which include severe irritation of the upper respiratory tract—are delayed by at least several minutes. Adamsite is practically odorless, and this, coupled with its ability to break through the protective masks of the era, was another feature that has made adamsite a potentially insidious and effective CW agent. In the United States military, adamsite was originally designed to be delivered in the M6A1 grenade. The same Chinese military text referred to above describes a former Soviet munition that employed adamsite: "The former Soviet [KRAV-25] chemical munition is filled with 2.7 kg of adamsite, producing a vapor for about 9–10 minutes. The casualty-causing effects of its shrapnel and explosive force are about the same as conventional munitions. This type of CW ordnance is often used intermixed with conventional munitions to produce disorder and exhaustion on the battlefield" (p. 26).

There are numerous toxicological studies, but most are based on animal experimentation, and therefore it is difficult to arrive at a precise lethal dose for adamsite in humans. An accidental death was reported in one individual who was exposed to an estimated 1,000–2,000 milligrams per cubic meter of air (mg/m^3) concentration of adamsite for 5–30 minutes. The estimated median lethal concentration of adamsite is 11 gramsmin/m^3, a toxicity which pales in comparison to that of most other CW agents. But adamsite is far more toxic than other RCAs such as CS tear gas (*see* Riot Control Agents). CS is designator for the tear gas after its inventors and chloroacetophenon (CN), both used by civilian and military detachments for quelling public disturbances.

AEROSOL

When it comes to the delivery of chemical or biological warfare (CBW) agents, understanding the physical and chemical qualities of toxic or infectious substances is crucial. One of the most important factors in delivering CBW agents is the formation of aerosols. In nuclear warfare, aerosols represent a threat in the form of radioactive fallout. In conventional weaponry, fuel-air munitions (thermobaric weapons) can employ liquid fuel in the form of an aerosol that, upon ignition, causes great destruction over a wide area.

Although their behavior in the atmosphere may share similarities, aerosols are to be distinguished from gases and vapors. A gas is an amorphous, molecular form of matter. Vapors are those gases that evolve from liquids, especially those that are in liquid form at room temperature. Water vapor, for example, evaporates from water and can condense back into liquid. An aerosol can be briefly described as a suspension of tiny particles in air, these particles being either liquids or solids. Although some scientific disciplines have set strict guidelines on what makes a true aerosol, aerosols generally are airborne particles that stay aloft in the atmosphere for a certain period of time.

Smoke, mist, and fogs are examples of aerosols consisting of very small (0.25 microns) to relatively large (40 microns) particles. (A fog is essentially a cloud formed by particles with water droplets adhering to them.) With strong light and a dark background, the human eye can see floating particles in the air of about 30 microns in size. (For comparison, human hairs have an average diameter of 75 microns.) Atmospheric haze is thought to be largely caused by particles of approximately 0.1 microns or even smaller. Objects that are less than 0.2 microns cannot be seen even with light microscopy. Common substances that can form aerosols are listed in the table below.

Table A-1: Representative Particle Sizes

Some example particle sizes	*Diameter, microns*
Tobacco smoke	0.25
Flour dust	15–20
Pollens	15–70
Talc powder	10

The word *aerosol* itself is a throwback to World War I, when Professor F. G. Donnan first coined the word. An aerosol in the older context referred to the behavior of irritating arsenical smokes. Today, the science of aerosols has involved many disciplines, not the least of which concerns biological materials that exist in the air. Bioaerosol research involves, among many other things, the characterization of allergens (such as pollen) and infectious organisms (such as fungi) and how these affect human health. Chemical-based aerosols are, of course, very relevant when assessing risks from industrial and household pollutants.

Aerosols consist of particles that fall out of the atmosphere, but at a low rate of speed. Although gravity dictates that all particles must drop to the ground, their fall is influenced by the atmospheric interferences and aerodynamic fluctuations of variously sized particles. The chart below shows the relative rates of fall among particles ranging from 0.2 microns to 1 millimeter in diameter.

Table A-2: Particle Fall Rate at 20 Degrees Celsius

Diameter (microns)	*Weight (microgram)*	*Terminal velocity (cm/min)*
0.2	4.2×10^{-9}	0.014
0.5	6.5×10^{-8}	.06
1	5.2×10^{-7}	.21
2	4.2×10^{-6}	.77
3	1.4×10^{-5}	1.6
5	6.5×10^{-5}	4.7
10	5.2×10^{-4}	18
20	4.2×10^{-3}	72
30	1.4×10^{-2}	162
51	6.5×10^{-2}	432
100	5.2×10^{-1}	1,500
200	4.2	4,200
300	14	6,900
500	65	12,000
1,000 [1mm]	525 [.525 mg]	23,100

Brownian movement—motion of tiny particles caused by the ongoing dynamics at the molecular level—thermal forces, electrostatic charges, and other factors affect aerosol stability. However, when looking at the larger picture, wind and atmospheric changes as well as precipitation dramatically influence the nature of aerosols in a variety of contexts.

The utilization of aerosols is important for maximizing concentrations of chemical and biological warfare (CBW) agents. Whether chemical or biological, aerosols can be delivered in two basic forms: line source and point source. A line source can be visualized by using the crop duster model: Aerosols are released from a moving platform, an object that draws a line of cloud in its wake. Wind moving perpendicular to this line source can then spread the aerosol over a large swath of territory. Point sources rely on single bursts or from releases from a static position. After point release via spray or detonation with an explosive, air currents can carry these agents to saturate nearby targets. Point sources usually require redundant applications to achieve wider area coverage.

Because their behavior is similar to that of gases, aerosols are greatly influenced by wind velocity and thermal convection currents. CBW agents generally increase their effectiveness as a function of concentration (particles or milligrams of liquid per cubic meter of air, etc.) and time. The longer an aerosolized agent remains on target, while maintaining a high enough concentration to cause infection (if a biological weapon) or injury (if a chemical weapon), the more casualties will result. Therefore, conditions of stable air with little mixing of different temperature layers are ideal for disseminating aerosolized agents. Such a state is referred to as an inversion. An inversion is characterized by little vertical movement of air, and it usually occurs near dusk or dawn. Aided by low wind velocity, CBW agent aerosols released under these conditions will linger over the ground and stay relatively concentrated over time. Less ideal are conditions described as neutral, with little change in air temperature as one reaches higher altitudes. Here, winds are often stronger, with minor convection currents. Finally, air instability in the lapse phase is least ideal for aerosol delivery. Not only are the horizontal winds in this situation unfavorable, but strong vertical gusts of air break up and dissipate aerosols.

In chemical warfare (CW), the primary challenge in delivering toxic substances on the battlefield is to create concentrations high enough to cause a large number of casualties. Gases such as chlorine and phosgene can expand quickly over an area, but they also disperse just as rapidly, reducing their toxic effects. Even those CW agents that are volatile liquids present significant challenges to effective delivery. They do not form vapors quickly enough or in dense enough format to be effective. Therefore, modern CW has included the use of aerosols to maximize the effectiveness of delivery of toxic agents on the battlefield. By means of toxic aerosols, CW agents are more widely dispersed, and under favorable meteorological conditions, they remain in high concentration over time.

Chemical aerosols can be produced by means of explosive munitions, such as artillery shells or aerial bombs, or through the use of spray tanks with specially fitted nozzles. When aerosols are produced by explosion, a certain amount of agent will be destroyed in the detonation energy and possible conflagration. Loss of CW agent is not expected to be much more than 25 percent, however. A Chinese People's Liberation Army book on chemical weaponry describes the percentages of droplets, aerosol, and destroyed agent in a U.S. chemical munition in the following way: "In the case of the U.S. 155 mm VX explosive [howitzer] shell, about 60 percent of the agent is scattered within a 20 meter area, 15 percent being disseminated in an aerosol that floats downwind from the point of detonation in the air. The remaining CW agent is destroyed due to the blast."

Especially in the case of biological warfare (BW), aerosols are most effective when their average particle sizes fall between about 1 and 10 microns. Using experimental animals and corn oil droplets, early research conducted by the United States BW program in the 1950s showed the relationship of particle diameter to particles' ultimate fate in a model respiratory system (see table below).

Particles that can effectively reach down into the lungs and deposit in the alveoli—tiny air sacs where gas exchange takes place between the lung and the bloodstream—are absorbed more quickly. The

Table A-3: Experimental Distribution of Corn Oil Particles in Mice Lungs

Size microns (Particle diameter)	*% Lung (Number of particles found)*	*% Bronchi (Number of particles found)*	*% Terminal Bronchi and alveoli ducts (Number of particles found)*	*% Alveoli (Number of particles found)*
0.8–2.5	80	24	26	30
3.3–10	19	10	7	2
12–17	1	0	0	0
Total	100	34	33	32

highest alveolar deposition is for particles from 1 to 5 microns in diameter. Much smaller particles (such as the main constituent of tobacco smoke) can be so small that they are inhaled and exhaled without landing upon inner surfaces of the bronchi or lungs. Those particles 10 microns or larger become more prone to barriers in the respiratory system, depositing on hairs in the upper airways or bronchial tree. For some agents, such as mustard, however, large particles will cause severe tissue damage in the higher regions of the throat, causing death from respiratory blockage due to subsequent formation of dead tissue. With its predilection for membrane solubility, VX nerve agent will absorb into skin and upper tissues in the respiratory tract. Thus, even if the particles are not dispersed in the size of 1–5 microns, chemical casualties will still likely occur for unprotected individuals. The only difference may be the time before onset and the degree of severity.

Table A-4: Particle Size and Deposition in the Human Respiratory System

Particle diameter	*Areas where deposition is most likely to occur*
Larger than 10 microns	Throat and nasal passages
5 to 10 microns	Upper to lower respiratory tract
2 to 5 microns	Lung and bronchioles
Less than 2 microns	Alveoli

For biological weapons, average particle sizes are even more important, as most, if not all, modern applications of BW agents—save the dermally active trichothecene mycotoxins—utilize inhalation to cause injury or death. With some notable exceptions, the deliberate cause of disease through inhalation—the essence of BW—is best achieved by alveolar deposition of infectious particles. Experiments with animals and with human volunteers have shown the direct relationship between optimal particle size and the chances for infection to start via the lungs.

Even more so than chemical weapons, biological agents are difficult to disseminate efficiently in aerosols for creating large casualties. First, BW agents are sensitive to heat and violent shock. Production of aerosols by means of explosive devices is likely to kill 99 percent or more of the BW agent. Therefore, to expect battlefield success, bacteria, viruses, or toxins must be prepared in such a way that enough infectious or toxic doses remain effective following detonation. Second, the formulation of BW agents to retain shelf life and virulence—as well as having the right physical properties to create effective aerosols—takes considerable expertise and development. Finally, the controlled release of aerosolized particles that fit the "sweet spot," that is, in the 1–5 micron average diameter range, has been a difficult hurdle even for advanced BW programs.

In more conventional types of weaponry, aerosolized explosives can be used to create devastation. In the case of fuel-air munitions (or fuel-air explosives, FAE), combustible fuels can be aerosolized over a target and detonated, causing a massive detonation with significant overpressures. So-called thermobaric munitions can employ a highly flammable liquid/vapor such as ethylene oxide or propylene oxide. These large munitions are normally dropped from aircraft, their rate of fall slowed by parachute, and their contents released over a large area. After a delay, this aerosol is detonated with another charge that, after the cloud has formed something of a pancake shape, ignites the

Table A-5: Bacteria Required to Create Medical Conditions

Particles, diameter (microns)	*Number of bacteria required to cause infection/Respiratory virulence (RLD_{50}) Guinea pig* Francisella tularensis	*Number of bacteria required to cause infection/Respiratory virulence (RLD_{50}) Rhesus monkey* Francisella tularensis	*Number of bacteria required to cause infection/Respiratory virulence (RLD_{50})* Francisella tularensis *Human volunteers, infectious dose (ID_{50}, nonfatal)*
1	2.5	14	10–52
6.5	4,700	178	14–162
11.5	23,000	672	NA
18	125,000	3447	NA
22	230,000	More than 8,500	NA

cloud in a very large blast. One can compare the large force involved in grain elevator explosions, in which small quantities of grain dust are ignited by a spark, which leads to a massive blast. In a thermobaric device using aerosols, the resultant explosion creates very large overpressures capable of flattening structures in the immediate blast zone and causing considerable damage on the periphery. In addition to targeting troop concentrations, this type of aerosolized fuel-air munition has found a role in clearing land mines. Both the United States and Chinese militaries, for example, have fielded such systems for land mine removal.

AGENT ORANGE

Agent Orange was the name given to one type of chemical herbicide used by the U.S. military during the Vietnam War. The 1993 Chemical Weapons Convention prohibits the use of herbicides as a means of warfare. The United States, however, has reserved the right to use these chemicals for weed control at airfields, for example, and in limited amounts for security of its armed forces. Herbicides are included in this discussion on WMD not only because of the controversy surrounding their use, but also because of their capacity to cause extensive destruction to forests and jungle. Although the short-term environmental effects can be devastating, most herbicides (when used correctly) have little or no deleterious effect on human health. The same also can be said of Agent Orange.

Spraying liquid herbicides in large quantities from aerial applicators (such as crop dusters) was a pre-World War II idea. In the 1930s, the U.S. Army Air Corps refined techniques that would prove useful for the application of DDT, one of the most successful insecticides ever developed. During World War II, the U.S. Army aggressively pursued research into producing compounds that could destroy plants. More than 1,000 different compounds were investigated at Camp Detrick, Maryland. One chemical code-named LN-8 stood out from the rest. This formulation, 2,4-dichlorophenoxyacetic acid, or 2,4-D, proved to be one of the most effective herbicides ever synthesized. It is still a widely used herbicide for weed control and other agrochemical applications.

Highly effective herbicides based on the phenoxyacetic acids (chiefly 2,4-D) were tested at bombing ranges in Texas and Indiana during World War II. These trials were so successful that U.S. military planners considered the use of herbicides against the Japanese during the war in the Pacific. The strategy would involve using herbicides to mark the jungle, leaving lines of dead foliage to guide bombers to Japanese troop concentrations. This stratagem and other plans that included attacking Japanese rice crops in preparation of a final invasion, however, were eventually tabled.

During the Korean War (1950–1953), the U.S. Air Force made operational plans to use 2,4-D herbicide with 2,4,5-T (which would eventually be called Agent Orange during the Vietnam War) to destroy vegetation that could be of use to the enemy. The plan was never implemented because the ecology of the Korean peninsula was entirely different from that of tropical zones, and there was no perceived benefit in the use of herbicides in that conflict. Spraying equipment that was initially shipped to Korea was put in storage, and the chemical agents were destroyed in 1955.

While fighting against Malaysian communist insurgents at about the same time, the British military used trioxene and diesolene herbicides against enemy crops. Some operational lessons from this conflict were useful for future U.S. military engagements. In the late 1950s, artillery range exercises in the United States were hampered with overgrowth, and Dr. James W. Brown was brought in from the U.S. Army Biological Warfare Laboratories to devise a solution to the problem. He supervised the aerial spraying of sugar maples using a combination of 2,4-D and 2,4,5-T. These practical experiences led to the use of this mixture in the Vietnam War, especially during the years 1961–1971.

As the United States became more actively involved in the South Vietnamese struggle against communist forces, herbicides were considered for use against enemy cover and food. South Vietnamese President Ngo Dinh Diem and his brother Ngo Dinh Nhu were enthusiastic supporters of defoliation operations. President John F. Kennedy and the U.S. Joint Chiefs of Staffs, however, recalled how Chinese communist propaganda had (falsely) accused the use by the United States of chemical and biological warfare against North Korea a decade earlier. Before authorizing the use of herbicides in Vietnam, then, the Kennedy administration first looked into the legality of such a venture. In 1961, Secretary of State Dean Rusk assured President Kennedy that the use of defoliant did not violate international law concerning CW and was an accepted tactic of war. Still, the use of herbicides in warfare, along with the use of tear gas (CS) and napalm, drew criticism from both international and domestic circles.

Although the U.S. Air Force employed a number of herbicide formulations during the Vietnam War, Agent Orange was used in the greatest quantity and was arguably the most effective.

Table A-6: Representative Herbicides Used in South Vietnam, 1965–1971

Herbicide	*Gallons*
Orange (2,4-D and 2,4,5-T phenoxyacetic acids)	10,645,904
White (80% 2,4-D and 20% picloram)	5,632,904
Blue (cacodylic acid)	1,144,746

The U.S. Air Force conducted a massive defoliant campaign in Vietnam called Operation Ranch Hand. The initial goal of the herbicide program in Vietnam (and also in neighboring Laos) was to deny the enemy protective cover, especially along the borders with North Vietnam, and to eliminate manioc (tapioca) groves that were being used by the Viet Cong guerillas for both cover and as a food source. Less than 10 percent of the herbicides used in Vietnam and Laos were directed against enemy crops, the remainder being used to clear fields of fire for finding and fixing the enemy, and to maintain security around military facilities by removing vegetation that obscured sightlines. Results of the herbicide campaign were mixed. Some studies showed that the Viet Cong were hard pressed to make up for the food shortages caused by the operation, but others found Operation Ranch Hand to be politically and militarily counterproductive.

The United States eventually abandoned the South Vietnamese, and it may be impossible to assess fully the merits or demerits of Operation Ranch Hand. The ecological aftermath of Operation Ranch Hand also offers a mixed picture. Most of the devastation occurred primarily in the mangrove forests; some estimates claim that it will require 100 years for the forests to grow back. But most other areas recovered within about a year after the last spraying sorties.

Following the Vietnam War, many U.S. veterans claimed that they suffered illness due to exposure to Agent Orange. Studies subsequently found that dioxin, a highly toxic and carcinogenic substance, was present in small concentrations within Agent Orange. No scientific evidence, however, has thus far been able to link Agent Orange and very small concentrations of dioxin to significant human disease.

AGROTERRORISM (AGRICULTURAL BIOLOGICAL WARFARE)

Agroterrorism, or agricultural BW, is also referred to as agricultural bioterrorism. None of these terms, however, seem to discriminate between military programs and smaller, less sophisticated attacks on a food supply (e.g., bioterrorism or sabotage). Still, they are interchangeably understood to mean the deliberate use of pathogens against crops or livestock. The social and economic consequences of a concerted agroterrorist attack could be quite extensive. Because industrialized countries are increasingly dependent upon large-scale, dense, and efficient mechanized farms, there is an acute vulnerability to deliberate attack using plant or animal pathogens. Such attacks could cause huge economic losses.

Vulnerability of Livestock

For example, Newcastle disease (caused by a virus) primarily affects birds, resulting in severe illness with a high mortality rate (between 95 and 100 percent). Humans can also be infected with the Newcastle disease virus (though the disease is relatively benign in humans, unlike in birds), and it is possible for people to spread the virus to animals. In 1971, southern California experienced a Newcastle disease outbreak that led to the slaughter of 12 million chickens in an effort to control its spread. Another serious epizootic, avian influenza virus (fowl plague), has been known to jump from one species, such as fowl or pig, to humans (and vice versa). In 1983–1984, an outbreak of avian influenza (H5N5 strain) in Pennsylvania led to a campaign to destroy all infected birds in the vicinity. As a result, prices for poultry rose some $350 million that year. Another strain of avian influenza, H5N1, killed six people in Hong Kong in 1997, also demonstrating the virus's ability (albeit rare) to jump from one species to another.

In one of the most serious animal disease outbreaks to occur in the previous century, foot-and-mouth disease (FMD) in 1997 devastated Taiwan's swine industry, leading to some $25 billion in direct and indirect losses to the country's economy. Although FMD is not nearly as deadly to animals as other diseases such as rinderpest, a deadly viral disease that can wipe out whole herds of cattle, it is still among the most feared disease in agriculture, especially in the cattle and swine industries. The disease generally results in many sick and, therefore unproductive, animals. In addition to fever, anorexia, and general malaise, infected animals manifest blister-like sores on and inside the oral cavity and on the teats, as well as ulcerating patches on the hooves (thus the name *foot-and-mouth*). The 1997 outbreak probably began with the smuggling of an infected animal across the Taiwan Straits from mainland China. Although some have suggested this was a deliberate attack perpetrated by the Chinese, most Taiwanese veterinarians believe it was unintentional. Another outbreak of FMD a few years later, this time in the United Kingdom, also led to billions of dollars in economic losses, primarily in the sheep rearing industry. These examples of natural outbreaks of animal disease demonstrate the potential threat from agroterrorism.

Food Security: "Farm to Fork"

There is another dimension to the threat from agroterrorism, namely that of food safety. In both developed and developing economies, there has recently been an increased focus on security surrounding the "farm to fork" cycle of the food industry—that is, the vulnerability of the food supply to deliberate contamination with toxins or pathogens. Such an attack could occur at the locations where crops or animals are first raised, at the midpoint processing facility, or even on the grocery shelves and at other points of sale. So far, the deliberate poisoning of food or beverages in modern societies has largely been a phenomenon reserved for criminal or malicious activity, and not organized warfare or terrorism. During the late 1990s, in China, a substantial number of cases occurred in which jealousy or hatred led individuals to contaminate food or beverages with rat poison, including the acutely toxic rodenticide tetramine (tetramethylene disulfotetramine). Mass poisonings have sometimes resulted, including a 2002 incident in which 40 people died and 300 others were seriously poisoned with tetramine.

Attacks on agriculture, however, could stem from purely financial motives. For example, after deliberately spreading a disease among cattle or corn, and thus causing a dramatic rise or fall in their prices on the world market, a malevolent actor might be able to take advantage by speculating on commodity futures.

Like the categories of pathogenic organisms that affect human beings, BW agents that could be used against agriculture include bacteria, viruses, fungi, and insects. Today, a number of possible BW agents have been recognized that could be used against crops or livestock animals (see tables A-7 and A-8 below). These lists, however, are by no means exhaustive.

Table A-7: Potential Anti-Crop BW agents

Bacterial diseases	*Bacterial agents*
Rice blight	*Xanthomonas oryzae*
Corn blight	*Pseudomonas alboprecipitans*
Viral diseases	*Viral agents*
Tobacco mosaic	Tobacco mosaic virus
Sugar-beet curly top	Curly top virus
Fungal diseases	*Fungal agents*
Late blight of potato	*Phytophthora infestans*
Rice blast	*Pyricularia oryzae*
Black stem rust of cereals	*Puccina graminis tritici*
Brown spot of rice	*Cochliobolus miyabeanus*

Table A-8: Potential Anti-Animal BW Agents

Rickettsial diseases (Bacteria)	*Rickettsial agents*
Heartwater of sheep and goats	*Cowdria ruminantium*
Viral diseases	*Viral agents*
Foot-and-mouth disease (FMD)	Foot-and-mouth disease (FMD) virus
Rinderpest (cattle plague)	Rinderpest virus
African swine fever	African swine fever virus
Aujeszky's disease	Herpes virus
Newcastle disease (poultry)	Newcastle virus
Avian influenza	Avian influenza virus
Fungal diseases	*Fungal agents*
Aspergillosis (poultry)	*Aspergillus fumigatus*

Targeting Crops and Animals: World War I and World War II

The devastating consequences of crop diseases were keenly felt by Germany during World War I, when large stores of potatoes were destroyed by potato blight (*Phytophthora infestans*), the same disease that accelerated the famines in Ireland during the mid-1800s. Some have even suggested that this potato famine contributed to Germany's capitulation and the end of the war. Also during World War I, Germany was probably the first to employ infectious agents (such as glanders, or *Burkholderia mallei*) against the Allies' horses and mules. These were small-scale sabotage operations, and it is unclear what the ultimate result was of these efforts.

Research programs among the Allies to defend against—as well as to offensively employ—crop and animal diseases began in earnest during World War II. In 1938, the British scientist J. B. S. Haldane proposed the notion that both Germany and England could be vulnerable to an attack on their respective agricultural industries by the highly destructive Colorado potato beetle. In 1939, French veterinary and BW experts even proposed dropping potato beetles on Germany's crops. None of these plans, as far as it is known, were ever carried out. In the early 1940s, the potential BW threat to Allied agricultural targets, as well as possible weaknesses in Axis food supplies, led to further research into a number of pathogens that could cause disease in crops and domesticated animals. Beginning with a recommendation by U.S. governmental experts in March 1942, a number of plant and animal pathogens were considered as possible biological weapons for use by the United States (see table A-9).

Anti-Livestock Agents (World War II)

Throughout the war years, animal diseases were very much a security concern for the Allies, as well as being potential weapons to be used against the Axis powers. During World War II, as far as U.S. intelligence was concerned, rinderpest (cattle plague) was one of the most threatening of the animal pathogens, because it was largely unknown in the Western Hemisphere at the time. Falling into the same group of viruses (morbillivirus) as human measles and distemper virus in dogs, rinderpest only infects animals (primarily cattle). The virus can be transmitted via contact with infected material, especially animal urine, as well as by airborne droplets. Rinderpest is so deadly and spreads so fast that—as in the case of FMD—the usual method of control is simply to destroy infected animals. In a joint American and Canadian project conducted at Grosse Ile on the St. Lawrence River, studies were led into developing large amounts of rinderpest vaccine against a possible BW attack by Germany against Allied agriculture. Allied military scientists also studied the foot-and-mouth virus during World War II.

Table A-9: World War II BW Research in Anti-Crop and Anti-Animal Pathogens (United States and Canada)

Project	*Code*	*Location*
Anti-crop agent		
Blight of potatoes	LO	Main Agricultural Experiment Station, Orono, Maine
Rice diseases	IR, E	Texas Sub-Station No. 4, Beaumont, Texas
Southern blight	C	Bureau of Plant Industry, Beltsville, Maryland
Anti-animal agents		
Fowl plague	OE	Harvard University
Foot-and-mouth disease	OO	Joint War Research Service–USDA Committee
Rinderpest	GIR-1	War Disease Control Station, Quebec, Canada

The most concerted Allied military program to attack Germany's agriculture, however, was dubbed Operation Vegetarian, in which Great Britain undertook to kill Germany's supply of domestic livestock. In 1943, an English soap factory molded some 5 million cakes impregnated with a slurry of anthrax (*Bacillus anthracis*) spores, which were designed to attract grazing cattle, horses, and sheep. Upon consumption, the anthrax bacteria would then cause a gastrointestinal form of the disease. (Although the primary goal was to destroy an important food source, this project also had the potential to cause human anthrax cases as well, via secondary infection.) The original plans required at least 1,250 planes to fly across Germany, each aircraft dropping about 10 boxes of the anthrax cakes per sortie. Ultimately, however, the plan to attack Germany's livestock with anthrax-laden cakes never materialized, and 30 years later, the last of the remaining cakes were destroyed.

Anti-Crop Agents

In 1943, Dr. E. C. Tullis at the Beaumont, Texas, facility noted that Japanese rice varieties grown in Arkansas were often subject to a fungal disease called rice blast (also known as rotten neck or Pyricularia blight), caused by *Pyricularia oryzae.* This fungal organism—along with another, brown spot of rice caused by *Helminthosporium oryzae* (*Cochliobolus miyabeanus,* code letter E), was researched for its possible use on Japanese rice fields. Rice blast is a severe threat to rice crops, and an outbreak of it was partly responsible for the 1942–1943 Bengal famine that led to the deaths of more than 2 million people. Its fungal spores are now found in the Western Hemisphere as well as Africa and Asia. During World War II, the United States investigated this disease as a potential weapon (code IR), but found that the conidia spores—the means by which the fungal agent reproduces and spreads from plant to plant—did not survive well in warm weather conditions. It was therefore not viewed as having much potential. By end of World War II, such research with fungal agents was largely inconclusive. The development of effective growth regulators for herbicidal applications—primarily the chemical herbicide 2,4-D—replaced schemes that would have used biological agents to destroy crops during the war. (Another mitigating factor against targeting rice crops was concern about the imminent military occupation of Japan and about the future source of food for the Japanese population.)

The Allies also observed at this time that Germany was economically dependent on potatoes. The United States conducted research into Southern blight (*Sclerotium rolfsii,* code C), a fungus that appeared to have potential as a BW weapon. By war's end, however, it was found to have little efficacy against resistant Japanese crops and was not pursued any further. Another fungus (*Phytophthora infestans*), the cause of potato blight that had destroyed Irish and German potato crops throughout the prior century, was known to be a potentially powerful BW agent. But this fungus was difficult to store, and a method of devising its large-scale production remained elusive. One method of delivery devised for potato blight involved the use of navy beans and specially made pellets. Again, these means of warfare were never used.

Cold War Activity

During the first half of the Cold War (1950–1969), work continued with anticrop agents in the U.S. offensive biological weapons program. Having revived earlier work with agents such as *Sclerotium rolfsii* (the cause of Southern blight or Sclerotium rot), the U.S. military later stockpiled some 30 tons of *Puccina graminis tritici* fungal spores (black stem rust). At that time, the United States considered the Chinese rice plantations and the extensive wheat fields in the Soviet Union (Ukraine) as potential targets. Early prototypes of delivery systems used feathers that were to be dropped in 500-pound propaganda leaflet bombs. These were judged by American bioweaponeers to "carry a sufficient number of spores to initiate a cereal rust epidemic" (Rogers, Whitby, and Dando, pp. 73–74). The former Soviet Union also led a significant research and development program into agricultural BW agents, many of these being similar to those studied in the West. The full extent, however, of Soviet and Russian work in offensive agricultural BW is still unknown. All U.S. work regarding the use of BW agents against crops and animals was halted in 1969 with President Richard Nixon's announcement forbidding further offensive biological weapons research.

Charges against the United States of using agricultural warfare continued throughout the Cold War, however. These included allegations by Fidel Castro's government in Cuba that the United States was deliberately disseminating an aggressive, fruit-burrowing insect (*Thrips palmi*) against Cuba's citrus crops. East Germany often accused the West of using Colorado potato beetles (the so-called *Ami-Kafer*) against Soviet bloc countries. Even in the late 1990s, the Russian BW expert General Valentin Yevstigneyev suggested that the United States was responsible for past beetle infestations in the former Soviet Union. These and similar charges were never substantiated.

During the 1980s, the Iraqi bioweapons program also conducted investigations into the use of anti-crop agents, including *Tilletia* fungus. Recognized as a serious disease in wheat since the 1700s (then described by the English agronomist Jethro Tull), *Tilletia* grows in the kernel of grains and develops into a "dirty" black center that completely devours the food portion of the plant. This wheat cover smut, or bunt of wheat, continues to devastate field grains throughout the world. In their work with fungi, Iraqi BW scientists tested wheat cover smut (*Tilletia* spp.) fungal spores in field trials, in combination with aflatoxin derived from *Aspergillus flavus.* During their experiments, Iraqi BW scientists used fine-powdered silica as a carrier for dry dissemination of a mixture of aflatoxin and wheat smut fungi. This could have served as a means to attack the food supply of Iraq's neighbor Iran, or perhaps Iraq's Kurdish populations to the north. It is noteworthy that Iraqi scientists used silica to distribute the agent in fine particulates, an indicator of a rather sophisticated BW program. In other areas, Iraq apparently worked with camel pox, a close relative to human smallpox (*Variola major*). The ultimate goals of this research are unclear. It is possible that Iraqi BW scientists were looking to employ antianimal attacks against an erstwhile enemy (e.g., Iran), or perhaps were looking for a surrogate for smallpox to use against human targets.

Although vaccines are available for a number of animal diseases, such as FMD, rinderpest, and *peste des petits ruminants* (e.g., "goat plague"), for various reasons these are not normally used in the developed world for prophylactic purposes, due to unit costs of the vaccine and the demands of regulated livestock markets. Furthermore, as with human viral diseases, effective chemotherapeutic treatments are lacking. Viruses also happen to be the cause of the most worrying of animal diseases—FMD, Newcastle, highly pathogenic avian influenza, etc. As a consequence, the primary defenses against agroterrorism are early detection of disease outbreaks, the separation of diseased animals (usually by culling) from healthy ones, and vaccinating a ring around the affected populations to stop the outbreak. In the United States, the primary defense against exotic and otherwise devastating diseases in plants and animals is the U.S. Department of Agriculture's (USDA) Animal and Plant Health Inspection Service (APHIS). The research and development of diagnostic, surveillance, and detection techniques are conducted at the Foreign Animal Disease Diagnostic Laboratory at Plum Island Animal Disease Center in New York. To develop an advanced warning capability, the USDA also has established its own intelligence units to analyze and predict future animal disease outbreaks.

AL-QAEDA

Al-Qaeda (Arabic for *base* or *foundation*) is the Islamic terrorist organization responsible for the September 11, 2001, attacks on the United States. The history of al-Qaeda is closely tied to the life of its leader, Osama bin Laden, and is mostly shaped by his experiences as part of the Arab *mujahideen* (holy warriors) in Afghanistan in the 1980s and his role as a Saudi political dissident.

In the early 1980s, the Saudi government supported the *mujahideen* resistance against the Soviet Union's invasion of Afghanistan, recruiting and sending Arab men from Saudi Arabia and other countries to fight in the name of Islam. At that time, bin Laden, with the help of the Saudi government, established the Islamic Salvation Foundation with the same purpose. After the withdrawal of the Soviet Union from Afghanistan—which was seen by the *mujahideen* as a victory for Islam produced by their efforts—many of these volunteer soldiers returned to their native Saudi Arabia, only to be disaffected and alienated from a government that they felt no longer appreciated them or upheld the values of Islam. Sharing this sentiment, bin Laden became a key player in the founding of a dissident organization known as the Advice and Reform Council.

Meanwhile, bin Laden was also active in south Asia. The World Muslim League and the Muslim Brotherhood organizations in Peshawar, Pakistan, led by Abdullah Azam, served as the center for the Arab *mujahideen* that remained in the vicinity. After Azam's assassination in 1989, bin Laden took over these organizations, forming them into al-Qaeda with the goal of developing a broad-based alliance among former Arab *mujahideen.*

Al-Qaeda's ideology is based on the Wahhabi branch of Sunni Islam, which demands the strict application of Islam to every aspect of political and social life. Additionally, al-Qaeda has elevated the concept of *jihad* (holy war) to a position of central importance in its interpretation of Islam. Al-Qaeda defines *jihad* as a duty for all Muslims to fight against *kafir* (infidels or unbelievers). For al-Qaeda, unbelievers include all non-Muslims, as well as those Muslims it believes do not adequately uphold the teachings of Islam. The Saudi royal family is among the Muslims targeted for destruction.

Al-Qaeda has four main grievances. First, it claims that the Saudi royal family is corrupt and does not uphold its professed Wahhabi beliefs. Second, it opposes Saudi cooperation with and reliance on the United States. Third, it sees the U.S. military presence in Saudi Arabia since the end of the first Gulf War as an "occupation" of Islamic holy sites. Fourth, it opposes U.S. support for Israel. Not only is al-Qaeda geographically disparate; it is also ideologically diffuse. In different geographical locations, certain issues are given emphasis by local cells. In all cases, however, local conflicts between cells are seen in the broader context of *jihad* against unbelievers.

This ideology of *jihad,* combined with al-Qaeda's grievances against what it saw as insufferable American cultural influences, led bin Laden to declare *jihad* against the United States in 1998, even though, as a secular leader, bin Laden lacked the religious authority to issue this type of edict. The original *fatwa* specifically mentions the United States, but also includes its allies: "The ruling to kill the Americans and their allies—civilians and military—is an individual duty for every Muslim who can do it in any country in which it is possible to do it, in order to liberate the al-Aqsa Mosque and the holy mosque from their grip, and in order for their armies to move out of all the lands of Islam, defeated and unable to threaten any Muslim. This is in accordance with the words of Almighty God, 'and fight the pagans all together as they fight you all together,' and 'fight them until there is no more tumult or oppression, and there prevail justice and faith in God'" (quoted in Poonawalla, 2003, online). Even before

Seventeen sailors on the U.S.S. Cole *died in an al-Qaeda–sponsored suicide attack on October 12, 2000. (Reuters/Corbis)*

declaring *jihad* against the West, however, al-Qaeda was on the path to war. Al-Qaeda is believed to have been responsible for attacks against Americans worldwide: eighteen U.S. soldiers killed in Mogadishu, Somalia, in 1993; five U.S. soldiers killed in a Riyadh, Saudi Arabia, bomb attack in 1995; and nineteen U.S. military personnel killed in Dhahran, Saudi Arabia (Khobar Towers), in 1996. Among the perpetrators of the Khobar Towers bombing was Ibrahim Salih Mohammed Al-Yacoub, who was indicted in Virginia. (Suggestions made in 2003 implied that Iran also may have played a role in the Khobar Towers bombing.) Al-Qaeda is also suspected of being involved in the 1992 bombings in Aden, Yemen; the 1993 World Trade Center bombing; a 1994 plot to assassinate President Bill Clinton; and a 1995 plan to blow up a dozen U.S. jetliners over the Atlantic Ocean. More recently, al-Qaeda has been charged with perpetrating the U.S. embassy bombings in Kenya and Tanzania in 1998, as well as the attack on the U.S.S. *Cole* in 2001.

Since its formation, al-Qaeda has attempted to acquire or develop weapons of mass destruction, including nuclear, chemical, biological, and radiological weapons. In November 2001, U.S. forces in Afghanistan discovered the blueprints for a crude nuclear bomb in a house in Kabul. It has been reported that al-Qaeda has tried on numerous occasions to obtain uranium or other radioactive materials. Reports by both U.S. and British intelligence sources indicate that al-Qaeda was successful on at least one occasion. Under interrogation, a senior al-Qaeda official, Abu Zubayda, indicated that al-Qaeda had in fact constructed a radiological "dirty" bomb. British intelligence sources have confirmed this information, adding that the crude device was constructed in an al-Qaeda laboratory in the town of Herat, Afghanistan.

Al-Qaeda has also made attempts to develop chemical and biological weapons. Bin Laden has expressed his desire for the group to develop a CBW capability. Files recovered from al-Qaeda computers and equipment found in al-Qaeda laboratories in Afghanistan support bin Laden's statements and indicate that the group at one time had the capability to produce limited quantities of some CBW agents. For example, one lab near Kandahar was equipped to produce anthrax. Finally, in August 2002, the

Cable News Network (CNN) broadcast al-Qaeda–produced videotapes that it had obtained in Afghanistan that showed dogs being killed by clouds of unknown toxic chemicals. These were probably trials or demonstrations of hydrogen cyanide gas.

AL SHIFA

On August 20, 1998, in response to the U.S. embassy bombings in Kenya and Tanzania two weeks prior, the United States struck the Al Shifa Pharmaceutical Factory in Khartoum, Sudan, with twelve cruise missiles, destroying the factory, killing one person, and injuring ten. Al Shifa was located in an industrial area northeast of Khartoum. It consisted of four buildings, one for administration and three production buildings. Construction of the factory, funded by Bashir Hassan Bashir and Salem Baboud, began in 1992 and was completed in 1996. In March 1998, Bashir and Baboud sold the plant to Salaheldin Idris, a Sudanese-born Saudi businessman.

Al Shifa was the largest of six pharmaceutical factories in Sudan, employing approximately 300 people and providing 50 to 60 percent of the country's pharmaceutical needs. The factory produced veterinary medicines, as well as medicines for the treatment of malaria, diabetes, hypertension, ulcers, rheumatism, gonorrhea, and tuberculosis.

Prior to 1998, the United States had neither officially nor publicly identified the Sudan as a chemical weapons proliferation state of concern. There had been previous accusations leveled by the West, including the U.S. government, of CW activity in Sudan dating as far back as 1989, however, although few of these charges had appeared credible. Beginning in 1997, Human Rights Watch and various Sudanese opposition groups began to claim that three facilities within Sudan were involved in CW activities: Kubar, Kafuri, and Shegarra. All three were located near Khartoum. Neither Human Rights Watch nor the Sudanese opposition groups mentioned Al Shifa.

After the 1998 bombings of U.S. embassies in Africa, U.S. intelligence linked Al Shifa to Osama bin Laden, his global terrorist network, and his attempts to acquire WMD (*see* Osama bin Laden and Al-Qaeda). The United States alleged that the factory was a closed facility, guarded by elements of the Sudanese military, and that it did not produce any commercial pharmaceutical products. The United States claimed to have evidence indicating that Iraq was involved in CW activities at Al Shifa and that its new owner, Salaheldin Idris, was connected through the Egyptian Islamic Jihad organization to bin Laden. Finally, the cornerstone of U.S. allegations of CW activities at Al Shifa was a soil sample purported to show high levels of a VX nerve agent precursor chemical (O-ethyl methylphosphonothioic acid, also known as EMPTA). U.S. officials claimed that EMPTA had no legitimate commercial use and was therefore an indicator of illicit CW activities at the Al Shifa facility (*see* EMPTA).

Within days following the U.S. strike on Al Shifa, U.S. allegations regarding the plant came under serious scrutiny. Since the incident, the United States has been accused of acting hastily based on limited intelligence and without the participation of the full U.S. intelligence community. After the incident, U.S. documents apparently unknown to those who decided to strike Al Shifa, as well as eyewitness accounts from the factory, indicated that the factory did indeed produce commercial pharmaceutical products. Eyewitness reports from the factory before the strike also indicated that it was not closed, nor was it guarded by the Sudanese military. Furthermore, independent, unclassified reports were inconclusive as to the relationship between the factory's owner, Salaheldin Idris, and either Osama bin Laden or the Sudanese government. Finally, after the strike, spokespersons for the Organization for the Prohibition of Chemical Weapons (OPCW) announced that EMPTA is considered a dual-use chemical, with applications in the production of fungicide, pesticide, and antimicrobial agents.

Although the presence of EMPTA in the aforementioned soil sample is persuasive, it is still unclear whether Al Shifa had been involved with the manufacture of VX agent, whether at the time of the strike or perhaps several months earlier (*see* V-Agents).

AMITON (VG)

Originally developed as a pesticide, amiton was among the first series of phosphonothiolate esters synthesized by Ranajit Ghosh, a chemist at British Imperial Chemical Industries, in the 1950s. Later, a commercial insecticide included amiton in an oxalate salt for civilian uses. Although not as toxic as other V-agent analogues, amiton (also known as Tetram; U.S. military code VG) had potential for use by the military as a nerve agent. A highly toxic organophosphate (OP), amiton has since been made obsolete due to safety concerns. Because of its highly toxic nature and its potential for use as a chemical warfare (CW) agent, it is listed as a Schedule 2 toxic compound in the Chemical Weapons Convention (CWC). The chemical structure of amiton is quite similar to that of VX nerve agent, the direct carbon-phosphorus bond being the significant chemical group separating VG from VX.

In mammals, the toxicity of amiton is significantly lower than that of VX. For example, tests on laboratory rats show the average lethal dose for oral administration of amiton to be 5 milligrams per kilogram of body weight. The lethal dose for VX, by comparison, is estimated at 12 micrograms for the same animal and route of exposure, or about 400 times more toxic than amiton. Still, amiton is relatively easy to manufacture, especially when compared to other nerve agents such as VX. Its chemical structure is also likely to provide a relative degree of persistency in terms of physical characteristics, and its moderate oil solubility makes VG capable of penetrating the skin. Therefore, considering its potency as a nerve poison, VG could be manufactured by state military programs trying to achieve a chemical weapons capability inexpensively, or perhaps by terrorist organizations looking for a simple method for producing a highly toxic OP compound.

AMMONIUM NITRATE FUEL OIL (ANFO)

Ammonium nitrate fuel oil (ANFO) is a low-velocity (meaning the speed of expansion following a blast is less than higher-yield explosives such as TNT), pushing-type secondary explosive (see definition below) used primarily to move earth and rock. Because the materials involved in its production are readily available, it is easy for individuals in the agricultural industry to produce large volumes of ANFO without attracting attention.

In the 1650s a chemist by the name of J. R. Glauber prepared what he called "*Nitrum Flammans,*" now known as ammonium nitrate. He did not recognize its utility as a component in explosives. In the early nineteenth century, researchers Grindel and Robin looked to develop black powder—the classic explosive of the time until smokeless powder was introduced—using ammonium nitrate instead of potassium nitrate. The results of this excursion are unclear. In the early years of mass production and use of ammonium nitrate, numerous and sometimes disastrous incidents including explosions occurred. Still, its utility as an explosive went largely unnoticed until the twentieth century.

Texas City Disaster: 1947

A French cargo vessel, the S.S. *Grandcamp,* docked at Texas City on 16 April 1947, was carrying a supply of ammonium nitrate fertilizer. (The shipment was destined for use as fertilizer as part of the Marshall Plan for the reconstruction of war-ravaged Europe). When a fire accidentally broke out on the ship, subsequent attempts to douse the flames resulted in pressurized steam, and put the ammonium nitrate cargo under pressure. Meanwhile, black smoke issued from a bright orange flame, and local inhabitants decided to go outside to witness the spectacle. Despite the fact that ammonium nitrate was known to be a potentially hazardous oxidizer—known to react explosively with a variety of fuels such as oil and kerosene—none seemed to be aware of the danger.

At 9:12 A.M., the ammonium nitrate on the boat detonated. Someone immediately speculated that "the Russians" had dropped an atomic bomb on the city of 18,000 people. The event registered as far away as Oklahoma City (480 miles) on a seismograph. Creating a two-thousand-foot mushroom cloud—and an explosion that could be heard for 150 miles—it probably could have been mistaken for a nuclear device. Secondary fires erupted at the Monsanto Chemical Plant, while additional conflagrations spread to nearby petroleum refineries. Another blast occurred early the next morning at about 1 A.M., when another vessel carrying ammonium nitrate, the *High Flyer,* erupted in even more spectacular fashion. This time nearby oil depots were set ablaze, along with warehouses and a grain elevator. In all, at least 581 people died, and over 3,500 were injured. Over 30 percent of the residential homes in Texas City, or about 500, were seriously damaged, and two thousand people were subsequently made homeless. This horrific incident showed the obvious dangers of handling ammonium nitrate, while also highlighting its potential utility as an explosive.

Ammonium nitrate fuel oil was developed in the 1950s as a low-cost earth-moving charge to replace dynamite. The primary problem encountered in using this explosive is water ingress: ammonium nitrate readily absorbs water, which decreases its sensitivity and slows its detonation. The introduction of fuel oil helps to dissipate this effect, and it promotes uniform caking of the material, leading to more efficient combustion.

Oklahoma City Bombing, 1995

The most horrific domestic use of ANFO as a weapon has been the bombing of the Murrah Federal Building in Oklahoma City in 1995. In seeking out an explosive for his purposes, Timothy McVeigh selected ANFO for several reasons. The primary components were easily acquired in bulk in the agricultural communities of the American Midwest without drawing any attention from law enforcement, and the materials for bomb construction were inexpensive. McVeigh created a very large device because he believed that, due to the lower yield of ANFO in relation to other high explosives, a large container would be needed to construct a very powerful weapon. McVeigh probably did not realize that the compressed air shock wave produced by slower-detonating materials (e.g., ANFO) is highly effective against rigid building components.

McVeigh rented a delivery truck, filled it with ANFO in 55-gallon drums, added booster charges, and parked it at the curb next to the Murrah Building. The tricky part of the operation involved setting all the detonators to go off simultaneously. Due to the comparatively low sensitivity of ANFO, a single detonation might have pushed most of the AFNO harmlessly away from the primary blast. Ultimately, McVeigh succeeded in creating a simultaneous detonation of the AFNO, which produced extensive damage to the Federal Building and hundreds of casualties. The federal courthouse across the street was severely damaged, and glass was broken in the windows of many downtown buildings. Injuries in other buildings from the shock wave and flying glass added to the numbers of victims.

The Murrah Building tragedy, coming just weeks after the Aum Shinrikyo attack on the Tokyo subway system, led the U.S. Congress to take action to help the nation's largest cities to prepare to respond to terrorist attacks. The Nunn-Lugar-Domenici amendment to the 1997 Department of Defense Appropriation Bill provided funding for the Department of Defense, Department of Health and Human Services, Department of Justice, Federal Emergency Management Agency, Environmental Protection Agency, and Department of Energy to join the nation's 122 largest cities in the Domestic Preparedness Program.

Technical Aspects

Ammonium nitrate fuel oil is a secondary explosive (the more powerful of the two types; see Explosives) and may require a booster to detonate it, depending on its water content. ANFO produces shock waves that cause indirect shattering or compression of its target (as compared to some other explosives, which work by direct shattering or "cutting" through the target material). Ammonium nitrate has 42 percent of the efficiency of TNT. Thus, it detonates at a velocity of only 8,900 feet per second as compared to TNT, which detonates at 22,600 feet per second. Given that the prime ingredient of ANFO is ammonium nitrate, most high-grade fertilizer is acceptable as a component. A minimum of 32 percent of the fertilizer, by weight, must be ammonium nitrate, and the material must be as dry as possible. The secondary ingredient, fuel oil, can be either diesel fuel oil or a 1 to 1 mixture of motor oil and gasoline. The less ammonium nitrate that is present in the fertilizer, the more fuel oil is needed to offset the moisture.

As mentioned previously, ANFO is used in industry as an earth- and rock-moving charge for mining and earthworks. In commercial use, ANFO is mixed at the site, and only as needed. The American military also uses ammonium nitrate for earthmoving and as a cratering charge to destroy buildings, fortifications, and bridge abutments. The military munition is a 40-pound device containing 30 pounds of ammonium nitrate and 10 pounds of TNT-based explosive as the booster.

The simplicity of ANFO and availability of materials have made it popular among various terrorist groups for decades. In Europe, ANFO explosives have been used so widely that government regulations require AN to be produced in prills too large to be able to be used in explosives. Vehicle-borne ANFO bombs became a standard item, particularly with the Provisional Irish Republican Army. Over time, these vehicle bombs grew in size to include trucks.

Ammonium nitrate is used every day by law-abiding individuals in their legal pursuits. Following the Oklahoma City bombing, increased law enforcement awareness and legislation has been pursued surrounding fertilizers with heavy ammonium nitrate concentrations. Due to the huge volume of this material used in agricultural and commercial operations, it is highly unlikely that complete control over its sale and movement will ever be established. Policing is left largely to the retail fertilizer industry, and that policing relies on making note of individuals seeking this material based on its composition and dryness, as well as keeping track of the location, volume, and method of payment for each purchase.

ANTHRAX

Anthrax is an acute infectious disease and one of the most feared BW agents, due, in part, to its high fatality rate. Anthrax is classified by the Centers for Disease Control (CDC) as a category A bioterror threat because it can be easily disseminated, it can result in high mortality rates, it has the potential for a major public health impact, it can cause public panic and social disruption, and it requires special action for public health preparedness. Although numerous other category A threats are deadly, anthrax in particular elicits a sense of fear since September 2001, when it was deliberately spread through the U.S. postal system. This attack caused twenty-two cases of infection and five deaths. This act of bioterrorism caused the first death from inhalatory anthrax since 1976.

Background

Anthrax was the first disease for which a microbial origin was definitively established (by Robert Koch in 1876). *Bacillus anthracis,* the causative agent of anthrax, is a disease of grazing mammals (sheep, cattle, etc.) that can be transmitted to humans (zoonose), although this is uncommon nowadays. This large, gram-positive (absorbs the color stain), nonmotile bacterium occurs in two distinct forms: the vegetative, rod-shaped form, which is the actively growing and replicating phase, and the spore form, which is the dormant, resistant phase. When conditions become unfavorable for this microbe's survival (e.g., lack of nutrients), it forms a rigid outer shell through a process called sporulation. These spores are oval, colorless, odorless, tasteless, microscopic, and hardy, capable of surviving in the soil for years.

An envelope tested positive for anthrax spores at the Daily Jang *newspaper offices in Pakistan (November 2, 2001). (Reuters/Corbis)*

Although humans are more resistant to anthrax than grazing mammals (such as sheep), *B. anthracis* can cause three distinct diseases in humans depending on the route of exposure. The first and deadliest form, inhalation anthrax, is contracted by inhaling the spores and is the only form that poses a serious BW threat. Inhalation anthrax is characterized by flulike symptoms including a sore throat, fever, muscle aches, and malaise. After this acute phase, there is sometimes a brief improvement, followed by respiratory failure and shock, with meningitis also frequently developing. Chest X-rays usually show a characteristic widening of the mediastinum—tissues surrounding the lymph in the chest—due to hemorrhaging of local lymph nodes. (For more information on how anthrax spores cause disease in the body, see Biological Warfare.) Case-fatality estimates are extremely high even with treatment, and close to 100 percent of those infected with inhalation anthrax will die without treatment. In 2001, five of eleven inhalatory anthrax cases ended in death. Improved treatment resulted in a fatality rate lower than previously estimated, however.

The second and most common form of anthrax, making up some 95 percent of all cases, is cutaneous anthrax. This type usually occurs after contact with infected animals or animal products and is usually related to occupational exposure (anthrax was once called wool sorter's disease). The bacterium gains entry through a break in the skin, and infection begins as a papule, progressing into an ulcer with a central black necrotic area. Other symptoms include fever, malaise, headache, and regional lymph node swelling. The term *anthrax* is derived from the Greek word for coal, *anthrakis,* because of the characteristic black skin lesions. Fatality of this type is less than 1 percent with treatment and between 5 and 20 percent without.

The third form, gastrointestinal anthrax, is rare (no confirmed cases in the United States), usually follows consumption of contaminated meat, and is characterized by severe gastrointestinal symptoms. The fatality rate is 25–60 percent even with treatment.

Symptoms can appear within 7 days of contact for all three disease types but can take up to 60 days to appear for inhalatory anthrax.

Diagnosis and Treatment

There is no rapid screening test for early inhalatory anthrax diagnosis, and because many illnesses begin with flulike symptoms, the disease is difficult to spot. Diagnosis is made by isolating and culturing *B. anthracis* from the blood, skin lesions, or respiratory secretions, measuring serum antianthrax antibodies, or DNA testing. Results are usually obtained within 24 hours.

Upon infection, *B. anthracis* multiply fast, rapidly producing toxins and spreading from the lungs into the bloodstream, resulting in death within days. Once flulike symptoms appear, the bacteria have already produced copious amounts of toxins, against which antibiotics are useless. Therefore, once a victim is symptomatic, anthrax has nearly always progressed too far for treatment. Anthrax is usually susceptible to the antibiotics amoxicillin or doxycycline, but in a BW attack, antibiotic resistance is possible due to the potential of genetic manipulation by the weapon designer; therefore, alternate antibiotics such as ciprofloxacin ("Cipro") may need to be used. Before the 2001 attacks, ciprofloxacin was considered the first line of defense for anthrax. To avoid individuals' developing resistance to ciprofloxacin, however, the CDC now recommends initially considering other antibiotics that are equally effective (in the absence of resistance), are less expensive, and have fewer side effects. Treatment is continued for 60 days due to the possibility of delayed spore germination.

History

In 1876, Robert Koch first described *B. anthracis* as the cause of anthrax, which helped lead to the first animal anthrax vaccine, developed by Louis Pasteur in 1881. Max Sterne developed an improved attenuated (mutated) live animal vaccine in the 1930s, which is still used today.

Human vaccines (live attenuated) were developed in the Soviet Union in 1940 and in the United States and Great Britain (bacteria-free filtrates from attenuated strains) in the 1950s. An improved version called Anthrax Vaccine Adsorbed (AVA) is produced by BioPort and was approved in 1970 by the U.S. Food and Drug Administration for those at risk. The government intends to make AVA more widely available once further requirements are met. The immunization involves six shots over a period of 18 months, with annual boosters.

During a quest for improved vaccines, the U.S. military researchers at Fort Detrick, Maryland, requested a strain of anthrax from the Department of Agriculture. They received a particularly virulent strain from Texas A&M University in 1981 (but mistakenly attributed it to the USDA laboratory in Ames, Iowa) and have since referred to that strain as the Ames strain. During the bioterrorist incidents in 2001, this strain was the same used in the anthrax letters mailed in the United States.

Anthrax has played a long and devastating role in human history. An epidemic in seventeenth-century Europe caused 60,000 deaths. Today, only approximately 2,000 human cases are reported worldwide annually; these are mostly the cutaneous type and occur mostly in developing countries (rarely do any cases occur in the United States). The largest international outbreak in modern times has been in Zimbabwe (1979–1980), with more than 10,000 people infected and over 180 deaths. Nearly all of these were of the cutaneous form of anthrax, although some cases of inhalational and gastrointestinal anthrax cannot be ruled out.

Before the advent of safer handling processes, vaccines, and improved veterinary management of domesticated animals, "wool sorter's disease" was a relatively common occupational hazard in wool-related textile mills, especially during the eighteenth-century Industrial Revolution. This deadly job-related illness was caused by inhaled anthrax spores liberated from newly spun wool, causing not only cutaneous but also the more deadly inhalational anthrax. This hazard became much less common in the twentieth century, however, and is nearly unheard of today. According to the Center for Nonproliferation Studies, between 1900 and 1978 only eighteen cases of inhalatory anthrax were reported in the United States. Two of those occurred among researchers working in a medical laboratory.

One landmark case occurred in 1957 in Manchester, New Hampshire, when nine workers at a goat hair processing plant became infected after handling a contaminated shipment of skins from Pakistan. Four of the five workers who contracted inhalation anthrax died. Interestingly, the individuals who died were not vaccinated against anthrax.

Although the numbers of actual cases were too small for a proper scientific conclusion, one of the lessons learned from this incident is that inoculating workers with anthrax vaccine probably protected them from the inhalational form of the disease.

Bioterrorism

Evidence suggests that during World War I, Germany used covert operations with anthrax-infected animal feed and livestock against the Allied forces and injected anthrax into American livestock. Japan also conducted BW research in occupied Manchuria, China from 1932 to 1945. Approximately 3,000 scientists worked to weaponize anthrax and other disease agents. The Japanese research program, designated Unit 731, tested anthrax bombs on humans. Anthrax-contaminated food was dropped on Chinese cities, and anthrax-filled chocolates were given to children in Nanking, China. By the end of World War II, the Japanese BW program had stockpiled nearly 900 pounds of anthrax, to be used in specially designed fragmentation bombs. After the war, Unit 731 leaders were granted immunity from war crimes prosecution in return for the disclosure of their research.

The United States and Great Britain weaponized anthrax during World War II as a potential retaliatory weapon against a German BW attack. In 1942, the United States formed the War Research Service. About 5,000 anthrax-filled bombs were produced at Camp Detrick, Maryland (now Fort Detrick). The British tested anthrax bombs on Gruinard Island off the northwest coast of Scotland (1942–1943). They also stockpiled anthrax-laced cattle cakes.

President Richard Nixon terminated the U.S. offensive BW program in 1969, and the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) was established to develop BW defenses. The United States, Soviet Union, Iraq, and many other countries later signed the 1972 Biological Weapons Convention (BWC).

Despite their treaty obligations, however, the Soviets maintained a huge BW program until at least 1992. They built a production facility for anthrax bombs at Stepnogorsk (located in Kazakhstan). On April 2, 1979, Military Compound 19 (the Microbiology and Virology Institute) in Sverdlovsk (now Yekaterinburg) accidentally released anthrax spores into the atmosphere, causing the largest inhalatory anthrax epidemic in this century. The official Soviet statistics reported years later that 96 people were infected, resulting in 64 deaths. Others have estimated that between 68 and 600 deaths were caused by this accidental release of anthrax. Soviet officials attributed the outbreak to contaminated meat, but in 1992, Russian President Boris Yeltsin acknowledged that military-related anthrax study was conducted at the research institute. In addition, Soviet BW testing was conducted on Vozrozhdeniye Island in the Aral Sea in the 1970s and 1980s.

In 1997, Russian scientists reported that they had created a genetically engineered vaccine-resistant strain that caused anthrax in laboratory animals, but have denied other researchers access to their discovery. The Pentagon announced plans to copy the Russian experiment to test the efficacy of the current U.S. vaccine. Currently, the United States and Russia are in discussions over how to obtain this strain for additional testing.

In 1985, Iraq began an offensive BW program and, after the Persian Gulf War, Iraq admitted to the UN Special Commission (UNSCOM) that it had amassed 6,000 liters of anthrax, deployed 5 Scud missiles and several 122-mm rockets filled with anthrax, and produced 50 bombs filled with anthrax spores. They also had spray tanks fitted to aircraft that could distribute biological agents over a specific target. These “death-drones” were targeted during Desert Fox, the joint U.S./U.K. air attack on Iraqi BW installations in December 1998.

Aum Shinrikyo, the doomsday cult behind the deadly sarin gas attack in Tokyo’s subway in 1995, tried twice to disperse aerosol anthrax from the roof of Aum Shinrikyo’s office building in Tokyo in 1993. The attacks failed, partly because they used the nontoxic vaccine strain (Sterne).

The threat from state-sponsored programs using anthrax as a biological weapon is difficult to assess, as many countries are capable of producing and delivering this weapon. But, as the case below demonstrates, even smaller groups or individuals are capable of causing great harm and anxiety using anthrax as a weapon of terror.

The 2001 U.S. Anthrax Attack

Shortly after the terrorist attacks on the World Trade Center and Pentagon on September 11, 2001, four anthrax-laced letters were mailed from Trenton, New Jersey, to the *New York Post,* the NBC Television studios in New York, and Senators Tom Daschle and Patrick Leahy. A fifth letter (sent to American Media, Inc.) was apparently discarded after being opened. An estimated total of 10 grams of spores were contained in the letters, leading to 22 anthrax cases in 4 states (New York, New Jersey, Florida, and Connecticut) and the District of Columbia. The CDC confirmed that eleven victims were infected from inhalatory anthrax (five of these victims died), and eleven others suffered from cutaneous anthrax.

Genetic analyses of the anthrax in the letters matched perfectly with Fort Detrick's 1980 Ames strain. Therefore, the source of anthrax was probably the U.S. biological warfare program, which had officially destroyed its stores of weaponized anthrax in 1969. Given the origin of the anthrax and the warnings contained in the letters ("We have this anthrax. You die now. Are you afraid?"), the perpetrator's motive was probably not to kill large numbers of people but to raise public fear. Although the death toll was relatively low, the strikes crippled business, government, and postal services and strained the public health system.

Table A-10: Chronology of Events in 2001 U.S. Anthrax Attacks

9/18, Trenton, NJ	Anthrax letters mailed to NBC, *NY Post*, and probably to the *National Enquirer* (AMI).
9/19–25, NYC	NBC received and opened anthrax letter; not recognized as dangerous and not reported by media.
9/22, NYC	First suspected case of cutaneous anthrax, 30-year-old woman, *NY Post* employee.
10/5, Boca Raton, FL	First death from inhalatory anthrax (Stevens, 63, photo editor, American Media, Inc. [AMI]).
10/8, Boca Raton, FL	Second AMI person sick (Blanco, 73, mailroom worker); inhalatory anthrax later confirmed; FBI takes over investigation.
10/9, Trenton, NJ	Anthrax letters mailed to Daschle and Leahy.
10/10, Boca Raton, FL	Third AMI worker (mailroom worker) tests positive for anthrax. Anthrax strain appears to be Ames.
10/12, NYC	Cutaneous anthrax case reported at NBC (Tom Brokaw's assistant).
10/13, NYC	NBC anthrax letter first reported.
10/13, Boca Raton, FL	At least 6 workers at AMI have tested positive for anthrax.
10/5, Washington, DC	Daschle's office opens anthrax letter.
10/16, Trenton, NJ	Two postal workers report symptoms; by 10/20 are diagnosed with inhalatory anthrax.
10/19, NYC	Anthrax letter found unopened in mailroom.
10/20	First mention that source is probably domestic.
10/21, Washington, DC	Several DC postal workers may have anthrax. Second anthrax death (Morris, 55, postal worker).
10/22, Washington, DC	Third anthrax death (Curseen, 47, postal worker).
10/31, NYC	Fourth death (Nguyen, 61, hospital worker). Presumed cross-contamination of mail.
11/6, CT	Fifth anthrax death (Lundgren, 94). Presumed cross-contamination of mail.

Technical Aspects

To reach the lower lung and be most effective, anthrax spores need to be delivered in particles 1–10 microns (µm). Particles of much larger size are more apt to stick in upper airways and the throat, where a higher dose is required to cause infection. As the spores measure approximately 1 um, a powder of individual spores is best, but natural surface charges cause spores to clump and to stick to surfaces, making aerosolization difficult.

Anthrax "weaponization" is the purification, separation, and concentration of spores into fine particles capable of aerosolization (i.e., having a neutralized surface charge), with a very narrow size range (1.5–3 microns in diameter) and an extraordinary concentration (one trillion spores per gram) and purity. The anthrax spores contained in the 2001 senators' letters were uniformly tiny and had no surface charge, and were therefore weaponized.

Inhalatory anthrax is the most likely form of disease to follow a BW attack and will likely involve the aerosolized delivery of spores. An aerosol spray of spores would leave little to no indication of dispersal until a resulting, sudden outbreak of inhalatory anthrax occurred. It has been estimated that a release of 100 kilograms of spores upwind of Washington, D.C., would result in up to 3 million deaths (WHO Expert Committee, 1970).

Current anthrax defensive research involves improving rapid diagnostic methods and prophylactic and advanced therapeutic regimens. Some new treatment methods might include specially prepared antibodies, and substances designed to block the anthrax toxin at the cellular level.

ARALSK SMALLPOX OUTBREAK

Although smallpox has been eradicated for more than 25 years and was nearing extinction as a disease in many parts of the world, an outbreak of smallpox occurred in 1971 in Aralsk, Kazahkstan (at the time still part of the Soviet Union). Alan P. Zelicoff, M.D., a researcher at the U.S. Department of Energy's Sandia National Laboratories, has reported (2002, Tucker and Zilinskas) that the origin of the smallpox outbreak in Aralsk was most likely the result of Soviet biological weapons testing of *Variola major* virus, the causative agent of smallpox. Other experts are more reserved, and some wholeheartedly disagree with Zelicoff. In the event the fact that there was a smallpox outbreak at Aralsk or that the Soviet Union had weaponized the smallpox virus was unknown until the 1990s.

From about 1936 to 1992, Vozrozhdeniye (Renaissance) Island, located between Kazakhstan and Uzbekistan, was the site of open-air field testing of BW agents developed by the Soviet military. At various times, Soviet military scientists tested the BW agents *Francisella tularensis* (tularemia), *Yersinia pestis* (bubonic plague), *Bacillus anthracis,* and smallpox virus (*Variola major*) at the Vozrozhdeniye Island facility. Vozrozhdeniye Island lies on the Aral Sea, as does the city of Aralsk, then a city with a population of about 50,000. In fall 1971, an outbreak of smallpox infected ten people, three of whom died. Officially, the Soviet Union had eradicated smallpox as a disease on its extended territory by 1940. (Cases of smallpox had been reported by the Soviet Union in 1961, but apparently these infections were brought into the country by travelers.)

In 1952, concerned that the United States could use offensive BW against the Soviet Union, the Soviet military restarted a field testing program for biological weapons at Vozrozhdeniye Island. Two years later, the Soviet military established a center for smallpox research at Zagorsk (now Sergiyev Posad). At first, the mission of the Scientific Research Institute of Medicine (now called the Virology Center of the Scientific Research Institute of Microbiology) at Zagorsk was to develop smallpox vaccine, but by the 1960s, intense efforts to weaponize BW agents, including *Variola* virus, were underway.

On about July 15, 1971, a Soviet research boat began an extended voyage in and around the Aral Sea, starting from Aralsk. It made about twenty-five stops at various research stations before returning home. On board were a number of scientific researchers and staff, including an expert on fisheries (ichthyologist). The job of this individual, who would turn out to be smallpox patient number 1, was to cast nets and collect fish and plant specimens. Because her duties required her to be outside on the boat, it is possible that she was more vulnerable to exposure to smallpox from Soviet open-air testing. On August 6, the researcher developed symptoms that would later be diagnosed as smallpox, but only after she had infected nine more people.

If indeed the researcher had acquired her infection as a result of open-air testing of *Variola major* virus, it was mostly a function of Soviet military secrecy that prevented early diagnosis of smallpox among the victims of Aralsk. Because the Soviet Union had officially eradicated smallpox 30 years prior to the incident, attending physicians first ascribed the illness to various causes and did not initially consider smallpox as the source. Eventually, three of the ten people who became ill with smallpox died. The three who died had not been vaccinated against the disease and developed the most serious form of hemorrhagic smallpox. Thirty years later, during an interview with the Russian press in November 2001, Dr. Pyotr Burgasov, former chief hygiene medical officer for the Soviet Union, said that a female researcher on a research boat that had neared Vozrozhdeniye Island had been infected with smallpox and had subsequently spread the disease to others in Aralsk. Dr. Burgasov claimed that the outbreak was caused by the open-air test release of about 400 grams of smallpox virus. Because Dr. Burgasov had previously been known to deny the existence of a Soviet BW program (particularly concerning the Sverdlovsk anthrax outbreak in 1979), his anecdote is especially important to support the theory that the smallpox outbreak in 1971 indeed was caused by Soviet BW testing at Vozrozhdeniye Island.

Although the exact cause of the Aralsk smallpox outbreak has not been officially determined by any government—including that of Russia—the preponderance of evidence leads to the conclusion that an accidental exposure from open air testing on Vozrozhdeniye Island was the source of the infection.

ARBUSOV REACTION

Two giants in the development of organophosphorus chemistry—Carl Arnold August Michaelis (d. 1916) and Aleksandr Ermingeldovich Arbuzov (d. 1968)—are often cited in the scientific literature as having described a chemical reaction that is typical in nerve agent synthesis. Both Michaelis and Arbuzov conducted groundbreaking research in the synthesis and description of countless phosphorus-containing substances. The German chemist Michaelis was in many ways the founder of this particular subset of chemistry, and Arbuzov (as well as his son and daughter) continued this work. Today, there still stands the A. E. Arbuzov Institute of Organic and Physical Chemistry of the Kazan Scientific Centre of the Russian Academy of Sciences (Volga region).

The Arbuzov (or Michaelis-Arbuzov) reaction occurs when a carbon atom or chain (alkylation) is combined to a trivalent phosphoric ester, that is, an acidic phosphate surrounded by three alcohol groups. The carbon-phosphorus bond—a key feature of the more toxic nerve agents (e.g., Sarin, VX, etc.)—can then be produced by an alkyl halide (a carbon group with a halogen), such as methyl iodide. According to Japanese sources, the terrorist cult Aum Shinrikyo used an analogous route of synthesis when producing sarin nerve agent. Aum operatives disseminated sarin on at least three occasions, resulting in the deaths of seven people in 1994 (Matsumoto City), and in twelve deaths and more than 1,000 people being injured during an attack on the Tokyo subway in 1995.

Curiously, neither Michaelis nor Arbuzov themselves produced organophosphate esters that were exceptionally toxic to mammals—or if they did so, these went unreported. This would have to wait for German chemists who synthesized tabun (quite by accident) and other nerve agents in the late 1930s.

ARSENICALS

Arsenic (As) has long been recognized for its highly toxic properties, as a pure metal or, more often, in its oxide form. Chemical experts in the Chinese People's Liberation Army (PLA) have written: "In the year 1000 (A.D.), there was one named Tangfu, who made poison fire grenades and gave them to the Chao court of the Song dynasty. The poisonous smoke ball, containing arsenic oxide (As_2O_3) and a type of poison derived from crotonaldehyde, looked a bit like a precursor to a chemical gas grenade. After lighting its fuse, this weapon would belch out smoke poisoning the enemy, and thus weakening their ability to fight" (Cheng and Shi, p. 7).

Metallic arsenic (and its use as a poison) has been responsible not only for countless murders, but it was also responsible for a horrific environmental catastrophe in Bangladesh. By the late twentieth century, some 70 million people in Bangladesh were at risk from arsenic poisoning from contaminated groundwater.

In CW, numerous toxic compounds containing arsenic, roughly categorized as arsenicals, were developed during World War I. Arsenicals first appeared in the form of substances that are immediately irritating to the eyes, nose and throat—such as diphenylcyanoarsine—but blister-causing types of agent (vesicant) also formed a significant part of the chemical weapons used during the war. (Lewisite, arguably the most important arsenical agent, was not used in World War I because it was invented too late for use on the battlefield.) The Japanese military made use of arsenicals, especially diphenylcyanoarsine, against Chinese troops on the mainland and Taiwan in the 1930s. Japanese forces also may have used lewisite (or a close analogue) during World War II, but only against Chinese forces. Other references have suggested that lewisite has never been used in appreciable amounts in warfare. By the end of World War II, both the United States and Germany had stockpiled large quantities of lewisite for chemical munitions, but those were later supplanted by more effective CW agents such as the highly toxic organophosphates (i.e., nerve agents).

It is difficult to conceive of most arsenicals in the same vein as weapons of mass destruction (WMD). Highly toxic lewisite is certainly a well-known CW agent, but other arsenic-based organic compounds are better described as irritating or riot control agents (RCAs, or tear gas). Also referred to as a vomiting agent, diphenylaminochlorarsine (DM) was independently invented by the German chemist Heinrich Wieland in 1915 and the American chemist Major Roger Adams in 1918. This RCA is often referred to as adamsite. It is not likely to be considered a CW agent with enough toxicity to warrant being used as a WMD. Even so, this and other arsenicals are extremely toxic, much more so than compounds such as CS tear gas (*see* adamsite).

One of the first arsenic-based chemicals used as a means of warfare was arsine gas (AsH_3). Despite its high toxicity, early efforts in weaponizing arsine were frustrated by its flammability. (Attempts during World War I to use hydrogen cyanide [HCN] failed for the same reason.) Chemical weapons designers in World War I then looked to organic compounds containing arsenic, such as ethyldichlorarsine, the effects of which had been well described as early as 1880. As LaCoste wrote, "[Ethyl dichlorarsine] has a very powerful irritant action on the mucous membranes of the eyes and nose, causes painful blistering of the skin, and is very dangerous for those working with it, since its vapor causes respiratory [distress], faintness, and long lasting paralysis and [numbness] of the extremities" (Vedder, 1925, p. 173). Drawing upon this knowledge, German chemical weapons scientists first used an arsenical in an artillery munition called Blue Cross, which contained mostly diphenylchlorarsine and diphenylcyanoarsine.

There were specific, tactical reasons for choosing arsenical compounds for battlefield use. By 1917, most belligerents were well prepared against inhalation threats on the battlefield. Since the introduction of gas warfare in 1915, the use of improved protective masks had reduced casualties produced by chlorine, phosgene, and other agents. Military chemists had not been able to devise substances that could break through gas masks, directly attack the skin, or both. The use of arsenicals such as diphenylchlorarsine ("Clark I") and diphenylcyanoarsine ("Clark II") was intended to render gas masks ineffective by delivering these agents in a fine aerosol, producing very small particles that would penetrate the filters used in protective masks at the time. (In fact, the term *aerosol* has its origins in research in the early twentieth century regarding the behavior of irritating arsenical smokes. See also Aerosol.) Because of their extreme irritation of the nose and throat, these CW agents earned the appellation of sternutators or sneeze producers. Their use was intended to force removal of the mask, making the enemy vulnerable to further assault with other toxic agents.

In September 1917, Germany launched the first significant barrage against Russian troops using diphenylchlorarsine at Uexhuell near the Dvina River. In July 1918, German military headquarters reported the following about Blue Cross shells: "In sufficient concentrations it penetrates the French mask effectively and the English mask to a lesser degree, in which case it forces the enemy to tear off their masks. For this reason a mixture of blue and green cross [that is, pulmonary irritants such as phosgene] is recommended" (Vedder, p. 174).

The German development of diphenylcyanoarsine was even more effective than its predecessor, diphenylchlorarsine. Augustin Prentiss, a World War I contemporary and expert on chemical weapons, commented on this CW agent: "In diphenylcyanoarsine, we have the extreme limit of effectiveness in low concentrations of all chemical agents used in the war. Thus, a concentration of 0.00025 mg. per liter is intolerable if inhaled for 1 minute. As a man at rest normally inhales 8 liters of air per minute, he would absorb only 0.0002 mg of the substance in that time. This is, however, sufficient to incapacitate him for an hour. For an average man, weighing 154 lbs (70,000,000 mg), this means that diphenylcyanoarsine is effective in the ration of 1:35,000,000 of body weight, which makes it the strongest of all the known irritants" (Prentiss, p. 211).

It proved difficult, however, to deliver these Blue Cross agents in particles small enough to achieve the desired effect of being a reliable mask breaker. Among the American Expeditionary Forces that had by this time entered the fray, statistics compiled found that only 577 casualties and 3 deaths were caused by these respiratory-irritant chemicals. Other statistics from casualty reports of the war support the conclusion that Blue Cross agents were not very successful.

By September 1918, Germany also had introduced phenyldichlorarsine, ethyldichlorarsine, and ethydibromarsine as toxic lung agents. In addition to its highly irritating effects, ethyldichlorarsine was recognized for its toxicological properties as a vesicant or blister agent.

The Arsenical Vesicants

The blistering effects of some compounds, including the arsenical ethyldichlorarsine, were utilized to some degree in World War I. By 1918, however, sulfur mustard became the dominant blister agent on the battlefield and the cause of most chemical casualties in the entire war. German military commanders saw a potential role for a CW agent that was fast-acting, more volatile, and would clear an area more quickly than mustard. Ethyldichlorarsine had such properties. In contrast, sulfur mustard caused injury only after considerable delay but was much more persistent, making it more suitable for defensive operations. Because Germany was planning a major offensive by spring 1918, ethyldichlorarsine was produced for the western front by March of that year. Referred to by the Germans as Dick and coded Yellow Cross I (differentiating it from Yellow Cross, which was sulfur mustard), its overall impact as a vesicant was largely overshadowed by its lung-irritating properties. It is not clear how many casualties were caused due to Yellow Cross I, including its less toxic relative, ethyldibromarsine.

Dr. W. Lee Lewis, an American chemist, invented chlorovinyldichloroarsine, which was subsequently named lewisite in his honor in 1917. It also was called the dew of death, given its possible use by dissemination from aircraft. Lewisite is a true vesicant as well as a highly irritating CW agent, and it may have been manufactured by Germany at the same time of Lewis's discovery. If Germany did manufacture lewisite in quantity, it is unknown why they did not use it. Full-scale manufacture of lewisite by the United States began at a facility in a Cleveland, Ohio, suburb in 1918. Before the Allies could employ lewisite in World War I, however, the armistice had brought an end to the conflict. Lewisite had already been shipped across the Atlantic, and due to its instability, it was dumped into the ocean for quick disposal.

Lewisite is absorbed through membranes of the skin, causing extreme irritation and blistering, as well as destruction of tissue in the upper respiratory tract. Lewisite has potent damaging effects on the eyes, and exposure without adequate decontamination may cause blindness. It is believed that the toxicological action of lewisite focuses upon inhibition of enzymes in the body.

Following World War I, military chemists compared the inhalation exposure toxicities of various arsenicals and blister agents (e.g., mustard), ranking them in order of most toxic to least toxic (figures are from Prentiss, 1937):

Table A-11: Toxicity of Arsenical Vesicants

Agent	
Lewisite	Most Toxic
Mustard	
Phenyldibromarsine	
Phenyldichlorarsine	
Ethyldichlorarsine	
Methyldichlorarsine	
Dibromethyl sulfide	Least Toxic

According to a Chinese text on chemical weaponry, which draws upon a reference by Franke (1967):

> Lewisite is a colorless, oily liquid that in its actual production takes on a brown color. Very low concentrations of Lewisite vapor produce an odor similar to geraniums. The volatility of lewisite is greater than that of mustard, easily forms high densities on the battlefield, and one does not need to add anti-freezing solvents to use lewisite during winter. Because of these properties, and the very close relationship between lewisite and mustard, they are often used in tandem. Lewisite hydrolyzes in water faster than mustard, but in this instance the degradation products are toxic. Additionally, lewisite in its liquid form penetrates the skin at a rate 3–4 times faster than mustard (Cheng and Shi, p. 17).

The mixing of lewisite with mustard was, in fact, a common practice in the Japanese military's use of vesicants, as well as in Soviet doctrine for chemical munitions. The need for this chemical cocktail was caused by the fact that sulfur mustard congeals at a relatively high temperature. Mixing mustard with solvents, including not only lewisite and other chlorinated hydrocarbons but also the nerve agent diisopropyl fluorophosphate (DFP), has been done to bring down the freezing point of mustard for use in winter.

In addition to the blistering and the irritant effect on skin, eyes, and the respiratory system, lewisite also serves as a systemic poison. Skin damage as a result of lewisite exposure, however, is expected to heal faster than that caused by mustard. Effects of lewisite on skin, including extreme pain and redness, occur within minutes of exposure, with blisters forming about 10–15 hours later. As in the case of mustard exposure, the first approach to treating victims of lewisite exposure is thorough decontamination. But there is also a chemical antidote using chelation therapy, that is, the use of chemicals to "grab" arsenic from solution. Because arsenic has affinity for certain chemical groups, especially sulfur, compounds such as dimercaprol, traditionally called British Anti-Lewisite (BAL), have been found effective in treating lewisite poisoning. Not enough data exist on human cases, however, to determine the extent of its efficacy. More recent improvements upon BAL include therapeutics that can be administered orally, namely the water-soluble dimercaptosuccinic acid (DMSA) and dimercapto–1-propanesulfonic acid (DMPS).

Although arsenic is poisonous, it has multiple uses in civilian applications. Due to its ubiquity, some arsenic compounds are controlled out of concern that they could be used to produce chemical weapons. For example, a common method of manufacturing lewisite is to start with arsenic trichloride ($AsCl_3$), a precursor that is restricted by the Chemical Weapons Convention (CWC). By the same token, existing stocks of lewisite that are slated for destruction may be recycled for peaceful uses. Because the former Soviet Union had a considerably large stockpile of lewisite-filled munitions (often mixed with sulfur mustard), chemical demilitarization efforts have focused upon extracting arsenic from lewisite stocks for recycling. Arsenic is used in a variety of industrial process, including gallium-arsenide semiconductor chips, although it is unclear whether such a venture is economically viable. Arsenic is still utilized in formulations for insecticides and in fungicidal treatments for lumber.

ATROPINE

The first line of defense against nerve agent poisoning is a drug called atropine. This compound has been used for centuries in various ways, one of these being to cause the dilation of the pupils in the eyes. At one time, it was very fashionable in Europe for women to have dilated pupils, and extracts from the belladonna plant were used for this purpose. (The same is done today for eye examinations; atropine is used to widen pupils to allow the practitioner to see better into the patient's retinal space.) This drug and others like it are still referred to as the belladonna group of compounds, from the Italian for *beautiful lady.* Atropine, a so-called alkaloid (nitrogen-carbon compounds that are noted for their pharmacological effects), is found in the deadly nightshade plant (*Atropa belladonna*) and in other related species of the genus *Solanaceae,* such as henbane. Related compounds that have similar effects include scopalomine. The latter drug has significant hallucinogenic properties and is the toxic principle in Jimson's weed (*Datura*). This family of compounds has been thoroughly investigated by chemical warfare programs in the United States, former Soviet Union, and Warsaw Pact nations (including East Germany). Some analogues were found to have potential value as incapacitating agents, such as BZ, the code name of one of these agents (3-quinuclindinyl benzilate).

The effects of the belladonna and *Datura* alkaloids on the human body have been known for centuries. Symptoms of atropine intoxication can be described in well-known similes: Blind as a bat (pupils become excessively dilated, blurring the vision); dry as a bone (atropine shuts down the sweat glands); red as a beet (atropine causes the skin to flush through dilation of the blood vessels); mad as a hatter (for its hallucinogenic and behavioral modification); and hot as a hare (lack of perspiration causes body temperature to rise). Although very small amounts of these drugs can cause physiological symptoms, humans can tolerate significant doses of atropine. One immediate danger from atropine intoxication is the propensity for hyperthermia.

Militaries and emergency responders can treat nerve agent casualties with atropine and oxime. (Reuters/Corbis)

Atropine is primarily known for its life-saving, diagnostic, and therapeutic uses in health care settings. There have, however, been instances when atropine has been utilized as a potential mass casualty weapon, including a plot to cause mass poisoning. In the late 1950s, a large number of saltshakers in a cafeteria that served employees of Radio Free Europe were adulterated with atropine, enough to have caused serious poisoning at least (although probably not death). The plot was foiled when a spy alerted the authorities about the poisoned salt, later assayed to find about 25 milligrams of atropine per shaker.

Relatively large doses (up to 1 gram) of atropine may be called for to treat cases of exposure to organophosphate insecticides, and there is a very different set of treatment protocols and treatment duration for these than for military nerve agents. Following exposure to a toxic organophosphate, administration of atropine counterbalances dangerously high levels of the neurotransmitter acetylcholine, a condition brought on by the effects of nerve agents (e.g., sarin). Nerve agents, having blocked or inhibited the function of acetylcholinesterase (AChE) enzyme that keeps the acetylcholine levels in balance, results in an increase in acetylcholine molecules. This chemical stimulates receptors in the nervous system, causing exhaustion in the breathing muscles, changes in heart rhythm, and secretions in the throat that can asphyxiate the victim. Atropine, on the other hand, is a so-called anticholinergic compound: it partially blocks receptors in the nervous system, protecting them from excessive levels of acetylcholine stimulation. Although atropine does little for involuntary twitching in skeletal muscles, it does help to dry up secretions and restore some normalcy to the rest of the nervous system.

Longer-term treatment of nerve agent poisoning may include administering chemical compounds called oximes. These help restore the normal activity of AChE by releasing the enzyme (via dephosphorylation, the breaking of the phosphate-enzyme bond) from the nerve agent's blockage. Oxime treatment in conjunction with atropine increases the chances of survival for victims exposed to nerve agents.

Atropine for treatment of nerve agents is fielded in the form of autoinjectors. These are spring-loaded syringes that deliver an intramuscular injection of 2 milligrams of atropine. A Chinese military textbook recommends the following doses for nerve agent exposure, which are typical of those found prescribed by various armed forces: "1–2 mg for light injuries, 3–5 mg for moderate, and 5–10 mg for serious exposures. If symptoms have not lessened in their severity after 10–30 minutes, one should consider increasing the above dosage. *Datura* and other Chinese medicinal herbs can also provide therapeutic benefit." (Cheng and Shi, p. 82).

The effects of atropine injected in humans at varying doses have been described in the existing literature. At 0.5 milligrams, there is dryness of the skin with a slowed heart rate. Between 1 and 2 milligrams, one sees dilation of pupils (madriasis) and faster heartbeats. Above 10 milligrams, there is delirium, apathy, and hallucinations, followed by unconsciousness. In the absence of nerve agent poisoning, the doses delivered in autoinjectors (2 milligrams) are tolerated quite well. In the false belief of a nerve agent attack during the Gulf War (1991), many Israeli citizens self-administered atropine in the midst of Iraqi Scud missile raids. No untoward effects were reported.

AUM SHINRIKYO

The Japanese apocalyptic group Aum Shinrikyo ("Supreme Truth") is generally credited with opening the Pandora's box of WMD terrorism with its sarin attack on the Tokyo subway system on March 20, 1995. Although this was not the first ever chemical or biological terrorism attack, it was of such a scale (5 trains on 3 separate lines attacked nearly simultaneously, resulting in 12 deaths and more than 1,000 people seriously injured) that it is generally regarded as the benchmark for the beginning of modern WMD terrorism. The subway attack was not the first Aum Shinrikyo chemical terror attack. It was preceded by attempts to develop and employ biological weapons. Thus, Aum Shinrikyo stands as a valuable case study regarding both the dangers of WMD terrorism and of the significant difficulties that even a well-financed group with internal technical expertise might encounter in employing WMD for mass casualty effects.

Aum Shinrikyo represented, at once, a "new religion," a political movement, and a fanatical apocalyptic cult willing to use mass casualty terrorism to accelerate and achieve what it saw as its preordained destiny. Aum Shinrikyo was founded by Shoko Asahara, based on the belief that Armageddon was inevitable and that only the devout believers in Aum Shinrikyo would survive the end of the world. As a religion, Aum Shinrikyo was successful in drawing recruits and donations. The group specifically targeted its recruitment at technical universities, and the group enjoyed a relatively well-educated and wealthy membership. At the same time that it was experiencing growth in membership and wealth, Aum Shinrikyo was singularly unsuccessful as a legitimate political movement, losing all of the Japanese elections in which it fielded candidates. The group was able to employ its wealth and some of its technically expert members, however, to support its WMD terrorism program. Even though Japanese authorities compiled a growing body of evidence on Aum Shinrikyo's terrorist objectives and chemical and biological programs preceding the Tokyo subway attacks, they hesitated to take action against the group because of provisions in Japanese law protecting religious freedom and practice. Aum Shinrikyo enjoyed the benefits as a self-described religious organization in furthering its political agenda through terrorism.

The inner cadre of Aum Shinrikyo's leadership was organized into a "shadow government," with a structure directly mirroring Japan's executive department and functions. Individual Aum Shinrikyo leaders were assigned positions in the shadow government to prepare them to assume the corresponding duties in the new order. Aum Shinrikyo blended a "new religion" veneer with a political core that was characteristic of traditional terrorism. Their preparedness to assume governmental functions complemented their absolute opposition to the existing government, inspiring preparation for violent action to accelerate or augment the coming apocalypse and to protect the group until that day arrived. Aum Shinrikyo developed hierarchical operational organs, a highly sophisticated infrastructure, and extensive support mechanisms. Using the broader religious periphery for first-level recruitment and basic funding, Aum Shinrikyo developed business enterprises and internally selected technical experts to support its action program. These included both conventional, chemical, and biological weapons labs derived from legitimate cover enterprises. The Aum Shinrikyo weapons program was ultimately as well financed and technically supported as many smaller programs of Japan's actual government. So, although Aum Shinrikyo was a broad-based and large, horizontal religious movement, it contained a vertically stratified and tightly disciplined action cadre at its political center.

The several violent actions carried out by the Aum Shinrikyo cadre looked much like traditional terrorism—the same individuals were involved in planning and executing the organization's terrorist acts, this group acted in close concert with an equally small and disciplined direct support cadre, and all were under the direct control of the central leadership of the group. The major difference between Aum Shinrikyo and traditional terrorists was that Aum Shinrikyo only used WMD in its attacks.

Aum Shinrikyo tried to develop and employ biological and chemical weapons as early as 1990. Testimony during the legal proceedings following the 1995 Tokyo subway attacks indicated that the targets of the mostly unsuccessful attempts included the general Japanese public, specific group rivals, disaffected cult members, investigative journalists, the Japanese legal system and government, members of the Japanese royal family, and United States military installations in Japan.

Aum Shinrikyo had extensive biological and chemical agent development programs, but their actual employment of WMD presents a very mixed story. As early as April 1990, the group attempted to employ botulinum toxin for mass casualty effects in Tokyo. The attack coincided with an island retreat by the Aum Shinrikyo leadership and membership, so that the group itself would not fall victim to the attack. The group attempted to disperse the toxin from truck-mounted dispensers: one outside the Diet (national parliament) building downtown, one outside the U.S. naval facilities in the southern port suburbs, and one at Narita International Airport. The attack failed when the dispenser sprayers may have killed the toxin in the dispersal process, or more probably the toxin was ineffective from the beginning. Aum Shinrikyo was forced to return to the drawing board.

The group again attempted to disperse botulinum toxin in June 1993, again from a truck-mounted spray dispenser. The target in this attack was the gathering of world dignitaries in conjunction with the wedding of Crown Prince Naruhito. This attack suffered the same fate as the 1990 botulinum attack: The dispersal system exceeded the environmental parameters and would likely have rendered the toxin ineffective.

Aum Shinrikyo then turned to anthrax as its agent of choice. Just weeks after the 1993 royal wedding attempt, the group dispensed anthrax from the roof of a cult-owned building in downtown Tokyo. Although a few people reported being affected by noxious fumes, this attack also failed to cause casualties. The anthrax strain Aum Shinrikyo used was an American animal vaccine strain, not a toxic strain.

Aum Shinrikyo's initial unsuccessful experiences with biological weapons caused the group to switch to chemical weapons. Beginning in 1993, reports suggested they had successfully experimented with sarin employed against sheep on a cult-owned ranch in Australia. (Later investigations, however, showed that tests on the sheep carcasses may have confused sarin with commercial pesticides used in "sheep dip.") Early in 1994, they chose the leader of a rival "new religion" and its associated political party as their victims, but the field application of their chemical weapon was unsuccessful when their effort to create a gaseous form of sarin resulted in the dispersal van catching fire. Aum Shinrikyo continued to rely on chemical attacks as their primary form of action, both to exploit their economic and technical capabilities in this arena and to further their end goal of creating broader effects to hasten the ultimate global conflict that would usher in their rise to power. Toward this end, Aum Shinrikyo was certainly willing to accept mass casualties; however, they continued to encounter problems with dispersal and application of WMD.

The group's second sarin attack, in June of 1994, also was not fully successful. It was intended to kill three judges who were presiding at a trial involving Aum Shinrikyo. The plan to gas the judges, their courthouse, and an adjacent police station was meant to be an attack on the justice system that was posing a threat to Aum Shinrikyo. Poor planning caused the attack team to arrive after the judges had left the courthouse, and the subsequent plan to attack their apartment complex failed when the gas dispersed too widely and the wind shifted, leading to only limited effects on the specific apartments of interest. The target judges fell ill, but they were not among the seven who were killed in the attack.

The March 1995 Tokyo subway attacks represented a direct application of terrorism for the dual purposes of producing mass casualties and intimidating the authorities for self-preservation. Japanese national police under the Ministry of Justice had finally amassed sufficient evidence to mount a raid on the Aum Shinrikyo compound and chemical weapons laboratory. The raid was set for March 22. Aum Shinrikyo first attempted to cause mass casualties at the Kasumigaseki subway station using botulinum toxin on March 15. Besides the disruptive effects of a mass casualty attack, Kasumigaseki station served as the Ministry of Justice headquarters, and the timing would have meant that many of the passengers on those trains should be Ministry of Justice employees. Aum Shinrikyo hoped to delay or divert the Justice raid on their own headquarters, which they had been tipped off was imminent. In this case, the group used dispensers hidden in briefcases, but the dispersal again failed.

Aum Shinrikyo then reverted to sarin, and they again attacked the subway system on March 20. This subway attack employed an unsophisticated dispersal method—plastic bags of liquid sarin punctured by the pointed ends of umbrellas. The operation involved rush-hour attacks on five separate subway trains in the Tokyo system, trains that were all due to arrive at Kasumigaseki station shortly before eight o'clock on a weekday morning. The earlier purpose and plan still applied: targeting Ministry of Justice employees, many of whom would be on those trains. Because of the primitive dispersal method, the five attacks resulted in many fewer casualties (12 killed, 1,000 injured) than might have been anticipated given the quantity of sarin involved, and the attack ultimately precipitated a much more complete investigation and prosecution of Aum Shinrikyo.

Finally, as the investigations and arrests following the March 1995 subway attacks began, Aum Shinrikyo returned to the Tokyo subway system one more time. On May 5, 1995, the group attempted to employ cyanide in Shinjuku station. In this case, the dispersal system involved sequential use of acid, then cyanide, but the device was discovered before it could do any harm.

Aum Shinrikyo had only limited success in fourteen separate biological and chemical attacks. The group employed or attempted to employ sarin and cyanide, as well as VX and phosgene gas. In terms of biological weapons, Aum Shinrikyo at various times was developing or seeking to develop anthrax, botulinum, Q-fever, and even Ebola for use as weapons. Aum Shinrikyo had up to twenty people dedicated to biological weapon production and testing. After the Tokyo subway attack, Japanese police found enough sarin precursors in the group's possession to produce tons of sarin nerve agent. At that time, work at Aum Shinrikyo labs also suggested that the group was continuing to develop or experiment with a variety of nerve agents—including VX, soman, and tabun—and other chemical weapons such as mustard and sodium cyanide. As many as eighty Aum Shinrikyo members worked on chemical weapons development.

Aum Shinrikyo also was involved with, and had specific interest in, both nuclear and conventional weapons. Nuclear weapons represented the ultimate apocalyptic tool to Aum Shinrikyo's leadership. The group widely sought nuclear weapons materials and expertise—from Australian uranium to Russian lasers (an experimental technology for producing fissile materials). They also showed interest in other "exotic" weapons that had relevance to Japan, including seismological weapons. They also procured and produced conventional weapons, notably the AK-74 rifle. The group's AK-74s were used for training and arming a small paramilitary cadre, and they served as a source of some revenue to Aum Shinrikyo. The variety of weapons and systems that Aum Shinrikyo procured, as well as insight into their future plans, was demonstrated by their efforts late in the group's action phase to employ a Russian military helicopter as well as some unmanned drone aircraft, all outfitted with aerial spray dispersal systems for chemical weapons.

Although the Aum Shinrikyo leadership, terrorist planning and operational cadre, and WMD technical development personnel were arrested, tried, and imprisoned after the Tokyo subway attacks, the group as a religious movement still exists in significant numbers, primarily in Japan and in Russia. Estimates from 1995 were that Aum Shinrikyo had more than 40,000 followers, with almost 30,000 of those in Russia, approximately 10,000 in Japan, and smaller numbers in other countries, primarily the United States and Germany. That same year, Aum Shinrikyo's financial assets were estimated at 1 billion dollars.

Aum Shinrikyo stands as the "poster child" for both the extreme threat of WMD terror and the difficulties faced by a nonstate actor in delivering on that threat. Aum Shinrikyo had several unique advantages that allowed it to advance its WMD terrorism program. It had a multilayered organization that allowed its religious component to serve as both cover and sponsor for its terrorism element. It had access to an array of resources—from millions of dollars in funding to member scientists to group-owned chemical companies for facilities and cover. And, significantly, the nature of its religious foundation—particularly as interpreted after the breakup of the Soviet Union and the concurrent display of United States conventional military power in the 1991 Gulf War led Aum Shinrikyo's leaders to conclude that a global apocalypse was not as imminent as they once thought—allowed the group to turn conventional wisdom that terrorists want many observers and few casualties on its head.

Even with all these advantages, however, Aum Shinrikyo's experience highlights several of the daunting obstacles that stand in the way of any group seeking to develop and employ WMD for the purposes of terrorism. First, although Aum Shinrikyo was able to procure dangerous chemical and biological agents, it was not able to gain access to some of the highly lethal biological strains that it sought. Safeguards on these strains do provide some significant protection against groups without state sponsorship attaining specific materials. Second, the dispersal problem for chemical and biological agents is very real, and even a well funded and technically gifted cadre within a terrorist group will face significant challenges in agent dissemination and utilization in the field. Third, the cold scientific rationality required to overcome these technical hurdles can be overshadowed by the emotional and ideological imperatives of terrorist leaders—the "action program" may not have the patience needed to allow the agent development side to complete its work. In the end, WMD terrorism remains a very real but difficult-to-deliver-on threat.

THE AUSTRALIA GROUP

The Australia Group is an informal network of thirty-three countries and the European Commission that aim to ensure that their exports do not contribute to the development of chemical or biological weapons. The Australia Group does this by licensing the export of certain chemicals, biological agents, and dual-use chemical and biological manufacturing equipment that can be used in CBW programs, based on common control lists.

History

In April 1984, a special investigation mission sent by the UN Secretary General to Iran found that chemical weapons (CW) had been used against Iran in the Iran-Iraq war, which was a clear and unequivocal violation of the 1925 Geneva Protocol. There was also evidence that Iraq had obtained materials for its CW program from the international chemical industry. In response to these findings, a number of countries placed licensing measures on the export of certain chemicals used in the manufacture of chemical weapons.

The countries concerned saw an urgent need to address the problem posed by the spread of CW and ensure that their industries were not, either deliberately or inadvertently, helping other countries to acquire and use such weapons in violation of international law and norms.

The measures originally imposed by these countries, however, were not uniform either in scope or application. It also became apparent that attempts were being made to use this lack of uniformity to circumvent these initial controls. This led Australia to propose, in April 1985, that representatives from the fifteen countries that had introduced licensing for exports should meet to examine ways to standardize the measures taken at the national level to prevent illicit trafficking in chemical weapons precursors.

The first meeting of what came to be known as the Australia Group (AG) took place in Brussels, Belgium, in June 1985. Participating countries agreed that there was benefit in continuing the process, and meetings of the group are now held in Paris on an annual basis. The emergence of increasing evidence of diversion of dual-use materials to biological weapons programs in the late 1980s led participants to take steps to address the increasing problem of the spread of BW.

Technical Details

AG participants have developed, through a consensus approach, common export control lists, which specify items that each AG participant undertakes to control through its respective national export licensing procedures.

Licensing procedures allow each participating country to consider whether a particular export could contribute to CBW and therefore breach the country's obligations under the Biological and Toxin Weapons Convention (BTWC) or the Chemical Weapons Convention (CWC). Every export license application is examined by the national authority on a case-by-case basis, with the decision about whether to supply the requested items resting solely with the country approached. An export request is denied only if there is particular concern about potential diversion for CBW purposes.

Australia Group participants have committed to consult each other before exporting items that another participant has previously denied because of proliferation concerns. This commitment to consult is referred to as a no-undercut policy, but it does not constitute a binding ban. Group participants also have implemented a catch-all provision, whereby a participant will not supply an item that is not on export control list when there is particular concern about potential diversion of the item for CBW purposes.

Group participants ensure that their countries' private sectors are informed of the dangers inherent in the uncontrolled export of dual-use chemicals and biological materials and equipment. Chemical and biotechnology companies, and traders conscious of their public image and corporate responsibilities, have welcomed the assurances provided by the controls implemented by Australia Group participants. The transparency generated by the Australia Group's activities increases confidence, creating an environment more conducive to the normal flow of commercial goods, equipment, and technology.

Current Status

Participating countries in the Australia Group are Argentina, Australia, Austria, Belgium, Bulgaria, Canada, Cyprus, Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Japan, Republic of Korea, Luxembourg, Netherlands, New Zealand, Norway, Poland, Portugal, Romania, Slovakia, Spain, Sweden, Switzerland, Turkey, United Kingdom, and United States. The European Commission is also a participant. Australia chairs the group and provides a secretariat within its Department of Foreign Affairs and Trade.

There are presently five common control lists covering fifty-four CW precursors: dual-use chemical manufacturing facilities and equipment and related technology; dual-use biological equipment; and biological agents, including plant pathogens, animal pathogens, and toxins.

The common control lists are reviewed and adjusted periodically to ensure their continued effectiveness. Australia Group members believe that export control measures should be effective in impeding the production of chemical and biological weapons, be practical and reasonably easy to implement, and not impede the normal trade of materials and equipment used for legitimate purposes.

All countries participating in the Australia Group are State Parties in good standing to both the CWC and BTWC. These countries consider the implementation of national licensing procedures based on the various AG lists as an essential means to ensure that they are fully implementing their nonproliferation obligations under Article I of the CWC and Article III of the BTWC. In applying export licensing procedures, group participants also seek to ensure that international trade in chemical and biological products for peaceful purposes is not hindered, in accordance with Article XI of the CWC and Article X of the BTWC.

Future Developments

Since its inception, the Australia Group has proven to be an important element in ongoing international efforts to impede the proliferation of chemical and biological weapons. Recent developments, however, have challenged the effectiveness of national export licensing measures. Economic globalization has seen the number of potential chemical supplier countries grow considerably. The rapid pace of technological change, particularly in the biotechnology sector, also poses new challenges for keeping common control lists up to date. Monitoring intangible technology transfer (know-how) is being increasingly complicated by rapid advances in communications and information transfer. Terrorists, not state actors, are now seen as being a potential CBW threat, but the Australia Group has not developed controls that are optimized to prevent terrorists from acquiring chemical precursors.

In response, recent technical reviews of the Australia Group's common control lists have taken into account changing technologies and chemical and biological terrorism issues. In addition, group participants are encouraging all exporting and transshipping (that is, goods being shipped across national borders) countries to implement similar measures. In recent years, the group has maintained a practice of briefing a large number of nonparticipating countries on the outcomes of its meetings. These briefings make available lists of chemical and biological agents and related equipment and technologies that are of proliferation concern, and they have helped other countries to adopt export control measures.

Although a small number of countries criticize the Australia Group for what they claim are restrictions on legitimate trade and technology transfers, there appears to be an increasing acceptance by most countries of the idea that adopting national export licensing measures based on the Australia Group's common control lists raises the barriers to both chemical and biological weapons proliferation and chemical or biological terrorism. Many countries also believe that the group provides a tool for implementing nonproliferation obligations under the CWC and BWC. A number of group participants and other countries have also used the various common control lists as a basis for domestic monitoring of listed items, as a means to increase the barriers to terrorism. The importance of the Australia Group and the use of lists of chemical and biological materials of concern are likely to increase in the years ahead.

B

BARI INCIDENT

On December 2, 1943, in what came to be referred to by some as a second Pearl Harbor, German JU-88 bombers attacked the port city of Bari, Italy, sinking seventeen Allied ships and damaging several others. Among the American vessels fatally struck that night was the Liberty class cargo ship SS *John Harvey,* which, in addition to its typical load of conventional arms, food, and other supplies, carried 2,000 one-hundred pound M47A1 bombs filled with the blister agent sulfur mustard (*see* Mustard [Sulfur and Nitrogen]). Due to the sensitive nature of, and thus the compartmentalized information regarding this cargo, only a select few crew members were aware of this dangerous freight. Unfortunately, all of these crew members were killed in the attack, leaving medical personnel ashore unaware of the need to treat casualties for blister agent exposure. Of approximately 800 American military casualties hospitalized following the raid, more than 600 were eventually diagnosed with gas exposure, and 83 of those died. Numbers of civilian casualties are less well documented, but estimates run as high as 1,000.

Although he had issued a statement denouncing the use of chemical weapons by any actor in World War II, President Franklin Delano Roosevelt had also reserved the right to retaliate in kind if chemical weapons were used by the Axis. He therefore ordered mustard-filled munitions to be forward deployed in Europe to provide the capability to launch a retaliatory strike in the event that the Germans initiated gas warfare. In 1943, the Germans were on the defensive. As a consequence, or so the Allies believed, Germany could have been desperate enough to use poison gas on the battlefield. To avoid triggering a preemptive strike by Germany with chemicals, however, the presence of the Allies' chemical munitions was kept secret. This was to play a tragic role in what transpired off the Italian coast.

Being oil miscible, liquid mustard released into the harbor waters mixed with oil from stricken vessels. This mustard agent came into contact with sailors who had dived into the water to escape their sinking ships. Sulfur mustard vapors were also released into the air. Because medical personnel were unaware of the mustard's presence, rescued seamen were allowed to remain in their oil-soaked clothing while those injured in the blasts were treated, prolonging contact with the agent. Victims began to exhibit the delayed effects of mustard exposure within hours, with burns on their skin, swollen eyes and genitals, and temporary blindness. More serious casualties were those involving respiratory exposures of mustard agent.

After the bombing, medical personnel at Bari, finding the symptoms exhibited by their patients to be consistent with blister agent use, called for an investigation. U.S. Army Medical Corps Lieutenant Colonel Stewart Alexander, a chemical warfare expert, travelled to Bari, where he determined mustard to be the source of the nonblast casualties. In February 1944, the U.S. government issued a statement acknowleging the presence of mustard in the *John Harvey's* cargo.

After the war, the United States disposed of unspecified amounts of phosgene, hydrogen cyanide, cyanogen chloride, and additional quantities of mustard off the coast near Bari. Studies performed by the University of Bari as recently as 1997 have discovered cases of mustard exposure among fisherman trawling these waters.

BHOPAL, INDIA: UNION CARBIDE ACCIDENT
The Bhopal, India, Union Carbide accident is an example of how industrial chemicals—whether in precursor, intermediate, or finished form—have the potential to create massive casualties. The accident also provides a window into the possible outcomes of an intentional release of CW agents.

On the night of December 3, 1984, Bhopal and its environs fell victim to the worst industrial accident in human history. As the city slept, approximately 40 tons of the highly toxic industrial chemical methyl isocyanate (MIC) escaped from two underground storage tanks, blanketing the highly concentrated population in an invisible, choking cloud. The gas cloud, trapped under a nocturnal temperature inversion, engulfed a 5-mile-wide perimeter, claiming the lives of thousands of men, women, children, and animals in its wake. The disaster is explained by the high toxicity of MIC, a more potent choking gas than phosgene. To compare, the safety limit for MIC exposure in humans over an 8-hour period is 0.02 parts per million (ppm), but phosgene is rated at 0.1 ppm.

Union Carbide India Ltd. (UCIL), a subsidiary of Union Carbide Corporation, first set up shop in 1934. Constructed in 1969, the company's Bhopal facility was originally designed for pesticide production, which required the mixing of stable chemicals. Finished pesticide would then be sold directly to the Indian government. The factory was located in close proximity to established working-class settlements in order to take advantage of the Bhopal-Ujain rail line.

In 1974, UCIL was licensed by the Madhya Pradesh (MP) government to manufacture 50,000 tons of pesticides per year. Soon, however, the market for finished pesticides began to wane, due in part to a decrease in cases of malaria and therefore in the need for mosquito abatement measures, but also because of aggressive competition from more than 300 smaller manufacturing firms. To cut production costs, UCIL began to manufacture key chemical intermediates instead of purchasing them from a separate supplier. In 1978, the plant was reconfigured to produce MIC, a volatile intermediate chemical used in the production of the carbamate (a category of chemical that has specific groupings of carbon, nitrogen, and oxygen) pesticide carbaryl (marketed under the trade name Sevin[r]).

The Bhopal plant had experienced a number of incidents prior to December 1984. Between 1981 and 1982, two separate phosgene gas (a chemical precursor of MIC) accidents claimed the life of one worker and injured twenty-four others. The plant suffered its first MIC leak in 1982. That incident injured four workers. Between 1980 and 1984, the number of UCIL operators assigned to the MIC unit was downsized to half its original strength. In May 1982, a confidential safety audit was conducted by a United States-based team. The team identified "61 hazards, 30 of them major and 11 in the dangerous phosgene/MIC units." Corrective measures were subsequently taken (Kalelkar, 1988).

The details of exactly how the lethal MIC was able to escape into the atmosphere on December 3, 1984, are still contested today. Much of the attention has focused on activity in the plant involving the use of water to flush the lines in the MIC manufacturing unit. This water, according to the Indian government's explanation, seeped inside the MIC storage tanks due to leaking valves. However, post-event investigations conducted by Union Carbide, the parent company, and by Arthur D. Little, an independent chemical industry consulting firm, found evidence of sabotage. In this scenario, a disgruntled worker may have deliberately introduced water into the tanks containing MIC, knowing that this would ruin the chemical used in the preparation of the final product. The individual probably had no inkling as to the ultimate consequences of his action.

Adding to the conditions that would portend disaster, three essential safety measures had been offline at the time of the incident. The refrigeration unit, which would have kept the tank temperature close to 0° centigrade, had been shut down in June 1984. Cooling the MIC to low temperatures might have reduced the ultimate reaction rate and volatility, but this is only speculation. Also, months before the incident, process vents—exhaust units for excess gases—were taken out for maintenance. Thus, the flare tower used to incinerate chemical exhaust that could have treated unwanted emissions was not available. Finally, the safety scrubber—another means of treating toxic effluents—had been turned off, although it was usable at the time of the incident.

In December 1984, up to 3,000 people died in the Bhopal, India, methyl isocyanate gas release. (Alain Nogues/Corbis Sygma)

The introduction of water into the tank with a volatile chemical at ambient temperature triggered a runaway, exothermic reaction. Although desperate efforts were taken by workers to control the gas release, these were futile and may have even added to the problem. Making the hazard worse still, numerous shantytowns had been built up around the plant, mostly because the land was government-owned and therefore rent-free. As a result, thousands of people were located close to the site of the MIC release.

Though the government reported that 3,800 people perished, other casualty estimates have ranged from 2,000 to 8,000 dead immediately following the accident. The government also reported that 40 people were left with permanent total disabilities and 2,680 people were left with permanent partial disabilities. Damage to renal, respiratory, reproductive, and sensory systems compounded most of the immediate injuries.

The years following the Union Carbide accident have seen a number of actions, each with varying results. In addition to medical recovery, the people of Bhopal now faced economic disaster. Immediately following the accident, the $25 million Bhopal production facility was closed at the cost of 650 permanent jobs. Months later, the neighboring research facility was cut to a skeleton staff. Two massive 3-week evacuations of the area led to business losses ranging from $8–$65 million. Although the government took steps to compensate the survivors, including monetary reparations and the construction of area hospitals, these efforts paled in comparison to the traumatic effects brought on by the accident.

At the same time, a number of lawsuits were filed against the Union Carbide Corporation in both the United States and India. After a long legal battle between the Indian government and the Union Carbide Corporation, which included a number of Congressional hearings and a battle over legal jurisdiction, an agreement was reached that ordered Union Carbide to pay $470 million to the Indian government in compensation. By 1993, after a number of bureaucratic procedural hurdles, distribution of the compensation finally began. As part of the dispersal plan, the Indian government intended to use the award for general community rehabilitation. Because this was not the original intent of the settlement, a public uproar ensued over the government's plan. As recently as 2002, the government backed down from this posture, stating that the money would be used for compensation to the victims. Relatives of the dead, and survivors suffering serious injuries, received an average of $3,000 apiece.

UCIL maintained a low profile in the post-Bhopal period. The aftermath of the accident sapped the economic strength of the corporation, leading to a buyout by its major competitor, Dow Chemical. Further lawsuits aimed at garnering additional compensation for the accident from Dow Chemical are currently pending.

BIGEYE (BLU-80)

Bigeye was the code name for a 500-pound binary chemical bomb designed by the U.S. navy for the delivery of VX nerve gas. *Binary* refers to the concept of using two nontoxic but poisonous substances that are mixed in flight to produce a lethal nerve agent. (*See* Binary Chemical Munitions.) This was done to ensure safer storage and handling of chemical munitions. Munitions already filled with chemical agents—so-called unitary weapons—had started to leak in the 1970s, and the Department of Defense was well aware of the negative public response to the dangers of these unitary chemical weapons. The Department of Defense needed a weapon that citizens would accept.

The Bigeye concept was conceived in 1959. Testing on Bigeye started in 1972, and about 200 test articles were produced at Pine Buff Arsenal, Arkansas. (Production never commenced, however, because the United States and the Soviet Union agreed to a chemical weapons destruction plan in 1990.) One canister of this binary weapon would be stored separately from the bomb itself and added just prior to flight (the bomb was to be delivered by plane). This separation would have extended the storage shelf life of the bomb and eased munitions maintenance requirements. Bigeyes were to be carried by tactical fighters, such as the A-6 and F-111, and they were to be used to attack second-echelon forces such as airfields and ammunition dumps to disrupt enemy operations behind the front lines.

General Accounting Office investigations uncovered fusing, mixing, and detonation problems with Bigeye, which led the U.S. Senate, especially Senator Richard Pryor (D-Ark.), to withhold funding and production go-ahead for the Bigeye bomb. There were two other binary chemical weapons in the U.S. arsenal: a multiple-launch rocket system submunition that never reached the prototype stage, and the 155-millimeter artillery projectiles called M-687, which did reach full-scale production.

The originally proposed deployment of the Bigeye bombs to Europe led to further controversy. The Belgian government nearly fell over the question, and the West German government only approved the deployment in a subministerial forum. A full ministerial approval would have led to a parliamentary debate that the government in Bonn did not want on the heels of the bruising Intermediate Nuclear Force deployment debate over deployment of American nuclear weapons on European soil. The European NATO allies were also disturbed by the adoption of the AirLand battle doctrine, which called for the use of chemical and nuclear weapons to achieve victory over Warsaw Pact forces in the event of war on the inter-German border.

With the signing of the Chemical Weapons Convention, the Pine Buff facility (where Bigeyes were produced) was inspected and then sealed in 1997 by the Organization for the Prohibition of Chemical Weapons, the implementing body established by the convention.

BINARY CHEMICAL MUNITIONS

Binary chemical munitions consist of two separate components that by themselves are relatively nontoxic, but when mixed together produce a toxic chemical warfare (CW) agent. Offering advantages particularly in their safer production and handling, binary chemical weapons are more advanced (if not generally superior) to unitary chemical munitions, which simply contain the CW agent (the final toxic chemical product) in the warhead fill. Some binary-type designs may be used in terrorist attacks, with simple designs most likely using more common chemical ingredients (e.g., cyanide).

During the late 1980s, the United States produced a number of binary weapons, including artillery projectiles (containing the nerve agent sarin) and the Bigeye VX nerve agent glide bomb—a ground attack weapon that sprayed agent as it flew over a defined area. Since the signing of the 1993 Chemical Weapons Convention (CWC), all components of binary chemical weapons are undergoing destruction in the United States. It is possible, even likely, that the former Soviet Union also produced binary chemical weapons, including one that produced a novel CW agent called *novichok*. As of this writing, no details on Russian-held binary chemical weapons are found in the open literature. Russia, like other CWC signatories, is enjoined to destroy all of its chemical weapons stockpiles.

The idea of binary chemical munitions is not new. Some concepts for binary chemical weapons were devised during World War II. In one design of an aerial bomb, for example, military chemists separated two components, magnesium arsenide and sulfuric acid, into chambers divided by a partition. When the bomb struck the ground, the partition would be shattered and the chemical components mixed to produce arsine (AsH_3) gas, considered to be a blood agent, that is, it attacks the blood-respiratory system in the body. It does not appear, however, that this chemical ordnance ever found service in any conflict. Another idea considered during the 1940s included the formation of a vesicant (blister agent). For this CW agent, a nontoxic molecule would react with another to form the toxic chemical product, the nitrogen-based blister agent methyl N-(2-chloroethyl)-N-nitrosocarbamate (code named KB-16). As far as it is known, this design was never fully developed into a chemical weapon.

Since the advent of modern chemical warfare, chemical weapons scientists traditionally have considered binary forms of weaponry in order satisfy three basic requirements. The first was to build a chemical weapon that could combine components to produce a constant and prolonged release of toxic chemicals. Another reason for binary designs was to add stability to the chemical components, avoiding the constant problem of shelf life found in unitary chemical munitions. The blister agent mustard and the blood agent hydrocyanic acid (HCN), for example, were notorious during World War I (and dangerous, in the case of HCN) for being unstable during storage. Finally, from the production base to logistics on the field, binary chemical munitions were designed to produce a weapon that was safer and easier to handle than highly toxic unitary weapons. This has become especially important since the discovery and development of modern nerve agents. One of the most important benefits of producing nontoxic binary components is that these can be manufactured at chemical production plants without a special safety process and control system. Furthermore, when the two parts are stored in different locations (as is done in the United States with its binary artillery shells), the chance of catastrophic accidents during handling is less likely with binary weapons than with unitary ones.

Maritime traditions are replete with exacting standards of safety. It should not be surprising that the hazards involved in transport and handling of chemical weapons were of special concern to the U.S. Navy. During the mid-1960s, the U.S. Navy had patented a design for a binary chemical weapon utilizing two chemicals—one liquid and one solid—that would react to form a toxic CW agent. This was probably the prototype for the VX Bigeye bomb that was developed two decades later. In 1969, the U.S. Navy submitted requests for proposals to defense firms that included research and development of "a chemical cluster weapon capable of mixing and reacting two non-toxic chemicals to generate toxic agent within the cluster payloads" (SIPRI, p. 307). This was a requirement for a binary chemical munition, probably involving the production of nerve agents such as sarin (GB) or soman (GD). By 1972, the U.S. military had been able to build a prototype of a binary chemical weapon for use in land-based artillery. This would later become M-687, the 155-millimeter howitzer projectile.

During the Cold War, the U.S. approach to binary chemical ordnance focused on two types: binary sarin (for an artillery projectile) and VX (Bigeye) agents. The M-687 projectile produced sarin by mixing difluoromethylphosphonate (or difluor) and isopropyl alcohol. After the weapon was fired, the membrane separating the component chemicals would be shattered by the force of gravity. Now spinning at thousands of revolutions per minute, the weapon's rotation in flight facilitated the mixing of the binary components to form sarin. When the projectile neared its target, a special fuse mechanism ensured efficient dissemination of the agent through the back of the projectile. One component of the M-687 projectiles was stored in Umatilla, Oregon, and the other was held in storage at Pine Bluff, Arkansas. All are soon to be destroyed pursuant to the CWC.

During the 1980s, the Ronald Reagan administration revamped the U.S. military's offensive chemical weapons arsenal as a means to better counter Warsaw Pact forces. In part because of its relatively simple design, significant numbers of the M-687 howitzer binary chemical round were produced until 1991, when offensive chemical weapons were renounced by the George H.W. Bush administration.

The VX Bigeye glide bomb, developed under the auspices of the U.S. Navy, was intended to spray VX from an aerial munition that would glide over the target. Two relatively nontoxic compounds, sulfur and a chemical code-named QL , would combine to form VX within the bomb itself. Although a working prototype was built, the project was plagued with technical problems, not the least of which was a tendency for the munition to burst prematurely because of expanding internal gases. The BLU-80/Bigeye was designed to deliver some 180 pounds of VX nerve agent.

Although binary chemical weapons clearly offer many advantages, they also have their drawbacks. The design used in the Bigeye VX bomb was clearly difficult and complex to engineer, and few countries can afford the cost of producing large numbers of this type of ordnance. Also, as one would expect in any synthesis, the chemical reaction in a binary system is not instantaneous. Furthermore, portions of the round consist of various non-CW chemicals, including some containing fluorine, which generate distinctive odors that could be quickly detected by an enemy.

Other Designs

Because of its ability to fire a large and redundant number of volleys, the multiple-launch rocket system (MLRS) has long been considered one of the more effective delivery platforms to increase the concentration of chemical warfare agent on a given target. The U.S. Army had produced both sarin and VX unitary warheads for the M55 rocket used by the MLRS.

A binary design that only made it to the prototype stage was for a so-called intermediate-volatile nerve agent munition for the MLRS. Although exact details are not available, it is possible that the binary components would have produced a nerve agent that had moderate persistence, perhaps soman (GD) or cyclosarin (GF). When using rockets in a direct-fire weapon like the MLRS—as opposed to a shell with a ballistic trajectory—one would have to consider the target and trajectory, allowing for enough time for components to fully react.

Because of the ongoing interest by the United States in refurbishing its chemical arsenal, combined with the massive Soviet military threat in the 1980s—or perhaps a combination of the two—China began to study the production of binary chemical munitions for its People's Liberation Army. Whether or not these munitions went beyond the blueprint stage is unknown. One diagram found in Chinese military writings on chemical warfare depicts what appears to be a rough design for a binary warhead, perhaps a sketch of the HY-1 (Hai-Ying) cruise missile (based on the original Soviet Styx). It is not certain if such a design would be effective, or if its aerodynamics would affect its trajectory. Chinese publications also have shown a design for a putative binary rocket for their MLRS that could be based on a real prototype. It features the binary components being mixed inside the rocket warhead, and explosive charges along the center being used to disperse the nerve agent.

Having signed and ratified the 1993 Chemical Weapons Convention (CWC), China has vowed to declare and destroy any past or remaining chemical weapons in their inventories. Little is known about past or present Chinese production or deployment of binary chemical weapons. Anecdotal evidence suggests that China considered producing binary chemical weapons, including those for artillery rockets, but considered the associated per unit costs to be exorbitantly high.

Western intelligence has long suspected that the former Soviet Union developed binary chemical weapons. It is likely that Soviet chemical weapons designers developed designs for sarin binary and perhaps VX nerve agent munitions. Following the breakup of the Soviet Union in the early 1990s, an intriguing story that came to light was the research into novel CW agents conducted by Soviet chemical weapons scientists. These included *novichok* (Russian for *newcomer*) chemical compounds, some being up to ten times more toxic than VX nerve agent. According to Russian dissident scientists, novichok agents were to be used in binary weapons. The usual means of treating nerve agent casualties would not be effective against this highly toxic chemical. Details on this and other novel CW agents reportedly developed in the former Soviet Union are still classified.

Terrorists may also utilize the basic concept of binary chemical systems for sabotage or even large-scale attacks. In 1995, immediately following the sarin nerve agent attack on the Tokyo subway by the Japanese cult Aum Shinrikyo, cyanide binary devices were discovered in subway restrooms. Consisting of two containers, one holding solid cyanide salt and the other a dilute acid solution, a crude timer was to have combined the components to form hydrocyanic acid (HCN) gas. Fortunately, these chemical devices were deactivated before they could do any harm. Another design found in the open literature proposes to mix two relatively nontoxic compounds that would form phosgene gas, a toxic lung irritant. It is uncertain if such a system could create sufficient concentrations of phosgene gas to cause death or injury.

BIOLOGICAL AND TOXIN WEAPONS CONVENTION (BTWC)

The 1972 Biological and Toxin Weapons Convention (BTWC—often referred to as the Biological Weapons Convention, or BWC) prohibits the development, production, and stockpiling of biological weapons. There are currently 147 countries that are party to the BTWC. Although not explicitly stated in its preamble, by inference the BTWC prohibits the use of microbial or other biological agents, or toxins, whatever their origin or method of production. Unlike the Chemical Weapons Convention (signed in 1993), however, as of 2004, the BTWC has no verification protocol—that is, the BTWC has no set rules or guidelines to verify compliance by its members. Although its current status as a "toothless" disarmament treaty does not make its obligations any less binding upon its parties, the BTWC is little more than a gentleman's agreement. A verification protocol for the BTWC is not likely to be concluded by the end of the first decade of the twenty-first century. Because it has thus far lacked verification provisions, confidence-building measures (CBMs) were adopted during the second BTWC Review Conference in 1986, and parties to the Convention are now submitting BW-related reports on an annual basis to the United Nations. After failed attempts to arrive at an acceptable protocol, the United States and other treaty members are engaging in efforts to enhance the effectiveness of the BTWC with biosecurity initiatives.

Background: CBW History

The first effort to prohibit the use of biological weapons—albeit with important loopholes and exceptions—can be found in the 1925 Geneva Protocol, sometimes called the Gas Protocol. Its full title was Geneva Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous, or Other Gases, and of Bacteriological Methods of Warfare. The inclusion of the term *bacteriological methods of warfare* was made nearly at the last minute by the suggestion of the Polish delegate. (Viruses were poorly understood in 1925, but they certainly would have been included in the title, had they been better understood at the time.) As in the case of chemical weapons, the Geneva Protocol of 1925 only prohibited the first use of such weapons against other parties to the treaty, and not the development, production and stockpiling of such weapons.

Prior to the 1925 Protocol, there had been acts of sabotage in World War I that used bacteria. The German-American agent Anton Dilger conducted a number of attacks on Allied horses and pack mules from 1915–1916, using the causative agents of glanders (*Burkholderia mallei*) and anthrax (*Bacillus anthracis*). Working from a makeshift laboratory in Washington, D.C., Dilger hired other agents—including longshoremen—to infect animals in their stockades along ports in the eastern United States. These acts of biological warfare (BW), however, were barely noticed by Allied authorities.

During the 1930s, biological weapons were still very much an unknown quantity. In December 1932, a report from the Special Committee on Chemical, Incendiary, and Bacterial Weapons—for the Conference for the Limitation and Reduction of Armaments—stated: "Chemical warfare is known from actual experience; bacteriological warfare, on the other hand, is a hypothesis. Nor are there any results of laboratory experiments on which knowledge can be based. The behavior of pathogenic microbes intentionally transported from the laboratory to natural media is practically unknown to us. It must nevertheless be admitted that such warfare is possible" (Fradkin, pp. 58–59). The Conference also predicted the future conundrum faced by arms control and disarmament in the realm of biological weaponry:

> We are not at present in a position to subject bacteriological research to effective supervision. Virulent bacteria, such as might cause epidemics, are to be found in all bacteriological laboratories (both public and private), and also in hospitals treating contagious diseases. There can be no question of hindering the progress of medical bacteriology, the objects of which are humanitarian (the preparation of sera, vaccines, etc.), by supervising and restricting experiments with virulent cultures. Such supervision, moreover, would never be complete and therefore always ineffective. (Fradkin, p. 59)

As military aviation made rapid advances during the early twentieth century, public and official concern about the threat posed by incendiary bombs or toxic biological and chemical mists increased. Elvira K. Fradkin, in a 1934 treatise called *The Air Menace and the Answer,* described how biological agents could rain death from the skies: "An airplane could carry enough of the botulinus toxin to destroy every living thing in the world if administration of the toxin were as simple a process as production and transportation" (Fradkin, p. 57). And although never quite certain of what threat existed from germ warfare, in 1938, the British scientist John Burdon Sanderson Haldane warned that yellow fever could be utilized as a biological weapon. A year later, Imperial Japanese agents visited the Rockefeller Institute in the United States in an attempt to acquire cultures of yellow fever virus. As yellow fever was not a disease endemic to the Far East, these surreptitious inquiries aroused suspicions by Western intelligence. These reports of Japanese efforts to obtain and develop potential BW agents—as well as (often spurious) intelligence indicating that Nazi Germany had an interest in biological weapons—encouraged the Allies to initiate their own BW programs.

During World War II, the United States, Canada, and the United Kingdom initiated substantial programs for BW defense and offense, including the production of virulent organisms such as anthrax spores. Although committed not to use such weapons unless for retaliation in kind, Presidents Roosevelt and Truman continued offensive research and development of biological weapons. North Korea and the People's Republic of China alleged that the United States used biological weapons during the Korean War (1951–1953). These allegations are not supported by any credible evidence.

Throughout the Cold War and until renouncing biological weapons in 1969, the United States tested and weaponized several offensive BW agents, including *Brucella,* anthrax, tularemia, staphylococcal enterotoxin B, and anticrop agents. Although U.S. military commanders were usually somewhat skeptical of their utility, American BW scientists were confident by the 1960s that their validated biological delivery systems could be effective in shutting down enemy ports, or indeed in bringing a whole country to its knees by the use of debilitating viruses, bacteria, or toxins.

Until the late 1960s, for much of the U.S. public, the idea of using chemical and biological agents was not particularly controversial, or at least it appeared that way. The use of chemical herbicides (including Agent Orange) and CS tear gas during the Vietnam War, however, led to protests against the perception that chemical warfare (CW) agents were being employed by the United States in that conflict. In March 1968, some 6,000 sheep were killed near Dugway Proving Ground, Utah. Their owner claimed that the U.S. Army was responsible when aircraft dropped VX nerve agent during training runs near Skull Valley, Utah. Although the U.S. Army paid the farmer $1 million in restitution, it did not admit to being culpable. Still, the impact of this incident—and ongoing operations by the United States in destroying obsolete chemical weapons by dumping them into the ocean—led to public questions concerning U.S. offensive CBW policies. In response, the Nixon administration reviewed the U.S. position with regard to both CW and BW in May 1969. Two months later, a chemical spill on a U.S. military base in Okinawa, Japan, exposed twenty-four people (including one civilian) to sarin nerve agent. Protests erupted in Japan as a result, and further revelations that U.S. chemical weapons were stored in West Germany added more fuel to the controversy.

Makings of a Convention

As the public outcry in the United States against chemical and biological weapons grew, the United Kingdom brought forth a proposal on July 10, 1969, to the UN's Eighteen-Nation Disarmament Committee that would ban production, development, and stockpiling of biological weapons. In 1968, this committee had considered a comprehensive ban on all forms of chemical and biological of warfare. At that time, however, Western countries such as the United Kingdom did not believe that BW would be as important as the immediate threat posed by chemical weapons, and they preferred that CW and BW be treated separately. In 1969, President Nixon made the decision to renounce biological warfare—specifically the use of disease-causing organisms—mostly because of their perceived technical problems, but also because enemies could plausibly threaten large populated cities in the United States. By supporting biological weapons disarmament, Nixon also hoped that this decision would improve the public image of his administration and the United States. After some further internal debate by 1970, biological toxins (not just disease-causing pathogens) were included in the unilateral renunciation of BW by the United States.

In the years 1970 and 1971, negotiations in Geneva over a biological and toxin weapons treaty had been making little progress for a number of reasons, mostly having to do with an insistence by the Soviet Union that chemical weapons also be included in the treaty. The Soviets finally relented on this point, however, and the final version of the BTWC was approved on September 28, 1971, opened for signature in April 1972, and put into force in March 1975.

Five years following the treaty's entry into force, the first Review Conference of the BTWC was held in March 1980. Intense discussions at this conference were spurred in part by the advances already made in genetic engineering, as well as by the increased military interest around the world in the biological sciences. Two controversies were brought forward during this time: the Sverdlovsk anthrax outbreak in 1979 and U.S. allegations of yellow rain (T-2 mycotoxin) being used by Soviet client states in the Middle East and southeast Asia. Reports concerning the Sverdlovsk outbreak appeared at the same time as the first Review Conference took place. Not surprisingly, the then-suspected (now confirmed) release of a biological warfare agent (anthrax spores) raised great concerns, not only about Soviet BW programs but also about the implications of future verification, inspections, and BTWC compliance.

During the second Review Conference in 1986, four important confidence-building measures (CBMs) were established in order to increase the level of trust among signatories and improve transparency: (1) Annual provision by signatories of data on high-containment facilities designed for work on dangerous biological materials; (2) Annual notification to signatories of outbreaks of unusual diseases; (3) Encouragement of publication of results of biological research related to the BW convention; and (4) Promotion of contact between scientists engaged in research, including exchanges of staff for joint research.

The overall response to the CBMs was tepid, with fewer than forty countries reporting regularly on an annual basis since the 1986 review. Most developing nations either did not send declarations, or their declarations were incomplete. Although China and the Soviet Union did supply information detailing their BW-related programs, by 1991 only 40 signatories out of 117 had established their own domestic legislation for implementing proper declarations, and only 70 (out of 135) had done so by 1996.

At the 1991 review, considerations for strengthening the BTWC were inspired by the recent Gulf War. Several proposals were made, including a measure to extend Article 1 to cover BW agents against plants and animals. CBMs added to the convention included:

- Declaration of data on national biological defense programs and facilities, as well as high-containment facilities
- Better definition of an unusual outbreak of disease
- Emphasis on publication of results
- Promotion and publicizing of contacts between staff involved in BW defense
- Declaration of legislation and other regulations to implement the provisions of the Convention and to control the export of BW agents
- Declaration of past activities in offensive or defensive biological programs since January 1, 1946
- Declaration of production facilities for vaccines against human diseases

To develop the technical means to verify compliance with the BTWC, the Ad Hoc Group of Government Experts (**Ver**ification **Ex**perts or VEREX) was established at the 1991 review. Within the two categories of on-site and off-site inspection measures, VEREX determined twenty-one means of verifying BTWC compliance.

Additional meetings of the VEREX group were held in Geneva between March 1992 and September 1993, resulting in a final report to the BTWC parties. Though VEREX was able to conclude that at least some combination of the measures listed above was promising, it did recognize that the dual-use nature of BW-related technology, basic equipment, and starting materials made verification of the convention problematic. During the Ad Hoc Group meetings in 1994, additional discussions called for measures to strengthen the BTWC, suggesting that challenge inspections and peaceful transfer of biotechnology should also be included. Later, the Ad Hoc Group held three meetings in 1995, two substantive meetings in 1996, and other meetings during 1997–1998. The eleventh session (June 22 to July 10, 1998) involving the fifty-two-nation Ad Hoc Group concluded with a 250-page "rolling text," which contained about 3,000 reservations from individual parties.

Current Status

In late 2001, BTWC protocol negotiations came to an impasse. In rejecting the last iteration of the draft protocol text, U.S. Undersecretary of State John Bolton said on November 19, 2001: "The draft protocol that was under negotiation for the past seven years is dead in our view. Dead, and is not going to be resurrected. It has proven to be a blind alley" (U.S. Department of State, 2001). This pronouncement not only crystallized U.S. officials' opposition to what they saw as a seriously deficient protocol; it also led to widespread doubt that little, if anything, would be accomplished at the fifth Review Conference. Upon concluding the November 2002 review, however, the parties were able to agree on some substantive issues and to plot a course for annual meetings before the next conference in 2006. In summary, the parties agreed to the following scheduled agenda: in 2003, domestic legislative initiatives and rules to govern the safe use and transfer of dangerous pathogens would be considered; in 2004, increased efforts for global disease surveillance and better mechanisms to evaluate the cause of disease outbreaks would be discussed; and in 2005, an agreed protocol for scientists and researchers conducting research relevant to the BTWC would be negotiated.

Although it seems naïve to suggest that criminalizing biological weapons will dissuade individuals or governments determined to acquire them, many believe that making the possession or use of biological weapons a universal crime could further biological weapons disarmament.

BIOLOGICAL TERRORISM: EARLY WARNING VIA THE INTERNET

The use of a biological weapon can be recognized by the appearance of a deadly pathogen or toxin in an unexpected place or an unexpected season, or by the appearance of a previously unknown agent. The key to containing the resulting outbreak of disease is rapid detection and reporting. In recent years, outbreaks of the previously unknown viruses Hendra, Nipah, and SARS (severe acute respiratory syndrome) in Asia and of anthrax, West Nile, and monkey pox viruses in the United States have met the above criteria. Although only the anthrax that appeared in the U.S. postal system turned out to be a terrorist attack, the Internet played a crucial role in providing early warning of many of these disease outbreaks.

The free, independent, public Internet network ProMED (Program for Monitoring Emerging Diseases) was launched by the Federation of American Scientists in 1994 to give early warning of bioterror attacks. It is now operated by ISID (the International Society for Infectious Diseases). On November 18, 2001, Dr. D. A. Henderson, director of the Office of Public Health Preparedness of the U.S. Department of Health and Human Services, wrote, "ProMED-mail with CNN was our main source of information through most of the recent anthrax outbreak!" (Henderson, 2001).

Plague is considered to be a potential biological weapon. On June 22, 2003, ProMED sent a newswire report of an outbreak of bubonic plague in Algeria by e-mail to its 30,000 subscribers in 150 countries, a report that was also seen by thousands more who accessed ProMED's website. Two days later, the World Health Organization (WHO) in Geneva posted an alert on its website after it obtained clearance from the country concerned to publish the report. If this had been a terrorist attack—Algeria has suffered from a number of nonbiological terrorist attacks in the past—the extra 48 hours' advance warning could have made a vital difference in terms of alerting physicians to look for suspicious symptoms in persons from the area, perhaps as they carried the disease to other countries.

Smallpox virus is another agent that has been listed as a potential bioweapon. All cases of suspicious smallpox-like rashes must be investigated and immediately reported to local health authorities and WHO. On June 7, 2003, the U.S. Centers for Disease Control and Prevention (CDC) issued a press release on its website: About seventeen cases of pox-like rash had occurred in people living in the western United States who had come into contact with sick pet prairie dogs. Onset of the first cases had been in early May 2003. The diagnosis was monkey pox, a disease never before seen in the Americas, and the source was eventually traced not to bioterrorism, but to infected Gambian giant rats from Africa. The rats, sold as pets, had been in contact with the prairie dogs in pet stores and at pet sales. As a result of this public announcement, fifty-four more cases were identified and 3 more states were found to be involved in the outbreak of monkey pox.

On June 23, 2003, a report appeared on the Internet of an outbreak of a pox-like disease in a remote area of the Republic of the Congo (Brazzaville). The report was sent in by a missionary doctor working in the region. Patient specimens were sent to the CDC, which diagnosed them to be cases of monkey pox, not smallpox. That was the first public notice of these cases, which had reportedly been occurring since mid-April 2003. Public health officials across the globe need to be informed rapidly of all such cases so that smallpox can be ruled out, or so that vaccination can be provided if smallpox does reemerge anywhere in the world.

On February 10, 2003, both WHO and ProMED received e-mail queries about an outbreak of a virulent form of pneumonia in Guangdong, China, subsequently named SARS (severe acute respiratory syndrome). WHO immediately asked for official confirmation, forcing the Chinese government to admit to the outbreak, but clearance for WHO to issue a public warning took 48 hours to obtain. ProMED is an independent network, so it was able to post the news by e-mail and on its website immediately. Once again, if this had been a terrorist attack, advance warning could have made a crucial difference in terms of response and containment.

The real importance of this episode was that individuals, not governments or public health officials, informed the world health authority and a public Internet list directly about a deadly outbreak.

It was later discovered that cases of SARS had been noted at least as far back as November 2002, and news about them had been circulating on the Chinese internet, so the early warning had been out there for anyone who knew where to look and could read Chinese. Health Canada's GPHIN (Global Public Health Intelligence Network) had distributed reports of outbreaks in the original Chinese with English headlines to a closed subscriber list. ProMED is developing a Chinese language website and e-mail list, and translations will feed into the open English language list.

Internet reporting had earlier helped to uncover another new virus in Asia. In October 1998, fatal cases of encephalitis began to be seen in parts of peninsular Malaysia where pig farming was practiced. The outbreak was initially attributed to Japanese encephalitis virus (JEV), but on January 17, 1999, a virologist posted a message on the Internet pointing out that the profile of the cases did not fit that of JEV infection. List moderators continued to query the official diagnosis thereafter, and two months later, the Malaysian government officially declared that a new virus was involved, which was named Nipah virus.

By contrast, the arrival of West Nile virus in the United States was not uncovered on the Internet. When crows were found dead in the Bronx Zoo in New York City in 1999, nobody thought to send a report on them to an Internet list with a wide, interdisciplinary readership such as ProMED. Such an alert might have alerted investigators to a possible connection between the avian deaths and the concurrent epidemic of human encephalitis in New York City.

Agroterrorism Warnings

Agroterrorism, or terrorism involving attacks on livestock or crops of major food or economic value, is now recognized as a potential threat. The huge and costly outbreak of Newcastle disease in poultry in four western and southern U.S. states, which was recognized in late 2002, probably did not enter the country through the commercial poultry trade, but via imported fighting cocks kept in private back yards. On the same day that the World Animal Health Organization (OIE is its French acronym) posted news of the initial outbreak on its website, ProMED copied it by e-mail to its 20,000 U.S. subscribers, reaching a much broader audience. This incident suggests that a comprehensive early warning system for bioterrorism events must also cover animal and plant diseases. Early warning is important because it enables owners to look for symptoms in their animals and to take precautions. A warning network can also raise suspicion in the minds of veterinarians treating sick livestock.

Brazil is the world's largest orange producer and exporter of frozen concentrated orange juice, generating annual revenues of about $5 billion. The Brazil orange crop is being progressively infected by citrus sudden death (CSD) disease, which had by 2003 spread into the state of Sao Paulo, an area that accounts for 85 percent of Brazil's 280 million trees. There is no cure for CSD; trees simply have to be replaced by planting resistant varieties, which take years to come into production. An attack on an important food or export crop such as oranges would therefore cause economic havoc and damage national food supplies; hence, important outbreaks of plant pathogens need to be reported widely in a timely manner. Here, there is room for improvement. The European and Mediterranean Plant Protection Organization (EPPO) sends out a monthly report by e-mail, but other regional plant protection organizations have yet to connect their members through the Internet. ProMED picks up food crop reports from the newswires and its own subscribers, but it does not cover economically important nonfood crops.

Technical Aspects

Web spiders and bots have been created by a number of organizations to comb the Internet for reports of outbreaks, using keywords. One of them is GPHIN, operated by Health Canada, whose output is made available to WHO but is otherwise closed to the public. There also are a number of similarly constructed military networks. The University of Guelph, Canada, operates networks on food safety and agriculture topics, FSNet and AgNet, which are open for paid subscription. San Diego State University hosts MiTAP (MITRE Text and Audio Processing), developed by defense contractors but open to the public. MiTAP monitors infectious disease outbreaks and other global threats. Hundreds of information sources are automatically captured, filtered, summarized, and categorized into searchable newsgroups based on disease, region, information sources, person, and organization. Critical information is automatically extracted and tagged to facilitate browsing and sorting, and an information retrieval engine supports source-specific, full-text keyword searches. The system processes thousands of articles daily, delivering up-to-date information to more than 600 users. The capability to handle foreign languages is being developed. MiTAP complements GPHIN and ProMED in the outbreak early warning field, but both MiTAP and ProMED face serious funding problems.

MiTAP requires the user to visit its site and browse, whereas ProMED, in addition to posting outbreak reports on its site, sends reports by e-mail so that subscribers get them as soon as they check their e-mail. ProMED is presently the only independent, free to the user, publicly accessible, global network that gives early warning of outbreaks of human, animal, and plant diseases that have the potential to impact international trade and travel. It is unique in that it receives reports not only from the major newswires, but also from local media; from its subscribers (through forwarding of new items); and from physicians, veterinarians, researchers, hospitals, and laboratories working with actual disease outbreaks. For instance, ProMED had contact with a physician in mainland China during the SARS epidemic, who was able to put the official reports about SARS in context. It received clinical details of the smallpox-like cases in the Republic of the Congo from the doctor who examined cases there. It received news directly from a hospital in Germany concerning a case of Lassa fever, a hemorrhagic disease that usually occurs in Nigeria. It has also received reports on outbreaks in Australia from chief veterinary officers there, including the first report of Japanese encephalitis virus from that country. All reports posted on ProMED are prescreened by a panel of moderators who are experts in their particular specialties, so that hoaxes and questionable reports are not posted to the list.

Thus, ProMED provides an important complement to official outbreak reporting networks such as those of the WHO and CDC, with the advantage that ProMED is unconstrained by the need to receive official clearance from the countries involved. In addition, ProMED covers animal and crop plant outbreaks, which WHO and CDC do not. But it is also evident that even a global network cannot catch every outbreak of potential importance. It needs to be supplemented by national networks, preferably with the same independence of operation. ProMED-style networks have already been set up in Brazil and the Netherlands, and one will soon be set up in South Korea. Using subscribers' own computers, university servers, and part-time staff, these national networks are highly cost-effective.

The examples given here show that the Internet has repeatedly proved its worth as a medium for early warning about outbreaks of disease that could have been caused deliberately.

—Jack Woodall

BIOLOGICAL WARFARE

Biological warfare (BW) refers to the use of living organisms, or of toxins produced by living organisms, as weapons against humans, animals, or plants. In the modern parlance, there is usually a distinction made between BW and bioterrorism, the latter referring to the terrorist use of BW agents and weapons. Although the effects of a bioterrorist incident could have far-reaching ramifications, generally speaking these would be smaller in scale and would probably employ less sophisticated technology than in state-level BW programs. BW agents have already been utilized in modern-day acts of terrorism, albeit with a relatively small impact in terms of total casualties (including both injuries and deaths). For example, five people died and twelve others were infected in 2001 by anthrax spores (*Bacillus anthracis*) that were mailed through the U.S. postal system by an unknown perpetrator.

In the military sense of BW, however, one would expect to have large numbers of casualties (in the thousands and even millions) caused by the large-scale delivery of BW agents suited for military (counterforce) or civilian (countervalue) targets. In fact, next to nuclear weaponry, biological weapons pose the greatest threat in terms of causing mass casualties. The major differences between nuclear warfare and BW include the lack of persistent contamination following the use of biological weaponry (with some important exceptions) and the fact that biological munitions do not damage physical structures (such as buildings or other infrastructure). Biological weapons might therefore be more accurately referred to as mass casualty weapons instead of weapons of mass destruction (WMD).

Before renouncing the use of BW in 1969, the United States possessed a significant stockpile of biological weapons systems. The Soviet Union had at least a rudimentary program since the 1920s, and it continued to develop BW agents and delivery devices long after pledging not to do so (from about 1975 to 1990). The Soviet Union researched, developed, and produced large quantities of potent BW agents including anthrax, smallpox, and plague for loading onto warheads that could hit U.S.-based targets (using intercontinental ballistic missiles). During the Cold War, the two superpowers had the capability of inflicting hundreds of thousands of biological casualties with the use of such weapons. Both countries, as well as many others who are party to the 1972 Biological and Toxin Weapons Convention (BTWC), have since agreed to ban the possession, research, and development of offensive biological weapons. But there exists today the possibility that other states could develop BW programs that could attain or even exceed the level of devastating potential once held solely by the United States and the Soviet Union.

Biological Warfare in History

There are historical cases of armies using infectious disease as a weapon going back at least 600 years. One incident was the siege of the city of Kaffa by Mongol forces in 1346 C.E. During this campaign, bubonic plague had already infected and killed many of the Mongol (Tartar) troops, and it was rapidly being spread by the ubiquitous presence of rats and their associated fleas. In a clever if somewhat desperate move, the leader of the Mongols decided to hurl his own dead soldiers over the walls into Kaffa (presumably using siege engines). The intent was apparently to spread disease among the European traders who had made Kaffa their refuge (Karlen, p. 87). It is unclear, however, if this technique really worked (Wheelis, p. 13). Although the tactic seemed to show the deliberate use of a BW agent, one should note that this would not have been an effective means to transmit plague. In the case of bubonic plague, the causative bacteria (*Yersinia pestis*) are spread by fleas that will only feed upon live hosts, and so it not likely that plague could have been disseminated by using corpses as a delivery system. The presence of rats, and the fleas that spread the disease, however, ensured that a pool of host animals brought plague throughout Europe. As a classic text on disease vectors noted, "The rat, as transported in commerce, constitutes the chief means of spreading the diseases [i.e., plague], the infection being carried from rat to rat by means of rat fleas. For this reason plague may appear in a city far removed from the original focus of infection" (Herms, p. 424). This was the likely and ultimate source of disease transmission, not human cadavers.

Similarly, there was clear intent to spread disease as a means of warfare during the French and Indian War (1754–1767) (Fenn, p. A11). During the wars against Native Americans, British military advisors in the New World plotted to use smallpox in order to "Bring about the Total Extirpation of those Indian Nations" (d'Errico). The colonial armies apparently proceeded to obtain blankets from smallpox hospitals and to give these to the native tribes. However, as in the case of plague during the siege of Kaffa (see above), it is not clear if the methods used here resulted in significantly higher rates of infection among the native tribes in the Americas than by the natural spread of smallpox. After all, millions of indigenous peoples had already died from the natural spread of smallpox following the arrival of the first Europeans to the New World. Also, the virus (*Variola major*) is not known to be transmitted by using bedding or linens that had contact with previous smallpox victims, but it is highly transmissible from aerosols and infectious droplets from active infections.

These premodern examples of BW occurred in an era when infectious disease was not well understood. Until the advent of modern microbiology, particularly the groundbreaking work of Louis Pasteur and others in the late nineteenth century, the conception of disease was usually linked to "foul vapors" or miasmas that mysteriously caused epidemics. (The name *malaria,* for example, comes from the Italian meaning *bad air.*) The idea that a germ could be the source of deadly disease took considerable time to find widespread acceptance. Only in the nineteenth and twentieth centuries were scientists able to isolate the disease-causing microorganisms and to confirm the identity of a pathogen. Thus, the historical references to BW are of relevance only in that there was the deliberate use of disease as a weapon.

By the 1930s, however, a number of scientists and military thinkers had begun to seriously consider the potential threat from biological weapons. For example, in 1925, a Polish military officer persuaded the conference for the Geneva Protocol (or Gas Protocol) of that year to include a ban on "bacteriological" weapons in addition to the prohibition of chemical weaponry. And although the threat of BW seemed real, the science and application of biological weapons still was very much terra incognita. We know now that the only practical and effective means of conducting offensive BW depends primarily upon the use of aerosols, which are infectious particles that can be spread through the air and inhaled into the lungs to cause disease (*see* Aerosol). In the 1930s, however, the idea that disease could be spread through the air still had its critics in the scientific community. At Geneva, Switzerland, during negotiations on limiting armaments, a Special Committee on Chemical, Incendiary, and Bacterial Weapons wrote the following in December 1932:

> The problem of bacteriological warfare is entirely different from that of chemical warfare. Chemical warfare is known from actual experience [e.g., World War I]; bacteriological warfare, on the other hand, is a hypothesis. Nor are there any results of laboratory experiments on which knowledge can be based. The behavior of pathogenic microbes intentionally transported from the laboratory to natural media is practically unknown to us. It must nevertheless be admitted that such warfare is possible. Furthermore, we can only imagine what it would represent and how it could be prepared, and deduce from such suppositions possible methods of defense. (Fradkin, pp. 58–59)

During the 1920s and 1930s, other voices such as that of the British scientist J. B. S. Haldane warned against the potential of biological weapons. Haldane suggested that yellow fever could be utilized as such a weapon. Indeed, in 1939, Japanese agents attempted to acquire yellow fever virus from the Rockefeller Institute in New York, but they failed in their somewhat awkward attempts to purchase the virus. (Yellow fever is not endemic to Asia, and thus Japan's interest in the disease appeared quite suspicious to U.S. intelligence agencies.) This incident set off a warning for the United States security apparatus, particularly as American involvement in war was looming on both the European and Pacific fronts. As a consequence, the Allies began to collaborate on developing, and defending against, offensive BW capabilities.

Although Germany had little in the way of an ongoing BW program, the Allies could not be certain of that at the time, and they therefore planned for the worst. As for Japan, it had already begun an active program in China, from about 1938 until the end of World War II. In gruesome experiments that sometimes included live vivisection of humans, the

Japanese scientists in Unit 731 and related detachments of its hygiene and veterinary services researched plague, anthrax, gas gangrene, and other diseases. The Japanese military scientists also developed weapons, including bombs that delivered plague bacteria using the flea as a vector (transmitting organism).

During World War II, the United States, Britain, and Canada jointly researched antihuman, as well as antiagricultural, BW agents. Although much of the research began as a means to defend against possible attack, bombs filled with anthrax spores were produced and tested on Gruinard Island (off the coast of Scotland). But in the European theater, no biological (or chemical) weapons were used. On D-Day in June 1944, the Allies had prepared enough botulinum vaccine (toxoid) to administer to all of the troops getting ready to land in Normandy. This massive toxoid program was begun based on faulty intelligence that the German military planned to use botulinum toxin against an Allied invasion.

During the Cold War (1947–1991), the United States developed a number of offensive biological weapons, the first being a bacterial munition loaded with *Brucella suis* in the early 1950s. Anthrax, tularemia, Q-fever, and Venezuelan equine encephalitis (VEE) were also researched and produced for delivery against Soviet or Cuban targets, and anticrop agents were stockpiled for use on the grain fields in Ukraine and China.

During this period, the Soviet Union also pursued biological weapons development, but their biological sciences were held back by poor technology and a political climate that wreaked havoc on their scientific community. When President Richard M. Nixon decided that the United States would unilaterally disavow offensive biological warfare in 1969, the Soviet Union had just started to come out of its relative dark ages in terms of modern genetics as well as other biological disciplines. To help catch up to the West, the U.S.S.R. embarked on a massive biotechnological initiative that was primarily touted for being the foundation for developing strategic biological weapons. The Soviet Union developed many of the same BW agents as the United States, including anthrax, tularemia, and antiagricultural biological weapons. The Soviet Biopreparat complex also researched and developed a plague weapon, as well as producing tons of smallpox virus for use in the event of an all-out war with the United States and its allies. Most Russian research in offensive BW essentially ended under the Boris Yeltsin administration, although some Western security analysts believe that such work continues even today, albeit on a much more limited scale.

Delivery of BW Agents: Basic Principles of Biological Weapons and Aerosols

The main operating principle of biological weaponry is the use of infectious aerosols. This is considered the most efficient method of delivering BW agents to infect large numbers of people. In a less likely scenario, however, insects could be bred near a living host (say, a rat) infected with disease-causing organisms, such as plague bacteria (*Yersinia pestis*). During World War II, for example, Japanese BW scientists used fleas that were raised alongside plague-infested rats. As fleas collect plague bacteria in their foregut (proventriculus), under certain conditions these organisms form a blockage of their digestive tract. Desperate for nutrition, when these hungry fleas find another host (such as a human), a flea discharges the mass of bacteria into the opening of its bite, causing an infection. In nature, animal and human diseases caused by bacteria are often due to the contamination of food and water, as well as transmission by arthropods (vectors). The bacterium that causes tularemia or rabbit fever (*Francisella tularensis*), for example, can sometimes infect humans through ticks carrying the pathogen; the organism is transmitted through the tick's bite. But the use of vectors (or of contamination of food and water) to spread disease on a large scale is not considered a significant BW threat. It is not an efficient mode of delivery to cover large targeted areas, and on the defensive side of the ledger, there are now a number of insecticides available to combat mosquitoes and other disease-carrying insects.

Biological weapons must therefore rely on aerosols for effective dissemination. Nearly all known BW agents must be produced and delivered in very small particles, ranging from about 1–10 microns in average diameter. (The one exception is the dermally active toxin T-2 and related trichothecene mycotoxins, although these toxins would also be effective when delivered as aerosols.) Particles ranging between 1–10 microns are more likely to lodge themselves into the very small alveoli, the tiny air sacs in the lung where oxygen and carbon dioxide are exchanged during respiration. Here, the alveolar wall is only about 2 microns thick, and pathogens can pass into the bloodstream. Particles larger than 10 microns (0.010 millimeters) are more apt to be caught in the upper respiratory tree and in the nasal passages. Many of these larger particles, instead of starting an infection, are instead brought back up and out by cilia, the tiny hairs that line the inner surfaces of the respiratory system. These particles are then gradually taken away by the body's own mechanisms for removing foreign matter, and they are thereby rendered harmless.

One should note in this discussion of particle sizes that the bioweaponeer must work under certain physical limits. Individual bacteria, such as *Bacillus anthracis,* for example, range in size from roughly one-half micron to 2–3 microns or more in diameter. To fashion bacteria into some sort of weapon, therefore, requires that the pathogens be separated into small enough particles, averaging less than 10 microns in diameter. Processing the biological material to such a fineness while maintaining its viability is technically demanding. Although finding, growing, and preparing bacteria is not technically difficult, producing a complete weapon system to deliver these agents in the desired aerosol parameters is no easy task.

Because BW agents almost exclusively require the utilization of aerosols to cause infection, one form of ready defense is simply filtering the air with a mask or with the filters found in collective shelters. One U.S. Army study showed that doubling over a towel once or twice and holding this over the nose and mouth was sufficient to filter out most particles in the sizes necessary for causing infection through the inhaled route. But though such protective measures are effective in theory, in practice one needs to first know that a biological attack is taking place. Aerosols are silent, invisible, and at present can only be detected in real time with special light-scattering techniques. Thus, it is unlikely that most people under a biological attack would be able to don protective masks in time to be of any use.

BW Agent Types

Bacteria

There are three main categories of BW agents: bacteria, viruses, and toxins. Bacteria are organisms that are more primitive than the cells making up animal tissue and that, with the right nutrients, can live and replicate by division. Bacteria used in yogurt, those that exist normally in the human gut (such as *Escherichia coli*), and anthrax bacteria (*Bacillus anthracis*) are all examples of bacterial organisms. Within the classification of bacteria is a family of rickettsial organisms. These are bacteria that can only survive in host organisms (i.e., living tissue); some rickettsia can cause serious disease in animals and humans, including typhus (*Rickettsia prowazekii*), Q-fever (*Coxiella burnetii*) and Rocky Mountain spotted fever (*Rickettsia rickettsii*). All three of these organisms have the potential to be used in biological weapons. The United States, for example, produced Q-fever as a weapon during the Cold War and researched Rocky Mountain spotted fever in a number of biological tests for weaponization. Typhus bacteria also may have been a part of the early Soviet BW program.

Viruses

Viruses are usually much smaller than bacteria. One of the largest viruses that cause disease in humans, smallpox (*Variola major*) virus, measures about 0.3–0.4 microns in diameter, or roughly one-tenth the size of anthrax bacteria spores. Viruses also differ from bacteria in their structure, and they are dependent upon living cells (prokaryotic, e.g., bacteria and eukaryotic, e.g., animal cells) for replication. In nature, viruses can be spread in ways similar to those of bacterial infections, such as vectors (e.g., mosquitoes) and contact with infectious hosts. But also like some bacterial diseases, many viruses are spread by aerosols and large infectious droplets, particularly through formation of infectious particles generated by coughing or sneezing.

Viruses can be harmless or can cause diseases, some more serious than others. Some viruses can grow quickly and create symptoms of disease within days or weeks, but others may take a much longer time to cause illness. The Human Immunodeficiency Virus (HIV), which causes Acquired Immunodeficiency Syndrome (AIDS), and the rabies virus are examples of infections that are fatal but that take considerable time before infected individuals may become deathly ill. For use as a biological weapon, the pathogen would need to be one that can cause disease quickly and that is likely to infect most humans following exposure. A viral BW agent would also require a formulation that could be disseminated in the form of an aerosol to be most effective in a biological weapon.

Toxins

Unlike CW agents that are synthetically manufactured, BW toxins are molecules produced by living organisms. One toxin, for example, is produced by the bacteria *Clostridium botulinum* and is the cause of some very serious forms of food poisoning (botulism). (*Botulus* is the Latin word for *sausage,* as the disease has long been associated with tainted meat products.) The toxicity of botulinum toxin is variously estimated to be lethal in amounts ranging from about 0.1 micrograms (ingested) to 5 micrograms (inhaled), the latter figure being 200 times smaller than the estimated lethal dose of the most toxic nerve agent, VX. However, the actual delivery of botulinum would present more difficulties than VX. Botulinum toxin is rather fragile, and if its chemical structure and integrity are damaged (denatured), it will cause no harm. Also, whereas VX can act through the skin, botulinum toxin must be delivered in the form of an aerosol or introduced into the body through wounds, injection, or ingestion. One biological toxin that is unusual in this respect is T-2, a compound derived from some species of *Fusarium* mold. This compound is especially toxic to skin upon contact. It is not clear, however, if T-2 was ever produced or used in any form as a means of warfare, although it and other trichothecene mycotoxins are suspected as being the active ingredient in yellow rain.

Using Biological Weapons

One major difference between CW and BW is that biological weapons, all other things being equal, have much more delayed effects (measured in days to weeks), whereas CW agents cause injury and death much more quickly (measured in minutes to hours). One can think of BW as the use of infectious disease against an enemy. There is usually a certain latent or incubation period between exposure to microbes and the appearance of actual disease symptoms. Like CW agents, some biological toxins may have faster action than others, perhaps only hours to a day or so before the effects become known. Staphylococcal enterotoxin B (SEB), for example, has a relatively short latent period. In cases of SEB ingestion or inhalation, symptoms may appear in a matter of a few hours (or less). Botulinum toxin, on the other hand, requires 12 to 24 hours or more before it takes effect.

Theoretically, any disease or disease-causing toxin could be fashioned into some sort of weapon. (See the sidebar for a list of potential BW agents.) However, only a small percentage of disease-causing agents are practical for large-scale biological attacks on humans. Bioterrorism could also involve a number of disease-causing microbes (pathogens) or toxins, although attacks using these would probably be on a smaller scale.

Because BW is essentially warfare by means of infectious disease—public health in reverse—it is important in studying BW to understand how microorganisms or their toxins cause injury or death. Anthrax is often cited as a typical BW agent, and it has been used in acts of terrorism both in Japan and, with more success, in the United States. Again, the importance of the aerosolized dissemination route of exposure cannot be understated. Using *Bacillus anthracis,* the bacteria that causes anthrax, involves the production of anthrax bacterial spores. As opposed to the growing and dividing phase of the bacterial life cycle, spores are very similar in concept to seeds of a plant. Although not part of a reproductive cycle, the bacterial endospore (or spore) is a means by which a bacterium can ensure its own survival. When faced with a lack of food or when under other physical stress, spore-forming bacteria like *Bacillus anthracis* and *Coxiella burnetii* can convert from their growth phase into a smaller, more spherical shape that includes a very thick, protective outer wall. This spore can remain in a stage of hibernation until it finds another environment with nutrients, water, and more favorable conditions. For use in a weapon, these spores are produced in such a way that they can be easily disseminated in an aerosol.

When the victim breathes in anthrax spores, tens to hundreds to thousands of spores (data are incomplete with regard to infectivity in humans) are necessary to cause disease, depending upon the individual. (In the case of Q-fever, it may require fewer than ten spores in order to cause infection. The resulting disease, however, is much less serious than inhalation anthrax.) If they are of the right particle size, they can reach the alveoli in the lungs. Here, they may sit for a while and do nothing until picked up by special cells that pick up foreign matter. These macrophages will surround the anthrax spore and carry it to the nearby lymph. (The lymphatic system is a special draining system that the body uses to rid itself of foreign bodies and

pathogens.) In some instances, however, when the *Bacillus anthracis* spores infiltrate the lung, instead of being dissolved and drained from the body, the pathogenic bacteria begin to grow and multiply. These bacteria would ordinarily be captured and killed by the body's immune system. Disease-causing forms of anthrax, however, produce a protective covering (capsule) that prevents the body from effectively finding, fixing, and destroying them. Anthrax bacteria then excrete a toxin complex: one component, called protective antigen (PA), is connected to another part called the lethal factor (LF) component. PA binds with cell receptors in the body, allowing the LF toxin to gain entry into the host's cells. Cell damage and death due to the LF toxin causes the body to make a frantic effort to fight off the disease, bringing about severe inflammation and producing fever, nausea, vomiting, and swelling of tissues. Unless treated aggressively with antibiotics, inhalation anthrax usually causes death in humans if not caught in the early stages of disease.

Other bacteria, such as plague and tularemia, also cause disease by toxic elements built within their cellular structures. Plague, unless treated with antibiotics, is likely to be quite deadly, especially if inhaled as an aerosol. Tularemia also can be deadly, but with treatment most victims will survive this disease.

Also best delivered in aerosol form, viral BW agents cause disease as they take over the cellular machinery in the body and use these to replicate themselves. The viruses can continue to infect more and more cells, killing them as they go in some cases, causing various disease symptoms such as headache, fever, chills, and nausea. Viral BW agents include smallpox, viruses that cause severe bleeding in tissues (hemorrhagic fevers), and viruses that cause severe disease in horses (such as Venezuelan Equine Encephalitis) but also produce illness in humans. VEE virus, grown in fertilized chicken eggs during the Cold War, was an important BW agent in both the U.S. and Soviet biological weapons arsenals. This virus can also be grown in other types of tissue culture and can be prepared in dry powder form for wide dissemination as an aerosol. Although most individuals exposed to this virus will contract the disease, and the symptoms (flulike and worse) are severe, few will die from VEE infection. For use by militaries against large, well-populated targets, VEE virus can cause widespread incapacitation of the enemy forces and their civilian populations.

BW Defense

The first line of defense against BW is early detection of the toxin or pathogen. This is most likely to be accomplished by health care professionals and by laboratories designed to identify microbial diseases and related toxins. (In 2004, work was underway to detect aerosols at a distance and to define those that constitute a biological threat; however, these devices are still in the early stages of technical reliability.) Probably, the first sign of a BW attack would be actual cases of disease that are diagnosed by physicians in a hospital, clinical laboratory, or medical office.

Once the BW agent has been identified, the next course of action would include treating the individual patient but also starting an aggressive public health action plan to treat other possible exposures.

Some BW agents can be treated with vaccines if the exposure to the agent is detected early. Smallpox is a good example. Being a disease that is easily transmitted from one person to another, it would be critical to vaccinate anyone near or in contact with the victim. This can both protect those exposed individuals from smallpox infection and slow or stop the spread of smallpox in the community. Without adequate vaccination, smallpox could spread like wildfire and could rage out of control even with strict measures to keep people from traveling or interacting outside their homes and neighborhoods.

Vaccines can be used against anthrax and plague, although at present it is not certain how effective these would be against inhalation forms of either disease. Vaccinations also would have to be done well ahead of time, days or preferably weeks before the actual BW attack. Some toxins also have vaccines (toxoids) for protection against exposure, such as that used for botulinum. Again, communities need to have an accurate threat picture and adequate time before the actual attack for these to be successful.

In most cases, vaccines would be most critical for contagious BW diseases like smallpox, and to a certain extent plague (in its pneumonic form). Other BW agents, however, are not known to be contagious. Bacterial and rickettsial diseases are treatable with antibiotics. Viral diseases are for the most part not successfully treatable with chemotherapy, although some antiviral medications have been shown to be efficacious in some instances. But for most viral infections, all that can be done is to provide supportive care to the victim—fluid replacement, breathing assistance, and pain regulation. These can be quite effective in reducing overall mortality.

BIOPREPARAT

During the latter half of the twentieth century, the Soviet Union (and later, to a much more limited degree, Russia) possessed the largest and most advanced biological weapons technology and production infrastructure ever known. The Soviet organization known as Biopreparat was ostensibly devoted to civilian biotechnology. It was, in fact, the research and development arm for the Soviet military to produce biological warfare agents and munitions. Some open source documents provide glimpses into past Soviet activities in offensive biological warfare. Much of what is known from the open literature about the former Soviet BW program, however, is based upon the testimony of Soviet defectors, including Vladimir Pasechnik, Ken Alibek, and other participants in the Biopreparat program.

Biopreparat—a parallel entity to the Soviet Ministry of Defense (MOD), from which it obtained financing—was officially subordinate to the civilian Main Administration of the Microbiological Industry

(Glavmikrobioprom). Referred to as the Concern, Biopreparat during its 20 years of activity (from 1972 until about 1992) served as the main technology and manufacturing base for the antihuman biological warfare (BW) agents in the former Soviet Union. Although its charge was to conduct offensive BW research and development, Biopreparat also produced civilian pharmaceuticals and was the second largest manufacturer of antibiotics in the world.

The civilian nature of Biopreparat and its connection with military biology is not surprising. The creation of a civilian-styled organization for developing biological weapons followed a Soviet pattern established decades before Biopreparat was formed. For example, because of the endemic nature of plague (sometimes called Black Death) throughout the Eurasian continent, it was logical that Soviet scientists had developed an extensive antiplague system for disease monitoring and surveillance. Such a civilian-oriented system would actually have dual roles: public-health-related research into infectious diseases, and militarily useful work in developing biological warfare (BW) agents. By the 1950s, the semblance of an infrastructure—again, civilian, at least in outward appearance—for biological weapons development had already been established in the Soviet Union. Referred to in official-speak as Problem No. 5, offensive biological weapons research and development was carried out by these antiplague and related organizations.

By the end of its biological weapons program (1992), the Soviet military had weaponized several viruses: smallpox, Venezuelan equine encephalitis (VEE), and Marburg. In the development stage were other hemorrhagic fevers, including Ebola, Lassa, Russian spring-summer encephalitis, Argentine and Bolivian hemorrhagic fevers, and possibly others. Lethal bacteria in the Soviet biological weapons arsenal included an especially potent form of anthrax (*Bacillus anthracis*), with less deadly but still virulent tularemia (*Francisella tularensis*) and *Brucella spp.* bacteria. (The latter BW agent was later replaced by the incapacitating biological agent glanders, or *Burkholderia mallei.*) Another incapacitating agent, Q-fever (*Coxiella burnetti*), was also produced in the Soviet Union, but like *Brucella,* it, too, eventually fell out of favor as a weapon. According to Ken Alibek, work with botulinum toxin was conducted in the mid-1970s. But aside from their roles as assassination weapons (such as those developed by Soviet KGB scientists), little is known about the role of this toxin and others in the Soviet BW program.

Brief History of Soviet Biological Weapons

Following the establishment of the Bolshevik regime in 1917, the Soviet biological weapons program grew in fits and starts. Begun largely because of the great losses Russia suffered in World War I, especially from chemical warfare, it is likely that past experience with diseases (e.g., typhus) were was a deciding factor in the Soviet Union's starting the program. The Soviet BW program would be interrupted by Stalin's purges and by the rise of Lysenkoism (see below), and then it would be reborn with the dawn of new discoveries in genetics.

The Soviet biological weapons program can be roughly divided into two phases: 1) the initiation of a full-fledged biological warfare program in 1928, and 2) the resurgence in the pursuit of military biotechnology following Lysenkoism in the early 1970s. Serious efforts on the part of the Soviet Union to develop biological weaponry took place just after signing arms control agreements meant to stem such activity.

In 1928, Yakob Moiseevich Fishman recommended to Red Army Commissar Kliment Voroshilov that the Soviet Union initiate biological weapons development. That same year, the Soviet Union acceded to the Geneva Protocol of 1925, forbidding the use (albeit with many loopholes and exceptions) of chemical and "bacteriological" warfare. Similarly, in 1975, when the Soviet government officially ratified the 1972 Biological Toxin and Weapons Convention (BTWC), it had already begun a massive project for military biological research and weapons production. A year after signing the BTWC, an organization was formed by the Soviet government that would be tasked with biological weapons research, development, and manufacture: the All-Union Science-Production Association, or Biopreparat (Order No. 131, April 1974).

Prelude to Biopreparat: Lysenko

The Soviet Union's decision to reinvigorate its offensive BW efforts followed a period termed Lysenkoism—or the Russian pejorative *Lysenkovshchina.* Until the 1970s, Soviet scientists had to their credit many advances in applied and basic research. But in the field of biology, the Soviet Union had in many areas fallen far behind the West. This state of affairs could largely be blamed on one person, the Ukrainian-born agronomist Trofim D. Lysenko (1898–1976). Lysenko relied on extensive self-promotion to make up for a lack of knowledge in the scientific field in which he eventually chose to work.

After receiving a certificate in agronomy in 1925, Lysenko started his professional career as an agricultural technician in Azerbaijan. While Lysenko was growing a batch of peas, a *Pravda* (a Russian newspaper) correspondent took special note of the young scientist, impressed most of all by Lysenko's proletarian origins. Through means of journalistic hyperbole, Lysenko was suddenly credited with making a qualitative leap in agricultural technique: the ability to grow abundant yields of crops in the winter soil. Emboldened by this publicity, Lysenko went on to claim that winter wheat could be grown to fantastic yields if the seeds were exposed to cold temperatures and were planted in spring instead of autumn. He was made responsible for directing the planting of wheat in the collective farms, and exaggerated claims of his yields were widely distributed. But what would turn out to be disastrous methods of Stalinist collectivization would only make Lysenko all the more famous.

Based on his own inchoate understanding of the science and without diligent scruples, Lysenko then turned his sights on genetics. He would later claim that geneticists, and all of those who accepted Mendelian laws, were wreckers, enemies of socialism and therefore enemies of the state. With the unfailing support of Stalin (who had a talent for ruthlessness and who, like Lysenko, came from modest, peasant beginnings), thousands of Russian scientists who did not toe the official line—especially the geneticists among them—were subsequently arrested and sent to the infamous gulags (labor camps). Many more were simply ostracized. In 1953, when Watson and Crick published their groundbreaking research on the DNA double helix, some of this antigenetics campaign was halted. But Lysenko's opinions on biology, particularly his animus against modern genetics, continued to influence the country until at least the mid-1960s, and ultimately, its effects were still felt long after Lysenko's death.

In the early 1970s, the forceful personality of a well-regarded Soviet molecular biologist, academician Yuri Ovchinnikov, entered the battle over the future of genetic research inside the Soviet Union. Unlike Lysenko, who derided scientific knowledge drawn from other countries, Ovchinnikov read the foreign scientific journals and knew of the advances in Western biotechnology. According to Ken Alibek, who was former deputy director of Biopreparat until his defection to the West in 1992, Ovchinnikov "decided to resolve the crisis in Russian biology by appealing to the self-interest of the masters of our [i.e., Soviet] militarized economy. In 1972, he asked the Ministry of Defense to support a genetics program devoted to developing new agents for biological warfare" (Alibek, p. 41). If many top Soviet leaders were unimpressed by Ovchinnikov's proposals, President Leonid Brezhnev was highly receptive. After all, if the Soviet Union were falling behind in scientific technology—no less being surpassed by its nemesis the United States and its NATO allies—this would require decisive action.

That same year (1972), the Soviet Council of Ministers also convened the Interagency Science and Technology Council on Molecular Biology and Genetics (ISTCMBG). This council was comprised of leaders from within the Soviet military, the Academy of Sciences, and the Ministries of Health and Agriculture. Chairing this secret body was Vladimir Zhdanov, an accomplished microbiologist whose specialty was viruses. The post of deputy director was held by Igor Domaradsky. Domaradsky had earlier been the director of antiplague systems during the 1950s, and having expertise with plague (*Yersinia pestis*), he would play a critical role for later research into weaponizing the bacterium. (This was no mean feat. During the 1950s and 1960s, when the United States still possessed an offensive BW program, American scientists tried to devise a plague-based weapon but were unsuccessful.) Along with Biopreparat, these individuals and organizations would play a crucial role in the research and development of biological weapons.

Organizations and Laboratories within Biopreparat

In 1973, Biopreparat had been formally established under the code name *Fermenty* (Enzymes). Requirements for biological weapons research and development were set according to the decisions made by the ISTCMBG. Located in Moscow, Biopreparat was listed simply as Post Office Box A-1063. The first director, a lieutenant general at the time, was Vsevolod Ivanovich Ogarkov. Thus, the military biological activities of Biopreparat were informally known in Russia as "*Sistema Ogarkova,*" or Ogarkov's System. Despite its civilian trappings, Biopreparat's institutes and production facilities were actually run by the fifteenth Directorate of the Soviet Ministry of Defense.

Alibek, who had been the organization's first deputy director from 1988 to 1991, reported that Biopreparat was meant to be the primary production source of biological warfare agents in the event of a war footing or outright hostilities with the West. Thus, in peacetime, Biopreparat was mostly on a "standby footing." "Mobilization" facilities included the Scientific Design Institute and Factory of Biopreparations Complex in Berdsk, Novosibirsk, Siberia; the Scientific Research Institute of Microbiology in Kirov (now Vyatka), 150 miles southwest of Moscow; and the Center for Military-Technical Problems of Anti-Bacteriological Defense in Sverdlovsk (now Yekaterinberg). There were several other important elements of the Biopreparat network. The State Scientific Center of Applied Microbiology was located in Obolensk (about 60 miles south of Moscow). This facility was involved in biological weapons research, including the genetic manipulation of microbial agents and their testing in aerosol chambers. Established in 1974 during the height of the Soviet BW program, the Center had a staff of about 1,500 people, half of whom were research scientists.

The Center of Virology in Zagorsk (now Sergiyev Posad), was located 50 miles northeast of Moscow. According to Alibek, the Center produced smallpox to meet an annual stockpile quota of 20 tons. Based on a highly virulent strain obtained from an Indian smallpox patient in 1967, this weapon had a refrigerated shelf life of six months. In the event of a nuclear exchange with the United States, smallpox virus (and other BW agents) was to be loaded in liquid form in bomblets on the SS-18 intercontinental ballistic missile (ICBM).

The Institute of Immunological Design was located in Lybuchany (outside Moscow) and was under the direction of Vladimir Petrovich Zav'yalov. In the 1980s, this institute was charged with the development of tularemia vaccine and diagnostic testing kits.

The State Scientific Center of Virology and Biotechnology (Vector) was located in Koltsovo (Novosibirsk, Siberia). The Main Administration of the Microbiological Industry (Glavmikrobioprom) established Vector in March 1985. In the early 1990s, Vector had a staff of about 3,000. Vector is one of two official repositories of the smallpox virus, the other being the U.S. Centers for Disease Control and Prevention (CDC), in Atlanta, Georgia.

The State Scientific Institute of Ultrapure Biological Preparations was located in Leningrad (now St. Petersburg). This facility was a crucial link in developing a technological basis for weaponizing BW agents, particularly the creation of very fine aerosols. Under the leadership of Vladimir Pasechnik—who in 1989 would defect and reveal to the West many secrets of the Soviet biological weapons program—the Institute was involved in the manufacture of cruise missiles capable of delivering infectious aerosols.

The Scientific Experimental and Production Base was located in Stepnogorsk, Kazakhstan. Stepnogorsk is a Stalinesque town built largely for uranium mining, located in the otherwise desolate steppes of northern Kazakhstan. It also held the largest biological weapons facility in the world. Due to an accident caused by a release of anthrax spores at Sverdlovsk (now Yekaterinberg) in 1979, production of anthrax was moved to Stepnogorsk because the Scientific Experimental and Production Base possessed superior air handling capabilities and was in a remote location. During a time of conflict, tons of anthrax could have been produced there within two weeks. Built at an estimated cost of 1 billion rubles (approximately U.S. $1 billion), the massive complex of buildings, tunnels, bunkers, and 20,000-liter fermenters at Stepnogorsk has since the end of the Cold War been gutted and almost completely destroyed. What remained of the equipment and staffing was converted to a commercial enterprise to produce commercial products ("joint-stock company") in 1993.

In addition to the testing of a variety of other BW agents, including Marburg virus, the Stepnogorsk facility was charged with the manufacture of weapons-grade anthrax and plague. With advances made in the 1980s in producing virulent strains of bacteria, it was here that Alibek managed the development of the 836 strain of weaponized anthrax, probably the most lethal ever produced.

Also located in Kazakhstan near the Uzbekistan border was Vozrozhdeniye (Rebirth) Island. After 1952, this was the Aral test facility, Aralsk-7, a biological weapons proving ground for the Soviet military. Biological weapons testing at this installation was likely the cause of a smallpox outbreak in 1971 near Rebirth Island.

At its peak, Biopreparat had an estimated 40,000–60,000 personnel, with about 40 laboratories and production facilities spread across much of the former Soviet territory. Even during the Gorbachev years (1986–1990) of Perestroika, a five-year plan continued to weaponize the Ebola, Marburg, and smallpox viruses. As far as it is known, however, the biological-weapons-related activity and associated elements of Biopreparat have largely been disbanded.

BIOREGULATORS

Bioregulators, or bioregulatory peptides, are genetically coded chains of amino acids that are produced naturally in the human body and are essential for normal physiological functioning. These substances resemble toxins in their nature and action, and in technical terms can in fact be defined as toxins, in that they are "chemicals of biological origin." Though the role of bioregulators in controlling biological processes has only begun to be understood, their effects are known to range from the mediation of sensations such as fear and pain to the regulation of the body's vital signs, namely blood pressure, heart rate, and respiration. When present at inappropriately elevated levels (e.g., as a result of intentional introduction into the body), a bioregulator can overwhelm the body's compensatory mechanisms, and its actions can go unchecked. Potential consequences include the sensation of pain, loss of consciousness, altered blood pressure, and altered psyche. These consequences, although profoundly incapacitating, are generally not lethal, although death is possible under certain circumstances.

In theory, a bioregulator can be introduced into the body in one of two ways. First, it can be introduced by using well-established genetic engineering techniques; the gene that codes for the bioregulator can be inserted into a microorganism, which is then delivered into the body via injection, ingestion, or inhalation. Upon gaining entry into the body, the microorganism produces the bioregulator, and its effects are felt. Second, the bioregulator itself can be chemically or enzymatically synthesized in a laboratory. Once a quantity of the bioregulator has been produced, it can be delivered on its own, again via injection, ingestion, or inhalation, in the same manner that any other biological weapon (or pharmaceutical agent, for that matter) would be delivered.

Bioregulators lend themselves to rapid synthesis due to the abbreviated nature of their constituent amino acid chains, and commercial and scientific developments have made the production of various peptides possible on a large scale. For example, 4 million kilograms of NutraSweet—a simple peptide consisting of two amino acids, aspartic acid and phenylalanine—were manufactured per year in the late 1980s. Such production has become increasingly affordable, and the synthetic techniques employed further allow for the enhancement not only of a bioregulator's potency, but also of properties such as its activity and selectivity, all of which helps to create a powerful, highly specific, and potentially very dangerous analogue. Given both the production and manipulation potential of bioregulators, the future illicit development—and subsequent use—of these substances cannot be ruled out.

Research in the Soviet Union

Soviet bioweaponeers engaged in extensive research on bioregulators throughout the 1980s under the code name Project Bonfire. As reported during a conference of Soviet scientists in 1989, the project had been a success: the gene coding for the bioregulator myelin toxin, named as such by the Soviets for its ability to damage the myelin sheaths of neurons and thus disrupt nerve transmission throughout the body, had been identified and—through the application of advanced recombinant DNA techniques—inserted into the bacterium *Yersinia pseudotuberculosis.* In laboratory tests, this single agent caused both the symptoms of the pathogen and the paralytic effects of myelin toxin. Notably, *Yersinia pestis,* the causative agent of plague, is closely related to *Y. pseudotuberculosis,* suggesting the possibility of transfer of similar genetic material into this potentially contagious, lethal pathogen to create an enhanced and truly formidable biological weapon. It has been reported that Soviet scientists did in fact successfully perform such a transfer before the collapse of the Soviet Union, but that the agent was not developed any further. It is not known whether other bioregulators were researched within the former biological weapons program. It is known, however, that a number of other bioregulators were studied, ostensibly for peaceful purposes, in the Soviet Union throughout the later years of the Cold War and in Russia today.

Research in South Africa

South Africa's apartheid-era chemical and biological weapons program, Project Coast, may have investigated bioregulators. Although the claims are largely unverified and may, in fact, have been criminally motivated, it has been suggested by scientists within the program (and in particular by program leader Wouter Basson himself) that such research was performed at two separate locations: the large-scale chemical weapons research and development facility Delta G Scientific, and the clandestine laboratories of Special Forces headquarters. According to Basson, efforts at the Special Forces laboratory led to the successful production of a peptide derived from the human thymus gland (different thymic peptides exist, each with various actions: alpha-thymosin, for example, is active in the development of a beneficial immune response, and different types of beta-thymosin have been linked to cancer), as well as growth hormone and other unspecified peptides produced by the pituitary gland in the brain.

It is theorized that Basson may have provided this information to substantiate his own claim that he had spent a large amount of government money on a peptide synthesizer. This peptide synthesizer later could not be accounted for, leaving open the possibility that Basson embezzled the funds and that these peptides were never produced by the scientists of Project Coast.

Bioregulators of Importance

Though in fact comprising a very broad category of chemicals, for practical purposes bioregulators can be narrowed in spectrum, based largely on their action and amenability to synthesis, to those with biological warfare (BW) implications. A selection of bioregulators often referred to in a BW context is represented in Table B-1.

Table B-1: Select Bioregulators and Some of Their Effects

Type	*Prototype Bioregulator(s)*	*Primary Effect(s)*
Algogen	Substance P	Sensory transmission of pain
Endogenous opioid	Endorphins, enkephalins	Analgesia similar to morphine
Hormone	Vasopressin	Water retention, vasoconstriction
Endothelium-derived factor	Endothelin	Vasoconstriction

—Rich Pilch

BIOTERRORISM

Generally speaking, bioterrorism refers to the use of biological agents—microbial pathogens or toxins derived from living organisms—as a means of perpetrating some terrorist attack. This seems simple enough, although arriving at a noncontroversial meaning of the very word *terrorism* can be fraught with difficulty. The U.S. Federal Bureau of Investigation (FBI) defines terrorism as "the unlawful use of force against persons or property to intimidate or coerce a government, the civilian population or any segment thereof, in the furtherance of political or social objectives" (U.S. Code of Federal Regulations, 28 Section 0.85). Forming a textbook definition of bioterrorism is difficult. In discussing bioterrorism, though, it may be much less important what one thinks it is and more important to consider the political, psychological, and emotional impact that might be created by the use of the term to describe some disease outbreak.

The concept of bioterrorism might be seen as different from simple criminality involving pathogens or toxins; one might call these types of events biocriminality or malicious mischief. Unless there is some clear motive that speaks to a wider political or social statement, the simple act of murdering someone by using a biological agent is still technically a homicide.

Often mentioned in the context of bioterrorism is the assassination of the Bulgarian dissident Georgy Markov with ricin toxin. In 1978, the Bulgarian secret service (with technical assistance from the Soviet KGB) assassinated Markov while he was working in London. The motive: Markov had criticized the tyranny of the Bulgarian authorities on Western radio. In a more legalistic view, this state-sponsored assassination of a governmental critic does not fit the typical definition of terrorism. The salient aspect of this case, however, is the fact that a biological toxin—ricin—was used as the weapon. Thus, bioterrorism is often ascribed to many deliberate acts using biological agents, even if the actual purpose does not exactly fit the terrorist model.

Since the Markov case, there have been many other instances of ricin being involved with terrorist activity. Most notably, the Islamist terrorist organization al-Qaeda has instructed its adherents on how to produce ricin from the castor bean plant. In 2003, several terrorists linked with al-Qaeda were discovered in Europe with homemade ricin toxin. These individuals may have been planning attacks on civilians or soldiers by poisoning their food. They were probably interested in ricin because it is relatively easy to acquire, not because it has a great utility as a weapon of mass destruction. Aside from some instances when food or beverages could be contaminated and distributed to many people, ricin appears to be a weapon of choice for assassinating individuals.

A 1984 *Salmonella* bacteria attack in Oregon, and the attempts by the Japanese cult Aum Shinrikyo to use botulinum toxin and anthrax bacteria in the early 1990s (*see* Aum Shinrikyo), have been the most concerted efforts made by nonstate actors to use biological agents in the pursuit of some political agenda—that is, bioterrorism. No one died as a direct result of these biological attacks, although the Rajneeshee cult in Oregon was more successful in terms of actually carrying out a biological attack than Aum Shinrikyo.

The Rajneeshee, a religious organization that established itself in Wasco County, Oregon, made extraordinary efforts to create its own society. Led by an Indian national named the Bhagwan (Hindi for "God") Shree Rajneesh, in 1984 the cult sought to control the Wasco County political establishment by swaying upcoming local elections in its favor. The attack that followed in September 1984 was part of a plan to make as many as possible of the noncult population stay away from the polls, chiefly by means of giving them diarrhea. Cult scientists considered a number of different pathogens that cause diarrhea, including *Giardia lamblia,* a parasite that causes giardiasis, and *Shigella dysenteriae* (bacteria that cause dysentery). Both diseases can be serious, but with modern health care they are usually self-limiting. In the end, the cult's technical advisor in the use of such pathogens, Diane Ivonne Onang (renamed Ma Anand Puja) decided to use *Salmonella typhimurium,* a common cause of food poisoning. In November 1984, cult operatives took vials of *Salmonella* bacteria and contaminated food at supermarkets and restaurants. They especially singled out salad bars at local restaurants for adulteration. As a result of this attack, 751 people became ill with salmonellosis.

An especially disturbing aspect of this case was that this deliberate act of food poisoning was not discovered until at least a year later. Eventually, Oregon prosecutors were able to arrest most of the key operatives involved in the biological attack. But long before the criminal proceedings were to begin, the cult's political aspirations were ultimately defeated by more prosaic circumstances.

Some commentators in 2001 referred to the Oregon case as a terrifying incident (Miller, Engleberg and Broad, 2001, p. 14). However, although there were a large number of casualties, none died as a direct result of the attack. Perhaps the important lesson from the Rajneeshee case is that, instead of disseminating microbes that cause gastrointestinal upset, even more virulent or lethal toxins could have been used.

In Japan, another idiosyncratic religious organization called Aum Shinrikyo—led by a self-styled guru named Shoko Asahara (real name: Chizuo Matsumoto)—looked to biological weapons as part of its agenda for seeking power. Fascinated with technology that included weapons of mass destruction, Aum Shinrikyo cult members lashed out at their enemies, including the government of Japan. After failed attempts to win parliamentary seats as a political party in the early 1990s, Shoko Asahara and his henchmen looked to the apocalypse concept. Their outlook now became more of an Eastern version of that of the Charles Manson family, but with much greater resources at their disposal. From approximately 1990 until 1995, Aum Shinrikyo cult scientists attempted to isolate and culture a number of biological agents, with most of their efforts focused on botulinum toxin and anthrax bacteria (*Bacillus anthracis*). In at least 10 instances during those 5 years, Aum Shinrikyo attempted to disseminate botulinum toxin as an aerosol, and they sprayed bacterial spores of an innocuous strain of anthrax bacteria (sterne) in Kameido ward, Tokyo.

The reasons for Aum Shinrikyo's ultimate failure to cause any harm through their efforts at biological warfare (although they were successful in using sarin, a chemical weapon) are still debated, but several problems encountered by the cult have been identified. Aum Shinrikyo's forays into manufacturing botulinum toxin were doomed from the start because the cult isolated a species of *Clostridium botulinum* bacteria that was not specific for toxicity in humans. An assessment of the cult's attempt to disperse anthrax spores is more complicated. The cult has since admitted (on their revised Internet website) that it did deliberately attempt to spray aerosols containing anthrax spores in 1993, but it claims that it knew the type of bacteria being used was basically harmless. Perhaps the more important aspect of Aum Shinrikyo's biological experiment with anthrax is that it used a potentially devastating, albeit crude, delivery method for anthrax spores.

The events of 2001 involving anthrax bacteria being mailed in contaminated envelopes brought home to the United States the disturbing reality of the bioterrorist threat. It was possible to describe this as a bioterrorist act even before there was a clear understanding of who or what was behind it. In early October 2001, less than a month following the al-Qaeda terrorist attacks on the World Trade Center and the Pentagon, the U.S. Centers for Disease Control and Prevention (CDC) identified a case of inhalation anthrax in Palm Beach, Florida. Two days later, federal and local authorities determined that this unusual case of anthrax infection was the result of a deliberate act. At this point, little more information was available, but it has been labeled a bioterrorist event. This first victim of the anthrax letter attacks died soon after the diagnosis. Later, more victims of anthrax infection were identified, and their exposure to anthrax spores was also associated with contaminated envelopes.

Letters were included in the contaminated envelopes, implying that Islamist terrorists or those with sympathies to them were responsible for mailing the anthrax. But as of 2004, the investigation is still ongoing as to the perpetrators of these attacks. Because at least some of the anthrax spores were delivered in very fine particles, it was belatedly recognized that there were potentially lethal levels of contamination in U.S. Post Office buildings and the Hart Senate building in Washington, D.C. Eventually, twenty-two cases of anthrax were determined to have resulted from direct or indirect exposure to these mailed anthrax spores. Half of these cases took the form of inhalation anthrax; the other eleven victims developed the cutaneous form of anthrax infection. Five died from inhalation anthrax. The costs associated with sampling suspect letters, decontaminating buildings, and using X-ray irradiation of mail in Washington, D.C., and its environs (not to mention other public health interventions made) were estimated to be in the billions of dollars.

BLEACH

Chlorine bleach (hypochlorite) has long been the workhorse for the decontamination of chemical or biological agents. There is, however, the possibility that bleach could be used as a lung irritant. This would involve the mixing of bleach with other chemical compounds, perhaps in some sort of chemical weapon that generates toxic by-products.

Incidents involving bleach and the production of toxic gas have mostly occurred in hazardous materials (HAZMAT) accidents and not through deliberate action. In some industrial settings—including hospitals that employ rigorous cleaning protocols—bleach and acidic compounds (e.g., phosphoric acid) are both used to ensure near-sterile conditions. On occasion, workers have been known to mistakenly mix the acidic solutions with the bleach, thereby creating chlorine gas. So much chlorine gas can be produced in this manner that deaths have resulted. In even more mundane settings, including the storage and use of civilian chemicals, the warning for citizens not to mix bleach with ammonia when cleaning their houses is especially well founded. Combining bleach with ammonia produces extremely toxic compounds called chloramines that can cause serious injury or death.

There has been one instance reported of a deliberate attempt to produce chloramine gas. During the 1980s, Dean Harvey Hicks had been protesting against the U.S. Internal Revenue Service (IRS). According to Hicks's federal indictment, part of his protest involved the placing of a car bomb near an IRS building. The trunk of his car contained two large containers: one holding bleach, the other, ammonia. Federal prosecutors claimed that Hicks intended the car blast to mix the chemicals together to produce a toxic gas cloud. The explosives, however, did not detonate as planned.

Use in Decontamination

As an oxidizing agent—in simple terms the chemical addition of oxygen—bleach is effective in the neutralization of most known chemical warfare agents, although its role in decontamination must be weighed against its irritating effects on the skin and the damage it can do to some materiel. A Chinese military manual on chemical weaponry describes the action of bleach on sulfur mustard, a blister agent (vesicant): "For example mustard, after coming into contact with bleach [calcium hypochlorite] can cause a reaction, the mustard gas being oxidized by the bleach, the bleach itself being reduced, and the mustard is then transformed from its original nature, losing its toxicity" (Cheng and Shi, p. 73).

As evinced by its widespread use in community water treatment, bleach is particularly effective in the denaturing of microbial threats, including bacteria and viruses as well as protein-based toxins. (The defensive mechanism in human cells utilizes the oxidizing power of hypochlorite when dealing with pathogens, for example.)

In military settings, calcium hypochlorite and a mixture known as Super Tropical Bleach have been standard items in the decontamination arsenal. For the U.S. military, however, a less toxic alternative was introduced in 1999 in the form of the Improved Chemical Biological Agent Decontaminant/Decontaminating Agent: Multipurpose (ICBAD/DAM). Still, for maintaining areas where contaminated casualties are handled or infectious materials are disposed of, regular bleach is still employed because of its effectiveness and relatively low cost. The Chinese military recommends what it calls three-and-two mix, containing three parts calcium hypochlorite and two parts calcium hydroxide. Although they are quite effective for decontaminating surfaces, only very dilute solutions of these extremely caustic compounds should be used for the human skin.

BLOOD AGENTS

Often referred to as "systemic poisons" due to their perceived route of action, hydrogen cyanide, carbon monoxide, and phosphine and arsine gases, inter alia, have been traditionally referred to as blood agents. These toxic chemicals (such as cyanide) were noted to have affected not a single part of the body, but its whole. Writing in 1937, Augustin Prentiss noted: "The systemic toxic agents are those compounds which, instead of confining their dominant action to some particular organ or part of the body, usually near the point of impact, have the power to penetrate the epithelial lining of the lungs without causing local damage. They then pass into the bloodstream, whence they are diffused throughout the whole interior economy of the body and exercise a general systemic poisoning action which finally results in death from paralysis of the central nervous system" (Prentiss, p. 170).

The term *blood agents* is both anachronistic and a misnomer. Nonetheless, because of its widespread use in military parlance (if not in actual warfare), the term is used here simply out of convention.

Carbon Monoxide

One potential chemical warfare (CW) agent, carbon monoxide, could truly be called a blood agent by dint of its action on hemoglobin, the oxygen-carrying protein found in red corpuscles. Because carbon monoxide's binding affinity with hemoglobin is about 250 times more than oxygen's, low concentrations of carbon monoxide are capable of causing death by asphyxia. Coal-based heating systems with inadequate ventilation are responsible for many deaths every year due to carbon monoxide poisoning, and a common method of suicide is to leave an automobile engine running in an enclosed area, exposing oneself to the carbon monoxide in the car's exhaust.

Carbon monoxide has features that make it appear to be a plausible weapon of mass destruction. It has a moderate toxicity: death can occur following a 5- to 10-minute exposure to 0.5 percent concentration by volume. Being odorless, carbon monoxide also is insidious. However, carbon monoxide is gaseous at room temperature and dissipates far too quickly for efficient use on the battlefield. Terrorists could possibly find enough carbon monoxide on the open chemical supply market and mount an attack by directing the gas into large, enclosed spaces. Still, as a practical matter, it is difficult to conceive of using this compound in such a way that would produce mass casualties.

Carbon monoxide has rarely been used as a CW agent, at least not purposefully. Nonetheless, because conventional explosives can produce (among other gases) carbon monoxide, deaths due to asphyxiation following detonation of a shell could occur, especially in tight spaces. During the Korean War (1950–1953), Soviet advisors looked into allegations that the United States was using chemical weapons against North Korea and the Chinese People's Volunteer Forces. They determined that at least some of the deaths they examined were caused by carbonic gas (i.e., CO_2) from a large-caliber shell that had detonated inside a tunnel with inadequate ventilation. It is likely that carbon monoxide could have been responsible as well.

After World War I, French and German military chemists employed carbon monoxide in some fashion as a CW agent. One formulation that had some promise was a mixture of another blood agent, hydrogen cyanide (see below), with metal carbonyls. These are metallic compounds containing five units of carbon monoxide in each molecule, such as iron pentacarbonyl [$Fe(CO)_5$]. Although the metal carbonyls have a certain degree of toxicity, they also readily decompose and liberate carbon monoxide. Germany possessed a limited number of chemical munitions using carbonyls in tandem with other agents (such as phosgene) during World War II. Under the right circumstances, not only could these produce lethal concentrations of asphyxiating gas, but the use of carbonyls could also overcome the utility of protective mask filters used at that time, as they did not afford protection against carbon monoxide. As there are no indications that Germany used such munitions in World War II, however, no data are available as to their actual effectiveness.

Cyanide

Cyanide and related compounds have been recognized for centuries as toxic substances. In 1782, the Swedish chemist Karl Wilhelm Scheele first described the chemical formula for hydrogen cyanide (or hydrocyanic acid). Although the exact cause is not known for certain, it is widely believed that his sudden death in the laboratory four years later was as a result of working with this compound. According to one account, in 1813 a pharmacist suggested to the Prussian General Bülow that cyanide could be used on bayonets. (A similar story is told concerning Napoleon III having gotten this idea during the Franco-Prussian War.) In World War I, France was equipped early on with cyanide-filled artillery munitions. It did not use them right away, possibly out of concern that using chemicals by means of projectile weaponry was in violation of the Hague Convention (1899). Following the major gas (chlorine) attack by Germany at Ypres in 1915, however, such reservations quickly seemed irrelevant.

In 1988, some 5,000 civilians were massacred by a chemical weapons assault—including nerve and mustard—at Halabja in northern Iraq. This was a largely Kurdish-populated village that had invoked the wrath of Saddam Hussein's military during the Iran-Iraq War (1980–1988). Because of the placement and condition of the casualties seen in photographs following the chemical attack, some U.S. intelligence sources and media claim that hydrogen cyanide may have been involved. Such reports, however, are unsupported by strong corroborating evidence.

Today, because of its use in the chemical industry (e.g., in the production of acrylonitrile, a widely used polymer for plastics) and its potential diversion from the market for use in CW, hydrogen cyanide is designated as a Schedule 3 chemical for regulation by the 1993 Chemical Weapons Convention.

Still used in a variety of commercial applications, cyanide was once widely found in pesticide formulations to kill rodents, especially in barns and other large structures such as naval vessels. Before World War II, Germany employed the so-called cyclone method, using hydrogen cyanide adsorbed onto wood chips or another material. Held in canisters, their contents would be released when ready for use. In the interest of safety, this "Zyklon" rodenticide also employed a very noticeable warning odor, often imparted by chloropicrin or another substance that is immediately irritating to the nose. Zyklon B—commercially produced in Nazi Germany—was employed to massacre millions of Jews during the Holocaust. Needless to say, this preparation had no telltale odor in it to warn its human victims.

The toxicity of cyanide is chiefly due to its inhibition of an enzyme critical to the body's uptake of oxygen and energy for cellular metabolism, cytochrome oxidase. Its ability to suddenly block transmission of energy in the body has been likened to shutting off a water hose. East German military chemist Siegfried Franke has described the physiological effects of cyanide in humans: "Depending on the concentration, death from hydrocyanic acid intoxication occurs in 15 to 20 minutes; concentrations of 0.4 mg/liter are unconditionally lethal. With higher concentrations those affected fall dead immediately, or they stumble, struggle for air, and start to scream, the scream ending in a rattle. They fall to the ground and die after 3 to 5 minutes after a brief phase of convulsive movements. The color of the skin of the victims is red to violet" (Franke, p. 179).

East German and Chinese references also describe widened pupils as being symptomatic of cyanide poisoning, but U.S. literature downplays the significance of this symptom. Some important idiosyncrasies about hydrogen cyanide (HCN) and its effects are also worth mentioning here. HCN is often described as having a metallic odor reminiscent of almonds. Dangerous concentrations of HNC, however, are reported to dull the olfactory senses. Also, depending upon which source is referred to, it is estimated that up to half of the world's population is genetically indisposed to detecting the odor in the first place.

Hydrogen Cyanide

Of all of the recognized blood agents, hydrogen cyanide is probably the most likely chemical agent for use in warfare or terrorism. Still, HCN suffers from many of the disadvantages of carbon monoxide and other highly volatile compounds. It is liquid at room temperature, but just barely. HCN volatilizes so quickly that it can leave behind a congealed spot due to rapid dissipation of heat. Maintaining the concentration necessary to cause death (some twenty-five times that necessary with a nerve agent such as sarin) is a difficult task and was a technical problem that was never really solved during World War I. For example, Franke reports that France used some 4,000 tons of HCN in chemical attacks during that conflict—all with no appreciable result. This, Franke notes, would have "sufficed to kill about a billion people under the liquidation system of Himmler's death factories" (Franke, p. 176). With the advent of the highly toxic organophosphate nerve agents (e.g., sarin), HCN has fallen even lower in usefulness as a potential war gas.

Making the process of weaponizing HCN even more problematic is its notorious instability. Left to its own devices, HCN will spontaneously polymerize—reacting with itself chemically in a violent explosion. Metals, including cobalt and nickel in oxalate salts, have been used in attempts to stabilize this compound. During World War II, some Japanese soldiers were equipped with glass jars filled with liquid HCN that had been chemically stabilized with copper or arsenic trichloride. Although some were thrown at British tanks during World War II, it is unknown if any Allied soldiers were killed by these gas grenades.

Other nations, including the United States, Germany, and the Soviet Union, also spent much effort to find methods of effective HCN delivery. Though most of these attempts ended in failure, some aerial dissemination techniques were developed that could have had potentially devastating impact on the battlefield. During World War II, German military intelligence reported that ongoing Soviet trials, using HCN delivered at low altitude and from slow-moving aircraft, were apparently successful in creating lethal concentrations over large areas. The trick here, apparently, was to conduct these air sorties at sufficient heights and speeds to avoid being shot down by antiaircraft guns.

Terrorists might at some point attempt to devise means of delivering HCN, either in its original form (perhaps having been acquired through the chemical industry) or by producing it in vapors from a reaction between cyanide salts with acid. In 1995, Aum Shinrikyo cult operatives shut down the Tokyo subway by releasing sarin nerve agent, killing 12 and injuring about 1,000 people. Not long afterward, binary devices were discovered in subway restrooms. These contained one container full of cyanide salt, the other of dilute sulfuric acid, and they were rigged to combine their contents by means of a timer. The binary cyanide devices were discovered before they could do any harm, but they clearly demonstrated how terrorists could deliver HCN by using simple chemistry. According to witness accounts and intelligence reports, it is quite likely that al-Qaeda terrorist operatives have experimented with using such compounds. Video footage seized in Afghanistan in 2002, for example, showed what appeared to be al-Qaeda members using a compound that has similar properties to HCN in tests using dogs. Because sodium and potassium cyanide are sold worldwide in quantities of thousands of tons, particularly for the gold mining industry, there is no lack of precursor material. (As a consequence, the Australia Group lists both of these salts in the category of its voluntary controlled chemical lists.)

If medical intervention is timely, humans can survive even multiple lethal doses of HCN poisoning. Antidotes prescribed for cyanide poisoning vary depending upon the country. Generally speaking, the formation of methemoglobin from hemoglobin in the blood—the latter instrumental for carrying oxygen through the body—by sodium nitrite (or amyl nitrite) helps to scavenge cyanide from cytochrome oxidase, increasing the victim's chances of survival. Sodium thiosulfate is used to further remove cyanide from the body by means of other enzyme reactions (by combining free cyanide with sulfur to form relatively harmless thiocyanate). Modern protective masks also help to decrease the risk of cyanide exposure by means of a chemical barrier such as chromium (oxidation state VI), or preferably zinc, as inhaled Cr VI has toxic properties.

Cyanogen Chloride (CN)

Much of the toxic nature of HCN is also found in cyanogen chloride (CNCl), although the lethal concentration of cyanogen chloride is reported to be about double—that is, CNCl is about half as toxic—as HCN. The immediate effects of cyanogen chloride are quite noticeable, especially in the mucosa, with a very strong irritating effect on the eyes and upper respiratory tract. In World War I, the French military utilized a mixture of HCN and cyanogen chloride, called manguinite. The goal was to create such an irritant to enemy troops that they would remove their protective masks, allowing HCN to finish them off. Cyanogen chloride, and related compounds such as the bromide form, held some promise for U.S. military use in World War I, but these compounds were also quite unstable due to spontaneous polymerization.

Other Systemic Poisons

Two other compounds, arsine and phosphine gas (in older literature referred to as arseniuretted hydrogen and hydrogen phosphide, respectively), were investigated during World War I as potential CW agents. Phosphine has been used as a rodenticide, and arsine is also toxic, but neither proved to be very effective as CW agents. Some work was performed in the area of forming binary devices to use with these chemicals, however, possibly during World War II. According to Chinese military CW specialists, an unnamed country "experimented with an aerial bomb, one with a separate chamber containing magnesium arsenide and another holding sulfuric acid. When the bomb was to hit the ground, a firing pin broke a membrane separating the two components. When they mixed, a chemical reaction produced the blood agent arsine" (Cheng and Shi, p. 27).

Tetraethyl lead and related compounds can act as a nerve-acting poisons, probably affecting the brain stem, resulting in convulsions and death. Decades ago, tetraethyl lead was commonly added to automobile gasoline as an antiknock agent. Some catastrophic accidents in the 1920s underscored the fact that this was an extremely toxic compound, so much so that Germany's stocks of tetraethyl lead were scrutinized after World War II out of fear about their potential use as chemical weapons. Nowadays, its use in automobiles has largely waned, and it is no longer considered a likely CW agent.

BOTULISM (BOTULINUM TOXIN)

Due to the extreme toxicity of botulinum toxin, it was one of the first agents to be considered as a biological weapon. In a list compiled by the U.S. Centers for Disease Control and Prevention (CDC) that includes bacteria, viruses, and toxins thought to pose the greatest risk for use in a bioterrorist attack, *Clostridium botulinum* falls under Category A—that is, the level of highest immediate risk. Clostridial neurotoxins are among the most toxic substances known to science. Their inclusion as a high-risk agent in bioterrorism is due not only to the very high toxicity of botulinum toxin, but also to its past development as a weapon and its relative ease of production. Clinically, botulinum toxin has been estimated to be lethal at very small doses for the average adult when ingested. When aerosolized, the lethal dose when inhaled is approximately five times larger than the lethal does when ingested.

Botulism is a disease that paralyzes muscles due to a toxin produced by the bacterium *Clostridium botulinum.* The main categories of botulism in the context of infectious disease are those of food-borne illness (particularly among infants) and complications arising from wounds that become contaminated with *Clostridium botulinum* spores.

Food-borne botulism usually occurs when a person ingests the causative bacteria and/or the botulinum toxin, leading to illness within about 24 hours. Until the ultimate source is found, such individual cases are considered a potential public health emergency, as many other people could be affected as well, depending on the food source. Infant botulism occurs in a small number of children, probably because their digestive tracts at their early stage of growth are more susceptible to ingestion of *C. botulinum* (this is the concern that has prompted warnings against feeding honey to infants, as sometimes *C. botulinum* spores are found in honey). Wound botulism takes place when wounds are infected with *C. botulinum*—found in soils and other materials in the environment—and the bacteria then secrete toxin (note that the source of tetanus, *Clostridium tetani,* similarly infects wounds in this fashion). (For more about these three forms of botulism, see below.)

Botulism is not spread from one person to another. Symptoms of botulism include double vision; blurred vision; drooping eyelids; slurred speech; difficulty swallowing; dry mouth; and muscle weakness (flaccid paralysis) that starts at the shoulders, spreads to the upper arms, and descends through the body. In the instance of paralysis of the breathing muscles, an individual can stop breathing and die unless assistance with breathing (mechanical ventilation) is given. If administered early in the course of the disease, the antitoxin is effective in reducing the severity of symptoms. Most patients eventually recover after weeks to months of supportive care.

History

The U.S. military began a concerted offensive biological warfare program in 1941, proceeding to develop biological weapons over the next 28 years. During World War II, the United States worked primarily on botulinum toxin and anthrax bacteria while also studying other diseases for warfare such as brucellosis, psittacosis, tularemia, and glanders. During World War II, intelligence information indicated that Germany was attempting to develop botulinum toxin as a weapon to be used against Allied invasion forces. At the time the Allied work to defend against this threat began, the composition of the toxic agent produced by *C. botulinum* was not clear, nor was the mechanism of lethality in animals and humans. Therefore, the earliest goals of research on botulinum toxin were to isolate and purify the toxin and to determine its pathogenesis. As it happened, there was apparently no effort on the part of German military scientists to utilize botulinum toxin against potential invasions. But due to this early intelligence—and due to strict rules regarding the compartmentalization of this intelligence—the Allies produced some 300,000 doses of botulinum toxoid (vaccine) for D-Day troops in 1944. None of these doses were administered.

One of the more lasting legacies of the early botulinum toxin biowarfare research was the development of the botulinum vaccine that is used today. It was clear that the scientists working with large quantities of the toxin needed to be protected from possible laboratory exposures and that a vaccine would serve them as well as the armed forces at risk of biological warfare attack. A formaldehyde-inactivated toxoid (i.e., a toxin that has been treated so as to destroy its toxicity but retain its antigenicity) proved effective in animal studies, and large quantities were prepared for human use. Many humans have since been vaccinated with this and similarly prepared botulinum toxin vaccines, and clinical experience has indicated that the vaccines are safe and effective.

In 1992, Russian President Boris Yeltsin admitted to a biological warfare program that had existed in the Soviet Union and Russia until early 1992, and he stated that he was putting an end to further offensive biological research. Botulinum toxin was one of several agents tested at the Soviet site code named Aralsk-7 on Vozrozhdeniye Island in the Aral Sea. A former senior scientist of the Russian civilian bioweapons program reported that the Soviets had attempted splicing the botulinum toxin gene from *C. botulinum* into other bacteria.

Four of the countries listed by the U.S. government as "state sponsors of terrorism" (Iran, Iraq, North Korea, and Syria) have developed, or are believed to be developing, botulinum toxin as a weapon. Of these countries, Iraq has been the greatest source of concern. After the 1991 Persian Gulf War, Iraq admitted to the United Nations inspection team that it had produced 19,000 liters of concentrated botulinum toxin, of which approximately 10,000 liters were loaded into military weapons. These 19,000 liters of concentrated toxin are still not fully accounted for, and theoretically they constitute approximately three times the amount needed to kill the entire human population on Earth. Iraq chose to weaponize more botulinum toxin than any of its other known other biological agents. Following the invasion of Iraq in 2003, Coalition forces failed to find large quantities of botulinum toxin in Iraq.

Chemical Properties

C. botulinum is a gram-positive (classification of bacteria that absorbs gram stain), obligate anaerobic (requires environments without oxygen), spore-forming, rod-shaped bacterium found worldwide in soils and marine sediments. Because it is found in the soil, it can contaminate vegetables. It also colonizes the gastrointestinal tracts of fish, birds, and mammals. Botulism and botulinum toxin are not contagious and cannot be transmitted from person to person. Food poisoning due to botulinum toxin particularly emerged as a problem when food preservation became a widespread practice. It is now clear that *C. botulinum* grows and produces neurotoxin in the anaerobic conditions frequently encountered in the canning or preservation of foods. The spores are very hardy, and special efforts in sterilization are required to ensure that the organisms are inactivated and unable to grow and synthesize their toxin. Modern commercial procedures have virtually eliminated the problem of food poisoning by botulinum toxin (through pasteurization), and most of the cases now seen are associated with home-canned foods or with meals produced by restaurants not adhering to safe food handling practices.

Seven distinct serotypes (classification within species of pathogens based on immune response) of botulinum toxin have now been isolated, designated A through G. It is interesting that not all serotypes have been associated with poisoning of humans. Serotypes A, B, E, and F have been clearly identified in numerous human poisoning episodes. Serotype G is the most recently isolated toxin and has only been identified in a few outbreaks. For serotypes C and D, only a single anecdotal case of human poisoning has been reported for each. These serotypes have been found in outbreaks involving various animals, including chickens and minks in domestic settings and ducks in wild environments. It is not clear why humans are typically not poisoned by serotypes C and D.

Although the seven neurotoxins (A, B, C, D, E, F, and G) are genetically distinct, they possess similar molecular weights and have a common subunit structure. The complete amino acid sequences of the various serotypes are becoming known. Regions of sequence homology (sameness) among the serotypes and between botulinum toxins and tetanus toxin suggest that they all employ similar mechanisms of action. In the case of botulinum toxin, nerve cells are prevented from secreting acetylcholine—a neurotransmitter that allows for nervous impulses to be transmitted in the body—due to the inhibition of proteases, enzymes that break cell walls to allow for secretion of acetylcholine in this case. Thus, botulinum toxin serves as a means to prevent nerve impulses from actuating or enervating nerve cell transmission, a reverse of the activity done by the anticholinesterases (nerve agents).

Other Varieties of Botulism

Apart from the main forms of botulism, that is, food-borne, wound, and infant, the two other clinical categories are adult infectious and inadvertent (following botulinum toxin injection) botulism.

Food-Borne Botulism. Onset generally occurs 24 to 36 hours after exposure. Initial symptoms can include nausea, vomiting, abdominal cramps, or diarrhea. After the onset of neurological symptoms, constipation is typical. Dry mouth, blurred vision, and diplopia (double vision) are usually the earliest neurological symptoms. They are followed by dysphonia (difficulty in speaking), dysarthria (loss of muscle control in joints, including slurring of words), dysphagia (difficulty in swallowing), and peripheral muscle weakness. Symmetric descending paralysis as described above is characteristic of botulism.

Wound Botulism. This can be defined as clinical evidence of botulism following lesions with a resultant infected wound and no history suggestive of food-borne illness. Except for the gastrointestinal symptoms, the clinical manifestations are similar to those seen in food-borne botulism. However, the incubation period is much longer because time is required for the incubation of spores, growth of the bacteria, and release of toxins (taking 4–14 days).

Infant Botulism. This is caused by the absorption of toxin produced by *Clostridium botulinum;* the organism can colonize the intestinal tracts of infants under 1 year of age, but occasionally it also colonizes the tract in adults (rare). It is often associated with ingestion of honey, and the first clinical sign is usually constipation. After a few weeks, progressive weakness and poor feeding are observed. The weakness is symmetrical and descending; it evolves over hours or several days. The infant has a weak cry, has either absent or diminished spontaneous movements, and shows decreased sucking, floppy head, and decreased motor responses to stimuli. The autonomic nervous system manifestations include dry mucous membranes, urinary retention, diminished gastrointestinal motility, fluctuation of heart rate, and changes in skin color. Hospitalization is necessary and may last from a few days to 6 months.

Botulism as an infection in adults occurs as a result of intestinal colonization with *C. botulinum* and toxin production in a manner similar to that of infant botulism. These patients often have a history of abdominal surgery, achlorhydria (lack of necessary hydrochloric acid in the stomach), Crohn's disease (a chronic disease of the digestive system), or recent antibiotic treatment. The disease may simulate a Guillain-Barré Syndrome (a neurological disorder typified by weakness of the peripheral muscular-nervous system).

Medical Response to Botulism

There are two basic alternatives for prophylaxis from botulinum poisoning: active immunization using a vaccine (toxoid), or passive immunotherapy using immunoglobulin, an antibody that helps to neutralize the toxin. The vaccine currently available is a toxoid that protects from serotypes A through E. This material is being used under Investigational New Drug (IND) status, from a license held by the CDC in Atlanta. The toxoid was developed by scientists at Fort Detrick in Frederick, Maryland, during the 1950s. It is a formalin-fixed crude culture supernatant—meaning the toxin produced from the culture is made nontoxic with the addition of formaldehyde for use as a toxoid—from strains of *C. botulinum* that produce the respective serotypes. Vaccinations are administered at 0, 2, and 12 weeks, followed by annual booster doses.

In addition to a recombinant vaccine, that is, a vaccine produced in genetically modified organisms presently in development, research on cocktails of better and more specific (monoclonal) antibodies is being conducted at the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) at Fort Detrick, to replace the antibody from horse serum. The latter is despeciated horse serum. The antibodies produced by the horse are cleaved by special enzymes to avoid side effects (serum sickness) posed by horse-specific proteins. This antibody, while an improvement over previous antibody preparations, could stand further refinements. Thus the more specific and pure monoclonal antibody approach will enhance the safety of the immunotherapy, and recombinant techniques could also reduce the cost of therapeutic antibody.

Botulism can thus be prevented by the presence of a neutralizing antibody in the bloodstream. Passive immunity can be provided by the horse-derived botulinum antibody or by specific human hyperimmune globulin, antibodies from human sera. For longer term immunity, immunization with botulinum toxoid is required. Use of antibody for postexposure prophylaxis is limited by a lack of antibody and its relatively high risk of side effects. Due to the potential risks of equine antitoxin therapy, it is not always certain how best to care for persons who may have been exposed to botulinum toxin but who are not yet ill. In order to achieve a balance between avoiding the potential adverse effects of equine antitoxin and needing to neutralize the toxin rapidly, it is current practice in food-borne botulism outbreaks to closely monitor persons who may have been exposed to botulinum toxin and to treat them promptly with antitoxin at the first signs of illness.

In the United States, an IND for use as vaccine containing a pentavalent (addressing five of the serotypes, A–E) botulinum toxoid is supplied by the CDC to laboratory workers at high risk of exposure to botulinum toxin and by the military for protection of troops against attack. Currently, however, preexposure immunization is neither recommended for, nor available to, the general population.

Botulinum toxin ("Botox") is the first microbial toxin to become licensed for treatment of human disease. In the United States, it is currently licensed for treatment of cervical torticollis (muscular disorder of the neck), strabismus (crossed eyes), and blepharospasm (involuntary blinking) associated with dystonia (the general term for the neurological condition typified by involuntary muscular contraction). It also is used "off label" for a variety of more prevalent conditions including migraine headache, chronic low back pain, stroke, traumatic brain injury, cerebral palsy, and achalasia (muscular disorder of the esophagus). More recently, the medication Botox has been used as a means to decrease facial wrinkles by paralyzing certain facial muscles.

BRUCELLOSIS (*BRUCELLA* BACTERIUM)

A gram-negative (bacterium does not absorb gram's stain) coccobacillus (a short rod-shaped bacterium), *Brucella* comprises at least four types of bacteria that cause brucellosis in humans but is found nowadays mostly in domesticated and wild animals: *Brucella suis* (swine), *Brucella melitensis* (sheep), *Brucella abortus* (cattle), and *Brucella canis* (dogs). Named after David Bruce, who isolated the organism, brucellosis has been called Malta fever (it was widespread among British soldiers stationed there during the Crimean War), Mediterranean gastric remittent fever, or undulant fever. *Brucella* bacteria can infect humans by means of ingestion of contaminated milk or meat, as well as through broken skin. Workers in slaughterhouses have often acquired brucellosis due to contact with diseased animals and infectious aerosols. It is not surprising, therefore, that *Brucella* would be researched for their potential use in warfare.

As a BW agent, *Brucella* bacteria are notable for being among the first to be weaponized in a modern U.S. military program. The *Brucella* bacterium, however, is best described as an incapacitant (versus a deadly pathogen), because in this antibiotic era, the lethality of brucellosis is quite low (5 percent mortality or less without treatment). Both the United States and the former Soviet Union prepared *Brucella* bacteria for use in biological weapons. Later, both countries replaced this organism with other BW agents that proved more reliable.

History

In March 1944, according to the official history of the U.S. biological weapons program, the U.S. Chemical Warfare Service (CWS) undertook investigations into *Brucella* as a potential BW agent. (Other sources suggest that the utilization of *Brucella* bacteria was actually proposed two years earlier.) Although clinically, the bacterial species *Brucella melitensis* is most often associated with serious human infection, it also proved more difficult to grow and to keep virulent. Animal experiments conducted at that time using Guinea pigs also showed that much fewer *Brucella suis* bacteria were required to cause infection when disseminated as an aerosol. Thus, during World War II, the U.S. Army selected *Brucella suis* for weaponization.

Pilot production of bacteria commenced in summer 1945 at Camp Detrick, Maryland (later named Fort Detrick), after infecting laboratory animals and harvesting their bacteria-laden spleens. Bacteria were then added in small amounts and then gradually to larger vessels containing growth media, demonstrating the viability of large-scale production of *B. suis* bacteria with reasonable standards of quality and safety. It was also shown that bacteria could be grown and collected in a concentration of about 4×10^{10} organisms per ml, "which was acceptable as filling for munitions" (Cochrane, p. 270), according to the U.S. history of the program. Production of *Brucella* was halted in September 1945.

At the end of World War II, the technology of the day was limited to liquid suspensions of *Brucella*, with refrigeration offering the primary means of maintaining live bacterial cultures for weapons fill. Thus, when it came to a practical design for biological munitions, this organism was problematic as a weapon. When compared to other organisms such as anthrax, however—and even though *Brucella* bacterial cells do not form hardy spores—the organism performed rather well during aerosol tests. A cryptic reference to additional studies—the results being "both negative and faulty" (Cochrane, p. 270)—on the transmission of *Brucella* by canaries suggests that even more novel methods of disseminating this bacterium were investigated.

In 1949, a year before the outbreak of the Korean War, the U.S. Army Chemical Corps selected *B. suis* as the first standardized biological weapon in the American arsenal. In 1950 and 1951, preliminary tests using aerial munitions dropped from B-29s were conducted at Dugway Proving Ground, Utah. Validating field trials in 1952 eventually gave way to the first standardized biological weapon in the U.S. arsenal. This consisted of M114 bombs (108 of them) that were clustered in formation with the M26 adapter, and the weapon was named the M33 *Brucella* cluster bomb. It was provided to the U.S. Air Force. Up to sixteen of these clustered munitions were deemed necessary to cover a square mile of territory. Each M33 package weighed approximately a quarter ton. Because the bacteria required refrigeration, the ordnance proved to be a logistical nightmare. It was never used in battle.

***Medical Characteristics of* Brucella**

In an aerosol, *Brucella* bacteria are among the more infectious, requiring only 10 to 100 bacteria to cause disease in humans. There is some risk in developing countries from infection of food or beverages, the classic means of acquiring infection being from unpasteurized milk or tainted meat by-products. Its low virulence and the existence of a wide spectrum of antibiotics mitigate against a modern threat from brucellosis as a weapon. Its effects also are widely variable. Some people may be exposed but remain nonsymptomatic, but others may develop symptoms over 5 to 60 days after exposure.

Like other bacterial diseases found in BW contexts, brucellosis infection starts as a flulike illness, with fever, headache, chills, and general malaise. Up to three-fourths of victims may develop gastrointestinal upset, with nausea, vomiting, and/or diarrhea. In a small number of cases, infection of the heart and nervous system can result in very poor outcomes. Endocarditis, albeit a rare condition, has been responsible for 80 percent of the deaths that have occurred as a result of *Brucella* infection. With a predilection for disease of skeletal joints during its course, brucellosis can also lead to arthritis in more than 30 percent of cases. Transmission from person to person is not likely during the infectious stage of the disease. However, because of the capacity for aerosol transmission, laboratories should have in place relatively high containment standards, at least biosafety level 3 (BL-3) when handling the organism, one step below the highest containment measures (BL-4). Treatment of brucellosis involves antibiotic therapy, with doxycycline plus rifampin being recommended, or doxycycline and streptomycin as an alternative. Although (live) vaccines are used for animals, no prophylactic treatment is currently available for human use.

When compared to other BW threats such as anthrax, brucellosis is not expected to top the list of bioterrorist or BW threats for the modern battlefield. However, its endemic nature as a zoonotic in some regions of the globe may present a public health threat for operations conducted overseas. Also, one cannot rule out the possibility of the use of *Brucella* as an antianimal disease to cause disruptions in the agricultural sector.

C

C-4

During World War II, the British military had developed a high explosive that could be safely handled and shaped—thus the moniker "plastic explosive." One formulation contained RDX (Royal demolition explosive) and an oil-based plasticizer, the resulting product being dubbed "Composition C" by the United States. Later, a need was found for a plastic explosive that did not harden at low temperatures. A composition that used about 90 percent RDX, and small amounts each of polyisobutylene, motor oil, and another inert substance, was called C-4. Since its first development, C-4 explosive has found multifarious uses in military and civilian applications. Terrorists also seek out C-4 and high explosives of similar specifications.

CARBAMATES

The toxic carbamates are compounds sometimes equated with nerve agents. They get their name from their general structure, which is based on carbamic acid. These compounds can inhibit the body's enzymes (cholinesterases) that regulate neurochemical transmission. As in the case of the toxic nerve agents that contain phosphorus, carbamates probably bind at or near the same site of the enzyme's molecule, blocking its normal activity. When the body is no longer able to split apart the neurotransmitter acetylcholine, there is runaway chemical stimulus at the nerve receptors. This results in an imbalance in the body's nerve impulses, possibly resulting in death; carbamates could thus be technically considered nerve agents. Carbamate compounds, however, have not been developed as a weapon of mass destruction (WMD) as have the organophosphate nerve agents. Typically, carbamates act as so-called reversible inhibiters of cholinesterase, and therefore their poisonous effects are milder and more transient than those of the more toxic nerve compounds. Some carbamates are highly toxic in mammals, however, including one compound estimated to be 30 times more poisonous than sarin.

Applications for carbamates include the agrochemical industry (insecticides), medical applications (e.g., treatment of myasthenia gravis, an autoimmune disorder that affects nerve receptors), and defensive prophylaxis for nerve agent poisoning (see below). In the civilian chemical industry, Sevin(r) (or carbaryl) has been one of the most widely used of the carbamate insecticides, and it is not very toxic in mammals. Unfortunately, the mass production process used for this insecticide sometimes involves a reaction between methyl isocyanate and naphthalene. Due to what was probably insider sabotage at the Union Carbide plant in Bhopal, India, a massive release of methyl isocyanate killed thousands of people in the early 1980s (*see* Bhopal, India: Union Carbide Accident). Another carbamate, Aldicarb, is a commonly used insecticide, but it has relatively high mammalian toxicity for both oral and dermal routes. For experimental animals (e.g., rodents), the average lethal dose of Aldicarb is hundreds of times lower (meaning that Aldicarb is hundreds of times more toxic in mammals) than Sevin. In the potential application as a weapon of mass destruction, it is possible that terrorists could divert Aldicarb or other toxic compounds like it into some sort of improvised chemical weapon.

The toxic chemical in the calabar bean is physostigmine, a carbamate compound that was named in 1864. (A year later, other investigators also discovered the active ingredient, calling it eserine. Therefore, there are now two names for the same compound.) In western Africa, the calabar bean had been traditionally employed as a so-called ordeal poison for certain tribal deliberations and in witchcraft ceremonies. If someone were accused of a crime, for example, the subject would be given calabar beans to swallow, and if he or she survived, his or her innocence was supported. (One theory suggests that those who partook of the ordeal with calabar, if they were truly innocent, felt no compunction about proving it and gulped down the beans quickly. As a result, their now-upset stomach would induce vomiting, and the full dose of the toxin was not absorbed. Guilty subjects, however, would tentatively chew and eat each calabar bean one by one, ensuring that the full dose was ingested into the alimentary canal and intestinal tract. These subjects suffered severe poisoning and death.)

Carbamates have found a role in the medical pretreatment of exposure to nerve agents. In the United States and other Western countries, the pyridostigmine bromide (PB) has been used as a means to prepare the body to resist possible poisoning with nerve compounds such as soman (GD). Because PB is a reversible inhibitor of acetylcholinesterase (AChE), it can bind to the enzyme and protect it from permanent immobility from the irreversibly binding (and highly toxic) nerve agents. In the event of nerve agent exposure, the carbamate holds AChE enzyme in reserve, and eventually releases it back into the body to restore normal activity.

China has employed carbamates for nerve agent prophylaxis, using substances called *cuixing'an* and *cuixingning*. Chemical weapons experts in the Chinese People's Liberation Army claim that these compounds are more effective than PB in protecting troops from nerve agent intoxication, and this may well be the case. However, both cuixing'an and cuixingning would affect the central nervous system and could therefore degrade performance in soldiers. Pending full studies and safety evaluations, however, it is possible that these compounds might find their roles as pretreatment for nerve agent poisoning in the west.

During the 1991 Gulf War, Coalition forces were especially concerned about intelligence that indicated that Iraq intended to use soman nerve agent. (Fortunately, Iraq had difficulty in finding the chemical precursors to manufacture soman, which was later determined not to be in Iraq's chemical arsenal.) Because soman irreversibly binds to AChE, and furthermore does so in a very short time, PB was distributed to U.S. forces as a precaution in the event of an Iraqi chemical attack. There are conflicting accounts of how many U.S. soldiers actually took PB pills when ordered to, or what dosages were eventually consumed. In the early 1990s, PB was designated an Investigational New Drug for use against nerve agent exposure, and it was later approved by the U.S. Food and Drug Administration for such use in 2003. Claims made by some Gulf War veterans that PB is the source of health problems, namely the vaguely defined Gulf War Syndrome, are unfounded.

PB also is used in large doses for maintenance therapy in myasthenia gravis patients. Medical uses may be found for other carbamates such as applications for Alzheimer's disease, but these are only in the early research stages .

CENTERS FOR DISEASE CONTROL AND PREVENTION (CDC)

The Centers for Disease Control and Prevention (CDC) is the lead federal agency for protecting the health and safety of individuals in the United States and abroad. Located in Atlanta, Georgia, CDC is an agency of the U.S. Department of Health and Human Services. It provides information to enhance health decisions, and it promotes health through partnerships with forty-seven state health departments; twelve national Centers, Institutes, and Offices; and public health authorities in forty-five other countries. CDC's mission is to improve health and quality of life by preventing and controlling disease, injury, and disability. It accomplishes this mission by working with partners throughout the nation and the world to monitor health, detect and investigate health problems, conduct research to enhance prevention, develop and advocate sound public health policies, implement prevention strategies, promote healthy behaviors, foster safe and healthful environments, and provide leadership and training.

With heightened concern about the spread of emerging infectious diseases and the deliberate dissemination of biological warfare agents by rogue state and nonstate actors, CDC recently upgraded its efforts to fight against infectious diseases, with particular emphasis on emerging and antimicrobially resistant infectious diseases. It has prioritized international work to reduce and eliminate reemergent infectious diseases. And it continues to strengthen the capacity of local, state, and national public health agencies to respond to growing threats from biological and chemical terrorism. In 2003, CDC allocated more than $1 billion to improve the readiness of state and local health agencies to respond to events such as bioterrorism, infectious disease outbreaks, and other public health emergencies. CDC has prioritized improvements in the rapid detection of, investigation of, response to, containment of, and recovery from a terrorist attack or other public health emergency.

The CDC has categorized biological threat agents according to the overall impact in terms of illness and death, the relative ease of developing the agent as a weapon, the affect on the general public at large from a psychological perspective, and the flexibility of delivering the agent as a weapon (whether as an aerosol, food contamination, and so on.) The CDC considers the causative agents of smallpox, anthrax, plague, botulism, tularemia, and hemmorhagic fevers to be category A agents. Category B agents include causative agents of Brucellosis, salmonellosis, glanders, Q fever, ricin, and cholera, among others. Category C agents include emerging infectious diseases, such as Nipah and hantavirus, that could arise in the future to endanger public health if utilized by bioterrorists.

CHEMICAL AGENT MONITOR

The chemical agent monitor (CAM) is a detection device for toxic chemicals. The CAM and its successor, the improved chemical agent monitor (ICAM), grew out of defense research at Porton Down, U.K., during the late 1970s, and was later manufactured by Graseby Dynamics. (Similar versions are produced in the United States under license.) Although other detection devices exist that work along the same principles, the Graseby CAM is the preferred model in use by militaries and security forces around the world. Not only does it detect low levels of mustard (sulfur and nitrogen) and nerve (G-series and VX), but it also can indicate the approximate degree of contamination.

The essential part of this hand-held point detection device is a drift tube that detects ionized molecules of certain types and characteristics. Similar in some ways to a household smoke detector, air is brought into an inlet tube and passes near an ionizing source. As molecules from the air being sampled encounter either a radiation source (such as Americium or Ni^{63}) or an electric corona discharge (an electrical ionizing charge) in the device, these particles will become ionized. (Some countries such as Japan, because of local regulations concerning the use of radioisotopes, will only use nonradioactive ionization sources—that is, the electric corona version—for chemical weapons detection.) As the ions move down a drift tube, certain compounds arrive at the sensor in a sequence determined by their rate of travel. Should a nerve agent be present, its characteristic ion mobility will cause it to reach a sensitive electrode at a time and in a manner distinct from other chemicals in the air. This electrode will then send the signal to an amplifier, which in turn sends the signal to indicate a visual display or aural warning. Although some chemicals may confound this and other detection schemes, these devices are generally considered to be highly accurate and reliable when used correctly.

Early chemical agent point detectors, such as Russian and British CW agent alarms, monitored a chemical reaction created by the presence of a nerve agent. The 1968 vintage alarm standardized in the United States used an enzyme that, upon being demobilized by a nerve-type agent, sent an electric signal and warned the operator. Mustard gas was much less toxic and easier to detect in the field, notably by distinct odor. By the 1991 Gulf War, however, the U.S. and North Atlantic Treaty Organization militaries came to the realization that detection of both nerve agent and mustard in a single device was mandatory. A hurried requisition brought thousands of ICAMs from England that could detect the presence of both nerve agents and mustard. These devices have also been improved in terms of maintenance and reliability.

ICAMs are used "up close and personal" to the potential contaminated area when investigating possible chemical agent contamination, and they depend upon the volatility of CW agents for timely and accurate detection. Thus, low-volatility CW agents such as VX may be more difficult to detect in the field. It is generally considered necessary to be in full protective posture (such as U.S. MOPP IV—use of a protective suit and mask) when using an ICAM, the rationale being that the suspected presence of chemicals demands such precautions.

CHEMICAL AND BIOLOGICAL MUNITIONS AND MILITARY OPERATIONS

When people speak of weapons of mass destruction, a common perception is of nuclear weapons within the Cold War arsenals of the Soviet Union and the United States, or within emerging nuclear weapon states. Chemical and biological weapons, however, are an emerging challenge of the twenty-first century. They are easier to produce than nuclear weapons, easier to hide from arms control inspection and verification measures, and in some cases they can be easier to deliver, especially when done by irregular means (i.e., terrorist groups). Yet, they can still produce mass casualties. Some biological weapons have the potential to produce casualties similar in scale to a large nuclear attack. In the context of the post–September 11 war on terrorism, chemical and biological weapons seem to be terrorists' weapon of choice because the technological complexity of nuclear weapons leaves them beyond the reach of most nonstate groups. Understanding the threat posed by chemical and biological weapons demands an understanding of the weapons themselves, including the different types, their effects, and how they would be used operationally, either by a state or a nonstate group.

Chemical Weapons

Chemical weapons employ toxic chemical agents, in either liquid or gaseous form, to either kill or incapacitate. The weapons vary in their lethality, in their persistency, and in how they enter the body and how quickly their effects are felt. The types of chemical agents available for use vary in effect, but they can be broken down into four main groups.

Nerve Agents

Nerve agents are the most lethal type of chemical weapon and include tabun, sarin, soman, and GF (NATO code for cyclosarin). The most lethal ones are VX and the new Russian novichok agents. Most nerve agents are clear, colorless liquids; sarin and VX are odorless as well. Nerve agents inhibit the functioning of the body's central nervous system, and they can cause death within minutes of exposure to an extremely small amount of agent. These agents can be inhaled or can penetrate the body through exposed skin. Inhalation of nerve agent leads to effects beginning within a few seconds to 1 minute, whereas penetration through the skin may result in effects emerging in anywhere from 30 minutes to several hours. The lethal dose varies with each agent, but with all nerve agents, the dose is very small.

Nerve agents, like all chemical weapons, have varying degrees of persistency, which is the amount of time that the agent remains lethal in an exposed environment. Tabun, for example, has a persistency of about 1 to 1.5 days, sarin only has a persistency of about 2.5 hours, and VX can remain persistent for up to 6 days. Thus, any materials contaminated by highly persistent agents can remain dangerous for a long time, requiring a military force to undertake nuclear/biological/chemical (NBC) protective measures, including the wearing of cumbersome NBC suits and respirators. The forces must also undertake ongoing extensive decontamination of personnel and equipment, all of which imposes severe logistical and operational challenges for a military force when they are being subjected to attack. In comparison, nonpersistent agents can be applied to a specific area, inflict heavy casualties, and then become inert after a few hours, allowing an enemy force to exploit the "cleared" area to break through.

Common symptoms produced by exposure to nerve agent poisoning include nausea and vomiting, dim or blurred vision brought about by contracted pupils, excessive nasal secretions and salivation, and constricted airways leading to shortness of breath. If a large amount were inhaled, or if no treatment were applied within minutes of exposure, then loss of consciousness would ensue, followed by convulsions, eventual cessation of breathing, and, ultimately, death. A nerve agent that penetrates through the skin as a liquid may lead to muscular twitching, and were a sufficiently large dose absorbed through the skin, the result would be convulsions, paralysis, loss of consciousness, cessation of breathing, and, ultimately, death within minutes.

During the late 1980s and early 1990s, a new class of nerve agents was produced by Soviet scientists. Known as novichok (or newcomer) agents, these came in a variety of forms. These may have been designed as binary agents made up of two harmless chemicals that, when combined, become a lethal chemical weapon. The novichok agents are reportedly as lethal as VX and, in some cases, up to ten times as lethal. They are also far more difficult for current chemical agent detectors (CADs) to detect on the battlefield, and they are resistant to nerve gas antidotes such as atropine. This makes their use on the battlefield much more effective, even if an opponent is equipped with modern NBC defensive measures. Furthermore, because they are binary agents, they can easily be produced covertly within civilian chemical facilities, and thus are ideal for circumventing the 1999 Chemical Weapons Convention (CWC).

Pulmonary Agents

A second group of chemical agents, known as pulmonary agents or choking agents, are designed to attack the respiratory systems of victims. If inhaled, these agents attack the membranes of the lung, filling the lungs with fluid and preventing air from entering. The victim then dies from a form of suffocation described as dry-land drowning. Both phosgene and chlorine are pulmonary agents and were used during the First World War, but they are no longer considered very effective because they evaporate quickly and can only be effective if inhaled. NBC protective measures such as respirators can fully protect against such agents.

Vesicant Agents

Vesicant agents (also referred to as blister agents) produce similar effects to pulmonary agents, but they also affect both the skin and eyes through

Modern militaries constantly train and prepare in the event of a chemical or biological attack. (Hulton-Deutsch Collection/Corbis) burning. The most commonly known vesicant is mustard, which is an oily liquid of light yellow to brown color with an odor of garlic or mustard. Mustard produces no immediate pain or other effects. Thus, persons can be exposed to mustard for several hours without realizing that they are becoming severely exposed. Most blister agents are persistent; mustard, for example, remains dangerous in soil for weeks to years and on other materials for hours to days. Mustard is quickly absorbed into the body via inhalation and skin, causing extreme irritation of the lungs, airways, and eyes. Furthermore, this agent produces effects similar to radiation sickness, leading to cellular death and alteration of the DNA.

Other blister agents include lewisite, which produces moderate to severe pain on contact with the skin or mucous membranes (eyes, nose, mouth, and airways). Lewisite also rapidly kills tissue, resulting in a grayish appearance to the skin.

Blood Agents

The final group of chemical weapons is blood agents, which include cyanide gas. These agents are in the form of liquids that vaporize into a gas shortly after release. Large doses of blood agents such as hydrogen cyanide and cyanogen chloride interfere with the ability of cells to use oxygen. Their most immediate effect is on the ability of the brain to gain sufficient oxygen to function. An exposure to a large amount of hydrogen cyanide leads to sudden loss of consciousness, followed by convulsions. After about 3–5 minutes, the convulsions cease as breathing stops, followed by heart failure within 10 minutes. Blood agents are nonpersistent, but compared to nerve agents, they have a high lethal dose and can be volatile.

Biological Weapons

Biological weapons can use both pathogens (such as bacteria and viruses) and toxins to cause lethal or incapacitating diseases in humans. Since the terrorist attacks on September 11, 2001, a great deal of media attention has focused on the threat posed by biological weapons, with emphasis on agents such as anthrax and smallpox that are ideal for delivery by terrorist networks. The main concern is that such agents, pound for pound, are far more lethal than chemical weapons such as VX. Biological weapons such as pulmonary (inhalation) anthrax could be delivered by a crop duster aircraft as an aerosolized agent; the World Health Organization (WHO) estimates that were such an attack to occur over a city of 500,000 people, approximately 125,000 would be incapacitated and 95,000 would die within 7–10 days.

An even greater challenge is posed by viruses such as smallpox and pneumonic plague, which have a high epidemicity and thus generate very high levels of casualties. Officially, only two WHO stocks of the smallpox virus remain, located at the Centers for Disease Control (CDC) in Atlanta and at Vector Laboratories in Koltsovo, Russia. There is increasing concern, however, that clandestine stockpiles may exist in other states, including North Korea. Prior to the 2003 Iraq conflict, there also were fears that the regime of Saddam Hussein had experimented with camel pox virus, a pathogen closely related to smallpox, possibly as a model for testing the weaponization of the smallpox virus.

With incubation periods ranging from 7 to 17 days, and onset of illness likely after 10 to 12 days, an infected person could spread smallpox unknowingly to people in his or her immediate vicinity through aerobic respiration, or by direct contact and transfer of bodily fluids. In such a scenario, successive waves of infection would then spread out through the population until the "first generation" of victims began to show symptoms. By then, the epidemic would be underway and would be extremely difficult to contain. Smallpox has a 30 percent mortality rate; furthermore, it is physically disfiguring and extremely painful during the later stages of the disease. Smallpox vaccinations last administered in the 1970s are now ineffective, meaning that substantial numbers of people are at risk.

The most likely scenario for a smallpox attack would be the deliberate spread of smallpox in crowded areas such as airports, train and bus terminals, shopping malls, and cinemas. National and global transportation networks would then act as vectors to quickly spread the virus through a population. Such a scenario was considered in a U.S. government terrorism exercise known as Dark Winter that was run at Andrews Air Force Base, Maryland, on June 22–23, 2001. Postulating a smallpox attack on the United States during an international crisis, the participants dealt with a situation in which 3 million people were infected over a period of several months, more than 1 million people died of the disease, and the economic and strategic power of the United States were crippled.

The nature of most biological agents makes them difficult to use militarily. It can be challenging to deliver biological agents on the battlefield, and once delivered and exposed to the outside environment, such agents—particularly viruses—can be killed by sunlight and its associated ultraviolet radiation, or by heat, cold, moisture, and other hazards. There is also the issue of "blow-back," in which a biological agent infects not only enemy troops, but also friendly forces.

Some biological agents could be useful militarily if they could be delivered effectively. For example, Q-fever can be delivered in an aerosol from aircraft or cruise missiles equipped with spray tanks. Once delivered, the agent has an incubation period of up to 26 days. Q-fever incapacitates rather than kills, is very stable as an aerosol, and is very hardy in an external environment. Furthermore, Q-fever is persistent, remaining active for up to 60 days. Those infected will suffer from weeks of fever, headache, chills, weakness, profuse perspiration, respiratory problems, and chest, muscle, and joint pain. As a result of a Q-fever attack, the military effectiveness of an opponent could be substantially reduced. Other "tactical" biological agents include Venezuelan equine encephalitis (VEE) and staphylococcal enterotoxin B (SEB). The latter's effects last just hours, making it of potential use to break through an opponent's defenses or paralyze rear areas at a crucial point in a battle.

Faced with such a prospect, a military force can take protective measures through the use of protective suits and respirators (known as NBC suits; see above), chemical and biological agent detectors, and reconnaissance vehicles to rapidly identify CBW agents should they be released on the battlefield, and by ensuring effective medical responses to CBW casualties. Adequate intelligence and warning, combined with NBC defensive measures, can significantly reduce the effectiveness of an adversary's CBW attacks, though not without a substantial impact on operational battle tempo and overall combat capability. It is the continuing offensive-defensive competition within the field of CBW that is leading to the development of new chemical weapons such as novichok nerve agents and promoting the development of more effective biological weapons designed to undermine defensive measures or deliver greater lethal capability.

Genetically engineered biological agents are a new threat that emerged in the early 1990s. Information gained from Dr. Vladimir Pasechnik (a leading figure in the former Soviet Union's main biological warfare agency, Biopreparat, who defected in October 1989) alluded to Soviet development of genetically enhanced plague and tularemia. The "superplague" has a high epidemicity like smallpox, highlighting the horrifying potential of applying genetic engineering and biotechnology to biological weapons. Through genetic engineering, "legacy agents"—that is, BW agents that will remain viable for longer periods of time—can be enhanced to become more effective, to be resistant to antibiotics, to change characteristics and thus become harder to classify, and to have greater longevity when exposed to the natural environment. Genetically enhanced biological weapons can be made "smart" by being genetically targeted against those with a certain genetic signature (the so-called racial weapon often referred to in the media). Existing nonweaponized viruses such as Ebola and Marburg can be weaponized, and natural toxins, such as snake venom, could be genetically merged through recombinant DNA techniques with pathogens such as the common cold to create devastating new weapons taken directly from nature itself.

It is the potential for genetic engineering to create entirely new and very lethal bioweapons by combining several viruses to produce "chimera agents" that has caught the attention of the popular press in recent years. Former Soviet biological weapons expert Ken Alibek has claimed that Biopreparat created a variety of such agents, including a combination of smallpox and Ebola. Were such a weapon to exist, it could spread rapidly due to the nature of the smallpox component, but, unlike smallpox with its 30 percent mortality, it would exploit the characteristics of Ebola to inflict up to 90 percent fatalities on an infected population, with no vaccine or cure currently available.

The operational utility of superweapons such as an ebola-smallpox chimera or the superplague mentioned above is questionable for nation-state actors. Pasechnik suggested that such weapons would only be used in a total war scenario of mutual annihilation between superpowers, and, as such, they would count as strategic weapons systems. To twenty-first century terrorists, however, such weapons give small groups the ability to lash out at an entire society, or indeed at civilization itself.

On the horizon exists a new class of tactical biological agents known as bioregulators. These are incapacitating agents that are genetically engineered to alter and control the activity of natural bioregulators within the human body—substances that control hormone release, body temperature, sleep, mood, consciousness, and emotions. Delivered as an aerosol, such a weapon would alter bodily functions according to which bioregulators the weapon was designed to influence. Thus, an attacker could deny an adversary force the ability to sleep (thus impairing their functioning), affect their perceptions and mood (perhaps leading to an inability to make decisions effectively or to maintain command of forces), or more drastically, suddenly drive up their body temperatures or undermine their emotional stability.

Chemical and Biological Munitions

The delivery of chemical and biological weapons against unprotected urban areas can occur through irregular means, such as terrorism. If such weapons were be used by a military unit, however, they would need to be delivered by specific munitions for that purpose. These commonly include spray tanks that can be attached to the wing of an aircraft or housed in the warhead of a cruise missile, artillery shells and battlefield rockets equipped with some form of spray dispersal mechanism, and free-fall bombs or cluster munitions designed to break open nonexplosively over a target.

Chemical land mines have also appeared in the arsenals of the Soviet Union and the United States. The U.S. M-23 land mine, for example, contained 10.5 pounds of VX and was capable of acting either in an antipersonnel or antitank role. Longer-range delivery systems for biological weapons might include warheads designed to fit on long-range ballistic missiles. The Soviet Union developed refrigerated warheads for delivery of viruses at intercontinental range with SS-11 ICBMs in the late 1980s, and a dried agent dispersal system for microencapsulated anthrax and plague delivered by SS-18 ICBMs. Such systems have equal application to shorter-range ballistic missiles now appearing in the arsenals of many states, but the complex refrigeration and high-speed dispersal systems are likely to remain technologically challenging for these states. For longer-range attacks, a nuclear weapons capability may be easier to achieve than an effective biological weapons strike capability.

A key development in munitions designed to deliver chemical weapons—specifically nerve agents—was the emergence of binary munitions in the mid 1970s. Rather than handling very dangerous nerve agents (namely sarin and VX) in hollow shells and bombs, the nerve agent was divided into two separate precursor agents that were transported to the battlefield separately. Immediately before firing, the second precursor would be loaded into the weapon (which already contained the first), and once the weapon was in flight, the two precursors would mix, creating the lethal nerve agent. A range of binary munitions was developed, including 8-inch artillery shells and 500-lb. Bigeye free-fall bombs. Binary chemical munitions warheads for the multiple-launch rocket system (MLRS) and the Lance battlefield missile were planned but not produced.

Munitions designed to disperse CBW agents directly onto a target through a free-fall bomb or artillery shell are often described as point source weapons, and delivery systems equipped with a spray tank that allows a CBW agent to be dispersed perpendicular to the wind are described as line source weapons. When working with biological weapons, it is more effective to avoid any sort of explosive dispersal, because the heat and shock generated by an explosive warhead would kill a large proportion of most BW agents. Hence a line source delivery system, such as a spray tank, becomes more effective in delivering such weapons on the battlefield and can allow a wider area to be affected by an attack.

The most sophisticated BW capabilities involve the use of dried agent biological weapons: Rather than using the liquid form of a biological weapon, the agent is converted into dry, powdery particles about 1–10 microns in diameter, which can be more effectively dispersed through the atmosphere. These can also be much more easily inhaled, bypassing many of the human body's defenses, and thus producing a more lethal dose than with liquid agents. Furthermore, unlike liquid agents, dry agents can be stored for longer periods and can be more easily delivered with less sophisticated dispersal mechanisms.

CBW weapons are at the mercy of meteorological conditions, unlike conventional high explosive weapons or nuclear weapons. With chemical weapons, the temperature, wind speed, and potential for precipitation may determine whether or not a chemical attack is successful. The higher the temperatures in the air and on the ground, the quicker a chemical agent will evaporate, making some persistent agents such as VX less effective in dry, hot climates such as the desert. Rainwater can undermine the effectiveness of chemical weapons by diluting chemical agents, dispersing them over a wider area, and reducing the concentration. Obviously, wind speed and direction also play a vital role in determining where a cloud of chemical agent is moving, with higher winds demanding that a greater quantity of agent be employed to achieve a similar effect to smaller amounts on a calm day. With biological weapons, the most favorable time for attacks is at night, and at dawn and sunset. At these times, there is less sunlight to impact the biological agents; also, a layer of cold air above the ground will trap an aerosol cloud close to the ground while further minimizing the effect of sunlight on biological agents.

The challenge posed by chemical and biological weapons is becoming more apparent as new technologies make the weapons themselves more lethal and as the post–September 11 security environment makes more salient the prospect for WMD terrorist attacks. Chemical and biological weapons could become the weapons of choice for states that cannot acquire nuclear weapons but who are challenged by the technologically advanced conventional forces possessed by the United States and its allies. As the "poor man's atom bomb," chemical and biological weapons could be perceived by adversary states as a relatively low-cost force equalizer to U.S. military superiority and as a tool of coercion against neighbors. Genetically enhanced biological weapons in particular open up a Pandora's box of possibilities, and they merit increased consideration as the first truly twenty-first-century weapon of mass destruction.

CHEMICAL WARFARE

Chemical warfare (CW) is the use of toxic chemicals in battle. The term *gas warfare* is a throwback to World War I–era terms such as *poison gas,* because the earlier battlefield employment of chemicals was indeed in the form of gases. In the modern era, however, chemical compounds used in warfare or terrorism can take the form of liquids, solids, or gases.

As mass casualty weapons, chemicals cause death or injury by their poisonous effects. All CW agents have two main characteristics: they are very poisonous in small quantities (high toxicity), and they have physical attributes that are amenable for use in weapons on the battlefield. CW agents and their precursors are often relatively easy to manufacture and store.

Chemical weapons can be further subdivided into the CW agent—that is, the toxic substance itself in the form of solid, liquid, or gas—and the weapon used to deliver that agent (bomb, artillery shell, etc.). Thus, a delivery system such as an artillery shell becomes a chemical weapon when filled with CW agent.

Chemical terrorism refers to smaller-scale attacks upon civilians or governmental institutions, and, like CW, chemical terrorism is a rare occurrence. In 1994–1995, however, a political/religious organization called the Aum Shinrikyo (Sect of the Supreme

Truth) in Japan used sarin nerve agent, an extremely lethal chemical agent, in two major attacks that killed at least nineteen people. (The organic chemist involved, Tsuchiya Masami, received the death penalty, and a similar sentence was likely to be given for the cult's guru, Shoko Asahara.) Sarin is a standard military CW agent that was stockpiled by both the United States and the former Soviet Union during the Cold War. Tens of thousands of tons of CW agents are still in storage, mostly in Russia and the United States, but these stockpiles are scheduled for destruction under the terms of the 1992 Chemical Weapons Convention (CWC).

Although the basic idea behind CW is simple, in practice, a chemical attack against a modern military force is an extraordinarily challenging undertaking. One might think that, in this modern industrial era, there must be hundreds of toxic chemicals that could be effectively used as means of warfare. In actuality, though, few are effective enough to be used in a battlefield setting. During World War I, for instance, traditional poisons such as hydrogen cyanide (HCN) failed to produce mass casualties. Through deliberate scientific research and a good deal of trial and error, several basic threat chemicals have been identified that could pose a significant battlefield or terrorist threat: nerve agents (e.g., sarin), blister agents (e.g., mustard, lewisite), blood agents (e.g., HCN), choking agents such as phosgene and perfluoroisobutylene (PFIB), and psychoincapacitants (e.g., BZ or 3-quinuclidinyl benzilate).

History of Chemical Warfare

Even in prehistoric times, people may have employed irritating smoke generated by burning branches and leaves to ward off predators or to draw prey into killing zones. Some of the earliest written accounts of using poison as a form of warfare go back to as early as the fourth millennium B.C.E. in India. These involved snake venom being applied to the tips of arrows, as well as other toxins being used to cause discomfort and confusion among the enemy. Chinese writings going back at least three millennia, including the *Gunpowder Epic* (*Wujing Zongyao*) and other military classics, mention the use of toxic smokes (including arsenic) against enemy sappers (engineers who conduct mining to destroy fortifications, as well as to conduct de-mining operations). Various forms of incendiaries such as napalm have traditionally been placed under the rubric of chemical weaponry, although few would now consider this classification valid.

Producing toxic fumes, especially in confined areas such as tunnels, is one classic technique that could be accurately termed chemical warfare. Long ago, ancient armies burned sulfur and pitch to force the enemy to surrender, or simply to harass enemy forces. In the fourth century B.C.E., the famous Greek military strategist Aeneias Tacticus noted the utility of using smoke to deter the enemy from digging mines under one's fortifications. Written at about the same time, the Chinese historical record *Mo Zi* contains prescriptions for how to combine firewood, grass, reeds, and other combustibles to defend against enemy miners.

The mining technique was also employed in Roman times (approximately 190 B.C.E.). One Roman commander, Marcus Fulvius, attacked a Greek city by tunneling under the city's fortified walls. The Greeks (Ambraciots), however, deployed large pots of burning coal and feathers that produced, in addition to rather toxic fumes, a horrific stench. In this way, the Greeks were able to drive back the Roman miners. The Chinese *Gunpowder Epic* also mentions using arsenic, a very toxic metal, in making smoke bombs, and this technique may have been used in battle by 1000 C.E.

With the advent of chemistry as a scientific discipline and of modern industrial technologies, mass production and use of highly toxic compounds became an obvious way to inflict significant casualties on an opponent's forces. The chemical sciences developed and flourished in the Islamic world during medieval times. It was not until the eighteenth century, however, that the Industrial Revolution could bring economies of scale in the mass production of chemicals. In the nineteenth century, the famous chemist Michael Faraday, who pioneered the technique of liquefying gases, was asked by the British government how chemicals could be used as weapons against Russia during the Crimean War. Although his expertise told him that such an idea was feasible, he also found the notion repellent, and refused to have anything to do with it. It also was about this time that remarkable advances were being made in the field of organic chemistry, with its many applications being used in rapidly growing industries such as textiles, pharmaceuticals, and explosives.

World War I occurred at a time when Germany was leading this chemical phase of the Industrial Revolution. Although Europe and, to a lesser extent, the United States were well equipped with technical and industrial expertise to make great profits from chemicals, Germany had established an effective government-business relationship in its society that further enhanced its share of the chemical market.

The use of chemicals in World War I left an abhorrent image of helpless soldiers in makeshift gas masks struggling for breath, or ranks of soldiers blinded by mustard agent attacks. In reality, though, chemical weapons caused relatively few deaths and injuries compared to conventional weapons; when the war was over, chemical weapons had caused less than 4 percent of all casualties. Furthermore, the death rate from chemical injuries in World War I ran about 3 percent. For the United States, approximately 2 percent of the gas casualties died, compared to the 8 percent death rate from gunshot wounds during World War I. One could ask why CW has gained such a fulsome reputation when its use did not fundamentally affect the course of World War I, or, arguably, of any war since then. Richard Price (1997) offers the following explanation in his book, *The Chemical Weapons Taboo:* "Chemical weapons, which had been temporarily singled out during The Hague's grand deliberations on international arbitration and the law of war, became an effective scapegoat for the disillusionment with the promise of technology that followed World War I" (p. 165).

Classification of CW agents

CW agents are grouped within categories based on their effects on the human body. Traditionally these are listed as choking, blister, blood (systemic), and nerve agents. Other CW agent types exist—including riot control agents (RCAs), incapacitants, and compounds that destroy vegetation (herbicides)—but these are not usually included in the traditional categories. Not all of the ways in which CW agents poison their victims have been satisfactorily explained, although two main mechanisms are often at work in the toxicology (study of poisonous compounds) of CW agents: reactions with molecules in the body that directly or indirectly cause tissue damage, pain, and other effects; and the binding and blocking of larger macromolecules called enzymes that are vital for normal bodily functions. Enzymes are protein molecule-based structures that catalyze (i.e., speed up and reduce) the activation energy required for chemical reactions. Some CW agents have a tendency to come into contact with and bind or otherwise impair important enzyme functions.

Choking Agents

Choking agents or choking gases are those that irritate and injure the lungs, causing a buildup of fluid (edema) in the lungs and preventing the uptake of oxygen. Chlorine and phosgene, for example, are classic choking gases that were used during World War I.

The first major chemical assault that produced significant numbers of casualties was done by the German military in 1915 with chlorine gas (Cl_2), released from cylinders into a cloud that drifted with the wind toward the opposing military forces. In this case, the Germans utilized about 500 tons of chlorine gas made available from stocks provided by the German chemical (dye) industry. The chlorine was loaded into canisters under pressure, and as the chlorine was released from a liquid state into a gas, it mixed with moisture in the air and made clouds of chlorine-water mists.

When chlorine is inhaled, a combination of hydrochloric acid and hypochlorous acid is formed. In large enough concentrations, these caustic and irritating compounds damage lung tissue. Damage to the lung tissue causes blood plasma to infiltrate through the injured sites in the lung and to fill up the spaces left by the damage. The result of inhalation injury by this choking gas can be so severe that frothy, blood-tinged fluid builds up in the lung and is coughed up following exposure. Even with assisted breathing, the victim chokes on his or her own fluid (thus the term *choking agent*). In old military manuals, this was also referred to as *dry land drowning.* The classic 1918 poem by Wilfred Owen, *Dulce et Decorum Est*—written about a gas attack during World War I—specifically refers to the "choking" and "drowning" of such victims (quoted in Sidell, 1997, p. vi).

Phosgene, a commonly used chemical for civilian industrial processes, is a compound that can affect the body's enzymes and tissues. This choking gas, also used in World War I (1915), may not have had the overall impact of mustard or other agents, but did cause more deaths in proportion to overall injury during World War I (approximately 80 percent). At the molecular level, phosgene gas is breathed in the lungs, and can react with vulnerable chemical constituents in enzymes and tissues. Furthermore, phosgene reacts with water in the body to produce hydrochloric acid. In combination with its reactions with key chemicals in the lung tissues, phosgene makes injury worse by producing acidic by-products. The overall consequences of inhaling phosgene are similar to those of chlorine, but phosgene is many times more toxic.

Blood Agents

Blood agents include the important compound cyanide, or more precisely hydrocyanic acid (HCN). Cyanide blocks the utilization of oxygen in mammalian systems. Because cyanide has been a classic poison throughout history, its effects have long been noted. And as cyanide seemed to early observers to affect the entire body, and therefore was assumed to somehow affect the blood, it was described as a blood agent. One could say that HCN is an asphyxiant in a sense, stopping oxygen uptake in the body. Cyanide directly reacts with an enzyme complex, cytochrome oxidase (the suffix *–ase* indicates an enzyme), that moves oxygen and electrons along in a chain reaction. If enough hydrocyanic acid is introduced to the human system, cyanide will stop this chain of energy and oxygen transfer, resulting in death. Some have likened this poisoning event to shutting off a water hose at the source.

Despite HCN's high toxicity, it actually is not as toxic as many other compounds. And although HCN is in liquid form at room temperature, it evaporates so quickly that creating lethal concentrations in the open field is quite difficult. Due to its high volatility, or tendency to form a vapor, HCN is quickly dissipated by the wind and by other atmospheric conditions. French, German, American, Japanese, and Russian militaries in the past several decades, for example, all tried to develop HCN as a battlefield weapon without much success. Subsequent developments included cyanogen chloride, a more stable version of cyanide, and was stockpiled in small quantities by the major powers. Although this improved version appeared later in World War I, this development did not make much of an overall impact, as the weapon still suffered from many of the same drawbacks as HCN.

Blister Agents

Blister agents include the mustard and lewisite compounds that were developed in the years 1917–1918. Although mustard did not cause as many deaths in proportion to total casualties, the blistering and blinding effects of mustard were extremely potent on the battlefield. Mustard has been used in considerable quantity in at least three major wars: World War I, the Italian campaigns in Ethiopia (1935–1936), and the Iran-Iraq War of 1980–1988. In the latter conflict, an estimated 45,000 Iranians were injured, 5,000 of these fatally, by Iraqi use of CW agents. Most of these casualties were probably the result of mustard. Sulfur mustard is a relatively cheap and simple compound to produce, making it a likely CW agent. On the other hand, mustard is not nearly as lethal as are the nerve agents, and it is therefore unlikely to be a chemical sought by terrorists.

Mustard, at least until the development of the more highly toxic nerve agents, was considered the king of CW agents. Mustard is a rather thick or viscous liquid at room temperature, and it is less volatile than water. (Lightweight motor oil is a close comparative example to the physical properties of mustard.) For use against concentrations of soldiers in the field, mustard is most effective when delivered in the form of an aerosol (a suspension of very tiny droplets or particles that remain suspended in air for a significant period of time—fog is a rough equivalent to an aerosol). Mustard can be made into an aerosol by simply using an explosive charge in a shell or bomb that disperses the agent after a quick, violent blast of energy. The tiny droplets of mustard form a dense cloud of agent that presents two major threats: exposure via inhalation, and contact with the skin. Larger droplets that immediately fall to the ground are also a hazard: Shoes, garments, and equipment can become contaminated with the agent, and personnel can be exposed to these sources of mustard.

How mustard causes the blistering, irritation, and severe tissue destruction it causes is not exactly known. In 1985, however, Bruno Papirmeister and his colleagues at the U.S. Army Medical Research Institute of Chemical Defense hypothesized some very likely mechanisms of mustard poisoning in the human system. First, mustard (unlike water) can be absorbed through the outer skin layer. Second, the mustard molecule undergoes a change in its structure, becomes very reactive, and can bind (alkylate, or join on a molecular level) with key components in the structure of DNA. The nucleic acid guanine is particularly susceptible to reactions with the mustard molecule. This can cause breaks and errors in cellular DNA formation and repair, resulting in cellular death. (A similar process can take place in cases of ionizing forms of radiation.) Third, mustard can target other key components by chemically attacking the sulfhydryl (SH) groups commonly found in proteins and key enzymes. This process leads to the autolysis, or breakdown, of dead cells and their structures, reducing proteins and related compounds into smaller chemical components. Enzymes called proteases are released that break down cell walls and other cell parts that maintain the structural integrity of tissue. As the enzymes break down the cells into their basic components, including a substantial proportion of water, this results in pus-filled blisters. Depending upon the amount of exposure, blisters form about an hour or more following contact with mustard.

The eyes are especially sensitive to mustard, and exposure to this agent causes so much eye pain and itching that affected individuals must keep their eyelids shut. Permanent blindness caused by mustard-induced injury can occur, although most victims recover well enough to keep at least partial vision. Other areas of the body that are very vulnerable to mustard poisoning include the more delicate skin layers (epidermis) under the arms and in the groin. There can be severe irritation in the armpits, where the motion of the arms can aggravate the discomfort, and irritation in the groin area can make ordinary tasks such as walking unbearable.

The discomfort and tissue injury caused by blistering can leave permanent scars and requires a considerable amount of time to heal, but long-term side effects from single exposures to mustard are generally not life-threatening. Cancers and birth defects in children born of individuals exposed to mustard are possible, but they are most likely to occur in those who have routinely been in the presence of mustard, such as workers involved in its production over a period of months or years. Death from mustard can occur from contact with about two grams of this agent, such as the inhaling of a significant quantity of vapor. Mustard causes tissue damage in the upper respiratory tract, resulting in blockage of airways. Larger exposures can also involve the lower respiratory tree and the lungs. As in other cases of lethal CW agent exposures, asphyxiation is the direct cause of death.

Lewisite is another blister agent, and although it was produced in the United States in 1918, it was never used in World War I. Lewisite has some of the blistering effects of mustard, but it acts more quickly and produces immediate irritating effects. Lewisite has not been seen in many cases of actual warfare, and cases of human exposure are few. It is named after its inventor, W. Lee Lewis, who developed the compound as a "dew of death" in 1917. By the time large quantities were produced for use in battles, however, the war in Europe was nearly over. Because the molecule of lewisite is built around one atom of arsenic, it is classified as an arsenical-type agent. Lewisite is an extremely potent, irritating substance affecting skin and eyes, and it is also a significant inhalation and contact hazard.

Because lewisite freezes at a very low temperature, much lower than that of sulfur mustard, militaries such as the former Soviet Red Army often mixed lewisite with mustard for use in very cold weather. Not only would this mixture bring the freezing point down considerably below zero degrees centigrade, but the combined effects of both agents would also present a very dangerous contaminant for the battlefield. Lewisite poisons to a great extent by its ability to react with sulfhydryl (SH) groups in tissues, key enzymes, and amino acids such as glutathione. Lewisite produces redness, blistering, and irritation in human skin, and it also behaves as a systemic poison, causing further injury to various organs of the body. Although more toxic than mustard, lewisite is still far less deadly than the nerve agents. Therefore, although its military effectiveness is undoubtedly high, it is unclear what role (if any) lewisite may play in chemical terrorism.

Nerve Agents

Nerve agents were synthesized in the 1930s by both German and Allied (U.K.) scientists during World War II, although only Germany produced actual wartime stocks of these very toxic substances. In the later stages of the war (1944–1945), German military scientists produced large quantities of tabun nerve agent (apparently code-named after a nonsensical word). More commonly known nerve agents developed for use in CW are sarin and VX.

All nerve agents share the same toxic principle: Disruption of the biochemistry vital for normal function of the nervous system. These compounds have been used in the Iran-Iraq War (1980–1988) and in two major terrorist attacks in Japan during the mid-1990s.

Nerve agents were first created from investigative research into new insecticides based on organophosphorus molecules (those possessing carbon and phosphorus in their structures). In 1937, the German chemist Gerhard Schräder and his team synthesized a potential organophosphorus insecticide but found that it was highly toxic to mammals. A drop of the substance, later called tabun, fell on the laboratory table. Schräder and an assistant soon began to show signs of poisoning, including the classic symptom of pinpoint pupils (miosis). This compound was given to the German wartime government as a possible chemical weapon. During the 1940s, British scientists, notably Bernard Saunders, also experimented with nerve agent compounds, as well as with cyanide and other compounds with fluorine.

Nerve agents like tabun share in common a so-called leaving group, a chemical constituent of the molecule that leaves to reveal a reactive site. This site can react (phosphorylate) with susceptible groups in enzymes. The primary enzyme targeted by the nerve agent molecule is acetylcholinesterase (AChE). Normally, AChE performs the life-sustaining function of taking the nerve signal transmitter (neurotransmitter) acetylcholine and splitting it into acetic acid and choline, both of which are recycled by yet another enzyme to form acetylcholine again later when needed. AChE splits acetylcholine at a rate of hundreds of molecules per second. This enzyme not only provides for muscle fiber flexing, but also for fluid excretion and normal breathing, among many other bodily functions. If this enzyme is blocked or inhibited, levels of acetylcholine will continue to rise. This sets off a series of events that leads to death by respiratory arrest, either due to exhaustion or, more likely, asphyxiation by accumulating mucous and saliva in the airways. Thus, despite their very different mechanisms, nerve agents can also produce "dry land drowning" as does chlorine in the classic sense of "gas warfare."

Nerve agents are extremely toxic even when compared to other CW agents. All nerve agents are liquid at room temperature, but different types of nerve agents vary in their volatility. As with mustard, high concentrations of nerve agent are best delivered through the use of aerosols. VX nerve agent does not evaporate very quickly, much less so than mustard, but sarin, a nerve agent used on the Tokyo subway by terrorists in 1995, volatilizes at about the same rate as water. Therefore, although militaries would use nerve agents as aerosols to maximize their effectiveness in the field, terrorists may employ simpler, even crude methods of delivery.

Other CW Agents

Incapacitants

A number of compounds have been developed to harass rather than kill the enemy, thereby making opposing soldiers a less effective fighting force. A nonsubtle form of this is the use of riot control agents (RCAs), commonly referred to as tear gas. Usually, these compounds are not very toxic (certainly less poisonous than other CW agents), and they are meant to cause discomfort to the enemy. Chloracetophenon (CN) is a liquid agent developed during World War I, and although it was produced too late for use in that conflict, it has been used since then. In large concentrations, CN is quite toxic, but in smaller doses it usually only causes irritation to the nose, throat, and especially to the eyes (thus the term *tear gas*). Mace is a commercial product that uses CN for civilian, personal protection.

Most often used in modern times is CS, a crystalline substance that is usually delivered as a powdery aerosol, but also can be used in the form of a thermal vapor. Although CS causes much more immediate and severe discomfort to the eyes, nasal passages, and upper respiratory tract than CN, CS is less poisonous than CN in terms of general toxicity. Therefore, governments and their police agencies sometimes use CS against civilians to quell riots or prison disturbances. Using CS to encourage unruly mobs to disperse is considered to be more humane than using clubs or bullets to restore the peace.

BZ is a very potent incapacitant that was once a part of the U.S. chemical arsenal. This drug actually belongs to the same group of compounds as atropine, although BZ is significantly more potent, causing severe (although temporary) mental disturbances when administered. Persons intoxicated with BZ will have distorted perceptions of visual and other sensory realities, as well as altered states of situational awareness. The distortion of mental behavior may last for several hours to a few days, but it usually goes away without lingering effects. Its unpredictability as a weapon was a major reason the U.S. military decided to get rid of its BZ stocks in the late 1980s and early 1990s.

Herbicides

No longer part of U.S. military strategy (except for use in specific tasks such as clearing vegetation around airfields), herbicides such as weed killers were used by the British army in Malaysia in the 1950s and to a much greater extent in Vietnam by the U.S. Air Force. The main targets of herbicides are plants and trees that may give cover to the enemy, as well as crops grown by the opposition for food. Although herbicides only attack plants, by assaulting enemy food supplies one could indirectly consider the use of herbicides as a form of CW. One of the most effective herbicides, 2,4-D (2,4-dichlorophenoxyacetic acid) formed the significant portion of Agent Orange, the mixture (2,4-D and 2,4,5-T) used in Vietnam by the U.S. military.

As a so-called growth regulator, 2,4-D kills plants by inducing changes in their growth cycle, and it is nontoxic to mammals. 2,4-D is still commonly used today and can be found in local nurseries and hardware stores. Many U.S. Vietnam War veterans claimed injury due to a contaminant in Agent Orange used during the war, dioxin (2,3,7,8 tetrachlorodibenzo-*para*-dioxin). Although dioxin was present in Agent Orange as a by-product of its production, no scientific study has yet proven a causal link between dioxin and disease in humans.

Treatment of CW Agent Casualties

Some CW agents and their injuries are treatable, but others lack effective remedies besides supportive care. Mustard poisoning, for example, is still not effectively treatable once the agent has absorbed through the skin surface or respiratory tissues. Advances in supportive therapy, however, including the use of antibiotics to keep bacterial infections in check, have increased the likelihood of CW survival. Lewisite has a standard treatment that attempts to take out arsenic through a process called chelation. Still, the so-called British Anti-Lewisite (BAL) treatment has yet to be proven fully effective as an antidote for lewisite poisoning. Given a timely medical response, antidotes for cyanide poisoning are effective. One method involves using a drug (amyl nitrite) to induce a chemical change in hemoglobin, the oxygen-carrying component in the blood. This change in the structure of hemoglobin, now called methemoglobin, attracts the cyanide molecule to the hemoglobin much faster than it would otherwise bind to cytochrome oxidase. This forms a harmless molecule (cyanomethemoglobin) complex that the body can safely process, keeping free cyanide from interfering with the cytochrome oxidase oxygen transport system.

Nerve agents are the most toxic and lethal CW agents thus far devised for use as weapons. Fortunately, there exist effective treatments for nerve agent intoxication. The first line of defense against nerve agent poisoning is a drug called atropine. This compound has been used for centuries in various ways, one of these being to cause the dilation of the pupils in the eyes. At one time, it was very fashionable in Europe for women to have dilated pupils, and extracts such as atropine from the belladonna group of plants were used for this purpose. Today, atropine is used to widen pupils during eye examinations. This drug and others like it are still referred to as the belladonna group of compounds, from the Italian for beautiful (bella) lady (donna).

To a certain extent, the effects of atropine counterbalance those of nerve agents. Nerve agents block or inhibit the function of acetylcholinesterase (AChE) enzyme, resulting in an increase in acetylcholine molecules. This acetylcholine continues to stimulate receptors in the nervous system, causing exhaustion in the muscles used for breathing, changes in heart rhythm, and secretions in the throat that can asphyxiate the victim. Atropine, on the other hand, is a so-called anticholinergic compound that partially blocks receptors in the nervous system, protecting them from excessive levels of acetylcholine stimulation. Although atropine does little for the involuntary twitching in skeletal muscles caused by nerve agents, it does help to dry up secretions and restore some normalcy to the rest of the system. Longer-term treatment for nerve agent exposure may also include chemical compounds called oximes. These help restore the normal activity of AChE by releasing the enzyme (via dephosphorylation) from its bonds to the nerve agent. Oxime treatment in conjunction with atropine increases the chances of survival for those exposed to nerve agents.

Additionally, pretreatment for nerve agent exposure can be effective in protecting against intoxication. In some instances, militaries may gather intelligence indicating that an enemy plans to use nerve agents in battle. Soldiers then can be prepared by taking one of a family of drugs called carbamates. Carbamates, such as pyridostigmine bromide, actually behave somewhat like nerve agents: Carbamates can bind themselves with AChE, but they do so only temporarily, forming reversible complexes. In the event of nerve agent exposure, lethal nerve agent molecules now have to compete with the carbamates already in the system. Because carbamates only loosely attach themselves to AChE, the enzyme is eventually released back to normal function while the nerve agent molecules are gradually cleared (detoxified) from the system. Carbamates are especially recommended if nerve agents like soman may be used against one's military forces. Soman, more than other nerve agents, has a tendency to bind permanently and block AChE, making the protection of available enzyme by the use of carbamates even more desirable.

CW Agents and Terrorism

Terrorism can be generally described as an act of political violence aimed at a government and its citizenry. Most terrorist acts—car bombs, hijacking of aircraft, and assassinations—still employ age-old techniques and devices including explosives, bullets, and sharp instruments. Also, most terrorist attacks are not intended to cause mass casualties, but rather to create destructive events that may cause death and injury in spectacular fashion. Often, terrorists have wider political goals in mind, such as the formation of a separate country (separatist movements), removal of what is perceived as an occupying power, or criminal activities. The act of violence itself, rather than trying to directly attack an enemy, is an attempt to make a larger impact by frightening, bullying, or causing a government and its people to feel insecure.

There are examples of terrorists using chemical weapons, but these are actually rather few in proportion to the many acts committed during the past century or so. The numbers of deaths and injuries from chemical weapons in terrorism have also been relatively low, especially when one considers the potential impact that large amounts of chemical agents could actually create. It is unclear, furthermore, why terrorists would use chemical weapons if other more proven methods—explosives, bullets, or knives—have achieved their goals.

Chemicals, nevertheless, may represent a notable and fearsome weapon in the arsenal of the terrorist, with an impact that goes beyond just numbers of casualties. CW agents can act as silent and unseen killers, further adding to the mystique sought by terrorists.

CHEMICAL WEAPONS CONVENTION (CWC)

The 1993 Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on their Destruction (known more simply as the Chemical Weapons Convention, or CWC) entered into force on April 29, 1997 as the first verifiable treaty to ban an entire category of weapons of mass destruction. As of January 11, 2003, 148 nations had formally ratified participation in the Convention by their governments, or simply acceded, and 20 had neither signed nor ratified it. Among states of particular interest, India, Iran, Pakistan, Sudan, and states that made up the former Yugoslavia (Bosnia and Herzegovina, Croatia, Serbia and Montenegro) are parties to the treaty. Egypt, Iraq, Libya, North Korea, and Syria are among the nonsignatory states. Israel has signed but not ratified the treaty. (The reasons for Israel's nonratification and the refusal of some Arab states to sign the CWC are generally related to broader political considerations, such as the political linkage between chemical and nuclear weapons. Some states in the Middle East have indicated that they will not ratify the CWC until Israel becomes party to the Nuclear Nonproliferation Treaty.)

Definition of a Chemical Weapon

The CWC defines a chemical weapon as essentially consisting of one or more of three elements: (1) toxic chemicals and their precursors in a type and quantity not consistent with the object and purpose of the treaty, (2) munitions and devices that are specifically designed to cause death or harm through the use of such chemicals, and (3) any equipment specifically designed for use directly in connection with the employment of munitions and devices specified in (2). A key element in the CWC's definition of a chemical weapon is the fact that it bans the production, development, stockpiling, and use of *all* toxic chemicals and their precursors except when used for peaceful purposes. This so-called general purpose criterion is incorporated in the definition of a chemical weapon. The reasoning behind it is to ensure that chemicals not listed in the CWC's Annex on Chemicals are still prohibited as a means of warfare, while also taking into account any relevant future technological and scientific developments that could be utilized in chemical weaponry. The definition was structured so as to assist in the verification of destruction of storage tanks, unfilled munitions, and binary chemical weapons components.

Background

The main international legal instrument dealing with chemical weapons prior to the CWC's entry into force was the Geneva Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous, or Other Gases, and of Bacteriological Methods of Warfare (the Geneva Protocol, 1925). The Geneva Protocol did not, however, prevent the stockpiling of chemical weapons. Furthermore, many of the major powers attached conditions to their instruments of ratification: for example, provisions that a state would not consider itself bound by treaty obligations if first attacked with chemical weapons, or if it were involved in a military conflict with nonsignatory states or with military coalitions that included one or more nonsignatory states.

Other agreements regarding chemical weapons include the International Declaration Concerning the Laws and Customs of War, signed at the Brussels Conference of 1874; the conventions signed at the First International Peace Conference (The Hague, 1899) and the Second International Peace Conference (The Hague, 1907); the Treaty of Peace with Germany (also known as the Treaty of Versailles, signed on June 28, 1919); and the Treaty of Washington of 1922, Relating to the Use of Submarines and Noxious Gases in Warfare (signed in Washington, D.C., on February 6, 1922).

Groundwork in CWC negotiations began in 1968 within the framework of the UN Eighteen-Nation Committee on Disarmament (the present-day Conference on Disarmament). Discussions on a treaty banning biological and toxin weapons were conducted separately from those concerning chemical weapons and resulted in the 1972 Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Bacteriological and Toxin Weapons and on their Destruction (the Biological and Toxin Weapons Convention, or BTWC).

The CWC was negotiated within the context of the Cold War. The United States and the Soviet Union negotiated a bilateral agreement on chemical weapons in parallel with the multilateral negotiations on chemical disarmament. The bilateral negotiations resulted in the Agreement on Destruction and Nonproduction of Chemical Weapons and on Measures to Facilitate the Multilateral Convention on Banning Chemical Weapons, signed on June 1, 1990. Although the latter agreement was never fully implemented, the CWC's verification of compliance procedures are largely based on that bilateral agreement. Provisions for providing emergency assistance to member states that are the victims of chemical weapons or are threatened with chemical weapons, as well as technological assistance and cooperation provisions, were also included toward the end of the 1990 bilateral chemical treaty negotiations.

The OPCW

The Organization for the Prohibition of Chemical Weapons (OPCW), based in The Hague, Netherlands, is mandated to verify the destruction of chemical weapons—including old and abandoned chemical weapons—as well as to verify the destruction or conversion of former chemical weapon production facilities. It also has the tasks of confirming that national defense establishments and national chemical industries are not engaged in prohibited activities, of monitoring the trade in certain chemicals that could be useful to a chemical weapons program, of providing assistance and protection to states that are threatened by or are the victims of chemical weapons, and of promoting economic and technological development in the field of chemistry among treaty parties. The OPCW has also provided parties with technical expertise and advice on chemical weapon-related matters such as the planning and implementation of weapon destruction programs.

Parties are required to provide annual declarations on defense-related activities and on the production, consumption, and transfer of certain chemicals. Chemical weapon-related facilities (including chemical weapon storage and destruction facilities), and facilities working with small quantities of chemical warfare agents for research, medical, pharmaceutical, or protective purposes are then subject to international inspections. Segments of the chemical industry are also subject to visits by inspectors. These result in a final inspection report to help provide assurance among parties that they are all in compliance.

Schedule 1, 2, and 3 Chemicals

Although any use of chemicals as a means of warfare is prohibited under the CWC, certain chemicals known to have been used as CW agents are listed in schedules, while others are included due to their potential use as CW agent precursors. In the Schedule 1 category, CW agents that have typically been developed for warfare—and have no other practical purpose—are listed, including the nerve agents (e.g., sarin) and mustard agent. States may produce these in small quantities only for peaceful defensive purposes, and there are strict reporting guidelines in these cases. Schedule 2 chemicals include toxic chemicals that could be utilized as a means of warfare, such as amiton (nerve agent), or other chemicals that could be used to produce Schedule 1 chemicals. Countries may produce Schedule 2 chemicals but only for peaceful purposes, and their trade is restricted to CWC parties. Finally, Schedule 3 includes classic World War I–era gases such as chlorine. These chemicals are often used in commercial products, and their strict regulation would be too burdensome for the chemical industry worldwide. These can be produced in large quantities so long as they are for peaceful uses.

The chemical industry is subject to declaration and inspection requirements in two ways. One is on the basis of chemicals contained in the CWC's Annex on Chemicals and certain other, unlisted discrete organic chemicals that may contain the elements phosphorus, sulfur, or fluorine (DOC/PSFs). These elements are found in nerve and mustard agents, thus their inclusion for verification purposes. The second is through the general-purpose criterion mentioned above.

Implementation of the CWC

The CWC is implemented by the OPCW. The OPCW consists of the Conference of the States Parties (CSP), the Executive Council (EC), and the Technical Secretariat. The CSP is the highest decision-making body. It meets in regular session once per year. The EC, which is composed of forty-one members representing five geographical groupings, meets in regular session three to four times per year. It develops and considers draft recommendations, decisions, and guidelines for the approval of the CSP, including the annual draft program and budget. It also plays a key role in implementing the CWC's provisions on consultations, cooperation, and fact-finding, up to and including challenge inspections—that is, states must comply with on-the-spot, "any time, anywhere" inspections if and when approved by the OPCW—and investigations of alleged chemical weapon use. The Secretariat, which currently has about 500 employees (200 of them inspectors), is responsible for carrying out the treaty's verification measures and providing administrative and technical support to the CSP, EC, and various subsidiary organs, such at the Scientific Advisory Board (SAB) and the Commission on the Settlement of Disputes Relating to Confidentiality. The OPCW's budget for 2003 was approximately 68.6 million euros, funding provided on a sliding scale by each State Party.

As of December 2002, the OPCW had conducted a total of 1,276 inspections at 5,237 declared sites and facilities (both military and civilian). Four countries had declared chemical weapon stockpiles totaling some 70,000 agent metric tons: the United States, Russia, India, and South Korea. The CWC mandates these stockpiles' destruction within 10 to 15 years after the CWC's entry into force; large-scale destruction operations are underway in all four countries. By 2003, sixty-three chemical weapon production facilities in eleven party nations had been declared, and nine parties had declared their possession of old chemical weapons. (Old chemical weapons are those produced before 1925, or chemical weapons produced between 1925 and 1946 that have been determined to be unusable.)

The countries that have declared chemical weapon production facilities—defined as any facility that produced chemical weapons at any time since January 1, 1946—are Bosnia and Herzegovina, China, France, India, Iran, Japan, Russia, South Korea, the United Kingdom, the United States, and Yugoslavia. Three parties have declared having abandoned chemical weapons (i.e., leaving chemical weapons abandoned after January 1, 1925 on the territory of another state without the consent of the latter). The largest quantity of abandoned chemical weapons was those that were left in China by Japan at the end of the Second World War, totaling at least one million munitions. The CWC does not require that chemical weapons dumped (such as in the ocean) before January 1, 1985, be declared. Nor does it require that chemical weapons buried on a party's territory before January 1, 1977, (and that remain buried) be declared. As of 2003, no sea-dumped chemical weapons had been declared, nor had there been any challenge inspections or investigations of alleged use or production of chemical weapons.

Inspections have generally proceeded smoothly from an operational point of view, and no party has been formally accused of noncompliance. However, parties, including the United States, have requested and received clarification regarding other parties' declarations through the CWC's provisions for consultations, cooperation, and fact-finding. Currently, most outstanding verification-related issues relate to cost, scope, and intrusiveness, especially with regard to the chemical industry.

Although the United States has questioned Iran's compliance with the CWC, it has done so outside the framework of the OPCW. Iran did not declare a chemical weapon stockpile, but rather a past production capability. (For its part, U.S. statements have not referred to an existing chemical weapon stockpile in Iran.) More general discussions are currently taking place in the OPCW on how much detail parties should give on past programs and capabilities. There is a desire to increase openness among parties in this area, but there is also concern that some types of detail could be misused politically.

International cooperation and assistance programs are a major attraction for becoming a party to the CWC. Under the OPCW's Associate Program, for example, small groups of scientists and engineers from developing countries undergo a short course of study at a selected university in a participating state. Following the completion of studies, they are placed at modern chemical industry facilities for practical training designed to assist participants in better familiarizing themselves with modern industrial practices. The participants are asked to work on a specific problem, usually related to improving a chemical process. All participants, including the companies involved, have generally been pleased with the results.

Current and Future Challenges

Two of the main areas of focus since the CWC's entry into force have been the destruction of chemical weapon stockpiles and achieving universality in terms of state participation. With some notable exceptions, the treaty is now essentially universal, that is, nearly all important states are participating in the CWC. As chemical weapon stockpiles are gradually eliminated, the OPCW's focus will shift toward other areas, including technological assistance and cooperation, monitoring of chemical transfers, and taking measures to help ensure that the treaty regime keeps up to date with continuing scientific and technological changes. Parties also need to remain aware of possible toxic chemicals not on the CWC's list that may be used for prohibited purposes and of new developments in chemical industry manufacturing processes that may facilitate hiding of prohibited activities. The latter is particularly suited to smaller, more versatile facilities that produce relatively small quantities of fine chemicals to order in "batch mode." Such facilities may use lines of automated microreactors capable of producing chemical agents or toxins that could be used in weapons. In addition, the distinction between biological and chemical processes is increasingly blurred. The SAB has played an important role in these and other areas.

There is a continuing need for the OPCW to acquire periodically updated measurement and analytical equipment, for the Secretariat to continue to carry out practice challenge inspections and investigations of alleged use in cooperation with member states. The OPCW also needs to take steps to ensure that inspectors are familiar with the latest scientific and technological developments and that relevant institutional memory is maintained. The OPCW also should devote greater attention to ensuring that it is in a position to provide assistance and protection to member states who are threatened with, or have been the victims of, an attack using chemical weapons.

The CWC regime is a relatively robust regime as compared with other multilateral arms control and disarmament treaties. CWC implementation has resulted in significantly greater transparency of past and present chemical weapon-related programs and activities among parties. Much of this transparency has not been extended to the broader public because parties—with some exceptions—are responsible for indicating how much of their information may be disseminated outside the OPCW. There is little reason to suppose, however, that the CWC cannot continue to play a necessary and useful role in the future, as long as parties remain politically and financially committed to the treaty.

CHLAMYDIA PSITTACI (PSITTACOSIS)

Psittacosis, or ornithosis, also called parrot fever, is a worldwide disease primarily of psittacines (parrots, parakeets, etc.) caused by the bacterium *Chlamydia psittaci.* The genus *Chlamydia* is a group of bacteria responsible for various diseases. Transmission to humans from infected birds usually occurs via direct contact or inhalation of dried droppings and secretions. Birds that otherwise appear healthy can shed *C. psittaci* bacteria intermittently, especially when stressed, and even brief exposure can lead to infection. Human-to-human transmission is very rare.

According to the U.S. Centers for Disease Control and Prevention (CDC), psittacosis is a category B bioterror threat, a less serious but potential biological weapon agent (*see* Centers for Disease Control and Prevention). This classification is due to the pathogen's moderately easy dissemination, moderate morbidity, low mortality, and the requirement for specific enhancements in diagnostic capacity and disease surveillance. Although cited as a potential adversary agent (presumably aerosolized), it is not known to have been used. The Soviet Union, the United States, and Canada have performed research on psittacosis in the past, mostly during the World War II era and the early years of the Cold War (1950–1960s).

Psittacosis was first recognized in 1892 in Paris. That year, it was responsible for the death of sixteen out of forty-eight infected people. Between 1985 and 1995, a total of 1,132 cases (undoubtedly underestimated due to the difficulty of diagnosis) of psittacosis were reported worldwide, mostly resulting from exposure to pet birds. Since 1996, fewer than fifty annual confirmed cases have been reported in the United States.

The severity of the human form of the disease ranges from nonapparent to abrupt, systemic illness (1–4 weeks, but sometimes years, following exposure). Symptoms include fever, headache, chills, nausea, lethargy, and a nonproductive cough, potentially followed by severe pneumonia. The elderly are particularly susceptible to the disease. No vaccine is available, but effective antibiotics (mainly tetracycline) have reduced the fatality rate from 20 percent to less than 1 percent.

The severity of avian psittacosis (also called avian chlamydiosis) depends on the species of bird, strain virulence, and stress factors. Signs include lethargy, weight loss, ruffled feathers, nasal discharge, diarrhea, and excretion of green urates. In the absence of treatment, the disease can lead to emaciation, dehydration, and death (usually due to an unchecked infection of the heart). *C. psittaci* has been isolated from more than 100 bird species. Various strains can infect other animals, including sheep, goats, and cattle, causing reproductive infection and abortion; and felines, leading to rhinitis and conjunctivitis.

Due to the transmissibility of *C. psittaci,* its resistance to environmental stress (*C. psittaci* can remain infectious for several months, and the bacteria are stable in seawater for up to 24 hours), and its lack of overt symptoms in some birds, this organism could potentially be used in a covert attack on agriculture. An attack using *C. psittaci* could target the poultry industry using a form of aerosol delivery, causing widespread bird-to-bird infection. This would likely lead to wholesale culling of poultry from infected areas in order to control the disease, and large financial losses. Infection of poultry farmers, veterinarians, and poultry handlers could also increase, with an initially moderate to low mortality rate, with infection and mortality decreasing over time with the eventual identification of the causative agent and with the resulting appropriate antibiotic treatment. The diagnosis of psittacosis, however, can be difficult.

Although *Chlamydia* is an obligate intracellular pathogen (i.e., requiring host cell nutrients for reproduction), making it relatively difficult to produce and weaponize, a number of countries have the capability to produce and disseminate this agent. The infective dose, however, is unknown. Targeting humans directly with aerosol delivery is also possible.

CHLORINE GAS

As a lung irritant, chlorine (Cl_2) is the quintessential agent once found in true "gas" warfare. The World War I chlorine gas attack by the Germans at Ypres, Belgium, on April 22, 1915, was considered a signal event that heralded the era of modern chemical weaponry. Clouds of chlorine gas broke the salient at Ypres for a short time, but German infantry reserves were not sufficient to exploit the breakthrough offensive. Although not the first use of chemical weapons in World War I, this attack was unprecedented in terms of scope and overall effectiveness.

In 1823, the British chemist Michael Faraday (1791–1867) first liquefied chlorine gas. Since then, chlorine has been one of the most widely used chemicals for industry. Mass production of chlorine is carried out by electrolysis, the use of electricity to separate the elements of salt (sodium chloride), collecting the chlorine gas as it is separated from the brine, while also producing sodium for use in making another useful chemical (caustic soda). In World War I, the amount of chlorine brought to the war

Chlorine is still widely used and hazardous—as in this accidental release of the gas in New York in 1944. (Bettmann/Corbis)

front in April 1915 (approximately 170 tons) represented a sizeable portion of Germany's available industrial stock. In 1945, some 150,000 tons of chlorine were produced in the United States. By 2001, U.S. consumption of chlorine was estimated at 14 million tons.

When liquefied under pressure, chlorine gas can be released into the atmosphere by simply allowing it to escape via a pressure valve or a puncture of its container. The density of chlorine gas keeps it low to the ground. This feature made it an attractive weapon for use against dug-in trenches in World War I. And yet, not long after the infamous German use of chlorine (and Allied responses in kind a few months later), this chemical became obsolete due to its relatively low toxicity and the use of protective masks on the battlefield.

Chlorine gas is only effective as a weapon through the inhalation route. The toxicity of chlorine gas is primarily due to the production of acidic by-products upon contact with the body's moist airways (especially in the lungs), resulting in the release of hydrochloric and hypochlorous acid. Chlorine gas can produce an immediate irritating sensation in the nasal passages, with tightening in the upper airways followed by a very severe cough. Depending on the amount of exposure, damage in the lungs leads to swelling of tissues (pulmonary edema), with blood leaking from the injured alveoli. Very severe cases of chlorine inhalation lead to frothy, blood-tinged sputum. Thus the old term *dry-land drowning:* as their own body fluids enter the lung air spaces, no further gas exchange can take place, and victims choke to death. Apart from assisted breathing and supportive care, there is little medical intervention that is effective in the event of significant levels of chlorine inhalation. Survivors, however, usually make full recoveries.

In January 1915, the German chemist Fritz Haber saw that the use of high explosives was not sufficient to change the momentum on the battlefield. At this stage in World War I, the great armies were nearly at a standstill in trenches that served as nearly impenetrable redoubts stretching for miles. After experiments showed that gas could be brought to bear on the enemy, Haber won approval to do so from General von Falkenhayn, who diverted chlorine gas cylinders from industry. A total of 5,730 cylinders were assembled along a 6-kilometer front, and they were distributed with about one cylinder per meter.

Germany had not undertaken this venture without considering international law. The Hague Conference of 1899 forbade the use of poisons in warfare, and Germany was a signatory to it. However, a German account of the events by Dr. Rudolph Hanslian (1940) suggests that before the use of chlorine at Ypres, the following considerations were made: "Haber laid his reflections and his plan before Falkenhayn and the latter agreed. No fundamental scruples based on international law existed in the view of Falkenhayn, nor was the toxicity of chlorine as great as that of the materials bromethylacetate and chloracetone already introduced by the French" (Hanslian, p. 12).

These references made to French use of chemicals may have been with regard to irritating compounds such as ethylbromoacetate (which had also been employed as a riot control agent in Paris as early as 1912). Sporadic use of these chemicals had also found its way to the battlefields of World War I, often delivered in the form of French rifle grenades. Thus, at least according to the version of events mentioned above, Germany saw the use of chlorine as a measured response—in degree if not in kind—to the previous use of chemicals by French grenadiers. Following the war, some apologists for Germany also noted that using static gas cylinders was technically not the use of "poisonous projectiles" as described in the Hague document. Haber could not find a ready supply of adequate artillery shells to deliver chemicals, and at that time chlorine cylinders were the only practical means of gas dissemination.

It appears certain that Allied claims of 5,000 soldiers having perished and 15,000 having been injured along the front at Ypres must be an exaggeration for propaganda purposes. It is now the considered opinion of most analysts that no more than 800 Algerian, Canadian, and French soldiers died during the April 22, 1915, gas attack. Further postwar commentary, including that by Russian military experts, suggested that a combination of chlorine and phosgene would have been much more effective at Ypres. The German military was certainly aware of this, but it claimed that it did not use that mix out of consideration of international law.

Concerns about toxic industrial chemicals in warfare were also raised during the conflict in the Balkans, particularly in the mid- and late 1990s. With this in mind, a U.S. Army field manual (*FM 3-06.11*, 2002) has drawn the following assessment, using data compiled by Croatian engineers: "The models indicated that with a normal load of 16 cubic meters per railcar, a lethal concentration of chlorine could extend up to 5 kilometers downwind and that serious adverse health effects could occur as far as 12 kilometers downwind" (*FM-3*, section FM-7, b). These estimates roughly parallel the World War I experience at Ypres in 1915. Just as Germany confiscated chlorine from its domestic chemical industry for use by its military, chlorine poses a modern risk primarily due to its possible diversion from the commercial market by terrorists.

CHLOROPICRIN (PS, TRICHLORONITROMETHANE)

Chloropicrin was first synthesized in 1848 by the English chemist John Stenhouse, who derived this product from a reaction with picric acid and calcium hypochlorite. Chloropicrin originally got its name from the chemicals used in its preparation, that is, chlorine (in the form of bleach) and picric acid. Variations of this method were later used for large-scale production of chloropicrin.

During World War I, Russia was the first major belligerent to use chloropicrin (also called trichloronitromethane) as a chemical weapon; this was in August 1916. Soon the British were also using chloropicrin in a 30:70 ratio with chlorine in a mixture called Yellow Star gas. Chloropicrin was prepared for delivery in artillery shells, bombs, and land mines. Some German chemical munitions in World War II also contained chloropicrin, combined with obscurant smoke preparations such as titanium chloride and tin chloride. It is unknown whether these were used in the European theater of combat. In the older and now defunct U.S. chemical inventory, munitions included a combination of chloroacetophenon (CN) and chloropicrin (PS in NATO terminology) together in a chloroform solvent (20:40:40). This chemical munition was coded CNS. Other suggested uses for chloropicrin (in the form of CNS) involved its dissemination from aircraft with other CW agents such as mustard. Mixtures of CNS and ethyldichlorarsine (ED) were at one time considered to be potentially effective for use in aerial spraying and bombardments, and Prentiss (1937) recommends spraying these as a means of "harassing" enemy troop concentrations. Following the development of more toxic chemical compounds such as mustard and the nerve agents, however, as well as the development of improved protective mask canisters, chloropicrin after World War II was largely considered obsolete as a war gas.

Military chemists in World War I found chloropicrin particularly advantageous for its ability to remain liquid over wide temperature ranges: it boils at about 112° C., and freezes at -64° C. An oily, colorless liquid, chloropicrin has traditionally been considered an extremely effective lacrimator, irritating the eyes and the mucous membranes in the respiratory tract. Furthermore, chloropicrin causes damage to the pulmonary tract and was therefore classified as a lung irritant following its initial use in World War I. An estimated concentration of 0.2 milligrams per liter is sufficient to incapacitate soldiers, and 2 milligrams per liter over 10 minutes of exposure is likely to be lethal. As in the case of other lung irritants such as phosgene, treatment of severe cases of chloropicrin inhalation is generally limited to mechanical ventilation and other supportive care, with no specific antidote currently available.

Although chloropicrin is not quite as deadly as phosgene, it penetrated most of the early gas masks used in the initial stages of gas warfare in World War I. Until activated charcoal was introduced for protective canisters, chloropicrin often forced the enemy to take their masks off, leaving them vulnerable to simultaneous attack by other lethal agents. Thereafter, chloropicrin was often used in quality control for testing gas masks, their filter canisters being rated by the number of hours they could defend against chloropicrin exposure.

In the early twentieth century, chloropicrin was commonly used by itself to kill vermin such as rodents in Russia and the rest of the former Soviet Union. Thus, the Red Army had large stockpiles to draw upon for use as a CW agent. Later, in World War II, for example, large numbers of voles contributed to an outbreak of tularemia on the Stalingrad front. (Former Soviet BW scientist Ken Alibek has suggested that the Soviets deliberately used tularemia bacteria as a biological weapon during the siege of Stalingrad. This claim is difficult to substantiate.) Soviet hygienists were dispatched to combat the rodents with arsenic compounds (possibly arsine gas or solid baits) and chloropicrin. Red Army chemical defense schools also reportedly used chloropicrin to simulate contaminated ground for training. Combinations of chloropicrin with mustard agent and phosgene were also used for chemical weapons in the former Soviet chemical weapons stockpile.

Chloropicrin is an example of a CW agent that has commercial as well as offensive (dual-use) applications, and today it is used in large quantities as a fungicidal soil fumigant for high-value crops (flowers and strawberries, for example) and as a warning odor adjunct in pesticides—as a safety precaution, the pungent aroma will signal that the area is under chemical fumigation. Pest control companies, for example, are required by law in the United States to use about 1–3 ounces of chloropicrin (depending on the size of the structure) when fumigating structures with fumigants such as sulfuryl fluoride (VIKANE). In recent years, concerns over the environmental impact from the use of methyl bromide (purportedly a contributor to ozone depletion) as a common soil fumigant have led to the adoption of chloropicrin for the purpose instead. Commercially, chloropicrin can be found in a number of trademarked fumigants, including Acquinite, Chlor-O-Pic, Larvacide, Pic-Chlor, and Tri-Clor, as well as combination formulations such as BromO-Gas and Terr-O-Gas.

Because it is so widely available in the agrichemical industries, chloropicrin has the potential for diversion for use in chemical warfare or terrorism. But again, the toxicity of chloropicrin is by no means exceptional, and there are many other widely available compounds that could be similarly used in weapons of mass destruction.

CHOKING AGENTS (ASPHYXIANTS)

Choking agents or asphyxiants—also technically referred to as lung irritants—are the chemical compounds that gave rise to literal gas warfare in the modern era. Asphyxiating agents used in chemical warfare injure the respiratory pathways, most importantly the delicate alveoli in the lungs where critical gas exchange takes place. Serious lung injury brings about pulmonary edema and asphyxia. As the lung spaces fill with the body's own fluid, the victim can no longer respire enough oxygen, and he or she dies. In other types of toxic inhalation, casualties may result from being overwhelmed by a number of chemical substances such as by-products of fires, explosives, or the use of riot control agents (tear gas) in enclosed spaces. For example, it is possible that many of the eighty victims who died in Waco, Texas, at the 1993 Branch Davidian complex siege expired from suffocation and not as a result of the fire at the complex. Both the fire and resultant deaths were likely caused in part by large quantities of CS tear gas delivered in methyl chloride solvent.

Some household products have the potential to become lethal choking gases. Most notable among these are the extremely toxic chloramines that are created from mixing bleach (sodium hypochlorite) with ammonia. The resultant gas can be more toxic than bleach or ammonia by themselves, as chloramines can dissociate into both compounds upon contacting the moist upper and lower airways.

Choking agents were the first CW agents produced in large quantities, and they were used extensively during World War I. Gases that are heavier than air, such as chlorine and phosgene, filled depressions and sank into revetments, a characteristic well suited to the trench warfare that typified combat at that time. In World War I, the choking gases initially made a significant impact, but they contributed proportionately less to overall casualties as the war progressed. For example, American Expeditionary Forces arriving late in the war (1917) were much more affected by the use of mustard agent, a vesicant, than by the combined use of the choking gases by the enemy, for which they were better prepared.

Chlorine

Because these are for the most part highly volatile liquids or gases at room temperature, the classic lung irritants disperse rapidly in the atmosphere. This characteristic, combined with their relatively low toxicity (when compared to the nerve agents, for example), makes their use as a weapon of mass destruction less appealing to state militaries or to terrorists. These compounds are also less of a threat for the twenty-first century battlefield because of changes in battlefield tactics and advances in protective masks. Terrorists, however, could acquire choking gases in some form, perhaps diverted from the chemical industry in bulk form, and could manage to kill or injure large numbers of unprotected citizens.

Although the use of chlorine as a weapon is now generally considered obsolete, occasionally it does reappear in modern conflicts. According to an unconfirmed report, the Liberation Tigers of Tamil Eelam (LTTE) used chlorine in a 1990 attack against Sri Lankan forces. Little more information is known about the incident, and this attack did not result in serious casualties. A report in 1997 claimed that Muslims in the Bosnian city of Tuzla, the site of a significant industrial chemical facility, produced 120-millimeter chlorine-filled mortar rounds in anticipation of conflict with Serbian-led forces. It is not known whether any of these shells were used.

Among the first recorded uses of choking gas was a 431 C.E. campaign by Spartans, who burned pitch and sulfur to generate sulfur dioxide smoke. In one siege, the use of this toxic gas helped persuade the Athenians to surrender. The advent of modern chemical warfare essentially began in April 1915, with the successful use of chlorine (Cl_2), a choking gas, on the World War I battlefield of Ypres, Belgium. This chlorine, diverted from the German dye industry, was brought in canisters to the front. When the wind speed and direction were right (i.e., blowing toward the enemy), the German line opened the valves on the cylinders, releasing the gas. At least 800 Allied soldiers died in this attack. Other lung irritants, as well as phosgene, diphosgene, and chloropicrin, were introduced during World War I, these chemicals being delivered in shells such as the Livens projector, a type of mortar that fired a large gas cylinder.

For the conditions of World War I, chlorine satisfied some essential requirements for a chemical weapon. Although it was found to be sufficiently toxic for its purpose (although not as toxic as many other CW agents), chlorine was inexpensive to produce, especially for industrialized nations. Even before the mass production of chlorine got underway during World War I, chlorine sold for about a nickel a pound. As a poisonous gas, chlorine upon exposure almost immediately irritates the nasal passages, constricts the chest, and, in larger amounts (approximately 2.5 milligrams per quart of air), causes death by asphyxiation. Although it was initially effective in World War I, chlorine's distinctive bleach smell—and eerie, greenish color—quickly made its presence known, and the advance warning allowed for defensive preparations and tactical retreat.

Chlorine gas reacts quickly with the moisture in the body's airways and lungs, forming a mixture of hydrochloric and hypochlorous acids (thus the bleach odor one finds in hypochlorite). Although the body can absorb a certain amount of acid without complaint or injury, large doses create injury in the lung tissues. Hypochlorous acid reacts with a number of protein and fat constituents in the lungs, most severely in the alveoli. This damage leads to pulmonary edema (swelling and fluid buildup), with coughing exacerbating the injury and bringing up blood-tinged sputum. When Lieutenant Wilfred Owen wrote his poem about chemical warfare (CW) in World War I, "*Dulce et Decorum Est,*" he referred to the physiological effects of chlorine: "As under a green sea, I saw him drowning. In all of my dreams, before my helpless sight, He plunges at me, guttering, choking, drowning" (quoted in Sidell, 1997, p. vi). Owen was killed in France on November 4, 1918.

Chlorine's high reactivity with a number of substances made possible ad hoc protective measures. In World War I, soldiers quickly found that makeshift masks soaked in certain chemicals (sodium thiosulfate, glycerine, and alkali) offered good protection against chlorine. Six months after first being used in World War I, chlorine by itself no longer made a significant impact on the battlefield. But chlorine remained as an essential part of phosgene mixtures later on, and it was a critical part of the production process for more toxic and highly lethal compounds to follow.

Phosgene

Phosgene was first used as a weapon by Germany in December 1915. Compared to chlorine, phosgene gas is a much more insidious and deadly chemical agent. Even at toxic levels, phosgene (carbonyl dichloride) has little distinguishing odor and usually kills its victims only after a considerable delay (up to 24 hours). In one instance during World War I, a soldier was given the responsibility of checking phosgene canisters. A day later, the same soldier died from phosgene exposure, unaware that one of these canisters had formed a small leak. Although it may not have contributed to a large percentage of casualties overall, phosgene was alone responsible for some 80 percent of those killed by chemicals in World War I. In World War II, the U.S. Air Force had in its arsenal 500-pound phosgene aerial munitions, although these and other chemical weapons were never used in that conflict.

The common perception once was that phosgene exposure led to the formation of acid in the lungs, which then destroyed tissue. However, this explanation is not adequate to explain how phosgene, even in very small concentrations, can do so much irreparable damage to the lungs. (The toxicity of phosgene, for example, is 800 times that of inhaled hydrochloric acid.) Phosgene reacts with a number of biochemical components in the body, especially enzymes and the processes required to maintain proper surface tension in the lung alveoli. An examination of World War I gas warfare victims found that, in addition to its effects on the lungs, phosgene also causes specific injury to the central nervous system.

Phosgene has been used in at least one instance by terrorists. In this case, a Japanese reporter who had written stories about Aum Shinrikyo was singled out for assassination by the cult. Aum henchmen dispersed phosgene through the mail slot in the journalist's apartment. After a brief hospitalization, the reporter made a full recovery. Aum Shinrikyo also had a substantial presence in Russia during the early 1990s; during this time, Russian security personnel also found phosgene in the possession of Aum Shinrikyo in an apartment in Moscow.

As with chlorine gas exposure, treatment for phosgene injuries is mostly limited to supportive care. World War I chemical masks utilized hexamethamine tetramine (HMT) to defend against phosgene. In the late 1930s, some research suggested that this compound was useful for protecting against phosgene-related injury, but the data are still not clear. It was also considered impractical to use this chemical prophylactically on the battlefield.

Diphosgene

Diphosgene essentially relies upon the toxicological properties of phosgene, but diphosgene also released chloroform. As a solvent, chloroform may have been utilized as a "mask breaker." Germany used diphosgene for the first time in 1916, and the French responded later in kind.

Chloropicrin

Chloropicrin was first used by Russia in World War I. It was probably derived from the pesticide industry. Chloropicrin is an immediately irritating substance, and it is still used to create a warning odor for the fumigation of large structures. California law, for example, requires about 1 ounce of chloropicrin during the "tenting" of houses for insecticide treatment. Concerns over the environmental effects of methyl bromide for soil fumigation have led to considering the use of chloropicrin instead. (For more on this chemical, see the separate entry Cholopicrin.)

Perfluoroisobutylene

Another highly toxic gas, perfluoroisobutylene (PFIB), known as the agent in "polymer fume fever," is a potential military or terrorist chemical threat. Because it is many times more toxic than phosgene, PFIB was made a Schedule 2 toxic chemical in the Chemical Weapons Convention (1993). The inclusion in Schedule 2 was suggested due to its potential use as a weapon, and the fact that it can be commonly found as a byproduct or intermediate chemical in some industries. PFIB can be generated during processes for the manufacture of fluorinated polymers (e.g., Teflon), or in heating these polymers to high temperature (over 500° F.). Military-specified materials used in tarpaulins and ropes contain Teflon; following an incendiary attack, for example, fires could generate toxic levels of PFIB.

Nitrogen Oxides

Finally, although not likely to be related to a deliberate use of toxic gas on the battlefield, nitrogen-containing explosives generate significant quantities of NO_x (as in nitrogen oxides, NO_2, N_2O_4, etc.). These by-products can be the source of toxic inhalation injury in battlefield settings, and casualties may present in many ways similar to those exposed to lung irritants such as chlorine or phosgene. The Chinese People's Liberation Army still makes the claim that the United States used chemical weapons during the Korean War (1950–1953). It is likely, however, that many of the battlefield casualties among the Chinese People's Volunteers during the Korean War died from asphyxiation due to off-gases from exploding munitions. Many Chinese soldiers were essentially holed up in earthen fortifications that allowed toxic gases like NO_x, carbon dioxide, and carbon monoxide to accumulate. Soviet military advisors who were requested by the Chinese government to investigate allegations of chemical warfare in the Korean War came to the same conclusion.

Industrial Accidents

The hazards of choking agents present themselves most often in industrial settings. A tragic example of this was the Bhopal disaster of 1984, which involved the massive release of methyl isocyanate in a densely populated area of India. Due to what probably was insider sabotage, thousands of pounds of methyl isocyanate—an extremely toxic lung irritant—killed at least 3,000 people, injuring thousands more (*see* Bhopal, India: Union Carbide Accident). Because potentially harmful chemicals such as chlorine and anhydrous ammonia (NH_3) are used throughout the industrialized world, their bulk storage could present targets for terrorist attacks. Chlorine is ubiquitous, not only as a chemical reactant for commercial processes but also for water treatment. Ammonia is widely used in rural areas in concentrated form as fertilizer, and it is also a cost-effective coolant for public utilities.

For these industrial chemicals and the hazards they could pose, meteorological conditions play a critical role. In the case of Bhopal, the release of methyl isocyanate occurred during an inversion, the optimal situation for high concentrations of a gas to linger for a long period of time. Alternatively, chemical releases are mitigated during conditions of unstable air (lapse) and of high winds that quickly dissipate the concentration.

CHOLERA (*VIBRIO CHOLERAE)*

Vibrio cholerae is a gram-negative bacterium that causes cholera, a diarrheal disease, in humans. Infection can lead to a massive, secretory diarrhea that results in a life-threatening loss of fluids in the infected patient. Transmission is typically through an oral route, usually as the result of drinking water contaminated with *V. cholerae.* The organism grows in the small intestine and secretes an enterotoxin (choleragen) that disrupts the osmotic homeostasis of the intestine, resulting in the secretion of water into the intestinal cavity. Cholera could potentially be employable as a biological warfare agent by contaminating food or posttreatment water supplies. Another species, *Vibrio parahaemolyticus,* also causes severe diarrhea in humans following the consumption of infected raw seafood (especially in Japan). This bacterium also could have a potential role in sabotage, such as poisoning food and water.

In 1848, the British physician John Snow, a trained anesthesiologist, set out to find the source of an especially severe outbreak of cholera in London. In his classic work *On the Mode of Transmission of Cholera* (1849), Snow concluded that contaminated water was the source of the widespread disease. Using techniques recognizable today in modern epidemiology, Snow also sought to understand the origins of another serious cholera outbreak in 1854, tracing victims and water sources to a single water pump. Known for having obtained a pure culture of *Bacillus anthracis* (anthrax), Robert Koch discovered the causative agent for cholera in 1883.

Vibrio cholerae is capable of causing epidemic and pandemic disease. Cholera is particularly devastating in areas with marginal hygiene or inadequate medical support, particularly in refugee camps and among impoverished populations with inadequate water treatment infrastructure. The German army is alleged to have used cholera in Italy in World War I, although evidence for this is largely anecdotal. Cholera was one of several biological agents developed by the Japanese in the infamous Unit 731 offensive biological warfare laboratory. Cholera was reportedly disseminated against Chinese villagers in 1940, along with typhus and plague, in support of Japan's invasion of China.

Following the Japanese attack on Pearl Harbor, the threat of water-borne agents (including cholera) was among the key concerns behind a biological threat reduction plan for U.S. bases in the Pacific theater. Germany's biological warfare program was considerably less advanced than their work with chemical agents, but they had experimented with, and perhaps had produced in volume, cholera as an antipersonnel agent that could be used against logistical units in support of large military forces. Soviet scientists purportedly developed strains of *Vibrio cholerae* that exhibited enhanced virulence and antibiotic resistance as part of the USSR's biowarfare research initiatives. Claims of the use of cholera by U.S. forces against North Korea were levied by

China and Russia in 1952. It is possible that North Korean prisoners were exposed to cholera and plague by Chinese field advisors to the North Korean army and were then flaunted as "victims" of the U.S. biological attacks.

The world is presently experiencing the seventh pandemic (worldwide outbreak) of cholera. The current pandemic is thought to have started in Indonesia in 1961 and has spread through the Middle East, Asia, Africa, and South America. Of concern to public health officials is the emergence of a second biotype of *V. cholerae* in Bangladesh and its subsequent spread throughout Southeast Asia. In modern industrialized countries, cholera is less of a threat due to residual chlorine in the water supply that keeps bacterial populations low in number. In Peru, an especially severe outbreak of cholera (biotype El Tor) was exacerbated in 1991 when Peru lowered the amount of residual chlorine in its water system, and the disease spread to sixteen other Latin American countries.

Medical Properties

Cholera is generally acquired by oral ingestion of water or food containing *V. cholerae,* typically as the result of fecal contamination from patients or from asymptomatic carriers of the bacteria. The organism colonizes the lining of the small intestine and secretes choleragen, a toxic protein. Infection causes a spectrum of disease severity, and many individuals do not exhibit the profound diarrheal illness often associated with cholera; however, asymptomatic individuals can pass *V. cholerae* in their feces and can serve as reservoirs of the disease agent. The biochemical properties of the intestinal epithelial cells are altered by choleragen such that these cells lose their ability to regulate water loss from the body. The resulting pathology contributes to massive, watery diarrhea, with patients reported to have lost between 10 and 20 liters of fluid during the course of the infection. Mortality may exceed 50 percent in the absence of supportive therapy. Infection with *V. cholerae* is treatable with readily available antibiotics; fatality rates can be reduced to less than 2 percent with effective intervention. Multiple biotypes (or serogroups) of *V. cholera* exist. Most important to human disease are the O1 (synonym El Tor) and O139 (synonym Bengal). Both are recognized as potential agents of epidemic and pandemic disease. Rehydration therapy and supplemental electrolyte solutions significantly reduce the morbidity and mortality of cholera infection.

Cholera continues to be considered a potential biological threat, although it is a low-risk threat agent for domestic terrorism in most industrialized nations. Cholera vaccines are no longer available to the general population in the United States, principally as a result of their rather limited and short-duration protection. Oral vaccines are available outside the United States that afford better protection and may convey protective immunity following a single-dose administration. Public health authorities do not recommend vaccination for travelers, given the lack of an efficacious vaccine and the negligible risk of exposure. The duration and extent of the seventh cholera pandemic is unknown, but it is not considered to be a significant health risk to most travelers.

The lack of serious risk of cholera, even in the context of domestic bioterrorism, has reduced the level of federally funded cholera research in the United States. It is quite likely that a considerable level of concern would be needed before substantive reinvestment in cholera research or vaccine development would occur. Developments continue, however, on rapid detection kits and sensors for cholera toxin.

CONOTOXIN

Conus, or cone shells (also called marine snails), are predacious animals whose venom is used to immobilize their prey. They are found resting in shallow-water sand or under coral or rocks in the daytime. At night they become active predators. *Conus aulicus, C. geographus, C. gloria-maris, C. marmoreus, C. omaria, C. striatus, C. textile,* and *C. tulipa* are capable of inflicting human fatalities.

To acquire food, a conus extends a radular tooth (a harpoonlike apparatus) to inject venom, paralyzing the prey. The conus venom contains a variety of polypeptide toxins, composed of amino acids bonded in a chain. These various toxins affect different aspects of the nervous system. There are also types of conotoxin that induce sleep (sleeper peptides) and muscle damage (myotoxin). Conotoxins and other types found in marine animals have been suggested as possible biological warfare agents. However, these are also fragile proteins, and their toxicities are not generally high enough to make effective weapons.

CRIMEAN-CONGO HEMORRHAGIC FEVER

Crimean-Congo hemorrhagic fever (CCHF) is a viral disease that occurs sporadically in western and central Asia, eastern Europe, and Africa. It was first observed in workers clearing agricultural lands in Soviet Crimea during World War II. Natural transmission of the virus is often through tick bites or contact with infected livestock. The resulting illness often shows hemorrhage and shock. Convalescence can be prolonged, and death occurs in 10–30 percent of patients who come down with the disease. Infection of animals exposed to CCHF is often inapparent, even while the virus circulates in the bloodstream (viremia). The body fluids of slaughtered animals are thus a frequent cause of unexpected disease. Accidental inhalation of virus-contaminated fluids during care of human patients has been a recurring cause of hospital-centered CCHF outbreaks. For this and other reasons, CCHF virus is one of several candidates for aerosol dissemination in biowarfare.

In 1969, Jordi Casals showed a link between Crimean viral illnesses reported in the former Soviet Union in 1944 and a disease of African patients in the Congo that occurred in 1956. Despite such a wide geographic separation, viruses from these ecologically diverse regions nonetheless generated antibodies that were indistinguishable from each other. Many species of forest and domestic animals can acquire CCHF infections, and small wild animals or livestock serve as reservoirs of the virus. This in turn supports an infected population of blood-feeding ticks to serve as vectors. Virus spread among ticks can also be sustained by infection of the eggs in female ticks and transmission to offspring.

CCHF is caused by a midsize virus (0.1 micron) belonging to the family of bunyaviruses (genus *Nairovirus*). Its genes form helical strands of RNA and are protected by a protein coat and fatty envelope, facilitating virus entry into host cells by utilizing receptors on the surface. In the first round of virus multiplication, RNA of the host cell primes expression of the virus genome, the essential genetic information for replication. The virus then becomes self-replicating and produces proteins that are essential to its maturation and release from the cells. After contamination of broken skin or a tick bite, the virus multiplies in local tissues. The onset of clinical disease is rapid. In addition to common flulike symptoms and joint soreness, patients may complain of abdominal pain or sore throat. Within 24–96 hours, the virus spreads through the bloodstream to multiply in many of the body's organs. The liver, especially, is a major site of virus multiplication. This disrupts production of blood clotting factors and contributes to bleeding manifestations.

Signs of hemorrhagic fever include bleeding from the gums or nose, seepage of blood under the skin (ecchymoses), and blood in the urine or stools. Hemorrhagic complications often indicate life-threatening disease; they reflect a combination of liver failure, virus growth in the lining of blood vessels, and exhaustion of clotting factors. CCHF is fatal in up to 30 percent of cases, with most deaths occurring within 1–2 weeks. The virus can persist for up to 10 days in the blood or other tissues and can be detected by tissue culture, brain inoculation of suckling mice (for culture growth of virus), or more recent techniques utilizing polymerase chain reaction (PCR, which can multiply small amounts of genetic material for easier detection). In the past, diagnosis usually depended upon laboratory detection of protective antibodies that appear 7–10 days after infection. In fatal cases, though, there may be a poor antibody response, so virus culture or PCR detection is essential for diagnosis. Patients with CCHF often become weak and lethargic, and convalescence can require 3–6 weeks.

Vaccination with heat-inactivated CCHF virus has been tested on a small scale in eastern Europe, but the efficacy and safety of the vaccine are uncertain. Protection through the use of clothing and insecticides by livestock handlers are basic measures that can limit the spread of CCHF. Hospitalized patients suspected of having the disease must be strictly isolated to prevent spread to medical workers. Physicians should be wary of mistaking the abdominal signs of a virus infection for a surgical emergency. Treatment of CCHF usually is symptom-oriented. Replacement of fluid loss or clotting factors may be necessary. In severe cases, the antiviral drug ribavirin or immune plasma from recovered patients may help to control infection.

The potential for criminal use of CCHF as an aerosol obviously exists. Exposed military or civilian populations could be severely debilitated for many weeks. To date, however, no known artificial outbreaks of this disease have occurred. A type of virus sharing similarities to CCHF, Rift Valley Fever (RVF), has been tested for use in biowarfare by the U.S. Army, although the results are classified. This agent was not reported to be a major consideration in the Soviet bioweapons program.

CROP DUSTERS (AERIAL APPLICATORS)

The threat from aircraft dispensing a lethal substance has been a concern since at least the beginning of military aviation. During World War I, the extremely toxic arsenical compound lewisite was synthesized and developed in 1917, intended for delivery by aircraft over enemy concentrations. (This was partly what earned Lewisite its moniker, dew of death.) Shortly before the outbreak of World War II, an erudite commentator from the 1930s described the threat from "aerial chemical warfare," and suggested that sulfur mustard could be poured from modified barrels kept in the fuselage of a aircraft.

The large-scale spraying of pesticides from aerial applicators was also a pre-World War II idea. In the 1930s, the U.S. Army Air Corps refined techniques that would prove useful for the application of DDT. As a consequence of dealing with disease-carrying vectors and unwanted vegetation during modern times, the techniques and engineering were already in place for the herbicidal campaigns conducted by the U.S. military during the Vietnam War. These were conducted largely from the air, dispensing enormous quantities of herbicides such as Agent Orange over South Vietnam and Laos. Although herbicides and insecticides like DDT are only toxic to the targeted pests in question, it is not a great leap to convert aircraft to deliver highly potent chemical warfare (CW) agents. By using a highly toxic substance such as VX, an aerial application system could be utilized to spray lethal droplets of nerve agents over densely populated areas, with catastrophic results. Furthermore, with the myriad applications of aerial chemical spraying used every day around the world, one can easily imagine the possible role of aerial applicators in bioterrorism.

From the perspective of delivering chemical warfare or biological warfare (BW) agents, crop dusters used in the modern civilian agricultural industry could be diverted into weapons of mass destruction (WMD) platforms. These include rotary and fixed-wing aircraft that are capable of disseminating particulates and aerosols, usually for the purpose of crop protection, mosquito abatement, and other civilian uses. For example, in the 1990s, while attempting to account for and disarm Iraq's various WMD programs, United Nations inspectors had suspicions about Iraq's work with aerial spray mechanisms. Although Iraqi officials claimed that these were solely for use in agriculture, U.N. Special Commission (UNSCOM) inspectors in Iraq found that these so-called Zubaidy devices were in fact modified—possibly to deliver bacterial aerosols from helicopters.

In 2003, the U.S. Central Intelligence Agency (CIA) warned that terrorists (including the organization al-Qaeda) could utilize crop dusters and related techniques to dispense deadly biological aerosols. One pamphlet produced by the CIA reported, "Spray devices disseminating biological warfare (BW) agents have the highest potential impact. Both 11 September attack leader Mohammad Atta and Zacharias Moussaoui expressed interest in crop dusters, raising our concern that Al-Qaida has considered using aircraft to disseminate [biological warfare] agents" (*Terrorist CBRN*).

Technical Details

When CW or BW agent is sprayed from a moving aerial platform such as a crop duster, it is described as a line source. As opposed to a point source, in which a munition releases its contents at a single spot, a line source describes a trail of released particles generated by shear and gravity forces caused by the moving aircraft. Crop spraying mechanisms also include pumps. Crop dusters can release a line of particles in their wake over a considerable distance, depending on rate of release, payload, and other factors. Winds approaching the line spread the dispensed particles to form a cloud of increasing size, blanketing the target below. The ultimate behavior and fate of these particles will depend upon the wind velocity, temperature, release height, and average droplet size. In the case of mosquito abatement, for example, the average particle size is approximately 20–50 microns—generally outside the optimum range for inhaled aerosols causing infection with pathogenic organisms. This would be more than adequate, however, for some CW agents such as mustard or VX nerve agent.

The efficient delivery of chemical or biological agents—and the potential effects of such an attack—depend on a number of factors such as the type of agent involved (chemical versus whole cell or virus) and the form, whether liquid suspension (slurry) or dry forms of payload. And even more so than in the commercial utilization of aerial applicators, efficient delivery of BW agents requires proper average particle size, usually considered to be within the range of 5–10 microns. One also needs to consider the engineering modifications necessary to deliver a CBW agent payload versus an agricultural treatment via aerial application. Liquid (slurry) suspensions of a BW agent are probably more practical for bioterrorists in terms of production and delivery. BW agents suspended in liquid, however, are more apt to degrade over time (i.e., they have a short shelf life). Furthermore, using suspensions of microorganisms can create problems during the hydrodynamic flow from holding tank to spray nozzle, potentially clogging the apertures. Flow agents would probably be required to ensure efficient spraying of CW, but especially BW, agents. Dried preparations of BW agents would offer the advantage of a long shelf life, but these also require substantial modifications to the dissemination process.

Among the models that most closely resemble a worst-case scenario—say, an aerosolized release of anthrax bacteria delivered over large, densely populated area—studies on the use of biopesticide (*Bacillus thuringiensis*) for eradication of gypsy moths are instructive. In North America, gypsy moths have been responsible for devastating losses of forests both in Canada and the United States. By spraying forests with aerosolized formulations of *Bacillus thuringiensis* (Bt) bacterial spores, the populations of gypsy moths have been dramatically reduced. After the caterpillar ingests a Bt spore, a toxin generated within the vegetating bacteria destroys the gut lining of the caterpillar. (Unlike some of the more toxic organophosphate insecticides, Bt bacteria are safe to use around animals and humans.) Most of the Bt particles range from about 4–7 microns in diameter, and they have been shown to drift more than a kilometer from the targeted area. Following the application of Bt spores—in many ways similar to *Bacillus anthracis* insofar as their physical properties are concerned—bacteria have been cultured at relatively large numbers inside buildings as well as outdoors.

The challenges for terrorists using crop dusters are the technical hurdles required in manufacturing lethal chemical agents, and especially the none-too-trivial tasks involved in the isolation, growth, and formulation of BW agents. The final product would then have to be configured for dissemination in some form—liquid or dry—compatible with an aerial platform using commercially available equipment. Other factors to consider are the operational details of flying crop dusters near populated areas without being seen. Environmental conditions (inversion) most amenable to disseminating aerosols occur during the evening or early morning hours, and during such times, the likelihood for visual spotting of aircraft from the ground would be poor. But there would still be some risk to the terrorist that something unusual would be seen and that the attack would no longer be covert.

Given adequate warning, and depending on the level of CBW agent detection available on the ground, it would then be possible to warn and medically treat those exposed with collective protection, nerve antidotes, and (in the case of biological agents) prophylactic vaccines and antibiotics. In the event of a chemical attack, detection techniques would be much more rapid, but so would be the effects from the CW agent. Therefore, quick detection, decontamination, and evacuation would be required. In biological attacks from aerosol delivery, there would be more time to react. Viral exposures (e.g., smallpox) can also be successfully treated with vaccines, especially during the first few days following exposure. In short, if the bioterrorist attack is discovered, much of the impact of the biological agents can be mitigated.

The Human Factor in Bioterrorist Use of Crop Dusters

Finally, one must also consider the human element involved in a venture to employ crop dusters to deliver biological weapons. Because of the interdisciplinary nature of CW and BW, with both involving a number of different areas of expertise, such operations leave themselves more vulnerable to penetration by law enforcement and/or intelligence agencies. From a preventative standpoint, human intelligence sources are required to ensure that plots to execute a CBW terrorist event are discovered before they can be carried out. Other considerations include more mundane, but critical, aspects to a WMD terrorist scenario using crop dusters. For example, in the aerial application industry, pilots are highly trained and specialized in the exacting business of spraying agrochemicals, flying sorties at heights as low as 5 feet off the ground. A bioterrorist would be limited, therefore, to hiring someone from within this relatively tight-knit and professionalized community of aviators. Terrorists could obtain their own aviation skills and training elsewhere, but in light of special attention given to the threat from crop dusters in bioterrorism, especially since the September 11 terrorist attacks in the United States, potential terrorists would be hard pressed to do so without attracting attention from interested authorities.

CS

CS is the code that refers to the riot control agent (RCA) most often used nowadays for crowd control (chemical name ortho-chlorobenzylidene malononitrile). Originally named after its inventors Corson and Stoughton, CS has high potency with a large safety margin. However, if used in confined spaces, and given large enough doses, CS tear gas can be lethal.

CYCLOSARIN (GF)

Cyclosarin (cyclohexyl methylphosphonofluoridate) is a less-well-known organophosphate that can be used as a nerve agent in chemical munitions. Also referred to as CMPF (its chemical abbreviation) during its early stage of development by the U.S. military, GF (named for being a continuation of the German series: GA, tabun, GB, sarin, GD, soman, etc.) was devised as a way to create a more persistent agent that was also volatile enough to cause mass casualties. Iraq used GF in its 1980–1988 war against Iran, and it later stockpiled the agent for use in aerial bombs as well on its al-Hussein (modified Scud) missile warheads. During the Iran-Iraq War, Iraqi military units often combined difluor (DF) with cyclohexanol and isopropyl alcohols just before an aerial assault on targets. This procedure formed a near equivalent mixture of GF and sarin (GB) from the respective precursors.

GF is a volatile, odorless, and colorless liquid. It is nearly insoluble in water and is quite stable for storage purposes. The cyclohexanol portion of the molecule, however, has a ring structure that can revert into benzene, making it a less stable compound than other nerve agents. GF is, however, believed to be highly persistent, and splashed GF liquid can last up to a couple of days under normal weather conditions.

Cyclosarin primarily affects the victim through the respiratory tract, although cutaneous and digestive entries can be quite harmful to the body as well. It probably shares a similar toxicity profile to that of sarin (GB). Exposure to a small amount of vapor from cyclosarin can cause dimness of vision, runny nose, chest tightness, and tearing of the eyes within minutes of exposure. As with other nerve agents, exposure to high amounts may lead to loss of muscle control, twitching, paralysis, coma, and death due to the inhibition of acetylcholinestrase (*see* Carbamates). The most common cause of death after acute exposure is respiratory arrest.

D

DECONTAMINATION

Decontamination—the removal of contaminants from people, materiel, and the environment—would likely be required in the event of real or suspected nuclear, biological, chemical, or radiological (NBCR) incidents. Each particular weapon type may, of course, necessitate its own specialized decontamination regimen. In general, however, several steps are common to most efforts at decontaminating personnel or physical objects to mitigate the consequences of an NBCR event. Materials (including military equipment) may require extensive cleaning with water, soap, and oxidizing chemicals such as bleach and peroxides. The decision to use solvents or caustic chemicals for decontaminating equipment largely depends on the resiliency of the materials used in the equipment's construction. In the case of treating individual persons, one authority in responses to NBCR events notes, "the use of bleach and water solution in terrorism decontamination is no longer considered an acceptable practice" (Hawley, p. 153). For people, removing all clothing and bathing with soap and water is usually sufficient.

Generally speaking, a hazardous materials (HAZMAT) response approach can be used in the early stages of an NBCR incident. Conventional weapons such as a very large explosive device are not likely to cause significant long-lasting toxicological hazards. In the immediate aftermath of a conventional detonation, however, there will be large quantities of toxic gas (carbon monoxide, nitrogen oxides, and so on) that could cause a short-term danger to personnel. These gases, unless trapped in an unventilated area, will disperse quickly. Conventional explosives also may produce secondary damage at facilities that contain toxic or radiological materials, in which case decontamination may be necessary if the materials are released from containment.

Radiological Decontamination

In the aftermath of a nuclear detonation or radiological event, decontamination would be needed. Fallout from a nuclear device includes smoke and dust particles that emit beta radiation, leading to surface-layer tissue damage if allowed to remain on the skin. But in the event of a true nuclear explosion—that is, an actual fission device—triaging casualties would first require a judgment based on the unlikely, probable, or definitive symptoms of partial or full-body exposure to high-energy radiation (X-rays, gamma rays, and neutrons). Such radiation exposure is instantaneous with the initial nuclear blast itself. Most casualties of severe and immediate nuclear radiation cannot be saved if they have been exposed to large (especially full-body) doses. In these unfortunate cases, cleaning the skin of radioactive fallout is only a palliative measure, although it may be useful to ensure a cleaner environment in the medical treatment facility and for safer burial of remains. Others who may have only received partial exposures can certainly benefit from complete decontamination using soap and water, once their conventional injuries (including, probably, severe burns) have been assessed.

Following radiological events—nonfission explosions that spread radioisotopes in so-called dirty bombs—relatively straightforward decontamination measures such as discarding clothing and bathing can be undertaken to prevent serious injury to exposed individuals and to clean up the environment. Compared to an actual fission explosion, such events are relatively benign in terms of risk from radioactive exposure.

Biological Decontamination

In the event of biological warfare (BW) or bioterrorism, decontamination is largely a secondary issue. The immediate hazard—and the type more

Diluted bleach is one of the most effective decontamination agents, although caution must be used with bare skin. (Reuters/Corbis)

likely to cause mass casualties—is the exposure to infectious aerosols. Following their release, these aerosols quickly degrade in both potency and concentration, lessening the need for deliberate efforts at decontamination. Environmental factors including air currents, inversion conditions, ultraviolet light, and relative humidity all play a role in the decay rate of BW agent aerosols. Over time and distance, at some point the concentration of infectious particles drops below that which is dangerous to humans or animals. When particles have reached the ground surface, they are usually resistant to reaerosolization, and exposure to the elements quickly denatures pathogenic microbes and toxins.

Once individuals become infected, or suspected airborne particles containing BW agents are identified, it becomes important to prevent further exposures (usually by relying on air flow management and use of protective masks). However, following a biological attack, decontamination can become critical when airborne infectious particles can become reaerosolized. The anthrax letters that were sent in late 2001, for example, leaked *Bacillus anthracis* spores through the envelopes, and these generated sufficient infectious particles to cause casualties among U.S. Postal Service workers at the Trenton, New Jersey, Processing and Distribution Center. Contaminated surfaces were also found at the U.S. Senate Hart building in Washington, D.C. Subsequently, these offices were decontaminated using chlorine dioxide gas (ClO_2). In the event of contagious BW agents such as smallpox, secondary transmission is highly likely following initial infections. Here, quarantine and decontamination measures used in hospitals would play significant roles in stopping the spread of disease.

Chemical Decontamination

Although exposure to radiological and biological materials necessitates decontamination, particular immediacy is involved in the event of chemical warfare (CW) agents. Mustard (blister) agent, for example, acts upon the skin as well as the upper respiratory tract. Contaminated victims may have sufficient amounts of chemical on their skin and clothes to present a secondary exposure hazard to first responders. Most casualties from mustard can be mitigated and even avoided by means of physical removal of the material from the exposed skin areas, using absorbent materials to prevent any agent from reaching the skin, and thorough washing. Persistent agents such as VX nerve agent would also require fast and thorough decontamination. With a lethal dose of as little as 15 milligrams on the skin, VX is an extremely dangerous CW agent and must be dealt with using extreme caution. Some events may involve relatively volatile substances, such as hydrogen cyanide or sarin nerve agent. In such cases, preliminary steps toward decontamination can take place by moving victims from the contaminated area into fresh, ventilated air. Off-gassing from clothes and skin can occur, so emergency workers need to be cognizant of secondary exposures.

DEMILITARIZATION OF CHEMICAL AND BIOLOGICAL AGENTS

In the context of chemical and biological weapons issues, demilitarization refers to the elimination of both a country's weapons stockpile and its capabilities to reconstitute that stockpile. Under the 1997 Chemical Weapons Convention, the United States and three other countries declared possession of stockpiles of chemical weaponry: Russia, India, and South Korea. Of these states, Russia had the largest declared stockpile with more than 40,000 tons of chemical weapons, located at seven locations across the country. The United States followed closely behind with just over 30,000 tons.

U.S. Chemical Demilitarization Program

In November 1985, Public Law 99-145 mandated that the Department of Defense destroy 90 percent of the U.S chemical weapons stockpile. In 1992, Public Law 102-484 expanded that program to include complete chemical weapons demilitarization. Although timetables for destruction have shifted, the most concrete plan for demilitarization of the U.S. chemical arsenal was established when the United States ratified the Chemical Weapons Convention. The treaty requires member countries possessing chemical weapons to complete the elimination of their stockpiles within 10 years of the convention's entry into force, which will be April 2007. States that are party to the convention who need to extend this deadline may receive permission from the Executive Council of the Organization for the Prohibition of Chemical Weapons, the secretariat responsible for implementing the various aspects of the treaty.

When the U.S. chemical demilitarization effort began, eight sites in the continental United States and one site in the Pacific housed the tons of nerve and blister agents accumulated since the advent of the U.S. chemical weapons program in World War I. The locations of the U.S. stockpiles were Johnston Island, Johnston Atoll; Blue Grass Army Depot, Kentucky; Aberdeen Proving Ground, Maryland; Newport Army Ammunition Depot, Indiana; Umatilla Army Depot, Oregon; Pueblo Army Depot, Colorado; Anniston Army Depot, Alabama; Pine Bluff Arsenal, Arkansas; and Tooele Army Depot, Utah. Approximately 60 percent of the original stockpile was contained in bulk ton containers. The remainder was in weaponized form (e.g., rockets, bombs, mines, cartridges, projectiles, and spray tanks).

In addition to the actual chemical agents and munitions, the U.S. demilitarization program addresses the destruction of nonstockpile chemical materiel, including buried or chemical weapons, former production facilities, miscellaneous related materials such as containers or testing kits, and binary chemical weapons.

The Army was charged with overseeing the U.S. demilitarization effort. For most of the history of the program, responsibility was split between the Program Manager for Chemical Demilitarization, which supervised the actual weapons destruction program, and the U.S. Army Soldier and Biological Chemical Command, which administered the storage sites, handled safety and security issues, and assisted in the development of emergency response capabilities in communities near the sites. In February 2003, these tasks were combined and assigned to the Chemical Materials Agency.

Disposal of chemical weapons and materiel took many forms in the past. Between 1915 and 1969, weapons the United States wished to discard were sometimes buried, sometimes burned in open pits, and sometimes dumped at sea. By the time these methods were outlawed by the Chemical Weapons Convention, the United States was already well on its way to developing other destruction technologies. Although the Convention does not dictate how weapons are destroyed, it requires that countries utilize methods that are both irreversible and safe for people and the environment.

The decisions regarding what technologies would be employed to destroy the U.S. stockpile required years of deliberation. Incineration was the choice for destruction at five of the nine sites, where the stockpile chiefly consisted of weaponized agents. The Army found incineration to be the best way to dispose not only of the chemical agent, but also of contaminated weapons parts, propellants, and explosives. At the other four sites, an alternative destruction technology, neutralization, was chosen. Because the agent housed at these sites is predominantly in bulk form in ton containers, there is less peripheral materiel that requires destruction than in stockpiles consisting of munitions.

Another challenge for the demilitarization program was to determine where destruction of weapons would take place. The Army presented Congress with three alternatives: on-site destruction at each site; moving all the weapons to a single facility at Tooele, Utah; or a mid-range alternative, dividing the entire stockpile between two regional sites at Tooele and at Anniston, Alabama. Ultimately, it was decided that public safety could be better assured during on-site destruction than during transportation across the country to a single site.

As early as 1970, when the United States was drawing up initial destruction plans for some of its weapons, Congress required that the Department of Health and Human Services conduct a public health review of the disposal plans. The Centers for Disease Control and Prevention's National Center for Environmental Health (NCEH) retains responsibility for this mission. In addition to assisting in the monitoring of emissions, the NCEH has provided informed counsel to the Chemical Stockpile Emergency Preparedness Program, a joint effort of the U.S. Army and the Federal Emergency Management Agency to ensure that emergency responders in communities located near destruction facilities have the proper personal protective equipment and are properly trained should an accident occur.

Destruction Technologies

Important experience for the U.S. chemical demilitarization program was gained during regular disposal of weapons prior to Congress's decision to dismantle the stockpile. Even during the active U.S. program, chemical weapons in the arsenal could not be kept indefinitely because of corrosion or leakage problems. One munition in particular, the M55 rocket, suffered from instability in one of the elements contained in its propellant. Nitrocellulose in the propellant could degrade and cause the weapon to auto-ignite. Disposal of these weapons began in the late 1960s, when they were dumped in the ocean as part of "Operation CHASE" ("Cut Holes and Sink 'Em"). Opposition to the environmental effects of this type of destruction, and public reports such as that released by the National Research Council in 1969 that advised against further ocean dumping, led the Department of Defense to consider other methods.

Incineration and chemical neutralization were the two leading alternatives to dumping munitions in the ocean. Between 1972 and 1976 at Rocky Mountain Arsenal in Colorado, 2,700 tons of blister agent were incinerated and 3,700 tons of nerve agent were neutralized. To further test these two technologies, the Army constructed a pilot facility, the Chemical Agent Munitions Disposal System, at Tooele Army Depot in Utah where the largest percentage of the original U.S. stockpile was located. Based on the results of this testing, the Army chose incineration as its standard or "baseline" destruction technology. Several negative aspects of neutralization discouraged its selection, including the generation of more waste products, inappropriateness for use with certain agents, and the production of hazardous by-products that at that time would have required incineration for disposal. Likewise, incineration was found by a contracted study to be less expensive than the neutralization process.

A full-scale prototype incinerator, the Johnston Atoll Chemical Agent Disposal System, was constructed in 1985. The results of pollution monitoring during test burns in this facility met or exceeded U.S. national standards. The National Research Council issued multiple reports stating that the dangers of continued storage of weapons outweighed the dangers posed by incineration: Incineration destroys the entire weapon, through exposing the munition and the agent to extremely high temperatures.

The incineration process begins when Army personnel remove weapons from the storage area and transport them to the incineration facility in special protective containers, reinforced against fire and explosion. Upon arrival, personnel then inspect the weapons to verify that none of the munitions are leaking. Next, the weapons are placed on a conveyor belt and carried to a reinforced room, where a machine punches a hole in the munition and drains out the chemical agent. The weapon is then broken into pieces. The resultant parts of this process—agent, explosives, weapons parts, and packing materials—are divided and destroyed in separate, dedicated incinerators.

Concerned citizen groups representing the residents of communities located near destruction facilities have questioned the safety of incineration and expressed concern that insufficient consideration had been given to alternative technologies. In response, the Army created the Alternative Technologies and Approaches Program (ATAP) in 1992 to further investigate whether other methods of chemical weapons destruction might be workable at some sites. Chemical neutralization was again considered as an option. The Army found, among other drawbacks to this method, that draining chemical agents from individual munitions was too dangerous and complicated a process to merit changing the destruction method to neutralization at most sites. As some of the U.S. stockpile consisted of agent stored in bulk containers, however, implementation of neutralization was a more practical possibility in those cases. ATAP pursued research, development, and testing of chemical neutralization at two storage sites that contained single types of agent in bulk containers: Aberdeen Proving Ground, Maryland, and Newport Chemical Depot, Indiana. Full-scale neutralization was then adopted at these sites. In 1997, Congress created the Assembled Chemical Weapons Assessment to examine the possibility of also using alternative technologies for weaponized agents, such as the use of microorganisms for neutralization (biodegradation). Neutralization was ultimately chosen to destroy the stocks at two additional sites that had some assembled munitions: Pueblo Chemical Depot, Colorado, and Blue Grass Army Depot, Kentucky.

International Demilitarization

Due to economic difficulties, Russia's chemical weapons demilitarization efforts struggled in the initial years after ratification of the Chemical Weapons Convention. Russia consistently stated that international assistance would be required to destroy its extensive cache of nerve and blister agents. In 2001, the Group of Eight countries agreed to a "10 plus 10 over 10" commitment, in which, during the next 10 years, Canada, France, Germany, Italy, Japan, and the United Kingdom would pledge $10 billion to match a U.S. pledge of $10 billion to help rid Russia and other former Soviet states of their weapons of mass destruction. Some of those funds will assist in the destruction not only of Russia's chemical weapons, but also of the facilities that manufactured them. In 2002, Russia requested and was granted the allowable 5-year extension of the Chemical Weapons Convention's 2007 destruction deadline. It is likely that Russia will be given more time to complete its chemical destruction, probably until 2015.

India met its first two deadlines under the treaty, destroying 1 percent of its stockpile by 1999 and 20 percent of its most dangerous weapons by 2001. South Korea met the first 1-percent deadline but requested and received an extension of the 20-percent deadline during the fourth conference of the Chemical Weapons Convention's parties in 2002.

Biological Weapons Demilitarization

The Biological and Toxin Weapons Convention (BTWC) enjoins parties to destroy all stocks of biological weapons and biological warfare (BW) agents. In 1971, the United States completed the destruction of its offensive biological weapons stockpile. Destroying BW agents is, in many ways, simpler than demilitarizing chemicals. The goal of biological weapons demilitarization is to destroy the ability of BW agents to infect and to cause disease, and killing or denaturing pathogens and toxins can be accomplished by heating (pasteurization), mixing with harsh chemicals (bleach, phenol, alcohols, and formaldehyde), or a combination of steam and chemical treatment.

At facilities such as Pine Bluff in Arkansas, hot steam treatment and formaldehyde were both used to ensure that no organisms survived. In facilities inside the former Soviet Union, such as the biological weapons facility in Stepnogorsk, Kazakhstan, Kazakh workers used calcium hypochlorite in solution to spray down walls, and dry formulation mixed with earth to decontaminate equipment and other materials. Tons of anthrax bacteria that had been buried near the Aral Sea in Kazakhstan by former Soviet biological weapons scientists was finally mixed with calcium chloride and cement in 2003 by the U.S. Defense Threat Reduction Agency and other Department of Defense personnel. None of the anthrax spores were known to have survived following this last burial activity.

DIANISIDINE

A dye intermediate that is still produced today, dianisidine was among the first toxic chemicals to be used in modern warfare. In World War I, the chemist Walter Nernst recommended that the German military fill 105-mm shells with dianisidine chlorosulphonate (a chemical salt of the dye base). There were two purposes to this strategy: it would serve as a chemical weapon, while conserving explosive materials that were in short supply. The dianisidine salts were impacted as a powder and meant to shower the enemy with a sternatutory (sneezing) powder following detonation using a small charge in the shrapnel round. Although dianisidine is an irritating substance, especially to the eyes and upper respiratory tract, it was demonstrated later in the field that its toxicity was certainly not high enough to cause severe casualties.

On October 27, 1914, the Germans fired some 3,000 shells filled with dianisidine chlorosulphonate near Neuve-Chapelle, France, but none of the attacked British soldiers seemed to have taken notice of any chemical effects. Some have suggested that the TNT charge used in the shells was excessive and decomposed the chemical compound. Not knowing the full assessment of this failed attempt to use dianisidine chlorosulphonate as a weapon, Germany continued to experiment with chemicals in the field, later developing a stabilized artillery round with xylyl bromide. But it would later take the initiative of Fritz Haber, a bitter professional rival of Nernst, to take charge of using chemicals in warfare for Germany. Haber planned the first successful attack using chlorine gas at Ypres, Belgium, in 1915.

DIFLUOR (DF, DIFLUOROMETHYL-PHOSPHONATE)

Difluor is short for difluoromethylphosphonate, usually referred to in U.S. and NATO military code as DF. Going back to the first German synthesis of sarin nerve agent during World War II, diflour has been commonly used to react with other chemicals to form various G-nerve agents. Some processes utilize DF in combination with other compounds in a cascadelike reaction process using dichlor to manufacture sarin (GB). This is called the di-di method. Because of the highly reactive nature of fluorine, process equipment that is resistant to corrosion is usually required. In Nazi Germany, one step of the sarin production process took place in a solid silver vessel. In modern times, highly resistant pipes and reaction vessels, including those made of Hastelloy, steel that is especially designed to handle strong acids, would be needed for producing DF.

In recent decades, DF was the main component in U.S. binary chemical munitions, especially the

155-mm howitzer shell.. Although a number of proposed binary nerve weapons never entered into service, the United States did produce the M-687 GB binary projectile. This contained DF in one container and isopropyl alcohol in another, separated by a thin membrane. Another component, a so-called promoter, was used to push the reaction process to completion. When the shell was launched, the membrane was broken from the initial firing shock, and the rotational spin further mixed the chemical compartments to form sarin. The shell would then release the agent with a specially designed fuse mechanism. As in any chemical reaction, a certain amount of time is required for the reaction to run its course. In the case of the GB binary, this required about seven seconds. Thus, direct-fire use of binaries may have limitations. DF would also have found a role in certain ordnance such as the multiple launch rocket system in combination with other alcohols to form a so-called intermediate volatile nerve agent, but this ordnance was never produced.

DF is also a key compound for the mass production of sarin nerve agent. During the 1980–1988 Iran-Iraq War, the Iraqi military utilized DF in a method that could be described as a crude binary system—a kind of "quick-mix" procedure. They combined DF with the other necessary chemicals on the tarmac while aircraft were being readied to conduct bombing sorties. The chemicals were mixed in the aerial munitions, forming a roughly equal mixture of sarin and cyclosarin (GB/GF) before being dropped on enemy troops or Kurdish populations. DF was also used by the organic chemist of the Aum Shinrikyo cult in Japan to manufacture sarin. DF is listed as a Schedule 1 (B), a strictly controlled precursor in the Chemical Weapons Convention (CWC).

DIISOPROPYL FLUOROPHOSPHATE (DFP)

Diisopropyl fluorophosphate (DFP) is a toxic organophosphate that was investigated by both the Allies and German scientists during World War II. Its effects are nearly identical to those of other nerve agents in that it inhibits the enzyme acetylcholinesterase. Like the other anticholinesterases, DFP leads to overexcitation of the nervous-muscular system by increased levels of acetylcholine. DFP does have some commercial uses, primarily in the field of medical therapeutics. Though not specifically listed in the Chemical Weapons Convention toxic chemical lists, the use of DFP—as with any other toxic chemical—is prohibited as a means of warfare.

DFP is not nearly as toxic as other recognized chemical warfare (CW) agents such as sarin or VX. Nonetheless, if used in a weapon of mass destruction, large quantities of DFP—a volatile agent that could rapidly spread inside closed areas—would cause many deaths and injuries, and intensive medical treatment would be required for the survivors.

Although German chemists were the first to synthesize and develop the highly toxic organophosphates such as tabun, sarin, and soman (the G-nerve agents), ongoing research in World War II by British scientists followed along similar lines. The principal British researcher in the field of nerve agents was Dr. Bernard Saunders, who often subjected himself to dangerous experiments using these substances in order to evaluate their effects in humans. It had long been known that phosphorus could be poisonous in certain formulations, and fluorine had been recognized early as a highly reactive and caustic substance. During the course of work with these compounds, Saunders discovered that DFP caused one effect typical of nerve agents: pinpoint pupils. Saunders also found that by mixing DFP with mustard, the resultant product could remain liquid at much lower temperatures. British investigators found a relatively simple, almost one-step process for the manufacture of DFP. Thus, a weapon was conceived that not only included a nerve agent (DFP), but also increased the performance of blister agent in winter conditions.

It is not known if modern militaries have continued the production or deployment of chemical weapons using DFP. Its relatively low toxicity probably means that it is not favored by state programs. Terrorists, however, may consider the use of DFP in an improvised chemical weapon. An individual in the United States who held antigovernment attitudes and was probably active in the manufacture of illicit drugs was found with an empty container labeled DFP at his home in 1997. It was probably acquired from a commercial chemical supply house.

Although less toxic than modern nerve agents, DFP is still highly poisonous, with potentially devastating long-term consequences. One side effect of DFP poisoning, most marked in large doses, stems from its targeting of special enzymes in the nervous system; this can result in long-term neuropathy. Thus, although not as deadly as the typical nerve agents developed for warfare, DFP may pose greater long-term problems when it comes to casualty management.

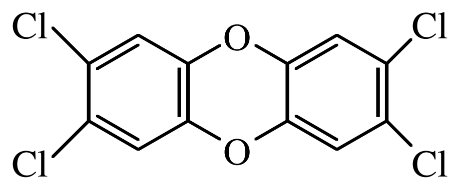
DIOXIN

Dioxin is the generic name for the chlorinated polycyclic hydrocarbon (2,3,7,8-tetrachlorodibenzo-para-dioxin) or TCDD. It is a chemical by-product and contaminant found in many modern sources, including the herbicide Agent Orange, which was manufactured during the Vietnam War.

In its pure form, dioxin is relatively toxic. Its toxic effect, however, is dependent upon the species of animal exposed to the compound. In small concentrations such as those found from industrial by-products, little evidence has been shown to link dioxin directly with human disease. In 1986, for example, Michael Gough wrote, "the position of the majority of scientists who have examined the human health effects of dioxin is that little or no harm has been done" (Gough, p. 254).

Some have suggested, however, that dioxin could be used as a mass casualty weapon. For example,

Figure D-1: Dioxin
(2, 3, 7, 8-tetrachlorodibenzo-para-dioxin)



during the 1970s, one writer postulated that dioxin could be used as a chemical warfare (CW) agent (Holmberg, p. 211). There is no evidence in the open literature to suggest, however, that dioxin has ever been seriously considered as a potential component in chemical weaponry. For the modern chemical industry, it would not be particularly difficult to mass-produce dioxin and to divert it for military use. At the same time, the conflicting data of dioxin's real or alleged toxicity in humans has probably led CW scientists to turn to other proven chemicals for use in warfare.

The notion persists that exposure to Agent Orange has been the cause of cancer and birth defects for Vietnam veterans and their families, including Americans, South Koreans, and Vietnamese civilians. Dioxin was formed as a contaminant during the manufacture of 2,4,5-T, a major component (50 percent) of Agent Orange, and it was implicated by U.S. veterans groups and the government of the Socialist Republic of Vietnam as the etiologic agent. Yet it is extremely difficult (if not impossible) to find adequate studies to prove a link between dioxin and veterans' illnesses. The most recent studies suggest that U.S. veterans who were exposed to dioxin from Agent Orange may have higher rates of diabetes than other populations. Even in the case of these findings, however, the results could be confounded by other non-dioxin-related risk factors such as obesity.

Dioxin and its alleged role as a toxic environmental contaminant continue to stir debate in scientific and other realms. Because of its ubiquitous nature as a very low-level presence in a number of consumer products, especially bleached paper and other goods, some have suggested that there is "no safe level" of dioxin. Such proclamations, however, have no supporting facts in the study of dioxin to date, or even in the field of toxicology itself. Still, prudence would dictate that levels of dioxin should be kept at below the point at which toxic effects

Dioxin can occur in many settings due to both natural and industrial processes. Its toxicity, however, is often exaggerated. (Bettmann/Corbis)

would be seen in human populations. When it comes to determining public health policy, knowledgeable toxicologists—and cautious governmental administrators—must determine how low these concentrations should be.

DIPHOSGENE

Diphosgene is also known as trichloromethyl chloroformate. It is a highly toxic lung irritant that first found use as a chemical warfare (CW) agent during World War I. Despite its well-earned notoriety as a war gas, diphosgene does not have the degree of toxicity or ease of acquisition that would make it a likely CW agent for use in weapons of mass destruction. Nor are there significant sources of the chemical in modern industry.

Diphosgene was first used by the German military at Verdun, France, in May 1916, probably as a response to the French use of phosgene in February of that same year. Diphosgene was later used by the French army in World War I under the code name Surpalite. In one World War I attack, 100,000 diphosgene shells were fired during a single engagement near Verdun. Diphosgene was probably the principal killing "gas" used in artillery shells during that war. In terms of total casualties, however, diphosgene was not nearly as significant as mustard gas in World War I.

Diphosgene was named on the apparent belief that it was the exact double of phosgene; that is, that phosgene ($COCl_2$) multiplied by two equaled diphosgene ($C_2O_2Cl_4$). Such a relationship is in fact spurious, as the chemicals are very different from each other in terms of chemical and physical properties. In terms of their action as lung irritants, however, their effects are similar. Fritz Haber, generally considered the father of modern chemical warfare, ranked diphosgene at an index of 500 in terms of toxicity compared to 450 for phosgene.

An oily liquid, diphosgene was derived by German military chemists. The toxic effects of diphosgene mirror those of phosgene: interacting with vital molecules and enzymes in the pulmonary system, causing pulmonary edema by irritating lung tissue. At sufficient concentrations, diphosgene has an odor like that described for phosgene, often characterized as newly mown hay. Treatment options for diphosgene exposure are similar to those for chlorine or phosgene intoxication; little can be done beyond supportive care and assistance in breathing.

Diphosgene remains liquid at a larger range of temperatures than other CW agents used in World War I. This makes it easier to fill munitions with diphosgene. Once fired at targets and after the detonation of shells, however, diphosgene still proved to be quite volatile, and lethal concentrations on the battlefield were difficult to create. It also was found that diphosgene was prone to decompose following the explosion of its delivery munitions. In addition, production of phosgene during World War I was easier than that of diphosgene.

As is the case of phosgene and some other World War I–era compounds, it is unlikely that diphosgene will pose a significant modern military threat. Some have suggested that diphosgene liberates chloroform upon contact with protective filters and that it perhaps defeated early gas masks. The Chemical Weapons Convention lists diphosgene (as it does phosgene) a Schedule 3 compound due to its potential use as a weapon.

DUAL-USE

U.S. technology and hardware items with both civilian and military applications are considered dual-use items under the U.S. Export Administration Regulations (EAR). In accordance with the EAR, all dual-use items are evaluated and listed on the Commerce Control List, which is used to determine whether a dual-use item may be exported from the United States. The Bureau of Industry Security in the Department of Commerce is responsible for administering the EAR, licensing exports, providing outreach services to U.S. industry, and enforcing the provisions of the EAR through civil and criminal legal actions against violators.

In some instances, dual-use items may require export authorization from the Department of Commerce. In determining whether a license is required, EAR guidelines consider both the technology to be exported and the country of destination. As a general rule of thumb, dual-use exports are more highly restricted to countries considered to be terrorist or proliferation risks.

Export restrictions on dual-use items are subject to review and change. Accordingly, the Commerce Control List is altered several times each year. In some cases, restrictions on exporting specific dual-use items are relaxed as the underlying technologies become more common or widespread throughout the world. Restrictions placed on individual countries also are reviewed and changed periodically, based on the proliferation and terrorist risk each country poses. Changes are coordinated through the Departments of Commerce, Defense, and State, as well as other federal organizations where applicable.

DUGWAY PROVING GROUND

Dugway Proving Ground is a chemical and biological weapons facility that once served as a vast test site for U.S. chemical and biological weapons. It is located in the Great Salt Lake Desert, about 80 miles southwest of Salt Lake City, Utah. The Dugway facility, 25 percent larger than the state of Rhode Island, was opened in 1942 as the United States, which had just entered the Second World War and feared the use of chemical weapons by the Axis powers, looked to expand its own production and testing facilities. Closed when the war ended, it was reopened and enlarged in 1950 in response to the outbreak of the Korean War. Biological weapons were tested there for the first time in 1953.

After it became a permanent installation in 1954, the infrastructure of Dugway grew over the years in response to the Cold War. As new and more effective chemical and biological agents were developed in U.S. government laboratories (primarily at Fort Detrick, Maryland), they were sent for testing at Dugway. Most testing involved the use of animals such as goats. In outdoor tests, animals would be tethered in test grids at increasing ranges from the release of agents. One such test of anthrax resulted in a section of Dugway being permanently contaminated and set off-limits.

Such open-air testing, however, was brought to a halt after an airborne dispersal experiment went awry in March 1969. The aircraft in question was carrying canisters that were designed to open and release VX nerve agent over the proving ground. The aircraft, however, continued to release agent as it turned away and left the confines of the proving ground. The agent contaminated an area 20 miles north of the perimeter, killing more than 6,000 sheep grazing there. The incident was worsened by the fact that, for more than a year, the military denied any responsibility for the deaths, noting that the dead sheep showed atypical signs of nerve agent poisoning. This incident alerted the U.S. public to the dangers of the production, storage, and testing of chemical and biological weapons and struck a chord with the burgeoning environmental movement. It also led to increased interest in more public accountability when it came to activities undertaken at the Dugway facility.

Although open-air testing ended at the facility, Dugway remained the prime U.S. site for the testing of chemical and biological warfare agents within facilities that could safely contain dangerous agents. In 1976, however, fifty wild horses died on the proving ground in mysterious circumstances. The military again denied responsibility for the deaths of these animals.

Today, Dugway is part of the U.S. Army Test and Evaluation Command (TECOM), headquartered at Aberdeen Proving Ground, Maryland. Some 500 people are still employed at Dugway, the majority of them civilian scientists. Most of their work is concerned with testing defensive measures against chemical and biological agents, but research also is conducted to perfect battlefield smokes and obscurants.

EA2192

EA2192 (named after the U.S. Army's Edgewood Arsenal) is a VX analogue. The chemical name for EA2192 is S, 2-(diisopropylaminoethyl) methylphosphonothioic acid. Because it possesses both high toxicity and a chemical structure very similar to VX nerve agent, EA2192 is classified as a Schedule 1A toxic chemical under the Chemical Weapons Convention (CWC). It is unknown whether EA2192 has been produced or utilized as a chemical weapon in the past or present. The toxicity of technical or pure EA2192 is on par with that of VX.

This compound is of recent interest given U.S. efforts to destroy its remaining stockpile of VX nerve agent. Due to environmental and other technical concerns, the U.S. Army decided that bulk VX would be chemically neutralized rather than sent straight to incineration. When VX is mixed with hot sodium hydroxide (NaOH), most of the toxic chemical warfare agent is hydrolyzed (broken down by water) into nontoxic compounds. Still, as VX is hydrolyzed, a small quantity of EA2192 is formed as a by-product. The potential hazard posed by EA2192 during the neutralization process is mitigated by the formation of a nonvolatile salt. Furthermore, the so-called hydrolysate remaining after neutralization has less than 0.1 percent by weight concentration of EA2192. The subsequent and large dilution factor makes the resultant hydrolysate an irreversible end product of VX destruction, and negligible amounts of EA2192 are eventually biodegraded by microorganisms found in nature.

EMPTA (O-ETHYL METHYLPHOSPHONOTHIOIC ACID)

EMPTA, for O-**e**thyl **m**ethyl**p**hosphono**t**hioic **a**cid, is a precursor for V-type nerve agents. EMPTA has few, if any, commercial uses. EMPTA is useful as a VX precursor, however, because although EMPTA is not especially toxic, much of the difficult chemistry required to manufacture the toxic nerve agent is already present in the EMPTA molecule. It is suspected that Iraq used EMPTA to produce VX, and other countries (e.g., the Soviet Union) may have also used EMPTA to create their chemical arsenals.

According to the schedules of precursor chemicals restricted by the 1993 Chemical Weapons Convention (CWC), EMPTA would be included (albeit not explicitly) in the Schedule 1 category. EMPTA has been a noted precursor for CW agents in the open literature since at least 1986.

Because Iraq had been using EMPTA as a means to produce VX nerve agent, this precursor had been on the current watch list by Western intelligence agencies for about 2 years before a soil sample was obtained in Khartoum, Sudan in late 1997. This sample was taken near the grounds of Al Shifa, a pharmaceutical plant that was ostensibly in the business of producing medicines for humans and livestock. After U.S.-based laboratory analysis, it was determined that the soil contained EMPTA. Other and more circumstantial evidence had also pointed to production of VX or a similar type of nerve agent at Al Shifa. According to newspaper reporting, Emad al-Ani, an important figure in Iraq's development of chemical weapons (the "father" of Iraq's VX program), had contacts with officials from Al Shifa.

Due to this evidence, and as a means to signal its capability to strike back at terrorists following two large bombings at U.S. embassies in Africa, the United States launched a cruise missile attack in 1998 against a suspected Osama bin Laden training camp in Afghanistan and at the Al Shifa factory, which was demolished by the attack.

Chemical weapons experts have since suggested that Fonophos, an organophosphate insecticide, had been used quite often throughout Africa and could have been "misinterpreted" for EMPTA. An unnamed spokesman from the Organization for the Prohibition of Chemical Weapons also said that Mobil Corporation and the International Chemistry Industries of America had published reports describing how EMPTA had possible commercial applications. Thomas Carnaffin, a British engineer who had helped to design the Al Shifa plant from 1992–1996, said that he never saw evidence of VX or its precursors being made at Al Shifa Pharmaceuticals, and he claimed that security was very lax during the time he was technical manager at the facility.

As to the veracity of the evidence and the appropriateness of the U.S. military response, the attack on Al Shifa remains controversial to this day.

ENTEROVIRUS 70

Human enteroviruses are a large family of ubiquitous viruses causing a spectrum of both common and uncommon illnesses with flulike symptoms, particularly among infants and children. After influenza, they are second only to the common cold as a source of flulike ailments.

Enterovirus-70 (EV-70) can cause acute hemorrhagic conjunctivitis (AHC), a highly contagious, self-limiting inflammation of the eye. Following an incubation period of 12 hours to 3 days, exposure causes a sudden onset of conjunctivitis with lid swelling, subconjunctival hemorrhage, and marked eye pain without systemic effects. These symptoms usually resolve within 1 to 2 weeks. Although not fatal and not listed as a high-priority bioagent by the Centers for Disease Control, AHC can be incapacitating.

AHC was first reported in Ghana and Indonesia in 1969 and was called Apollo conjunctivitis. A new enterovirus, EV-70, was identified as a cause of AHC in 1972. EV-70 was subsequently responsible for a pandemic of the disease in 1980–1982, during which it spread to tropical areas of Asia, Africa, Central and South America, the Pacific islands, and parts of Florida and Mexico. Small outbreaks associated with EV-70 have been reported in European eye clinics, among refugees in North America, and among travelers returning to North America.

UN Special Commission (UNSCOM) Chairman Richard Butler reported in a March 18, 1999 letter to the UN Security Council about inspections of a facility in Daura, Iraq, where research was undertaken on viral agents for Iraq's biological warfare program, including enterovirus.

This virus may be reemerging. EV-70 has led to various epidemics in India, including a major outbreak of AHC in Delhi, India, during the rainy season in August and September 1996. In August 1999, the Ministry of Health of Romania reported an outbreak of aseptic meningitis. The CDC and the Robert Koch Institute in Berlin, Germany, assisted in the investigation, and the responsible agents were found to be three separate enterovirus serotypes.

EV-70 only infects humans. It is shed in tears and spread via fingers, towels, clothing, and so on. As the virus can survive for weeks in water and other fluids, indirect transmission via food and water is seen in areas of poor sanitary conditions and overcrowding. Infants in diapers are particularly efficient transmitters of infection, as direct contact with feces occurs with activities such as diaper changing. This is a virus with mysterious epidemiological characteristics. It is responsible for sharp, severe outbreaks of intense conjunctivitis, which seem to cease as suddenly as they arise. In temperate climates, infections occur mainly in the summer and fall and can affect more than half of a community.

EQUINE ENCEPHALITIS (VEE, WEE, EEE)

Equine encephalitis (also referred to as the equine encephalitides) is a group of diseases affecting both horses and humans, caused by a family of viruses that are transmitted by the bite of mosquitoes. One of these viruses, Venezuelan equine encephalitis virus (VEE virus), was developed by the United States into a standardized biological weapon before the renunciation of biological weapons by the United States. Other viruses of this family, such as western equine encephalitis (WEE), eastern equine encephalitis (EEE), and St. Louis encephalitis (SLE), are less likely to be developed as biological weapon agents as they do not share the advantages of VEE in terms of infectivity. However, they too may be considered potential viruses for weaponization.

History and Background

The equine encephalitis viruses and the related Japanese B encephalitis virus were investigated as potential BW agents during WWII by the U.S. BW program. Immediately following WWII, the U.S. weaponization effort concentrated on VEE because of the large number of laboratory infections it caused and its ability to grow well in the laboratory.

VEE was developed primarily as an incapacitating BW agent because, in healthy adults, death or permanent disability from infection was very rare, but the disease was severe enough to incapacitate its victims for several days. Natural epidemics of VEE, however, showed considerable variations in the severity of the human disease, with significant mortality and permanent neurological damage in infants and children and indications that infection caused fetal malformations. Some strains appeared considerably more lethal, and these were investigated as lethal BW agents.

Technical Details

The VEE virus can be transmitted by the bite of an infected mosquito or by inhalation of an artificially generated infectious aerosol. In nature, VEE normally exists in a rodent-mosquito cycle that causes human cases only sporadically in restricted localities. When mutations occur that allow the virus to replicate in horses, large-scale equine outbreaks occur that can kill thousands of horses, spread for hundreds of kilometers, and persist for years. During these epizootics, infectious mosquitoes spread the disease to humans, sometimes causing human outbreaks.

The U.S. Army developed an attenuated live-virus VEE vaccine that was protective in humans but provoked reactions nearly as severe as the disease itself. This vaccine was never used in humans to control VEE outbreaks, but it proved to be an effective veterinary vaccine.

Current Status

VEE remains on the U.S. Centers for Disease Control and Prevention (CDC) Category B list of potential biological agents, although terrorists or hostile states would seem unlikely to choose an agent with such generally benign effects as a weapon of terror or mass destruction.

As a biological weapon, contemporary information about the genetics of VEE indicate that it is considerably less controllable than was believed during the period when it served as a U.S. biological agent. U.S. BW doctrine called for the use of noncommunicable agents to allow precise control of the extent of an outbreak in tactical scenarios in which an incapacitating BW agent such as VEE would be used. Yet, in retrospect, it has been found that many outbreaks of VEE that were once considered natural were in reality the result of the "escape" of laboratory strains, either through inadequately inactivated veterinary vaccines or other, uncharacterized environmental releases from virology laboratories. This propensity of isolated releases to develop into poorly controllable regional outbreaks reduces the attractiveness of VEE as a BW agent.

Brains from dead crows are tested for Eastern Equine Encephalitis (EEE), as well as West Nile Virus. (Wyman/Corbis Sygma)

After many spontaneous outbreaks in Latin America during the period 1938–1975, VEE outbreaks became quite rare after the mid-1970s.

Its benign effects make unmodified VEE virus unappealing for use as a terrorist BW agent. The fact that it can be grown to high titer (strength) and be delivered by direct aerosol suggests the possibility that it might form a basis for a molecularly modified BW pathogen. Its genome is small, and genomic variations are highly limited by the stringent conservation of its protein products, making such a "genetic vector" role problematic. The Soviet BW program attempted to incorporate VEE genes into a vaccinia virus, apparently in an effort to develop a better VEE vaccine.

ETHIOPIA (ABYSSINIA)

Italy's use of chemical weapons in Abyssinia (now Ethiopia) in 1935 is the only time a European power has used such weapons in a conflict since the end of World War I. This action contravened the Geneva Protocol of 1925, which Italy had signed and ratified, and which outlawed the use of gas and bacteriological weapons.

In October 1935, the Italian dictator Benito Mussolini was anxious to expand his African colonial empire. From bases in two Italian colonies in east Africa, Eritrea and Somaliland, Mussolini's forces invaded the neighboring independent state of Abyssinia. The Ethiopian troops, under their leader, Emperor Haile Selassie, despite being outgunned and poorly equipped, put up stiff resistance against the Italian invaders. Lack of progress in what the Italians expected would be an easy advance caused them to think about employing poison gas. The use of such weapons, despite their illegal nature, had been considered by Mussolini even before the invasion had begun. He had previously cabled his generals: "Authorized [to] use gas as last resort in order to defeat enemy resistance and in case of counterattack" (Coffey, p. 263).

The "last resort" apparently had been reached on December 23, 1935. On this day, a body of Ethiopian troops came under attack from Italian planes. Aerial bombardment was nothing new to these soldiers, but their commander noted that the planes dropped "strange containers that burst open almost as soon as they hit the ground or the water, releasing pools of colourless liquid" (Coffey, p. 196). Those splashed by the fluid "began to scream in agony as blisters broke out on their bare feet, their hands, their faces." Those that rushed to the river to alleviate their suffering with water found little relief, because the river was polluted with the same substance. Men took hours to die. Local peasants who drank water from the river shared the same fate as the soldiers who had been attacked with mustard agent.

Blister agents, such as mustard gas, were eventually employed widely by the Italians. Canisters gave way to the use of aerial sprays created by planes in formation. Whole areas became covered in blister agents that created a long-term danger for the barefoot Ethiopian soldiers and peasants. Grazing animals were also affected by the agent. The use of such agents by the Italians—who always denied employing them—proved very effective in the war. They began to achieve easy victories as Ethiopian morale crumbled in the face of chemical attacks. By the war's end in May 1936, when the Italians occupied the capital of Addis Ababa, some one-third of all Ethiopian casualties (15,000) had probably been caused by chemical weapons.

The international community was shocked by the Italian use of chemical weapons, and the League of Nations applied sanctions on the country. These sanctions, in keeping with the weak nature of the League in the 1930s, were soon dropped.

EXPLOSIVES

Explosives are energetic materials that expand or decompose quickly, giving off large amounts of heat and/or rapidly expanding gases. Black powder was probably the earliest explosive, used in warfare by the Chinese as early as 920 C.E. Commonly used explosives in both civilian engineering projects as well as warfare—including terrorism—are trinitrotoluene (TNT), nitroglycerine (component in dynamite), and ammonium nitrate fuel oil (ANFO) mixtures.

High explosives fall into three general categories based on their sensitivity: primary, secondary, and tertiary. A primary explosive is one that will detonate upon exposure to heat, shock, friction, flame, or static discharge. They are generally extremely sensitive and are used in small quantities as detonators to initiate secondary explosives.

Secondary explosives cannot be detonated readily by heat or shock. Several explosives in this category can be burned without detonating, and are relatively insensitive to shock, making them safer to handle than primary explosives. While a detonation may spontaneously occur, it is far less likely than with a primary explosive. In most cases a primary explosive must be used to initiate detonation of the secondary explosive. Thus, a "train" is needed for one group of explosives to link detonation to another less sensitive group of explosives.

The third group, tertiary explosives, is the least sensitive. ANFO falls into this category. Spontaneous detonation isn't likely unless several factors occur. In some cases a secondary explosive, functioning as a booster for the detonator, must be used to induce detonation. This creates still another link in an explosives train.

High explosives create two types of effects on the target material: shattering and heaving. All have both characteristics but tend to have one more than the other. Shattering is inducement of shock waves into the material that break up its composition. An example would be using plasticized explosives (such as C-4 or Semtex) to "cut" through steel; the target is destroyed but attached material inches away remains intact. Explosives with extremely high detonation rates are normally used for this type of activity. Heaving is the physical movement of material due to the expansion of gases from the explosion. An example would be using ANFO in earthmoving operations. It compresses rock beyond its elasticity threshold, thereby breaking it up. Explosives with low detonation rates are used for this sort of activity.

F

FENTANYL

The synthetic opiate fentanyl and its derivatives are among the many different pharmacological substances investigated for the purpose of incapacitating personnel. Especially during the Cold War, a great deal of research was expended by the United States and the former Soviet Union on chemical substances that would not necessarily kill, but would instead merely incapacitate the enemy. In the offensive U.S. chemical warfare (CW) program of the 1950s and 1960s, a large number of pharmacological substances were investigated for their potential as incapacitants, including depressants, hallucinogens (e.g., LSD), belladonna drugs (scopolamine, BZ), and the opiate derivatives. The opiates in particular, such as morphine, fit receptors in the human brain and nervous system as a key would fit into a lock, releasing painkilling endorphins and inducing a state of euphoria. Given the right amount, opium-based drugs can also induce sleep and unconsciousness. One U.S. Army study in 1989 used carfentanil—a synthetic opiate related to Fentanyl—and saw a nearly tenfold increase in its potency when delivered in aerosol form to experimental animals.

The properties of poppy-derived medicaments had been known for many centuries, and morphine had already found some use as an anesthetic agent by the late 1800s. However, the use of morphine as a total anesthetic (inducing unconsciousness, versus local, in which the patient is awake) sometimes led to deadly complications both during and following medical procedures. In 1939, the synthesis of meperidine and its improved safety profile led to renewed interest in the use of opiates for anesthesia. But arguably the most important development was the synthesis of fentanyl, its structure first patented by Paul Janssen in 1963. Fentanyl remains among the more commonly used compounds in combination with other drugs, or even by itself, for anesthesia. Large doses of fentanyl, however, can increase risks for complications, particularly in terms of respiratory depression during recovery.

Recently, a number of different analogues based on fentanyl have been introduced, including sufentanil, alfentanil, and remifentanil for use in anesthesia. If drugs like the belladonna alkaloids could be utilized in chemical weapons, some CW specialists have wondered if opioid derivatives could also play a role in warfare or in certain tactical operations. During their own research, however, U.S. military chemists found that the dose of opiate-related drugs needed to cause the desired degree of incapacitation was not far from their lethal dose. With such a narrow margin of relative safety, there was not much rationale for using these substances as incapacitating weapons.

Although considered unfit for large-scale production or weaponization, opiate drugs like fentanyl may have had some applications in specialized warfare or covert operations. During his tenure in southeast Asia (1966–1968), retired Major General John K. Singlaub recalls a time when the military use of fentanyl or similar drugs was considered for tactical roles in Vietnam. The U.S. Military Advisory Command (MAC) Studies and Observation Group (SOG) was assigned, among other things, to gather intelligence by capturing enemy officers for interrogation. This proved to be among the most daunting challenges that Singlaub and others faced along the Ho Chi Minh trail, where North Vietnam shuttled logistical and other support to the Viet Cong irregulars in the South. Although most of these Vietnamese carrying supplies on foot or on bicycles were low-ranked soldiers—mainly peasants pressed into labor—some high-ranking North Vietnamese Army officers were often also present. Often, when

SOG units engaged these caravans, it would quickly turn into a desperate firefight. General Singlaub wondered if there was a way to temporarily knock out some isolated individuals while scattering away the irrelevant logistical support units. He could then bring these NVA officers in for questioning. One of the plans was to utilize some type of tranquilizing dart with fentanyl or a related substance. In the end, however, the science advisor to General Westmoreland, commander of the U.S. military in Vietnam, did not approve of this venture, and only CS (a riot control agent) was ever approved for the southeast Asian theater of operations.

In October 1997, the Israeli Mossad (intelligence bureau) used fentanyl in either an assassination attempt or a snatch-and-grab operation that subsequently went awry. In this incident, Israeli intelligence operatives (including one physician) traveled to Jordan and followed Khalid Mishal, a Jordan-based Hamas (Palestinian-based terrorist organization) leader, in a car. The plan was to deliver fentanyl in a spray that would be absorbed through Mishal's ear, but Khalid Mishal was able to escape. He was reportedly affected by the drug, however, and required significant medical attention afterward.

On October 23, 2002, during an evening performance at a Moscow music theater, some 50 Chechen terrorists, equipped with firearms as well as large quantities of explosives, seized the venue and the 800 people inside. The terrorists threatened to kill everyone inside unless Russia ended the war in Chechnya. Although the Chechen militants agreed to release some of the hostages during the first couple of days, negotiations with the Russian authorities eventually stalled. Just before dawn on October 26, Russian special police units resorted to using an incapacitating gas based on the drug fentanyl to end the crisis. All of the Chechen militants were immobilized, and were shot and killed when Russian police finally stormed the theater. At first it appeared that most of the civilian captives survived. But although the operation was largely a success, 129 people eventually died from the effects of the gas, most of these being hostages. The fact that so many died because of fentanyl (or a related derivative) poisoning has been the source of some controversy about how the Moscow theater operation was handled. During the 2003 review conference of the Chemical Weapons Convention, the Moscow theater incident also led to increased discussions in the Organization for the Prohibition of Chemical Weapons in The Hague concerning the legality of incapacitants and riot control agents.

FERMENTER

Fermenters, or bioreactors, have wide and varied civilian applications in basic research and in large-scale chemical and biological processes in the pharmaceutical, food and beverage industries, and at wastewater treatment facilities, among many other applications. Although the understanding of fermentation was originally confined to the production of alcohol, it has since been found to be possible to utilize microorganisms (e.g., bacteria, fungi, and yeasts) for the efficient manufacture of other carbon compounds. Fermentation can suggest biological activity in which metabolism takes place in an oxygen-free environment (anaerobic). In recent years, fermentation has sometimes been understood to include such a process under aerobic (with oxygen) conditions as well. Virus production, especially for the production of vaccines, can also be accomplished using specialized cell lines in fermenters (also referred to as bioreactors).

Fermenters would be a necessary part of a biological weapons program, especially for the production of bulk agents—bacteria, toxins, and viruses. Past BW programs, such as those in the United States and former Soviet Union, used very large fermenters to produce biological agents such as anthrax. For example, at Stepnogorsk in Kazakhstan, the Soviet BW program utilized 20,000-liter fermenters. Transfers of certain types of fermenters are regulated by national export controls, including an informal export arrangement known as the Australia Group. The ubiquity of fermenters in a variety of commercial enterprises, from foodstuffs to vaccines, however, makes the control of fermenters problematic if not impossible.

Typical fermenters used to produce vaccines, for example, are likely not to differ when used to produce BW agents. In the case of diphtheria vaccine, for example, bacteria are grown and the toxin responsible for disease—diphtheria toxin—is detoxified following separation from the biomass. Typical production of other toxoids for childhood vaccinations, including against tetanus, might begin in a fermenter of about 1,000-liter capacity. The bacteria are cultivated under controlled conditions with sufficient growth media in a sterile environment. Although viruses require living cells to reproduce, this technique has also given way to using large fermenters to achieve large amounts of cells for viral production. This approach has made the manufacture of viral-based vaccines much more economical.

Among other intermediate and final products produced in processes involving the use of fermentation are acetone, amino acids, antibiotics, beer, cellulose, citric acid, enzymes, and perfume. In beer production, wort—the filtration product derived from a rice and barley mixture following heating—is fermented using yeasts such as *Saccharamyces cerevisiae.* During wastewater treatment, sludge is collected following preliminary treatment and separation. The sludge is then typically transferred into an enclosed tank (an "anaerobic digester"), where bacteria partially convert it into methane gas. The unconverted portion of the sludge may then be used in fertilizers, incinerated, dumped, or buried, and the methane may be collected for use as fuel.

The terms *fermenter* and *bioreactor* are often used interchangeably. Fermenters are vessels in which fermentation occurs through the optimized distribution of gases, liquids, and nutrients at selected temperatures and pH levels; the fermentation vessels may range in size from a few milliliters to tens of thousands of kilograms (liters). Fermentation processes generally require carbon and nitrogen sources, as well as other growth factors such as vitamins and minerals. There are a wide variety of fermenters differing in design and function. Some involve the immobilization of cells or their emplacement behind a membrane through which nutrient media may then be passed. Other fermenters are batch reactor vessels that are periodically emptied and sterilized before reuse. Still other fermenters operate continuously as feedstocks are added and product removed.

There are two broad types of industrial production configurations involving the use of fermenters. One is a traditional single-purpose plant, such as those found in the petrochemical industry, where large volumes of commodity chemicals are produced on a continuous basis. The other is a smaller, more versatile facility where smaller quantities of fine chemicals are produced to order in batch mode. Such facilities may, for example, use lines of automated microreactors capable of producing large volumes of specialized chemical or biological substances over a period of days or hours.

One of the most significant trends involving the use of fermenters and their possible application for the production of chemical or biological warfare agents is that the distinction between chemical and biological processes is increasingly blurred. This is reflected in the increasing use of biocatalysts (microbial enzymes) in the chemical industry, including for the large-scale production of cosmetics, food products, and plastics. Catalysts are often required to accelerate or induce desired reactions. The chemical and biotechnology industries have a growing interest in the research and development of biocatalysts because their use can reduce production costs. Biocatalysts, usually enzymes or enzyme-based substances, are more selective in their end products than traditional chemical processes. Processes involving the use of biocatalysts also generally involve fewer intermediate production steps than traditional chemical synthesis routes.

FOOT-AND-MOUTH DISEASE VIRUS

Long a scourge in animal husbandry, foot-and-mouth disease (FMD) is especially worrisome for modern agriculture industries that employ dense-animal farming. FMD is generally not a lethal disease in animals, nor does foot-and-mouth disease virus (FMDV) directly affect humans, although infections do occur (generally in a laboratory setting, and only with considerable effort). FMDV affects animals with cloven hooves, such as pigs, cattle, sheep, goats, and giraffes, but not single-toed animals such as horses. Infected animals generally develop painful sores (starting as vesicles) in the mouth. Vesicles also form at the hoofs and between the digits, with shedding of epithelium. Animals thus affected do not thrive. In cattle, sores can develop on the teats, ruling out milk production, at least during the course of disease. Most animals ordinarily will survive FMDV infection, although some strains of the virus are more potent than others (e.g., many pigs died from FMD in the 1997 Taiwan FMD outbreak). Death in animals from FMD is usually caused by damage to heart muscle, and surviving animals can suffer some long-term effects, including diabetes mellitus.

FMDV has been investigated as a potential BW agent by the United States, the Soviet Union, Iraq, and probably other states. During the Second World War, research was conducted on FMDV by H. W. Schoening at the U.S. Department of Agriculture as a joint War Research Service project with the United Kingdom, although little seemed to have resulted from this project.

Upon confirmation of an FMD outbreak in a country member of the Office International des Epizooties (OIE), the International Office of Epizootics, exports of domestic animals and related products are banned. The effects of an FMDV outbreak can have significant financial repercussions, as witnessed in Taiwan in 1997 (up to U.S. $25 billion in losses) and the United Kingdom during 2000–2001 (estimates range in the billions of dollars). One estimate in 2002 suggested that an FMD outbreak in the United States could cost as much as $27 billion.

Transmission of FMDV is usually due to contact with infectious animals or ingestion of contaminated feedstuffs. Hedgehogs have also been implicated in the transmission of FMD in cattle. The causative organism of FMD is a picornavirus (small RNA virus). Like other viruses of this type that can cause human disease (including the common cold

Foot-and-mouth disease can usually only be stopped by culling animals. (Reuters/Corbis) and polio), the viral particle is nonenveloped. Nonenveloped viruses are generally more resistant to environmental stresses, and can remain a source of infection for a considerable time. Although easily killed in acid (pH<6.8–6.5), FMDV is otherwise a very hardy organism. It can survive for long periods in soil and on fomites (infectious objects), and it can be carried in the throat passages of humans.

Though still a subject of some controversy, it has been substantiated that FMDV can be transmissible through the air and can survive being airborne, especially under conditions of high relative humidity. Swine tend to shed many more viral particles than other animals. This may help to explain why the outbreak in Taiwan was so devastating to its swine industry. The similarity between FMDV and swine vesicular disease, also caused by a picornavirus, also makes rapid diagnosis in the field difficult because both diseases share the same clinical manifestations.

Once it has occurred, the proper control of an FMD outbreak is a matter of some dispute, but it generally involves culling animals, setting up perimeters around infected herds, and vaccinating a ring of animals around infected herds. Although vaccines are available for FMD, the efficacy of inoculating herds is limited by the wide number of serotypes of FMDV and the fact that the vaccine may not stop animals from shedding virus. Furthermore, once vaccinated, the animal is thus serologically indistinguishable from other infected animals, and this confounds accurate disease surveillance. From an economic perspective, destroying infected animals and thorough cleaning of contaminated areas are usually the only practical options for controlling the disease.

FORT DETRICK

Although Fort Detrick, Maryland is today home to several U.S. government agencies including the National Cancer Institute, it is primarily known as the home of the U.S. military's biological weapons research program. As the Department of Defense's lead laboratory for medical biological defense, the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) is an organization designed to develop vaccines, strategies, treatments, training programs, and information packages to counter offensive biological weapons and naturally occurring infectious diseases that require special containment. The Institute is a world-renowned reference laboratory for definitive identification of biological threat agents and diagnosis of the diseases they produce. USAMRIID's staff of 500 includes physicians, microbiologists, pathologists, chemists, veterinarians, molecular biologists, pharmacologists, and physiologists.

Originally a National Guard airfield, Camp Detrick was acquired by the U.S. Army's Chemical Warfare Service in March 1943 as a center for research into biological weapons. Camp Detrick, near Frederick in the foothills of western Maryland's Catoctin Mountains, was ideal for such research because it was isolated, yet close to Washington, D.C., and to the already existing U.S. chemical warfare research establishment at Edgewood Arsenal. The U.S. Army needed a research facility to develop the defensive and offensive biological warfare (BW) capabilities that it lacked on entry into the Second World War. Of particular concern was the need to match Japanese biological warfare capabilities. There were strong rumors at the time that the Japanese had already employed biological weapons in the late 1930s following their invasion of China.

Background

Although much was known about the use of chemical weapons in the early 1940s, given their widespread use in the First World War, little was known about biological agents—the use of living organisms (bacteria and viruses)—as weapons of war. These weapons had the advantage over their chemical counterparts in that not only were they cheaper, but they were also more insidious; they could be used in an attack without the victim knowing that they were being used until it was too late to take defensive measures. The goal of research into biological agents was to manufacture a biological weapon that generated a highly infectious disease against which there was no natural immunity developer (e.g., vaccines) readily available. Research efforts went into ensuring that the biological agents could be produced in bulk and be "weaponized," that is, be able to survive outside the laboratory, be easily spread, and be easily absorbed into the human body. Research was undertaken into offensive biological warfare, creating the weaponized agents, and defensive BW, or developing counters to an enemy's use of biological agents.

During the Second World War, under conditions of great secrecy and under the direction of George Merck (head of the Merck pharmaceutical organization), Camp Detrick housed the testing, development, and production of both anthrax and botulinum munitions. Some of the facility's product was shipped to England later in the war in preparation for any German use of BW. None of these munitions was ever used either in Europe or in the Pacific theater.

After the war, research by the Army's Chemical Corps continued at Camp Detrick. Many new research data were gathered from captured Japanese scientists and military figures who, in the 1930s and 1940s, had participated in notorious BW experiments conducted at Unit 731 in Manchuria. Despite the war crimes committed in the course of that research, scientists from Camp Detrick considered the information from these Japanese BW scientists to be so vital to U.S. national security that they argued for the Japanese scientists to be granted immunity in return for their cooperation.

Although large-scale production of biological agents ceased at Camp Detrick after World War II, it began again in earnest again in 1950 following the outbreak of the Korean War. Against a background of the Korean conflict and a general fear that the new Cold War enemy, the Soviet Union, was developing a substantial BW, or "germ" warfare, capability, Camp Detrick was expanded. An eight-story windowless factory for producing perhaps the most virulent biological agent, anthrax, appeared, as did a structure four stories high to house a huge metal sphere for testing aerosols. Work was conducted not only on lethal agents, but also on incapacitants and hallucinogens. Some 60,000 animals per month were required for the testing of such agents during the 1950s and 1960s.

The increasing scale of the work of the scientists from Fort Detrick (as it was renamed in 1956 to imply its more permanent nature) was not confined to the facility itself. Large-scale experiments were undertaken by personnel from the Maryland facility, involving the release of clouds of what were then presumed to be safe bacteria in cities such as San Francisco, Minneapolis, New York, and even Winnipeg, Canada. These cities were chosen because they approximated in size certain Soviet cities. The scientists wanted to investigate the behavior of bacteria in the atmosphere, looking at how far they spread, how infectious they appeared to be, and how many people they might be expected to kill in a large city. The civic authorities in these test urban environments were told by the Detrick scientists that the "smoke" that appeared above their cities was related to the testing of radar. (Experiments involving biological agents were much too sensitive an issue to reveal to the public or even to local elected officials.) The fact that several mysterious deaths brought about by rare bacteria were recorded at the time of the experiments was only explained years later in the 1970s, when the actual work of the scientists from Detrick was brought to light.

By the end of the 1960s, the work at Fort Detrick had led to the weaponization of such lethal biological agents as anthrax, tularemia, and botulinum and of incapacitating agents such as brucellosis, Q-fever, Venezuelan equine encephalitis, and staphyloccocal enteroxin. These incapacitants were considered to be more humane than lethal agents and could be used, it was hoped, against targets where there might be large numbers of noncombatants. The scientists had also produced biological agents to target food supplies. These were designed to destroy crops, and they included cluster bombs containing turkey feathers impregnated with crop disease spores that were to be dropped from aircraft.

Viruses, too, had been engineered into weapons of war. Viruses are less complex than bacteria and often more deadly. Being much smaller, viruses such as Ebola and smallpox can invade the human body more easily than bacteria, and there are fewer treatments against them. Moreover, friendly forces could be immunized against viruses, enabling them to operate in environments where viral weapons were being used. The staff at Detrick also developed drugs for the U.S. Central Intelligence Agency (CIA) for use in interrogations, and they developed quick-acting poisons for assassinations. Gary Powers, the U-2 spy plane pilot shot down over the Soviet Union in 1960, was supposed to commit suicide, if captured, by using a shellfish (saxitoxin) poison produced at Detrick.

Ethical Concerns

In the heyday of Fort Detrick in the 1950s and 1960s, the scientists there were attempting to overcome several difficulties. Perhaps the most fundamental was the fact that it was impossible to target biological weapons; they were indiscriminate. They would kill military and civilian, friend and foe, without distinction. Some discrimination was attempted; research, for instance, went into developing weapons that only worked on certain ethnic groups. But such work was never popular among researchers.

Most researchers at Fort Detrick believed that the end justified the means, that the demands of national security justified their activities. For these scientists, any weapon, no matter how ethically dubious, that could help defeat a mortal enemy was a welcome addition to the arsenal of democracy. Moreover, there was a sense that whatever research was being conducted in the United States was being more than matched behind the Iron Curtain. The United States had to keep up, they felt.

Ethics, of course, made testing on human subjects difficult. It was vital, though, that such testing be carried out. Fortunately for the scientists at Detrick, some 2,000 men volunteered their services during the period from 1954 to 1973. These were servicemen, mostly Seventh-Day Adventists, who, rather than serve in combat roles (they were conscientious objectors), agreed to act as test subjects. Although subjected to various tests and often becoming ill, none of the servicemen actually died. Their assistance was useful in establishing the effect of individual agents, in developing protective clothing, in proving that certain antibiotics worked against such agents as Q-fever and tularemia, and in demonstrating that the vaccines designed for troops were effective. Although none of these volunteer servicemen died, three employees died in accidents at Fort Detrick over the years: two were killed by anthrax and one by Venezuelan equine encephalitis. Several hundred more have also become ill through accidents and carelessness, although no fatalities have occurred at the facility since the 1960s.

The End of U.S. Biological Weapons Research

After a series of accidents at U.S. military chemical and biological warfare installations and amid a general Vietnam-era disquiet over the role of the military, the U.S. public became more alarmed about the activities undertaken at Fort Detrick and other chemical and biological weapons facilities. Biological agents came to be perceived as doomsday weapons that had no place in the arsenals of civilized states. In 1969, President Richard M. Nixon, responding to the mood and speaking at Fort Detrick, announced that the United States would give up its BW program and destroy existing weapons stocks.

Scientists at Fort Detrick accordingly halted research into offensive biological weapons and destroyed large stocks of stored agents. Small amounts were retained so that testing work could continue, but this work could only be defensive in nature and had to be geared to developing protection, including vaccines, against biological agents. Nixon's initiative led to the Biological and Toxin Weapons Convention of 1972, which outlawed the storage of significant amounts of biological agents by any state. In the aftermath of Nixon's announcement, many workers left Fort Detrick, and the facility was downsized. In 1971, it was renamed the U.S. Biological Defense Research Laboratory and officially handed over to the civilian National Cancer Institute, which was one of a number of new civilian tenants at the base. Part of the camp, however, continued to function as a secure facility housing the USAMRIID.

Fort Detrick scientists have contributed to the treatment of various diseases. Researchers at Fort Detrick have produced vaccines, toxoids (toxin-based vaccines), and antibacterial and antiviral drugs, and they have conducted groundbreaking work in bacterial genetics. Fort Detrick, in the early part of the twenty-first century, remains a valuable resource in terms of developing protective measures against bioterrorism. Nevertheless, Fort Detrick remains controversial. The anthrax letter attacks that followed the September 11 atrocity in 2001 actually employed a strain of anthrax manufactured at Fort Detrick.

FUEL-AIR EXPLOSIVE (FAE)

The basic operating principle of a thermobaric or fuel-air explosive (FAE) is analogous to a dust cloud explosion, similar to those that occasionally occur in coal mines or grain silos. In the latter case, fine particles of grain dust in the air can suddenly ignite with a spark, setting off a huge conflagration in a chain-like reaction. Unlike a dust cloud explosion, however, most FAE munitions employ a volatile liquid such as ethylene oxide. An FAE generally consists of a fuel container and two separate explosive charges. At a predetermined altitude, the initial explosive charge ruptures the fuel container, diffusing the fuel, which then mixes with air, creating a vapor cloud. The second explosive charge ignites the vapor cloud, creating a massive explosion accompanied by an enormous shock wave and intense heat. The explosion can generate temperatures ranging as high as 2,500° to 3,000° Celsius. The shock wave can travel at speeds of more than 9,800 feet per second, creating overpressures of 427 pounds per square inch at the center of the explosion, flattening nearby structures. Anyone caught within the immediate blast area would be crushed by the intense pressure. Even those along the blast's fringes are likely to suffer serious internal injuries caused by the subsequent vacuum created by the shock wave. For this reason, the Russian military sometimes refers to FAEs as vacuum bombs. Both U.S. and Russian military analysts have compared the effect of an FAE to that of a low-yield nuclear weapon. Additionally, the psychological effect of such a weapon is significant.

FAEs were initially developed by the United States for use in Vietnam. U.S. forces used them to clear landing strips and to destroy North Vietnamese tunnel complexes. Prompted by the U.S. program, the Soviet Union developed its own FAEs and may even have employed some of its earliest versions against the Chinese military during a border conflict in 1969. The Soviet military did use FAEs against entrenched mujahideen (Afghan and Arab resistance fighters) positions during its invasion and subsequent occupation of Afghanistan. Since that time, the Russian military has used FAEs on several occasions during military operations in Chechnya. From 1994 to 1996, Russian troops regularly used FAEs on entrenched Chechen separatist positions in the mountains outside of the city of Grozny. When the conflict resumed in 1999, the Russian military employed limited numbers of FAEs on separatist-controlled villages near Dagestan.

Later, when Russian conventional arms once again failed to dislodge Chechen separatists from their fortified mountain positions near Grozny, the Russian government again authorized the use of FAEs. Although both FAEs and chemical weapons were initially considered for use against the Chechens, the use of chemical weapons was ruled out, perhaps due to concern that such an action would violate the Chemical Weapons Convention. The use of FAEs is not limited by either international law or arms control agreements. Recently, some man-portable systems produced by the Russian military have been sold to the Chinese People's Liberation Army. These disposable, shoulder-mounted devices fire a self-propelled shell containing ethylene oxide. Its effects—according to the manufacturer—are equivalent to those of a 122-millimeter howitzer shell.

Throughout the 1970s and 1980s, U.S. development of FAEs was primarily concentrated at the Naval Weapons Center in China Lake, California. FAEs developed at the China Lake facility proved their value in Operation Desert Storm, where they overwhelmed entrenched Iraqi forces and cleared minefields in preparation for the allied ground attack. Although FAEs are effective against any "soft target," such as personnel and light structures, they have proven to be particularly useful against minefields, bunkers, and caves.

Press reports during Operation Desert Storm often mistakenly identified FAEs as Daisy Cutters. In fact, the BLU-82B Daisy Cutter is not an FAE, but rather a 15,000-pound conventional explosive that includes both the agent and oxidizer. By comparison, FAEs weigh between 500 and 2,000 pounds and are oxidized by exposure to the atmosphere. Due to the difficulty of maintaining the proper fuel-to-air mixture, it would be highly problematic to develop an FAE as large as a Daisy Cutter

Despite their proven battlefield utility, ten years after the end of Operation Desert Storm, the U.S. military had decommissioned all but a few hundred of its FAEs, probably due to their uncertain roles in future conflicts. This put the military in an unwelcome position as it prepared for operations in Afghanistan in late 2001: It faced a severe shortage of a weapon designed for use against precisely the targets that it now expected to encounter in Afghanistan. To resolve this situation, on October 11, 2001, the Defense Threat Reduction Agency (DTRA) began a 60-day effort to develop a new weapon specifically designed to defeat underground targets. The development team included members from the Air Force, the Department of Energy, the Naval Surface Warfare Center at Indian Head, Maryland, and private industry.

At the end of 67 days, the team unveiled the BLU 118/B "Thermobaric Weapon." The term *thermobaric* comes from the Greek words for heat (*therme*) and pressure (*baros*). The BLU 118/B has a fuel-air explosive warhead fitted onto the body of a BLU 109 Penetrator that can punch through hardened concrete structures. As such, the BLU 118/B possesses the penetrating ability of a BLU 109 Penetrator and the destructive capability of a fuel-air explosive. On December 14, 2001, the BLU 118/B successfully completed both static and flight tests conducted at the Nevada test site. These tests included fitting a BLU 118/B warhead onto a laser-guided weapon and "skipping" it into the mouth of a tunnel to simulate the targets that the DOD (Department of Defense) anticipated using it against in Afghanistan.

On December 21, 2001, Edward C. Aldridge, Undersecretary of Defense for Acquisition, Technology, and Logistics, announced that the BLU 118/B had completed testing and was being deployed to Afghanistan to support Operation Enduring Freedom. Less than 3 months later, on March 3, 2002, the BLU 118/B was used for the first time on an al-Qaeda cave complex located in the Gardez region of Afghanistan. In less than 5 months, the DTRA team had been able to develop, produce, test, and deploy a weapon system critical to U.S. success in Afghanistan.

Since the attacks on September 11, 2001, the United States has perceived a growing threat from rogue states and international terrorist organizations that are attempting to acquire nuclear, biological, and chemical (NBC) weapons. Given the capabilities of current U.S. space-based reconnaissance satellites, clandestine NBC development and processing facilities are likely to be located underground. The U.S. Air Force and Navy are currently attempting to develop a conventional weapon capable of destroying a potential underground NBC target while limiting potential agent dispersal. The new BLU 118/B, with its ability to penetrate hardened structures and to produce significant amounts of heat, is a potentially significant step toward realizing this objective with a nonnuclear weapon.

G

GAS GANGRENE

Clostridium perfringens (C. perfringens) is a common bacteria associated with three distinct disease syndromes: gas gangrene, enteritis necroticans, and clostridium food poisoning. Clostridium bacteria produce at least twenty different toxins; the toxins produced by the clostridium bacteria are what cause disease in its victims. Although weaponization of *C. perfringens* would be a difficult endeavor, it is not impossible, and it therefore merits consideration as a possible biological warfare agent.

History and Background

Louis Pasteur, in 1861, identified the first clostridial species, *Clostridium butyricum.* Later, other scientists isolated a gram-positive anaerobic (see below) bacterium from gangrenous wounds. This organism, originally known as *Bacillus aerogenes capsulatus* (later *Bacillus perfringens,* then *Clostridium welchii,* and now *C. perfringens*), gained recognition for its appearance in battlefield wounds.

Despite the inherent difficulties associated with weaponization of *C. perfringens*—notably challenging would be the isolation of toxins or the use of the whole cell—the gas gangrene-causing bacterium has appeal as a biological weapon for its range as either a toxic or bacteriological weapon and its ability to exploit the condition of existing battlefield wounds. Although the toxins are lethal in and of themselves in an aerosolized form, the use of the *C. perfringens* spore bacteria in a shrapnel munition—either as a slurry or as a refined powder—would aggravate penetrating wounds and create a potentially fatal condition among its victims, at the very least removing them from the theater of combat.

At least three countries investigated the weaponization of *C. perfringens:* Japan, South Africa, and Iraq. Information on the measure of success each of these countries had in weaponizing *C. perfringens* is scant. It does appear that their efforts at the weaponization process were forestalled.

Technical Details

C. perfringens is an anaerobic (i.e., it is unable to grow in the presence of free oxygen) spore-forming rod bacterium. Commonly found in the environment and the intestines of humans and animals, its spores persist in soil, sediments, and areas subject to human or animal fecal pollution. Though the clostridium bacteria produce at least 20 types of toxins, four are of particular BW interest because they can cause potentially fatal syndromes: alpha, beta, epsilon, and iota. These toxins, one of the main causes of gas gangrene, can cause tissue death, destruction of blood, decrease in circulation, and leaking of the blood vessels.

Called gas gangrene because of the bubbles seen in the wounds (a result of bacteria-produced hydrogen gas), gas gangrene typically develops in deep crushing or penetrating wounds that have been cleaned improperly. Disease onset typically begins one week after the introduction of bacteria to the wound. The main initial symptom of gas gangrene—or "wet" gangrene—is pain at the site of the wound, which becomes progressively worse. Untreated, gas gangrene can be fatal; progression from symptomatic disease onset to death can occur within 2 days. The main treatments for gas gangrene are antibiotics and surgical removal of affected tissue. When the *C. perfringens* toxins are inhaled as an aerosol, severe lung damage results, leading to pulmonary edema and respiratory failure. When absorbed by the body, red blood cell destruction and liver damage occur.

GENEVA PROTOCOL

The "Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous, or Other Gases and of Bacteriological Methods of Warfare" was signed on June 17, 1925 and entered into force on February 8, 1928. Early signatories included the United States, Germany, Iraq, and Russia. Japan signed in 1970, and the United States formally ratified the Protocol in 1975. (Signing a treaty basically means that a state is willing to abide by its precepts, but its government will have to ratify it through a formal process before it becomes law.) The 1925 Geneva Protocol, also known as the Gas Protocol, was meant to codify an international opprobrium on using "asphyxiating, poisonous or other gases, and of bacteriological methods of warfare." Although the Geneva Protocol attempted to prohibit (with certain and significant exceptions) the use of chemical and biological weaponry, the historical record shows the agreement to have been largely ineffectual. Although the Chemical Weapons Convention (CWC) does not concern itself with biological weapons, since coming into force in 1997 the CWC has superseded the 1925 Geneva Protocol.

Background

Interrupted by World War I—and the advent of modern chemical warfare—the 1925 Geneva Protocol was really the culmination of previous attempts to outlaw the use of toxic chemicals on the battlefield. One of the first meetings of the major powers to address the use of poisons in war was the Hague Peace Conference of 1899, sponsored by Tsarist Russia. In line with what had been previously raised in the Brussels Declaration of 1864 that had prohibited poisons or poisoned gases meant to cause unnecessary suffering in war, three declarations were made at the Hague Conference of 1899: Reflecting the times and new technology, one declaration prohibited the use of projectiles from balloons. Another required that the treaty's parties agree to end the use of "dum-dum" or expanding bullets in war. Finally, the third prohibition concerned itself with those projectiles "the sole object of which is diffusion of asphyxiating or deleterious gasses." The American delegate, Admiral Alfred T. Mahan, was certainly not impressed, however, when it came to the latter prohibition of asphyxiating or deleterious gasses: "It is illogical and not demonstrably humane to be tender about asphyxiating men with gas, when all are prepared to admit that it is allowable to blow the bottom out of an ironclad at midnight, throwing four or five hundred men into the sea to be choked by the water, with scarcely the remotest chance to escape" (Fries and West, p. 6).

Germany signed and ratified the Hague agreement in September 1900, but the United States elected not to sign the Hague declaration. Those countries that did accede to the regime by signing the document pledged to "Abstain from the use of *projectiles the sole object* of which is the diffusion of asphyxiating or deleterious gases" (Hague Declaration, emphasis added). As Augustin Prentiss noted in his treatise on chemical warfare, at the time of the Hague Conference, such projectiles had not yet been perfected for use in battle. Later, this technicality would be invoked during World War I, some arguing that the use of static canisters to release poison gas was exempt as they were not "projectiles."

Despite earlier pessimism expressed by President William McKinley and Admiral Mahan, President Theodore Roosevelt put his imprimatur on a second round of talks to further discuss a prohibition of chemical weapons at the Hague Convention in 1907. It was concluded as Article XXIII of Hague Convention IV, regarding laws and customs of war on land, "in addition to the prohibitions provided by special conventions, it is expressly forbidden to employ poisons or poisonous weapons" (Hague Declaration, 1907).

PROTOCOL FOR THE PROHIBITION OF THE USE IN WAR OF ASPHYXIATING, POISONOUS, OR OTHER GASES, AND OF BACTERIOLOGICAL METHODS OF WARFARE

Opened for signature: 17 June 1925, entered into force: 8 February 1928

The undersigned Plenipotentiaries, in the name of their respective governments:

Whereas the use in war of asphyxiating, poisonous or other gases, and of all analogous liquids, materials or devices, has been justly condemned by the general opinion of the civilised world; and

Whereas the prohibition of such use has been declared in Treaties to which the majority of Powers of the world are Parties; and

To the end that this prohibition shall be universally accepted as a part of International Law, binding alike the conscience and the practice of nations;

Declare:

That the High Contracting Parties, so far as they are not already Parties to Treaties prohibiting such use, accept this prohibition, agree to extend this prohibition to the use of bacteriological methods of warfare and agree to be bound as between themselves according to the terms of this declaration.

The High Contracting Parties will exert every effort to induce other States to accede to the present Protocol. Such accession will be notified to the Government of the French Republic, and by the latter to all signatories and acceding Powers, and will take effect on the date of the notification by the Government of the French Republic.

The present Protocol, of which the English and French texts are both authentic, shall be ratified as soon as possible. It shall bear to-day's date.

The ratifications of the present Protocol shall be addressed to the Government of the French Republic, which will at once notify the deposit of such ratification to each of the signatory and acceding Powers.

The instruments of ratification of and accession to the present Protocol will remain deposited in the archives of the Government of the French Republic.

The present Protocol will come into force for each signatory Power as from the date of deposit of its ratification, and, from that moment, each Power will be bound as regards other Powers which have already deposited their ratifications.

In witness whereof the Plenipotentiaries have signed the present Protocol.

Done at Geneva in a single copy, the seventeenth day of June, One Thousand Nine Hundred and Twenty-Five.

For the United States military at the time, rules against using poisons in battles were already in place. General Order No. 100 by the War Department in April 1863 had laid down the following: “The use of poison in any manner, be it to poison wells, or food, or arms, is wholly excluded from modern warfare” (Smart, p. 13). Following the Hague Convention of 1907, the United States published its own regulation in War Department Document No. 468 that put more detail and emphasis into the agreement, adding that biological warfare was implied as well: “This prohibition extends to the use of means calculated to spread contagious diseases, and includes the deliberate contamination of sources of water by throwing into same dead animals and all poisonous substances of any kind” (Prentiss, p. 687).

The Hague Convention had attempted to outlaw the use of projectiles carrying toxic chemicals. What could not have been foreseen were the massive clouds of chlorine gas that augured in modern CW during World War I. In fact, not long after the chlorine gas attack at Ypres, Belgium, in 1915, a German newspaper explained that “the basic idea of the Hague agreements was to prevent unnecessary cruelty and unnecessary killing when milder methods of putting the enemy out of action suffice and are possible. From this standpoint the letting loose of smoke clouds, which, in a gentle wind, move quite slowly toward the enemy, is not only permissible by international law, but is an extraordinarily mild method of war” (SIPRI, p. 53).

Following the cataclysm that was World War I and the unpleasant memory of chemical warfare, polling data in the United States showed that a large percentage of Americans wanted to abolish chemical weapons. At the Conference for the Limitation of Naval Armament (1921–1922, later referred to as the Washington Arms Conference), the American delegation, chaired by General John J. "Blackjack" Pershing, argued for the prohibition of chemical weapons. Still, the delegation noted "that there are arguments in favor of the use of gas which ought to be considered. The proportion of deaths from their use, *when not of toxic character,* is much less than from the use of other weapons of warfare" (Ewing, p. 69). Nonetheless, the U.S. Senate unanimously ratified the treaty signed at the Washington Conference, with only minor objections made during floor debates. But the Washington Arms Conference of 1922 never went into force due to objections by France, a key player in the Conference.

In 1925, the League of Nations called for a meeting that was originally called the International Conference on Supervision of the International Trade in Arms and Ammunition and Implements of War. It was in this conference on arms regulation that the United States suggested adding proposals to ban chemical warfare, in order to lessen "the horrors of war and ameliorating the sufferings of humanity incident thereto" (Prentiss, p. 692). The U.S. State Department wanted an international approval of a ban on the export of war gases. France made the suggestion to ban the use of such chemicals, and Poland recommended that the agreement further prohibit bacteriological warfare as well. Thus came into being the 1925 Geneva Protocol.

The Geneva Protocol began with considerable vision and promise. Though farsighted in the sense that it banned both chemical and biological forms of combat, the Protocol also contained key conditions and exemptions that made it an ineffective treaty. For although the agreement prohibited the *use* of such weapons in battle, it did not expressly prohibit the use of CW agents against nonratifying parties, the retaliatory use of chemical weapons (making the Protocol a de facto "no first use" agreement), or the use of chemical weapons in civil conflicts within a country's own borders. Perhaps the most glaring flaw in the 1925 Geneva Protocol was that it did not prohibit research, production, or stockpiling of chemical or biological weapons, and some countries additionally reserved the right to retaliate using these weapons. Anticipating the proliferation concerns that would still remain 75 years later, the originator of the initiative to ban biological weapons in the 1925 Geneva Protocol, Polish general Casmir Sosnkowski, warned that the bacteriological weapon "can be manufactured more easily, more cheaply and with absolute secrecy" (Geisler and Moon, p. 66).

A campaign led by U.S. general Amos Fries, chief of the Army Chemical Warfare Service, argued that a vote for ratification of the 1925 protocol by the U.S. Senate would mean a decline in military readiness. The American Chemical Society was also against the agreement. Partly as a result of such lobbying, the United States did not ratify the Geneva Protocol until 50 years later. Other countries that did not ratify the Protocol in 1925 included Argentina, Brazil, Czechoslovakia, and Japan, but thirty-nine countries ratified the protocol before World War II. Regarding the Geneva Protocol and its lack of commitments from the global community, in 1937, Prentiss warned that "its apathetic reception by various governments has tended to defeat the purpose it was expected to serve" (Prentiss, p. 693).

With the 1993 Chemical Weapons Convention now in force, the Geneva Protocol is mostly only relevant today in its prohibition of biological warfare. However, its glaring loopholes (as presciently noted by General Sosnkowski) remain. As of 2004, movement toward a global treaty to enforce the toothless Biological and Toxin Weapons Convention has stalled, awaiting some initiative to achieve consensus among its parties.

GLANDERS (*BURKHOLDERIA MALLEI*)

Burkholderia mallei is the bacterium that causes the disease glanders. It has been researched, developed, and utilized as a biological weapon in wartime by national bioweapons programs.

Historical Background

Glanders was once the most feared and economically important fatal contagious disease of equids (horses, asses, and mules). It was eradicated by 1920 in western Europe and North America through the identification and destruction of infected animals. Before this, humans occasionally contracted glanders, which was often fatal. Autopsy material from equids that died of glanders and laboratory cultures of the bacteria were extremely dangerous to handle. Before it was eradicated, glanders was the most common cause of fatal laboratory infections among bacteriologists.

During World War I, the German military attempted to use glanders bacteria in a worldwide effort to infect the horses of the Allied powers and to disrupt shipments of horses and mules from neutral countries to the Allies. Saboteurs using glanders bacteria cultures were active in France, the United States, Romania, Spain, and Latin America. Despite these extensive efforts, the effects of this campaign were minimal in western Europe and North America. There was a single suspicious glanders outbreak that occurred in Britain in a military stable, but glanders cases among horses in combat units in France were few and easily contained. No significant disruption of the supply of horses occurred on the western front. Large outbreaks of glanders did occur in Russia and Portugal, but as glanders was endemic in these areas, it is unknown whether these outbreaks were natural or the result of BW sabotage.

During World War II, the Imperial Japanese Army's biological weapons program developed glanders as a major agent for both antianimal and antihuman biological warfare. In undertaking this program, the Japanese committed atrocities by intentionally causing fatal human glanders infections at their research facilities. Glanders bacteria were produced in industrial quantities and were employed with other biological agents against Chinese civilians, Chinese troops, and military draft animals during a campaign in 1942 in Zhejiang Province. This campaign resulted in hundreds of civilian deaths from glanders among the local Chinese population, as well as losses of military equids.

After erroneous reports of continued German interest in glanders as a BW weapon, the U.S. biological weapons program investigated the possible use of glanders as a weapon during World War II. The program inadvertently caused at least seven laboratory infections among workers, and investigation into the offensive use of glanders was stopped at the end of the war.

Technical Details

Glanders can be spread by inhalation, by inoculation, by ingestion, or by direct contamination of the nose and mouth. The signs and symptoms of glanders in humans vary. Rapidly progressive cases show fever and septic collapse, often with a rash similar to smallpox developing on the day prior to death. Direct exposure of the face often causes deforming ulcers in the nose and mouth. Slowly progressive and chronic cases develop persistent fever with multifocal pulmonary and liver lesions. Chronic cases often develop soft-tissue swellings, notably on the arms and legs, that break down into draining sores.

Under natural conditions, water troughs that were contaminated by nasal secretions transmitted glanders from horse to horse. Humans were infected by contact with this water or with contaminated bits and harnesses. The Japanese caused thousands of cases of human and equine glanders by contaminating rural Chinese water supplies with glanders. Fortunately, standard chlorination and other modern water purifying processes very easily kill glanders bacteria. There is, however, the potential for glanders to be developed into an airborne biological weapon.

Because glanders has been essentially extinct in Europe and North America for more than 50 years, and because it apparently does not cause human disease in areas where it is still endemic in equids, current hospital automated bacteriological laboratory procedures fail to identify it accurately in humans. Likewise, descriptions of human glanders usually do not appear in current, standard medical textbooks. This presents a major problem in the surveillance of glanders as a potential bioweapon.

The glanders bacterium currently has the name *Burkholderia mallei.* Its genus name, however, has often changed. It is closely related to the bacterium that produces melioidosis (*Burkholderia pseudomallei*). Glanders is classified as a Category B threat agent by the U.S. Centers for Disease Control and Prevention (CDC), a category that also includes less lethal BW agents such as Q-fever and Brucellosis. The U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) has begun to investigate it again, and a laboratory infection involving glanders occurred in 2000.

In its natural state, glanders apparently requires large, crowded urban or military populations of horses to maintain the dangerous, highly virulent strains so common before the twentieth century. With the advent of modern mechanized transport, these sorts of dense animal populations have generally ceased to exist. The remaining natural reservoirs of glanders in Asia consist of much-attenuated strains that seldom cause death in horses and that apparently do not infect humans. No human case of naturally occurring glanders has been reported in the United States since 1939.

Only a few specialized veterinary laboratories can claim legitimate civilian veterinary uses for even the highly attenuated laboratory strains of this organism used to produce diagnostic reagents. Glanders has ceased to circulate among horses in Europe, the Americas, and Oceania. It is no longer an important economic disease of horses even in areas where it remains endemic, including parts of Turkey, Iraq, Iran, Afghanistan, India, and Pakistan.

The fact that glanders is highly dangerous to handle, even in facilities as sophisticated as USAMRIID, means that accidental infections are likely to occur if it is handled in improvised or amateur biological weapons facilities. Even a single case of human glanders should act as a very important "sentinel event" for identifying clandestine bioweapons activities or an intentional BW release. If the low-virulence strains now circulating are modified to develop increased virulence, glanders could become the basis of a biological weapon.

GRUINARD ISLAND

Gruinard Island is an island off the northwest coast of Scotland that was used as a British biological weapons testing ground during World War II. Gruinard (pronounced "grin-yard") is a 522-acre island measuring 1.24 miles by 0.62 miles, situated one-half mile off Scotland's coast in Gruinard Bay. Although a handful of people lived on Gruinard at the turn of the century, there were no human inhabitants left by the 1930s. Early in World War II, based on intelligence concerning Axis biological research, the British War Cabinet decided to investigate ways to retaliate should the Germans employ biological warfare. Initial research on *Bacillus anthracis* (the causative agent of anthrax) had been conducted with American and Canadian help at Porton Down (U.K.), but by the summer of 1942, the British government sought a site for open-air trials to see whether *B. anthracis* spores would remain infective after explosive dispersal. Gruinard, being remote yet close to a large Allied military base at Loch Ewe, was chosen, requisitioned, and given the code name X Base.

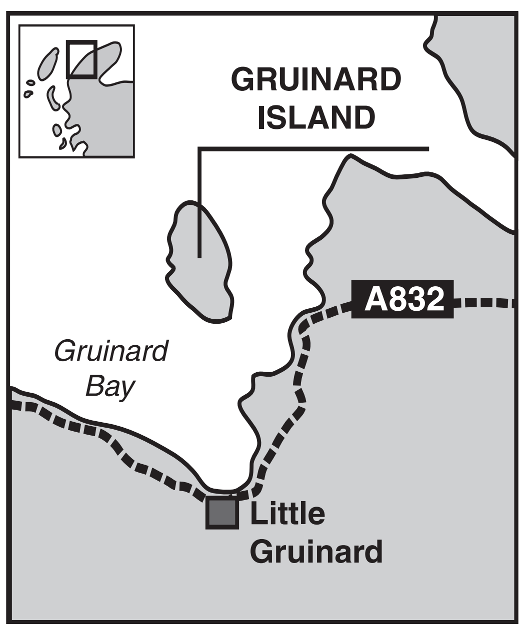
Under the project leader, microbiologist Paul Fildes, researchers first used an airplane to drop a 30-pound bomb filled with a slurry containing spores of *B. anthracis.* Subsequent trials included a variety of explosive devices suspended from wooden scaffolding 6 feet above the ground.

Gruinard Island—the site of World War II–era anthrax weapons testing—has since been returned to the original owners. (Topham/The Image Works)

These devices were detonated electrically near lines of sheep positioned at various distances downwind from the explosions. Afterwards, the sheep were transferred to an observation paddock. Dozens died, proving the efficacy of an anthrax bomb.

An unintentional outbreak of anthrax among livestock on the mainland in 1943 was apparently caused by a contaminated sheep carcass from Gruinard that had been unearthed by a storm and had floated to the mainland. No human fatalities were reported, and the outbreak was contained. Concerned about public safety, however, the British military ceased testing on Gruinard in August 1943 and declared the island off limits. Contrary to government expectations, samples taken in 1943, 1944, and 1946 indicated that the *B. anthracis* spores on the island remained viable, so in 1946 the United Kingdom bought the entire island of Gruinard, promising to return it to the original owners for £500 (about one pound Sterling per acre) when it was deemed safe.

Gruinard Island



Annual inspections between 1946 and 1968 revealed the continuing virulence of spores, and sampling was mostly discontinued until 1979, when responsibility for Gruinard was assumed by the Chemical Defense Establishment (CDE) at Porton Down. A comprehensive survey was undertaken and an improved assay technique was used that could detect three spores per gram of soil. This revealed that, despite the release of 10^{14} spores, only approximately 3 acres around the test site (less than 1 percent of the island's surface) were found to have been contaminated, with spores mostly found within the top three inches of soil. This finding meant that decontamination of Gruinard was feasible.

An interesting episode occurred in October 1981, when an ecologically motivated group called Dark Harvest placed a bucket with contaminated soil from Gruinard at the CDE in protest of perceived government indifference to the island's contamination.

In 1985, the Ministry of Defense initiated the creation of an Independent Advisory Group (IAG) for Gruinard Island, made up of eminent scientists to review the CDE's findings and decontamination proposal. In 1986, a private contractor was commissioned to decontaminate a total area of just over 10 acres on Gruinard. After spraying a herbicide and burning away the undergrowth, a system consisting of 30 miles of irrigation tubing was used to soak the ground with 280 tons of formaldehyde diluted in 2,000 tons of seawater in amounts of 50 liters per square meter. Topsoil was also removed in sealed containers and decontaminated. After retreating a few areas in July 1987, no viable spores of *B. anthracis* were detected on the island. As an extra precaution, forty sheep belonging to a local farmer were allowed to graze on the island from May to October 1987 and were closely monitored.

In its final 1988 report, the IAG concluded that Gruinard Island could be returned to civilian use, and, in May 1990, the island was sold back to the heirs of its original owners. Gruinard Island remained only an interesting historical footnote until the anthrax attacks in November 2001 in the United States, when reporters flocked to Gruinard to recall Britain's brief foray into biological weapons.

G-SERIES NERVE AGENTS

The NATO coded G-series ("G" as in Germany) nerve agents include the first toxic organophosphates produced for chemical warfare by the German military during World War II, starting with tabun (GA), sarin (GB), soman (GD), cyclosarin (GF), and some analogues synthesized many years after World War II (such as GV). There is no nerve agent referred to as "GC," probably because this had already been used in the U.S. military to code for gonorrhea. The more toxic of the G-series include GB and GD, but are less toxic than V-series agents (e.g., VX).

GULF WAR: CHEMICAL AND BIOLOGICAL WEAPONS

When a U.S.-sponsored coalition attempted to drive Iraqi forces from Kuwait in early 1991, there were fears that Iraq would use a weapon of mass destruction. This proved not to be the case, but for coalition leaders, the threat that Iraq might use a chemical or biological weapon was very real. Iraq had shown during the Iran-Iraq War that it had chemical warfare capability and was willing to use it against its adversary in the war and against domestic opposition groups.

Even before his invasion of Kuwait, Saddam Hussein had threatened to "rain down fire" on Israel, which a number of commentators interpreted as a threat to employ chemical weapons. Once the invasion of Kuwait had taken place, Iraq threatened to use such weapons against coalition forces and Israel. Hussein was attempting to establish a deterrence relationship with the coalition by suggesting that any attack on Iraq (including Kuwait, which Iraq claimed was its lost "nineteenth province") would justify retaliation with chemical weapons. By threatening to attack Israel, Hussein promised to spread any Gulf conflict throughout the Middle East and turn Arab public opinion to the Iraqi cause by somehow linking the seizure of Kuwait to the Palestinian-Israeli dispute. To reinforce this threat, Iraq reportedly established decontamination sites in the Kuwaiti theater of operations.

Prewar coalition assessments credited Iraq with a formidable arsenal of chemical weapons, including mustard, two nerve agents (tabun and sarin), and other compounds that were in development or production. In addition, the Iraqi military had experience in actually employing chemical weapons in combat. Little was known, however, about Iraq's biological weapons program. After the war, it was discovered that Iraq had accelerated its production of anthrax and botulinum toxin prior to Desert Storm. Rolf Ekeus, the Executive Chairman of the UN Special Commission (UNSCOM), was subsequently informed that authority had been delegated to local Iraqi commanders to use chemical and biological weapons in response to a massive coalition attack on Baghdad.

During the war, Coalition air strikes destroyed or damaged most of Iraq's chemical warfare production and filling capabilities, but stocks that had been relocated before the war were assumed to have survived. Subsequent UN inspections of Iraq revealed a significant chemical weapons infrastructure.

Reasons for Nonuse

Why did the Iraqi regime fail to use its chemical and biological arsenal during the Gulf War? Iraq had a variety of proven delivery mechanisms including aerial bombs, aerosol sprays, artillery shells, ground-to-ground and air-to-ground rockets, chemical warfare mines, and Scud missiles. Why it chose not to use this arsenal is not entirely clear. The weapons might have been viewed by the Iraqi regime as political and psychological weapons; once the war began and Iraq's bluff had been called, these weapons might have been held in reserve to guarantee the survival of the Iraqi regime.

Hussein also may have been deterred by the threat of U.S. dominance in the event of escalation of the conflict: if Iraq employed chemical weapons, it might have been subjected to devastating U.S. conventional or even nuclear retaliation. (In a final meeting before the outbreak of the war, U.S. Secretary of State James Baker had handed Iraqi Foreign Minister Tariq Aziz a letter from President George H. W. Bush, which was purported to carry a warning about Iraqi use of weapons of mass destruction.) In any case, it is doubtful whether Iraqi use of chemical weapons would have significantly altered the outcome of the war. After the war, no evidence was discovered that suggested that these weapons were even deployed with the fielded Iraq forces.

GULF WAR SYNDROME

As the name suggests, Gulf War Syndrome refers to a clinical syndrome experienced by a cohort of United States and other Coalition personnel who served during the 1990–1991 Gulf War against Iraq. Gulf War syndrome (GWS) is a poorly defined condition generally described as a constellation of fatigue, mood-cognition problems, and musculoskeletal pain. No causative agent—by itself or in combination with environmental pollutants such as chemical warfare (CW) toxins or biological pathogens—has yet been identified as the cause of the mysterious ailment. Following the overthrow of Saddam Hussein's government in April 2003, similar complaints that closely resemble that of GWS have surfaced among combatants participating in Operation Iraqi Freedom.

Despite exhaustive (and, in some instances, redundant) clinical and epidemiological studies, an organic cause of GWS has not been found. For example, nearly a decade following the first Gulf War (1990–1991), British researchers studied 1,000 self-selected members of a Gulf War cohort who suffered from GWS. They reported that "Fatigue, joint and muscle aches and pains, and affective symptoms (such as mood swings and anxiety) were the most common symptoms. Many other symptoms occurred, but no clinically consistent pattern existed to suggest a common underlying disease process" (Coker et al., 1999, p. 294). Nor do follow-up studies show any higher incidence of birth defects among the progeny of Gulf War veterans than in control groups.

Assuming that GWS can be clinically defined as an illness, a number of candidate agents have been offered as its cause. These include purported exposure to chemicals including chemical warfare (CW) agents, anthrax vaccine, botulinum toxoid, and other biological pathogens. As far as CW agents are concerned, there is one publicly known incident in which a U.S. soldier suffered injury following the Gulf War in 1991. His exposure to sulfur mustard led to minor burns while securing one of many Iraqi ammunition depots. After the war, U.S. military personnel destroyed the Iraqi ammunition cache at Khamisiyah, which later turned out to have contained unknown quantities of nerve agent. Thus, possible exposure to nerve agents was studied as a potential cause of GWS among those veterans in the region. No evidence has been found to show, however, that any coalition forces were exposed to toxic concentrations of nerve agent at Khamisiyah.

Other researchers have suggested that long-term effects of toxic compounds, particularly the organophosphate nerve agents, could cause neural deficits even at low concentrations. Toxicological studies of soman and sarin before and after the Gulf War, however, do not support this view. Unlike some insecticides and toxic organophosphates used in other contexts, exposure to nerve agent that would cause long-term (or delayed) neuropathy would require very large doses—and probably deadly ones at that.

Another purported cause of GWS is the use of nerve agent antidotes by U.S. soldiers, or more specifically, pretreatment against soman nerve agent exposure. Prior to Operation Desert Storm (1991), U.S. military planners were concerned that Iraq could use CW agents, including soman, a nerve agent that is difficult to treat due to its propensity to "age" the body's enzyme acetylcholinesterase (AChE). In addition to antidotes containing a combination of atropine and oxime to reverse the effects of nerve agents, U.S. personnel were prescribed pyridostigmine bromide (PB), a carbamate compound, in the form of tablets. PB temporarily inhibits a small portion of the body's AChE as a means to protect it from being permanently blocked by soman or perhaps another nerve agent. The doses of PB to be administered were relatively small, but they did cause some discomfort (intestinal gas and urinary urgency) among soldiers who took them. Anecdotal evidence also shows that more than a few soldiers simply decided not to follow this regimen. In any event, some advocacy groups and GWS researchers have suggested that PB tablets, in combination with other factors, could have played a role in postwar illness. These suggestions, however, are not supported by available data.

The use of vaccines to protect against biological warfare (BW) agents has also been suggested as a cause of GWS. Using last-minute approval from the Food and Drug Administration, the U.S. military vaccinated a limited number of personnel (about 8,000) with botulinum toxoid. In 1997, the Presidential Advisory Committee on Gulf War Veterans' Illnesses concluded that the use of botulinum toxoid did not play a role in developing GWS among veterans. In contrast to the small number of botulinum vaccinations, some 150,000 U.S. servicemen were inoculated against anthrax during the time leading up to Desert Storm (1991). Since then, a number of studies have been conducted to determine whether this might have contributed to ailments among Gulf War veterans. Here, too, the Presidential Advisory Committee concluded, "it is unlikely that health effects reported by Gulf War veterans today are the result of exposures to the BT or anthrax vaccines, used alone or in combination" (Presidential Advisory Committee on Gulf War Veterans' Illnesses: Final Report, p. 114).

In 1999, the periodical *Vanity Fair* carried a story that discussed claims by some medical researchers that squalene could be the cause of GWS. An intermediate compound found in cholesterol synthesis, squalene (molecular formula $C_{30}H_{50}$) is found in earwax and shark liver oil, among other sources. Squalene has been used as an adjuvant (a substance that can boost the immune system's response, enhancing the effectiveness of a vaccine) in human trials for possible HIV, herpes simplex virus (HSV-2), cancer therapy, and malaria vaccine research. After some studies found evidence of squalene antibodies in veterans who were complaining of GWS, advocates suggested a possible link, suggesting that squalene had been used as an adjuvant for anthrax vaccinations among U.S. military personnel during the 1991 Gulf War. There is no evidence, however, that squalene was ever used in anthrax vaccinations. Nor has a link between squalene and GWS been demonstrated.

Other chemicals that have been suggested as playing a role in GWS etiology include remnants of depleted uranium (DU) bullets (dense projectiles containing uranium depleted of U235 isotope; used against armor), petroleum smoke, and organophosphate insecticides in combination with mosquito repellent (diethyl toluamide or DEET). As with other claims that GWS was caused by certain types of chemical exposures during the Gulf War conflict(s), these have not been substantiated.

In addition to chemicals having been alleged to cause GWS, microbiological agents such as *Mycoplasma fermentans* have been implicated as a source of illness. No links between this organism and GWS were found in an extensive study performed by the U.S. Armed Forces Institute of Pathology (Lo et al., 2000). Another infectious disease agent, a parasitic organism that causes leishmaniasis (*Leishmania tropica*), a disease typified by skin lesions (Kala-azar), affected at least thirty-two Gulf War veterans, a dozen of whom developed the more serious visceral form.. (The other twenty developed the cutaneous form, also known as the Baghdad boil.) Leishmaniasis in this limited number of individuals, however, did not explain the wider prevalence of reported GWS among veterans.

In 1995, increased political pressure regarding GWS and its purported effect on U.S. Gulf War veterans led President William Clinton to form the Presidential Advisory Committee on Gulf War Veterans' Illnesses. In its 1997 final report, the committee concluded: "although some veterans clearly have service-connected illnesses, current scientific evidence does not support a causal link between the symptoms and illnesses reported today by Gulf War veterans and exposures while in the Gulf region to the following environmental risk factors assessed by the Committee: pesticides, chemical warfare agents, biological warfare agents, vaccines, pyridostigmine bromide, infectious diseases, depleted uranium, oil-well fires and smoke, and petroleum products." The report did suggest, however, that "stress is likely to be an important contributing factor to the broad range of illnesses currently being reported by Gulf War veterans" (Presidential Advisory Committee on Gulf War Veterans' Illnesses: Final Report, p. 114).

If there is an identifiable disease known as GWS, one is drawn after significant research into its origins to the conclusion that its cause is unlikely to be found. There is a possibility that GWS falls into a category of health conditions that have historically followed veterans and their war experiences. Following the U.S. Civil War, for example, the ailment was known as soldier's heart. Among World War I veterans in England, it was called effort syndrome, and U.S. military physicians termed it neurocirculatory asthenia."Many of the symptoms described in these syndromes are not dissimilar from those of GWS.

H

HAGUE CONVENTION

This treaty, developed at the First Peace Conference at The Hague, July 29, 1899, entered into force on September 4, 1900. The treaty discussed the most efficacious means of ensuring the benefits of real and durable peace and addressed how to stop the progressive development of armaments, including the prohibition of the employment of poison or poisoned arms in war.

The conference was convened at the invitation of Count Mikhail Nikolayevich Muravyov, the foreign affairs minister of Russia. It was one of a series of conferences intended to ensure a lasting peace among the great powers of Europe, and it followed in the aftermath of the partial successes of the Geneva Convention (1864) and Brussels Declaration (1874). The Hague Convention included many important declarations, the most significant being the Declaration on the Use of Projectiles the Object of Which Is the Diffusion of Asphyxiating or Deleterious Gases.

The asphyxiating gases declaration reached by the twenty-four states at the conference forbade the use of projectiles that are solely intended to diffuse asphyxiating gases, and it also forbade the utilization of asphyxiating gases as weapons on their own. This included the use of a cloud of gas that was produced with the sole purpose to engulf an enemy position, used as a single weapon with no other explosive element. The declaration also imposed a condition on the use of gases built into an artillery shell or bullet. The wording, however, was not clear in the condemnation of the use of gas in warfare. It left room for its meaning to be questioned with regard to what gas constituted a poison, whether the use and further development of gas-based weapons was justifiable in circumstances of retaliation, and what exactly was meant by the term *mass slaughter.*

Only one case was heard under terms of the Hague Convention of 1899—the North Sea Incident in 1904, when Russian boats fired upon a British naval ship—before the Second Peace Conference at The Hague on October 18, 1907. (The second convention entered into force on January 26, 1910.) Despite these two Hague agreements, chemical weapons were used by both sides in World War I, by Italy in Ethiopia and by Japan in China during the 1930s, and by both sides during the Iran-Iraq war in the 1980s.

The international community has established a regime to ban the use of chemical weapons in warfare and also to ban the very possession of chemical weapons. The Geneva Protocol (Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous, or Other Gases, and of Bacteriological Methods of Warfare) was signed on June 17, 1925, and entered into force on February 8, 1928. The most recent treaty that has banned the production and use of chemical weapons is the Chemical Weapons Convention (CWC), signed in 1993, which entered into force in 1997. The CWC complements the 1972 Biological and Toxin Weapons Convention.

HALABJA INCIDENT

The Iraqi use of chemical weapons on the northern Iraqi village of Halabja in 1988 illustrates the immediate and long-term damage that such weapons can inflict. The attack also demonstrates how

Saddam Hussein's chemical attack on Halabja in 1988 resulted in the death of about 5,000 people. (Faleh Kheiber/Reuters/Corbis)

chemical warfare agents can be used against an adversary, and it shows some of the possible motives for employing these weapons. Although allegations that Iraq used chemical weapons against Iranian and Shi'ite territories also exist—at least twenty similar attacks against smaller northern Iraqi villages occurred in 1987—none matched the scale or intensity of the chemical assault on Halabja.

On March 16, 1988, the Iraqi military, at the time also engaged in an 8-year-long war with Iran, launched a 3-day artillery and air attack against the Kurdish town of Halabja in northern Iraq. In addition to the chemical nerve agents tabun, sarin, soman, and possibly VX, Iraq employed the blister agent mustard in artillery and aerial munitions to eliminate segments of the Kurdish population that had become an irritant to Saddam Hussein. Some sources suggest that this attack was launched to experiment with different nerve agents. Estimates place the number of dead in the immediate aftermath of the chemical attacks at approximately 5,000. At the end of the operation, a total of 12,000 are believed to have perished. This was the largest chemical weapons attack against a civilian population.

The town of Halabja is situated approximately 15 miles west of the border with Iran. At the time, the town, with a total population of 40,000, was home to roughly 8,000 Kurds. As was the case with most of Iraqi Kurdistan, the inhabitants of Halabja supported the Peshmerga. These Kurdish fighters (the name *Peshmerga* literally means "those who face death") were in a state of perpetual revolt against the regime of Saddam Hussein, and they used the town as a safe haven and sometimes as a base of operations for insurgency against Saddam's Ba'ath regime. Whenever the tide of battle would turn and Iranian forces controlled the region, Halabja was used as a staging area for joint Iranian-Peshmerga operations against nearby Iraqi positions.

On the morning of March 16, 1988, following a successful joint attack between the Peshmerga and the Iranian military on Iraqi outposts surrounding the town, the Iranian Revolutionary Guard infiltrated and passed through Halabja. The town's residents assumed that an Iraqi retaliatory air strike was imminent due to the town's collusion with Iranian Revolutionary Guards, and began to take cover in cellars and other underground shelters. Eyewitness accounts reported that at approximately 10:30 A.M., an Iraqi helicopter appeared over the horizon, snapping aerial photographs and taking video of the town. Approximately one-half hour after the helicopter vacated the area, the Iraqi army began an artillery barrage on Halabja from a position in the nearby town of Sayid Sadiq. Shortly after the artillery bombardment began, Iraqi warplanes began to drop what is believed to have been napalm near the northern area of the town.

After 3 hours, the pace of the opening barrage began to taper off. As the explosions slowly subsided, a different sound was heard. As one survivor noted, it was like "pieces of metal just dropping without exploding." These were the first of many chemical weapons canisters that were dropped by Iraqi aircraft, including by helicopters. Another helicopter soon returned to Halabja, this time dropping small pieces of paper. It was later understood that the Iraqis were attempting to assess the wind direction and speed for delivery of their chemical weapons.

Coinciding with the sound of falling metal, survivors described a strange odor filling the air, reminiscent of a cocktail of garbage, eggs, garlic, and apples. As the inhabitants of the town began to panic, they once again rushed to the perceived safety of their cellars and underground bunkers. Tragically, these makeshift shelters quickly filled with the deadly mixture of gases, killing everyone inside.

The chemical cloud engulfed the town, contaminating water, land, and air. Those who ran became disoriented, dying in the streets as the wind blew the gas in all directions. Those who stayed behind in the shelters met similarly grisly fates, choked by the invisible fumes.

Each gas attack lasted approximately 45 minutes, with 15 minutes between each wave. The Iraqis made a total of fourteen sorties, each using between seven and eight warplanes.. The attack ended on the following day. Iranian forces returned and occupied the town shortly after the attack subsided, evacuating many of the sick and wounded to hospitals in Tehran.

Ten years after the attack, Dr. Christine Gosden, a British physician, became the first Westerner to visit the area, documenting the vast residual effects of the attack on the town and its people. In an April 22, 1998, letter to a U.S. congressional committee, Gosden noted that no systematic research had yet taken place to document the total impact of the chemical attack on Halabja. She reported, however, that reproductive dysfunction, congenital malformations, and long-term neurological and neuropsychiatric effects (particularly in those who were children at the time of the attack) found among the town's residents may have been linked to chemical exposure suffered during the 1988 attack.

Iran utilized the event for propaganda purposes, stressing that this particular atrocity was committed by Saddam's military, and many in the West echoed the sentiment that this chemical attack constituted a crime against humanity. In October 1988, the U.S. State Department declared: "We have publicly and unambiguously opposed the illegal use of chemical weapons in the Gulf War and by Iraq against the Kurds. We have worked to obtain Security Council resolutions condemning chemical weapons usage during the Gulf War" (Golden and Wells, p. 368). The incident at Halabja nearly led the Reagan administration to impose economic sanctions against Iraq, but it did not cut off all military assistance. The U.S. government has been criticized for its collaboration with Iraq in its war with Iran, given the Iraqi use of chemical weapons against Iranian forces and Kurdish civilians. Other foreign governments and businesses have been implicated in these attacks because they provided the Iraqi government with the means to produce and deliver chemical weapons.

HEARTWATER *(COWDRIA RUMINANTIUM)*

Heartwater is an acute infectious disease that causes serious morbidity and mortality in livestock and wildlife. The causative agent, *Cowdria ruminantium,* is a rickettsial bacterium that is transmitted by ticks when they feed on susceptible hosts. A consistent finding in animals infected with *C. ruminantium* is the abnormal accumulation of fluid in body tissues, leading to, among other problems, hydropericardium (literally, water surrounding the heart). Of considerable concern to U.S. officials are the lethality of infection in susceptible animals, the potential for rapid transmission to domestic livestock through infected ticks, and the importation of symptomatic animals capable of serving as a source of infection for other animals. The epidemic transmission of heartwater disease could have a catastrophic impact on U.S. livestock production and thus constitutes a potential biological threat to domestic agribusiness and related economic interests.

Cowdria ruminantium is endemic to sub-Saharan Africa and has been responsible for epidemics in both livestock and indigenous wildlife in that region. The most common vector of the bacterium is the tropical bont tick, *Amblyomma variegatum,* which was probably introduced to several Caribbean islands about 100 years ago in cattle imported from Senegal (formally French West Africa). The tick vector is now established throughout the Caribbean, and the disease has been aided in its dispersion by migratory birds such as the cattle egret. Of particular concern has been the migration of the cattle egret from the Caribbean to Florida, illustrating a potential route for the dissemination of *C. ruminantium* into the southeastern United States from the Caribbean islands. Heartwater disease is a serious threat, and its introduction could easily pass unnoticed until an epidemic occurred. Officials in the United States and other countries with developed livestock industries have several specific concerns about heartwater:

- Infection with *C. ruminantium* is difficult to diagnose in the field.
- Heartwater infection demonstrates variable expression in terms of causing disease, ranging from 40 to 100 percent in various livestock and many wildlife species, including white-tailed deer.
- Antibiotics such as tetracycline, doxycycline, and rifamycin are effective against heartwater, but only if administered early in the course of infection; delayed treatment has significantly decreased efficacy.
- Ticks, potentially those infected with *C. ruminantium,* can travel on a number of wild animals, reptiles, and birds.
- Tick species indigenous to the United States, such as *Amblyomma maculatum* and *A. cajennense,* are effective vectors for heartwater under experimental conditions.

Technical Details

Cowdria ruminantium is a rickettsial organism genetically related to *Ehrlichia* species, a group of bacteria that are known for causing numerous animal and human diseases. The bacterium is an obligate intracellular pathogen; that is, it requires a host to survive and replicate. *C. ruminantium* invades and multiplies in vascular endothelial cells (inner cellular lining) in capillary beds throughout an infected animal. Transmission is typically through the bite of an infected *Amblyomma* tick, although vertical transmission (i.e., from infected cow to calf) is also possible. The clinical signs and pathology of heartwater are caused by the degeneration of endothelial cells lining the microvasculature of tissues and organs in an infected animal. Vascular permeability—the tendency of fluid to leak from blood vessels—is severely altered with heartwater infection, resulting in the accumulation of fluids in body cavities and interstitial (in between tissue) spaces. The infection is characterized by fever, signs of neurological impairment and nervousness, and convulsions. Death can occur within 1 to 2 weeks of acute onset.

Efforts to mount an effective and coordinated program to eradicate tick vectors of heartwater in the Caribbean have met with limited success in their initial phases. Increased vigilance at the point of entry for exotic wildlife, birds, and reptiles is needed to minimize the importation of infected ticks or animal reservoirs of *C. ruminantium.* Heartwater remains a serious concern to U.S. agribusiness, in particular to domestic livestock.

Animals demonstrate protective immunity after exposure to *C. ruminantium,* suggesting that vaccination may be an effective countermeasure against infection. An attenuated strain of *C. ruminantium* has shown efficacy in controlled trails and may serve as the basis for a preliminary vaccine program. Strain variation and questionable cross-strain protection introduce considerable uncertainty into vaccine development research, however.

HEMORRHAGIC FEVERS

Hemorrhagic fever viruses (HFVs) damage the vascular system and are often (as their name implies) accompanied by hemorrhage, their unifying clinical feature, and by impairment of the body's ability to regulate itself, leading to fever. HFVs cause multisymptom syndromes, meaning that multiple organ systems in the body are affected. There are four distinct families of HFVs that have different clinical and epidemiological manifestations. All HFVs are zoonotic viruses, meaning they reside in animal or arthropod hosts, some of which are still unknown. Natural occurrence of this disease is usually restricted to the habitat of the host animal or arthropod vector. The viruses vary in their transmission but overall can be transferred to humans through the bites of arthropods (ticks, mosquitoes), contact with hosts (often rodents) or their droppings, exposure to infected livestock, or sometimes person-to-person contact. Based on numerous criteria, HFVs have been identified as biological agents that carry particularly serious risk if used as biological warfare (BW) agents against military personnel or civilian populations. Additionally, some HFVs can establish a large focus of infection in the local environment's animal hosts, which could exacerbate the impact of an attack.

History and Background

The Centers for Disease Control and Prevention (CDC) has designated two of the families of HFVs (filoviruses and arenaviruses) as Category A biological agents, meaning that they pose the greatest potential for "adverse public health impact" to the United States. This is in response to the severity of disease, the lack of treatments or vaccines, and the level of disruption and fear potentially caused by their large-scale dissemination. When evaluating the threat from potential disease agents, the U.S. Working Group on Civilian Biodefense, which sees HFVs as a serious risk to civilian populations, also took into consideration previous attempts to weaponize these agents.

State-run programs to research the weaponization of HFVs were known to have existed in the United States, the former Soviet Union, and Russia, with additional reports of potential ongoing programs in other states, including North Korea. The United States pursued research on Junin (responsible for Argentinean HF), Hantaan (responsible for Korean HF), Machupo virus (responsible for Bolivian HF), Lassa, yellow fever, Dengue, and Rift Valley fever virus. (Rift Valley fever, for example, was tested by the United States as a potential weapon in field aerosol tests, but it was never weaponized.) These programs were discontinued in 1969 when offensive biological weapons research and development was halted by order of President Richard M. Nixon. Despite having signed the 1972 Biological and Toxin Weapons Convention, however, the former Soviet Union continued with its own BW program. As far as is known from open sources, Soviet BW scientists successfully weaponized Marburg hemorrhagic fever and conducted research into the weaponization of Ebola (which was less successful), machupo, junin, Lassa, and yellow fever. Although research into biological weapons continues until 1992, it is not known if further research in HFV research continued by Russian military scientists. North Korea is suspected of having weaponized yellow fever.

Technical Details

All identified HFVs are simple, negative strand (a category of viruses with antisense, nonmessenger-RNA capable) RNA viruses that have lipid envelopes (fat-based covering making viral particles somewhat vulnerable), rendering them relatively susceptible to detergents, low-pH environments, and household bleach. They are stable at neutral pH, however, especially in the presence of proteins. Some of the viruses naturally aerosolize during disease spread and thus tend to be stable and highly infectious as a fine-particle mist. With the exception of dengue, all HFVs can be transmitted as aerosols to laboratory animals. It is this feature that makes these viruses attractive as potential BW agents for state-level programs and perhaps terrorist organizations.

The 1995 Ebola virus outbreak in Kikwit, Zaire, killed 245 people. (Patrick Robert/Corbis Sygma)

What is known about VHFs and their associated diseases has been deduced from clinical observation (records of natural outbreaks) or experiments on various nonhuman primates. The sporadic appearance of these diseases, often in areas not best equipped to record relevant epidemiological data, however, has caused information to be limited. Additionally, it is not known whether an intentional attack would follow similar patterns as naturally occurring disease outbreaks.

VHF is a disease associated with fever and bleeding. Early symptoms are nonspecific and include fever, rash, body aches, headaches, and fatigue. The characteristic bleeding can occur in the later stages of disease. The incubation time for VHFs is roughly 2 to 21 days, and the case fatality rate ranges from 0.5 to 90 percent, depending on the agent. When death occurs, it is usually 1 to 2 weeks after exposure and occurs as a result of multiorgan system failure preceded by hemorrhagic bleeding and shock. Diagnosis is difficult and usually depends on clinical symptoms, because few laboratories are equipped to recognize these pathogens in tested blood or tissue. Patient travel history, usually taken into consideration in diagnosis of VHF, may be of limited use in the event of an intentional attack.

VHFs are caused by four distinct viral families: *Filoviridae, Arenaviridae, Bunyaviridae,* and *Flaviviridae.* Marburg and Ebola are the only known members of the *Filoviridae* family thus far identified. Marburg virus was first detected in 1967 when laboratory workers in Marburg, Germany, and in Yugoslavia became infected after handling tissues from green monkeys shipped from Africa. The animal host or mechanism of initial infection for this virus is unknown; however, infected individuals can spread the virus through bodily fluids during and after illness, as observed by a transmission occurring through semen up to 7 weeks after clinical recovery. There is currently no treatment or approved vaccine for this rare disease, which has a case fatality rate between 23 and 25 percent.

Ebola HF is one of the most virulent diseases known to humans, with a fatality rate of 50–90 percent of all clinically ill cases. Ebola was first identified in 1976 outbreaks that occurred in Zaire (now the Democratic Republic of Congo) and Sudan. These viruses later proved to be distinct species and were named after the countries in which they first appeared. Two additional subtypes were later identified, Ebola-Reston and Ebola-Ivory Coast, with the former causing disease in nonhuman primates but not in humans. As with Marburg, the natural reservoir for this virus is unknown but is suspected to be an animal that is native to the African continent. The initial mode of infection is not understood, but the virus can be spread by contact with bodily fluids and possibly through intact skin, as both sweat glands and adjacent skin tissues have been shown to contain viral particles. As in the case of Marburg HF, there is currently no treatment or vaccine for Ebola. The incubation time for Marburg and Ebola ranges from 3 days to 3 weeks following exposure. Although it has never been directly demonstrated in human cases, airborne transmission of filoviruses cannot be ruled out.

The viruses in the family *Arenaviridae* can be divided into Old World and New World, all of which are transmitted through a rodent reservoir. For these viral diseases, contact with the excreta of infected rodents (often via infectious aerosols) is the primary mode of infection. Human-to-human transmission can occur through bodily fluids, and airborne transmission has also been suspected in these cases. There have been no reports documenting transmission during the incubation period. Lassa fever, one of the Old World viruses, is an acute illness with an incubation period of 6 to 21 days and a fatality rate of 15 percent among hospitalized patients. The New World viruses include junin virus (causes Argentine HF), machupo virus (causes Bolivian HF), Guanarito virus (causes Venezuelan HF), sabia virus (causes Brazilian HF), and a newly identified HFV that first appeared in California in 1999–2000. Each of the viruses has a unique species of rodent that serves as its natural reservoir and an incubation period of between 7 and 15 days. Many of the diseases continue to appear sporadically in their natural environment. The use of ribavirin, an antiviral medication, has proved helpful in the treatment of arenaviruses. With the exception of junin virus, approved vaccines are not available.

Members of the *Bunyaviridae* family are usually spread by arthropod carriers or exposure to infected animal tissues, with one notable exception. Hantavirus is transmitted through contact with infected rodents and their excreta. After the incubation time of 7 to 28 days, there is little treatment beyond supportive care for patients infected with hantavirus. Rift Valley fever is spread to humans and other animals by a wide variety of mosquito species as well as through infectious bodily fluids. Domestic livestock such as sheep, cattle, buffalo, and goats are susceptible to Rift Valley virus. Most cases of Rift Valley are relatively mild, with an overall human fatality rate of less than 1 percent. However, a small portion of those infected develop a hemorrhagic syndrome that has a 50 percent case fatality rate. The incubation period is 2–6 days, and there is currently no treatment or vaccine available. Other viruses in this family spread by ticks, such as Crimean-Congo HF, Xinjiang HF (China), and the various agents of hemorrhagic fever with renal syndrome (HFRS). The latter includes hantavirus, which continues to inflict a heavy burden of disease through natural outbreaks. In terms of BW, however, there are substantial technological difficulties in weaponization of such viruses, notably in culturing them, and as a consequence, hantavirus is not considered a major threat in the United States.

The last family of HFVs, *Flaviviridae,* includes viruses that are naturally transmitted by arthropods. One of these, yellow fever virus, remains silent in the body for an incubation period of 3–6 days, after which the disease manifests itself in two phases. The first, or “acute,” phase, from which most people recover, can be followed by a “toxic” phase in about 15 percent of patients. Of these, about 50 percent will die within 10–14 days. Although there is no specific treatment for the disease, an effective vaccine does exist for yellow fever. However, the vaccine would have limited use in the event of a bioterror attack due to the virus’s short incubation time. There have been no reported cases of person-to-person or hospital spread of the disease, although infection can result from inhalation of aerosols.

Dengue HF is caused by one of four distinct viral serotypes (DEN-1, DEN-2, DEN-3, and DEN-4) transmitted by a mosquito vector, resulting in a spectrum of clinical manifestations based on serotype and the predisposition of the patient. Incubation time is between 2 and 10 days. Although many cases resolve themselves naturally, untreated patients that go into shock have a 40 to 50 percent fatality rate; this drops significantly if intensive care is available. Currently, there is no vaccine for Dengue HF. Because *Flaviviridae* viruses are carried by arthropod vectors, there is a theoretical risk of the disease being established in the environment in the event of large-scale exposure.

Current Status

Different HFVs are endemic to various geographical regions. Outbreaks that occur beyond their natural geographically restricted areas could be from one of the following sources: (1) imported from a region where it is endemic; (2) resulting from laboratories doing research on these organisms or receiving specimens from patients with fevers of unknown origin; (3) imported from infected rodents or laboratory research animals; or (4) an act of biological warfare. Making a determination among these causes presents significant challenges.

Diagnosis of VHF should be made based on clinical criteria, with laboratory testing used to conclusively confirm or rule out disease. In the event of a large attack, the current laboratory capacity would likely prove insufficient because there are few facilities properly equipped to deal with these pathogens. There are limited quantities of ribavirin, an antiviral drug that has been shown to be useful in treatment of *Arenaviridae* and *Bunyaviridae* but has not been approved by the FDA for treatment of VHFs. Ribavirin has also been linked to birth defects in pregnant women, and safe doses have not been well established in children. In an emergency situation, however, the administration of ribavirin and other new antivirals in these populations should not be ruled out. Treatment for people who may have been exposed but are not showing clinical symptoms is not recommended. Ribavirin has not shown much effectiveness against filoviruses or flaviviruses. It has been recommended that intravenous and oral ribavirin be added to the U.S. National Pharmaceutical Stockpile. In any event, infection control measures will prove critically important in any large-scale outbreak of VHFs.

Developing Technologies

There are large gaps in knowledge about HFVs due to limited data about the diseases and the need to perform research in high-safety laboratory situations. Mechanisms of disease outbreaks, airborne transmission, and rapid and safe diagnostic methods all need to be further researched or developed. Better treatments and vaccines are needed; however, the diversity and relative unknown nature of disease manifestation have complicated this pursuit. Vaccines exist for yellow fever, Rift Valley fever, and Junin (Argentine HF); the junin vaccine may give cross-protection for Machupo (Bolivian HF). Only the yellow fever vaccine is licensed by most national drug authorities, and there is a limited global supply and capacity to deliver the vaccine. Following an attack using this viral agent, the prophylactic use of the vaccine would not be very effective, because the time needed to raise immunity after vaccination is longer than the incubation period for the disease. Other vaccines are being researched and developed against filoviruses and Lassa fever, but these efforts are hampered by the strict safety protocols necessary to conduct research.

HERBICIDES

Herbicides are weed killers. It is estimated that about 1,500 species of weeds cause serious economic losses to American farmers. Fifty-three percent of the herbicides in the United States is used to aid in corn production, 21 percent is used for soybeans, 6 percent for wheat, 5 percent for cotton, and 5 percent for other crops.

Herbicides commonly used in the United States for large-scale agriculture are shown in Figure H-1 and Table H-1.

Fig. H-1: Structures of herbicides used in large-scale agriculture in the United States

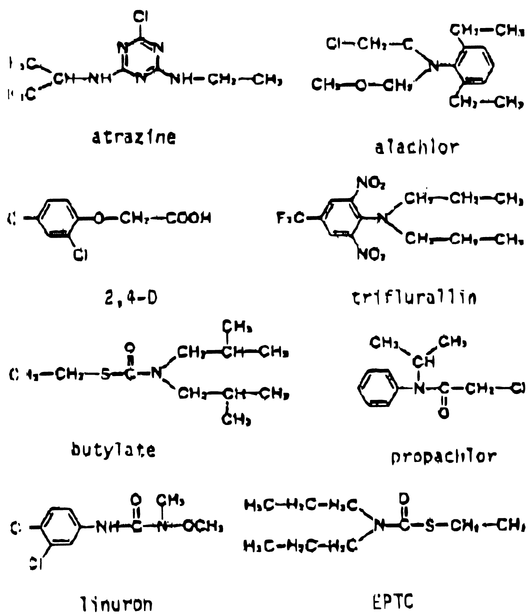

Table H-1: Herbicides Used in Large-Scale Agriculture in the United States

Common Name	*Trade Name*	*Amount Used (lbs.)*	*Percentage of Total*
atrazine	A Atrex	90.3 x 10^6	24.1
alachlor	Lasso	88.5 x 10^6	23.7
2,4-D	Weeder 64	38.4 x 10^6	10.3
trifluralin	Treflan	28.3 x 10^6	7.6
butylate	Sutan	24.4 x 10^6	6.5
propachlor	Bexton	11.0 x 10^6	2.9
EPTC	Eptam	8.6 x 10^6	2.3
linuron	Lorox	8.4 x 10^6	2.2
others	—	76.0 x 10^6	20.3

Some herbicides are water insoluble; these are dissolved in organic solvents for efficient distribution. For water-based weed killers, however, water-soluble herbicides are used. The best examples of water-soluble herbicides are diquat, paraquat, morfamquat, and chlormequat chloride. Because paraquat—a widely found and used herbicide—is water soluble, occasionally it is used for homicides by mixing it with juice or soft drinks and giving it to a victim to drink. Injection of paraquat into the human body is very dangerous, causing damage in liver and kidney tissues. Contact with paraquat causes skin, mucous membrane, and cornea irritation.

Phenolic and phenoxy-type herbicides are other commonly used types. Phenolic herbicides are usually nitro- and chloro-derivatives of phenol. Examples are dinitrophenol, dinitro-ortho-cresol, and pentachlorophenol. These phenolic herbicides kill weeds by contact with foliage rather than by uptake through the roots. Thus, they also are called contact herbicides. Phenoxy-type herbicides were used as defoliation agents during the Vietnam War by the U.S. Army.

There are many varieties of herbicides, and the mechanism of herbicide action is different depending on the compounds. The compounds 2,4-D and 2,4,5-T are similar in action to the plant hormone auxine. They promote rapid weed growth in a short time, creating an imbalance in the weeds' metabolisms that causes the weeds to die. Amitrole inhibits the biosynthesis of chlorophyll and carotenoids, which are essential for proper plant growth. Atrazine blocks the breakdown of water molecules into 2H and 1/2 O_2, which is a crucial step for photosynthesis in plants. Diuron inhibits the breakdown of water molecules and inhibits the enzymatic step between Q and plastoquinone in the photosystem II metabolic pathway, a critical step in photosynthesis.

Bipyridylium (Paraquat, Diquat) herbicides compete with electron acceptors, which are necessary for continuous exchange of energy in photosystem I in photosynthesis, causing weeds to die. Dinitrophenol, dinitro-ortho-cresol, and pentachlorophenol are toxic because they uncouple the oxidative phosphorylation used for energy transfer process in weeds.

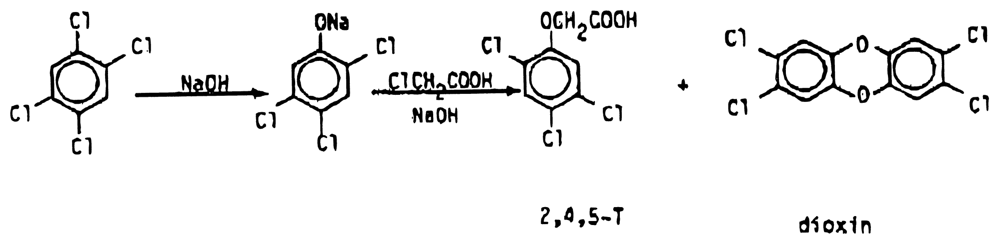
Herbicides are designed to kill plants; they generally have low toxicity in humans, with the exception of paraquat and endothal. Phenolic herbicides, however, are moderately toxic to humans. In mammals, they cause fever, sweating, fast respiratory and heart rates, and dehydration.

American troops in Vietnam were the first to use herbicides extensively for military purposes (e.g., to defoliate tropical vegetation used for cover by the enemy). The most well known herbicide used during the Vietnam War was Agent Orange, consisting of 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxy acetic acid (2,4,5-T). But U.S. forces also used other herbicide formulas called Agent White, Agent Blue, Agent Purple, Agent Pink, and Agent Green. They are shown in Table H-2.

Table H-2: Herbicides Used in the Defoliation Operation in Vietnam from 1965 to 1971

Code Name	*Herbicide*	*Quantity (gal.)*	*Period of Use*	*Dioxin (ppm)*
Orange	2,4-D; 2,4,5-T	10,646,000	1965–1970	1.98
White	2,4-D; picloram	5,633,000	1965–1971	—
Blue	cacodylic acid	1,150,000	1962–1971	—
Purple	2,4-D; 2,4,5-T	145,000	1962–1965	32.80
Pink	2,4,5-T	123,000	1962–1965	65.60
Green	2,4,5-T	8,200	1962–1965	65.60
Total		17,705,200		

Fig. H-2: Manufacture of 2, 4, 5-T and the by-product formation of dioxin



Agent Orange created environmental and health problems due to dioxin contamination (2,3,7,8-tetrachlorodibenzodioxin); when 2,4,5-T was produced (see Figure H-2), dioxin was produced as a by-product. The lethal dose of dioxin in rats is 1.0 g/kg by the oral route, meaning that dioxin is 100,000 times more toxic than 2,4,5-T. Although dioxin is highly toxic in nature (especially in soil), it degrades into less toxic products, albeit very slowly.

About 369,000 Vietnam veterans received treatment in Veteran's Administration (VA) hospitals for Agent Orange–related health problems. Among them, 9,600 were admitted to hospitals for further intensive care. About 17,000 veterans requested sickness compensation. The U.S. Department of Defense, however, has claimed that Agent Orange had nothing to do with veterans becoming sick and that the U.S. government had no obligation to offer compensation. Many veterans and their families were unsatisfied with this decision and filed suit against the U.S. government. To avoid costly and lengthy litigation, the U.S. government settled the veterans' claims out of court for $180 million.

After the Vietnam War, about 20,000 gallons of Agent Orange remained in storage. The U.S. Army destroyed this stockpile on an incineration ship in the middle of the Pacific Ocean at temperatures of 1,000–1,500° centigrade. High temperatures are essential for destruction of Agent Orange; otherwise, dioxin can be formed.

The problem of dioxin was not restricted to Vietnam. In 1976, a chemical plant in Seveso, Italy, accidentally released dioxin in a densely populated area. Because of the dioxin problem, the Environmental Protection Agency (EPA) has cancelled the use of 2,4,5-T on most food crops. In 1982, dioxin contamination was found in Times Beach, Missouri, and the EPA offered to buy the whole town to solve the problem. However, to date there are no studies to show that the Seveso incident or the Missouri case resulted in increased incidence of human disease linked to dioxin.

I

INDIA: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

Chemical Weapons

India's first contact with chemical warfare (CW) equipment and organization in the modern era probably began in 1920. When India was still a British colony, mustard was brought into India to deal with anticolonial rebels in the northwest.

Since World War II and the independence of India (1947), little has been revealed concerning India's offensive CW capability. In June 1997, India declared to the Organization for the Prohibition of Chemical Weapons (OPCW) that it possessed chemical weapons. Precursors—chemicals that could be used to make CW agents such as sulfur mustard—were also declared by India, including chloroethanol. According to Chinese CW defense sources, India possesses five chemical weapons production and storage facilities with 1,000 tons of CW agents in its stockpile, "making India the third largest chemical weapons possessor after the United States and Russia" (Zhang, Yuan, and Xiong, p. 43). Most of India's stocks were estimated by the Chinese military to have been in the form of mustard agent. As a member of the Chemical Weapons Convention (CWC), India is obligated to destroy its entire stockpile by 2007.

Biological Weapons

India ratified the Biological and Toxin Weapons Convention in 1974. Despite some open source reports that suggest that India possesses biological weapons, none of these allegations can be confirmed.

During the Indo-Pakistan War in 1965, the Indian intelligence apparatus became suspicious when they detected an outbreak of scrub typhus in northeast India. Caused by the organism *Rickettsia tsutsugamushi,* the outbreak of scrub typhus during the Indo-Pakistan War was undoubtedly a natural consequence of conflict—due, for example, to the disruption of sanitary measures. Similarly, in 1994, an outbreak of plague in Surat was deemed suspicious. Some Indian security specialists believed that outside actors—perhaps terrorists—might have been responsible for the plague outbreak. However, there is no evidence to support such a claim, and it appears most likely that the Surat plague outbreak was due to natural causes.

There were also unfounded rumors of bioterrorism during the dengue outbreak in 1996 in Delhi. Molecular studies of isolates from this epidemic showed an especially virulent type of the disease, and the director of the Indian Veterinary Research Institute was not willing to rule out a foreign point of origin. This case, however, was also most likely a natural outbreak of dengue.

Like many countries, India conducts research into defenses against biological warfare (BW). Military-related research into possible biological weapon threats is conducted at India's Defense Research and Development Establishment at Gwalior. Having a significant capacity to produce pharmaceuticals, notably vaccines, India has the potential to produce large quantities of BW agents should it desire to do so. There is no evidence from open sources, however, that India has ever pursued an offensive BW program.

INVERSION

Inversion is a meteorological phenomenon that occurs when the ground is cooler than the air above it, usually during early morning or dusk. Typically, there is little air turbulence in an inversion, and aerosols are not dissipated as rapidly as they would be under other conditions (i.e., air conditions known as neutral and lapse; see below). Inversions are generally considered to be optimum for the delivery of chemical or biological warfare agents. According to Chinese military experts in chemical warfare, "The effect of temperature inversion makes it difficult for contaminated air to disperse, making it stick close to the ground as it moves, and now a high concentration of agent is maintained with harmful effects lasting over a long period" (Cheng and Shi, p. 45).

Neutral conditions are less favorable for CBW agent delivery. In neutral conditions, the ground temperature is about the same as the layer of air above it (up to about 12 feet). There is some turbulence from convection currents due to fluctuations caused by warmer air, and winds are light to moderate. Such conditions are less ideal for CBW agent release. Finally, in the condition known as lapse, the temperature of the air is cooler than that of the ground. Cooler air moves toward the ground, creating air turbulence. This usually occurs during late morning and afternoon (usually with clear skies) and is the least favorable environment for disseminating aerosols.

During the Cold War when the United States possessed an offensive chemical weapons program, tables were used to calculate the effectiveness of nerve agents against enemy targets. Depending upon wind speed, ambient temperature, and inversion/neutral/lapse conditions, the table would tell the number of shells needed to contaminate a certain number of hectares of ground. During inversion, with moderate (20 degrees C) temperature and slow wind velocity, for example, the number of 105-millimeter sarin nerve agent howitzer shells needed might be as few as two or three per hectare. In contrast, under lapse conditions with high wind and high ambient temperatures, dozens of shells or more might be required per hectare.

Inversion also plays a key role in biological warfare. As seen in Table I-1, the behavior of particles under inversion, or lapse conditions will in large part depend upon their diameter. Some early calculations of particle behavior based on particle size showed that, with a wind velocity of about 5 miles per hour, most particles of 0.8 microns can remain airborne for 10,000 yards. But another phenomenon occurs during inversion. As particles increase in size, at a lower wind speed (2 mph), they fall out of the air more rapidly.

Awareness of inversion or lapse conditions is useful for offensive use of chemical and biological weapons. Because inversion conditions are best suited for the delivery of CBW aerosols, however, militaries and civil defense planners can also take into account meteorological data to mitigate the effects of chemical or biological weapons.

IRAN: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

Although Iran has limited indigenous skills and resources to manufacture weapons of mass destruction (WMD), it has consistently figured prominently in evaluations of international WMD proliferation threats. Unstable relations between Iran and the United States following the Islamic revolution of 1979 exacerbated concerns about Iranian weapons aspirations. Iran's efforts to acquire weapons capabilities have, as a result, been broadly curtailed by U.S. efforts to prevent arms and technology transfers between U.S. allies and Iran.

Iran's WMD aspirations gained additional urgency following the Iran-Iraq war, in which Iraq demonstrated superior WMD capabilities. Iran's conventional arsenal was also devastated in the war, and Iran turned to the Soviet Union for assistance in reconstituting its military. The Soviet Union viewed its cooperation with Iran as a means of extending its own influence in the pivotal Persian Gulf region, and it formally agreed in 1989 to bolster Iran's military capacity. Iran has also received extensive military assistance from China and North Korea.

Chemical Weapons

Iran's chemical weapons program is its most advanced effort to create and deploy weapons of mass destruction. Iran initially received chemical agent precursors from the United States, Germany, and Japan, and it received production technology from Germany and Hungary. After the revolution in 1979, China became Iran's primary supplier of these materials. Iran is reportedly close to self-sufficiency in terms of possessing a chemical weapons industry and could possibly become a supplier to other countries.

Iran is believed to have initiated a chemical weapons program in the mid-1980s, in response to the use of chemical weapons against it during its war with Iraq. Reports indicate that it began to stockpile cyanogen chloride, phosgene, and mustard after 1985 and to produce nerve gas in 1994. In 2000, U.S. intelligence analysts reported that Iran possessed at least several hundred metric tons of weaponized and bulk chemical agents, including nerve, blood, blister, and choking agents, and that it has attempted to obtain weapons-relevant technology, training, and chemicals from China and Russia. Iranian opposition groups have also reported that Iran has produced VX nerve gas and aflatoxin.

Iran signed the Chemical Weapons Convention in 1997 and submitted a declaration of its holdings as required by its membership. Iran disclosed that it had a chemical weapons program in the final months of the Iran-Iraq war, during which it was exposed to chemical weapons attacks by Iraq, but it has denied all accusations that it has an ongoing program. It has accepted visits from inspectors of the Organization for the Prohibition of Chemical Weapons (OPCW), who have not found evidence of treaty violations.

Biological Weapons

Iran initiated a biological weapons program in the 1980s during its war with Iraq. Little information, however, is publicly available about Iran's efforts to acquire biological weapons. Some observers suspect that Iran has a biological weapons laboratory at Damghan, has produced small quantities of biological weapons agents such as anthrax bacteria and botulinum toxin, and has weaponized several biological agents. Some experts doubt that Iran possesses stockpiles of biological agent but instead believe that it has created surge capabilities that would allow it to build a biological weapons stockpile on short notice. Iran has denied all allegations about developing or stockpiling biological weapons and maintains that it adheres to the Biological and Toxin Weapons Convention, which it ratified in 1973.

U.S. intelligence agencies have suggested that biomedical research conducted at institutions in Iran has been used in support of a biological weapons program and that Iran has received biotechnology from Russian research facilities. Some experts have also suggested that Iran likely accelerated its biological weapons program following revelations about Iraq's biological weapons program in 1995. Press reports have also indicated that Iran has recruited Russian weapons scientists to work on its biological weapons programs.

IRAN-IRAQ WAR

The Iran-Iraq War was an armed conflict between Iran and Iraq that lasted from September 1980 to August 1988. It witnessed the first confirmed use of chemical weapons in combat since World War I and the first use of nerve agent in warfare. Although precise figures are unavailable, the conflict produced more than 1.5 million war-related casualties.

The war was launched by Iraqi president Saddam Hussein, ostensibly over a territorial dispute over the Shatt al Arab, a waterway that empties into the Persian Gulf and forms the southernmost boundary between Iran and Iraq. The true sources of the conflict, however, were multifaceted. Saddam Hussein's main goal was to assert dominance over the Persian Gulf region, taking advantage of the power vacuum caused by the 1979 Iranian Revolution, in which Shah Mohammad Reza Pahlavi was overthrown by Shia forces loyal to Ayatollah Ruhollah Khomeini. The military, which had been intensely loyal to the Shah, was decimated by Khomeini, who had most senior military officers executed. Additionally, Khomeini's strained relationship with the United States now made it difficult for Iran to get spare parts for its equipment, most of which had been purchased by the Shah from the United States. This made Iran more vulnerable to attack. Other factors that influenced the onset and course of the war included the conflict between Sunnis and Shias (two Muslim sects), Arab versus Persian religious and ethnic disputes, disputed control of certain oil fields, and personal animosity between Hussein and Khomeini.

In the spring of 1980, the Iran-backed radical group Ad Dawah, which wanted to establish an Iranian-style Islamic government in Iraq, attempted to assassinate Iraqi foreign minister Tariq Aziz and minister of culture and information Latif Nayyif Jasim. In response, the Iraqis deported thousands of Shias to Iran. Saddam Hussein captured the leader of the Ad Dawah and his sister, executing them both in the summer of 1980.

Possession of the Shatt al Arab had been in dispute since the Peace Treaty of 1639 between the Persian and Ottoman Empires. Iraq claimed the 200-kilometer channel up to the Iranian shore as its territory, but Iran insisted that the thalweg, a line running down the middle of the waterway, was the official border. In the 1975 Algiers Agreement, a militarily weaker Iraq recognized the Iranian claim, but Saddam Hussein took advantage of perceived Iranian weakness after the fall of the Shah to press for total control. He also hoped to take the western Iranian region of Khuzestan, which had extensive oil fields.

Border skirmishes erupted on September 4, 1980, near Qasr-e Shirin, and Iraq launched a full invasion on September 23. The war continued to escalate to the point that, by 1985, both sides were launching air and missile strikes against their opponent's capitals.

Saddam Hussein had grossly underestimated the capability and resolve of the Iranians, who made impressive early gains. By 1982, the situation on the ground had grown desperate for Iraqi forces. Iraqi forces probably used the riot control agent CS, an extremely powerful tear gas, against Iranian troop concentrations that year. The first of ten documented chemical attacks in the war involving true casualty agents like mustard occurred during the Val Far II campaign near Haj Umran in August 1983. The Iraqis used mustard against an Iranian force on a mountaintop location, which had minimal impact because of both the altitude and unfavorable wind and weather conditions. Nonetheless, this marked the introduction of lethal CW agents into the war. By November 1983, Iraq had killed hundreds of Iranian forces with mustard.

As the war progressed, Iraqi CW tactics improved markedly. In an operation known as Khaybar I in February 1984, the Iraqis isolated the forward elements of an Iranian attacking force with mustard, cutting them off from food and ammunition supplies for days. According to Iranian claims, Iraq had conducted more than forty chemical attacks by this point. By mid-1984, there were credible reports of Iraqi use of a mustard variant known as dusty mustard, which impregnated solid particles with mustard agent to create a more militarily useful weapon. Iraq was also expanding its production of the nerve agents sarin and VX, with the former likely being used during the latter stages of the war. The largest documented attack was a February 1986 strike against al-Faw, in which mustard and tabun caused as many as 10,000 Iranian casualties.

The international response to these violations of international law (both Iran and Iraq were signatories to the Geneva Protocol of 1925, which prohibits the use of asphyxiating, poisonous, or other gases and of all analogous liquids, materials, or devices, as well as the use of bacteriological methods of warfare) was muted. In March 1984, United Nations secretary-general Javier Perez de Cuellar dispatched an international team to investigate the claims of CW by Iraq. They reported that chemical weapons were in fact being used, notably mustard and the nerve agent tabun. Despite this and despite continued pleas from Iran, little outrage ensued. The most dramatic step taken was the issuance of Security Council Resolution 582 on February 24, 1986, which merely "deplored" these violations of the Geneva Protocol.

In March 1986, de Cuellar, citing the report of four chemical warfare experts whom the UN had sent to Iran in February and March 1986, called on Baghdad to end its violation of the 1925 Geneva Protocol on the use of chemical weapons. The UN report had concluded, "Iraqi forces have used chemical warfare against Iranian forces"; the weapons used included both mustard and nerve gas. The report further stated: "the use of chemical weapons appear[ed] to be more extensive [in 1981] than in 1984" (de Cuellar, quoted in http://www.globalsecurity.org). Iraq denied using chemical weapons, but the evidence, in the form of many Iranian casualties severely injured by mustard agent and flown to European hospitals for treatment, was overwhelming. According to a British representative at the Conference on Disarmament in Geneva in July 1986, "Iraqi chemical warfare was responsible for about 10,000 casualties" (http://www.countrystudies.us).

Khomeini had reportedly ordered that no chemical weapons be used by Iranian forces because polluting the environment, even during a jihad ("holy war"), was a violation of the Koran. Nonetheless, in December 1986, Iran's former prime minister, Hussein Musavi, announced that Iran had developed "sophisticated chemical weapons." There are unconfirmed reports that Iranian forces used these weapons late in the war.

By 1988, the combination of CW deployment and imported military equipment from abroad had shifted the war in Iraq's favor. Iraq launched four major counteroffensives between April and August and won all of them. In April, Iraq used a chemical artillery barrage during an assault on Iranian positions on the Fao Peninsula.

In addition to employing them against the Iranians, Saddam Hussein used chemical weapons on his own citizens. One of the most notorious of these attacks was carried out in the north. Iraqi forces used a combination of mustard and nerve gas to kill approximately 5,000 civilians in the town of Halabja in March 1988. (*See* Halabja Incident.)

Iran finally agreed to a cease-fire pursuant to United Nations Security Council Resolution 958 on August 20, 1988. Ironically, in late 1990, Hussein readily gave up the minor gains he had achieved from these 8 years of fighting. In hopes of securing Iranian cooperation during the impending Gulf War that followed his annexation of Kuwait, he agreed to accept the terms of the 1975 treaty with Iran and to withdraw his troops from Iranian territory, as well as to exchange all prisoners of war. No formal agreement was signed, however, and both sides held thousands of POWs for many years. Several prisoner exchanges and releases occurred after 1988; the final exchange took place in 2003.

A complete tally of casualties suffered by both sides in the Iran-Iraq War will probably never be known. Iran calls the survivors of the chemical attacks living martyrs and claims that more than 60,000 soldiers were exposed to mustard and to the nerve agents sarin and tabun.

During the war, Iraq developed the ability to produce, store, and use chemical weapons, including H-series blister and G-series nerve agents. These were weaponized into rockets, artillery and mortar shells, aerial bombs, and warheads on the al-Hussein Scud missile variant. Iraq used Mig-23 fighter-attack aircraft to drop mustard- and tabun-filled 250-kilogram bombs and mustard-filled 500-kilogram bombs in random patterns from altitudes between 3,000 and 4,000 meters. They also deployed CW agents from Mi-8 HIP helicopters by generating an aerosol from two 1,000-liter spray tanks or by dropping 55-gallon drums filled with unknown agents (probably mustard) from altitudes of 3,000 to 4,000 feet.

Iran and Iraq also had nascent nuclear programs, and each took steps to prevent the other side from gaining nuclear weapons. Iran launched an unsuccessful attack on the Osirak nuclear reactor on September 30, 1980, in the first weeks of the war. (The facility was later destroyed by Israel in an air attack using F-16s on June 7, 1981. Israel justified this attack based on the fear that Iraq could develop a nuclear weapon to be used against Tel Aviv. Between 1984 and 1988, Iraq launched seven air attacks on the Iranian nuclear reactor at Bushehr during the Iran-Iraq War, ultimately destroying the facility.

IRAQ: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

Iraq's chemical weapons capability has been known for some time, but information about its biological weapons program only emerged after 4 years of inspections, to much consternation within the world community. Iraq used chemical weapons during the Iran-Iraq War as a means of offsetting its numerical inferiority. It also used these weapons internally, most notably against the Iraqi Kurds, but it chose not to use these weapons during the 1991 Gulf War. Removing Iraq's alleged possession of weapons of mass destruction was the principal reason given for a U.S.-led coalition's invasion of Iraq in 2003.

History and Background

Passed in April 1991, UN Security Council Resolution 687 called for the complete destruction of Iraq's weapons of mass destruction, including all of its chemical and biological weapons and the infrastructure supporting them. A United Nations Special Commission (UNSCOM) was set up to oversee the destruction of these weapons and to report this to the UN Security Council. They remained in the country until the end of 1998, when they were withdrawn following lack of compliance by Iraq, and the United States and United Kingdom engaged in air operations to try to force greater cooperation from the Iraqi government. Under the terms of the UN resolution, the Iraqi authorities were supposed to provide the full details of Iraq's various programs and to fully support the UNSCOM inspections. Their actual help proved less than satisfactory.

The United Nations Monitoring, Verification, and Inspection Commission (UNMOVIC) replaced UNSCOM in 1999. In 2002, the UN Security Council passed Resolution 1441, giving Iraq a final chance to cooperate. The inspection mission returned to Iraq under the leadership of Hans Blix in late 2002, but it was again withdrawn in March 2003 when a U.S.-led coalition decided to use force against Iraq, arguing that Iraq had again failed to fully comply with the UN. A U.S.-led inspection mission looked for evidence of Iraqi weapons of mass destruction for months after the quick victory in April 2003, but little evidence was found.

Iraq began work on developing a chemical warfare capability during the early 1980s in response to the failure of its attacks on Iran. In the war that followed, the Iraqi regime gained a considerable amount of combat experience in the use of chemical weapons through their use against Iranian forces and in their use against Iraq's own Kurdish minority. Chemical weapons use became a regular part of Iraqi military operations, and these weapons were used for both strategic and tactical effect to offset Iraqi numerical inferiority. The Iraqi chemical arsenal fell into the three usual categories of CS gas, mustard, and nerve agents. In the latter category, tabun and sarin development has been verified, and there is evidence to suggest that other agents were also under development. During Operation Desert Storm, extensive damage was done to known Iraqi facilities from the air, and the extent of this was subsequently verified by UNSCOM. UNSCOM's efforts to uncover the full extent of the chemical warfare program and the remaining constituent parts, however, were hampered by Iraqi efforts at denial and deception. When UNSCOM withdrew in December 1998, it could not confirm that it had fulfilled its mandate of destroying the Iraqi program in full.

Kurds inspect an unexploded bomb—possibly filled with a CW agent—following a 1988 attack by Saddam Hussein's military. (Ed Kashi/Corbis)

Iraq's biological weapons program dates back to the early 1980s and was also developed in the context of the Iran-Iraq War. At this time, the regime considered using such weapons, fired from field artillery, for both strategic and tactical purposes. This effort did not succeed, however, until after the end of the Iran-Iraq War. Prior to Desert Storm, Iraq accelerated its production of anthrax and botulinum toxin. UNSCOM's Executive Chairman, Rolf Ekeus, was subsequently informed that authority had been delegated to local Iraqi commanders to use these agents in response to a massive attack on Baghdad. After Iraq's invasion of Kuwait in August 1990, a coalition-bombing raid destroyed Iraq's prototype aerial spray tanks.

Initially, Iraq claimed that it had no biological program, and for the first 4 years of inspections, little was discovered about the Iraqi BW program. The scope and extent of the various programs was only finally revealed when General Hussein Kamel Hasan defected from Iraq in August 1995. His debriefing revealed many details about various Iraqi programs and led to the subsequent modification of Iraqi denials. It also led the Iraqis to move steadily toward acknowledging the actual scale of the program as the inspectors discovered further details about the various operations. This proved to be a major shock for the international community, which had been close to accepting the Iraqi denials about its chemical and biological programs and to removing economic sanctions as a reward.

The Iraqis had developed a wide-ranging weapons program that was based on viruses, bacteria, and fungi in both their living form and their toxin derivatives. These weapons ranged from lethal agents and incapacitants to crop-attack agents, and their delivery means included field artillery, aircraft with tanks, and al-Hussein surface-to-surface missiles (modified Scuds). Subsequent investigations by UNSCOM confirmed that the Iraqis had produced at least 8,500 liters of anthrax and 19,000 liters of botulinum toxin, more than the Iraqis had ever admitted. In addition to these lethal agents, the Iraqi regime reported that it had made weapons out of 1,580 liters (of a total of 2,200 liters produced) of the incapacitant aflatoxin (derived from a fungus). In addition, the Iraqi regime admitted to having conducted research and development tests on a range of agents—*Clostridium perfringens;* ricin; and viruses including hemorrhagic conjunctivitis, rotavirus, and camel pox—for weapons purposes, plus field trials on an anticrop agent known as wheat cover smut.

Current Status

With the end of the war in Iraq, U.S.-led inspection teams are looking to destroy Iraq's chemical and weapons programs once and for all. Little has been found, but the inspections continue.

J

JAPAN AND WMD

Twenty-first century Japan does not possess any weapons of mass destruction (WMD), including nuclear, biological, or chemical weapons. The Japanese military, however, employed chemical and biological weapons against China during World War II. Substantial evidence suggests that Japan also pursued a nuclear weapons research program until 1945 but did not make very much progress.

Japan also has the unfortunate distinction of being the target for chemical terrorism involving nerve agent (sarin). In 1994–1995, following the orders of their guru Shoko Asahara, operatives within the new age cult called Aum Shinrikyo used improvised chemical weapons against the Japanese authorities, killing about 20 people and injuring more than 1,000.

Japan's Nuclear Legacy

Japan is unique in being the only country to be subjected to atomic bombing. As a means to help shorten the Pacific War, on August 6, 1945, the United States dropped a uranium-235 nuclear device on Hiroshima; three days later, it dropped a plutonium device on Nagasaki. Out of a population of 250,000 in Hiroshima, at least 45,000 people died on August 6, many from the thermal and blast effects produced by the weapon. Nearly 20,000 died during the following 4 months due to their injuries, which included radiation sickness. In Nagasaki, some 22,000 people died from the initial blast, and another 17,000 succumbed to their injuries over the subsequent 4 months. There may have been many more who perished as a result of these bombings but who, for various reasons, were not recorded.

The legacy of the atomic blasts included 63 extra cases of leukemia among the 92,000 atomic bomb survivors (one would normally expect 21 cases in a normal population). As for genetic abnormalities among those who survived and their progeny, studies have shown that these are surprisingly rare. A recent survey concluded: "the expected increase of genetic damage in the atomic-bomb survivors is so low that it would not be detectable within the larger spontaneous incidence. In screening . . .the blood of 27,000 children of atomic-bomb survivors, only two children presented mutations that might be related to the radiation exposure of the parents" (Walden, p. 202).

Japan's Historical Use of Chemical and Biological Weapons

During Japan's colonization of Taiwan, brutal pacification campaigns were waged against local indigenous groups, particularly during the years 1910–1914. Local tribes revolted against the Japanese, including those in Wushe, a mountainous area in central Taiwan. Local historians agree that, during the infamous Wushe incident of 1930, Japan used chemical warfare (CW) agents to crush the rebellion led by tribal leader Mona Rudo. (Japan had begun production of CW agents in 1928 on Okunoshima Island.) During the 1930 uprising, 134 Japanese people were killed by resistance guerillas. In addition to employing co-opted tribe members as bounty hunters, Japan crushed the rebellion using "Green canister" shells (chloracetophenone, or CN). In the end, 644 of the indigenous people were dead, representing about half of the indigenous community in Wushe. This particular engagement may have been part of the experimental testing with CW conducted by the Japanese on Taiwan between 1930 and 1941.

Starting in 1937, the Japanese army employed a wide range of CW agents during its invasion of China. Quoting an "authoritative Soviet source," a book written by Chinese military specialists in CBW

defense claims that "during its war in China, the Japanese army had prepared 25 percent of their artillery shells to be chemical munitions, while 30 percent of its aerial ordnance were chemical bombs" (Wang and Yang, p. 97). According to these same authors, "Fascist Japan used CW over 2,000 times, causing 90,000 casualties" (Wang and Yang, p. 102). In 1991, the Chinese People's Liberation Army (CPLA) claimed that more than 80,000 people were killed in approximately 2,000 chemical attacks by the Japanese army during World War II. (It is possible that translators have confused casualties with fatalities, which might explain the discrepancies.) Yet another source tallies 10,000 deaths and 80,000 wounded from Japanese chemical weapons. More precise (if not accurate) statistics record that from July 18, 1937 to May 8, 1945, Japan carried out 1,059 chemical attacks in China, including the use of CW agents diphenylchloroarsine, diphenylcyanoarsine, chloroacetophenone, chloropicrin, hydrogen cyanide, phosgene, mustard, and lewisite. A 1938 report from the Red Cross, signed by five physicians on the scene, reported that at Xuzhou "a large number of wounded soldiers was rushed to the hospital. Among them they found several cases showing generalized skin blisters and lesions resembling more or less those caused by smallpox . . . photographed evidence is available" (Hoo, p. 1).

Although it is difficult to evaluate the extent of Japanese use of chemical weapons in China, it would appear that mainland sources exaggerate the overall importance of CW to explain Japan's success against Nationalist (Kuomintang) armies. Japanese soldiers, especially those serving in China, were highly disciplined and ruthless, operating under a well organized command structure. The latter qualities were not to be found among the Chinese resistance, already fractured by a rivalry between the KMT and Chinese Communist Party forces led by Chiang Kai-Shek and Mao Zedong. Although it certainly assisted the Japanese forces in certain engagements, it is difficult to conclude that CW played a decisive role in the Sino-Japanese war of 1937–1945.

Biological Warfare in China

During the years 1931–1945, Japan pursued a BW program and conducted biological weapon field tests against Chinese military and civilian targets. Much has been written about the gruesome experiments conducted by General Ishii Shiro and his Unit 731, and by other specialized detachments in China during World War II (*see* Unit 731). Sheldon Harris has compiled the following numbers of casualties that resulted from Japanese BW activity in China, although there are many instances in which casualties can only be estimated.

Table J-1: Japanese BW Operations in China, 1937–1942

Ningbo, summer 1940, October–November 1940	99 deaths from plague reported
Changteh City, Hunan Province, spring–summer, November 4, 1941	400–500 deaths; minor epidemic resulted, +24 fatalities
Chekiang Campain, Yushan, Kinhwa, Futsing, summer 1942	Chinese casualties evaluated as high, but attack boomeranged, causing numerous Japanese casualties (estimated to be as high as 10,000)

Kojima Takeo, a captain in the Japanese Imperial Army, reported that "about twenty thousand Chinese died from cholera" as a result of Unit 731 field operations (Gold, p. 249). Total Chinese deaths due to Japanese BW—that is, actual weaponized use in the field (not including the 3,000-plus Chinese, Korean, and other prisoners of war who died from Japanese BW military experiments)—could start at 21,000. Perhaps not unexpectedly, Chinese estimates of deaths caused by Japanese BW activities are much greater. According to one Chinese source, "During Japan's invasion of China, BW was carried out among twenty or more provinces and cities in China, causing more than 200,000 casualties among the Chinese people" (Liu, p. 368). Other Japanese and Chinese scholars have since come to the conclusion that "at least 270,000 Chinese soldiers and civilians were killed as a result of Japanese germ warfare between 1933 and 1945" (Shi, 2001). However, no information to date can support such a figure, nor is it likely that Japanese BW activities can be definitively linked to every occurrence of plague or other infectious diseases in China at that time. Plague, for example, has been endemic to China since 1894, and during wartime it is common for public hygiene to collapse completely, leading to the rapid spread of infectious disease.

JOHNSTON ATOLL

Johnston Atoll, a group of four islands located 825 miles southwest of Hawaii, played a key role in the U.S. nuclear, biological, and chemical weapons programs. An unincorporated U.S. territory, the islands were first used for atmospheric nuclear testing in the 1950s. Then, beginning in 1964, a series of biological tests was conducted offshore of the islands to measure the susceptibility of rhesus monkeys located on barges to biological agents released by aircraft overhead. Most significantly, the United States moved chemical weapons that it had previously stored abroad to the atoll, where they were kept until their destruction was completed in November 2000.

In 1969, an accidental leak of VX nerve agent stored by the United States on the island of Okinawa injured twenty-three U.S. military personnel and one civilian, leading the Japanese government to request the removal of the weapons (*see* V-Agents). Plans were made to move the stockpile to Umatilla Army Depot in Oregon. Before the transfer was completed, however, Congress passed Public Law 91-672, which prohibited the army from relocating chemical weapons stored overseas to anywhere in the continental United States. Instead, in a 1971 effort designated Operation Red Hat, the weapons from Okinawa were transported to Johnston Island, one of the islands comprising the Johnston Atoll. Almost 20 years later, following the conclusion of a bilateral chemical weapons destruction agreement with the Soviet Union, the United States in 1990 relocated another cache of weapons from Germany to Johnston Island in Operation Steel Box. Before actual destruction took place in the 1990s, 6.6 percent of the original U.S. chemical weapons stockpile was stored on the atoll.

Built in 1990, the Johnston Atoll Chemical Agent Disposal System (JACADS) was the first U.S. chemical weapon destruction facility to become operational (*see* Demilitarization of Chemical and Biological Agents). Using incineration technology, the facility destroyed more than 400,000 projectiles, mortars, bombs, rockets, and mines containing mustard, sarin, and VX (*see* Mustard, Sarin, and V-Agents). Eight months after the final destruction of the weapons and agent was completed, the U.S. Army Chemical Activity, Pacific, the unit responsible for the storage, security, and transport of chemical munitions and agent on Johnston Atoll—was deactivated.

The army's plan to dismantle JACADS was approved by the Environmental Protection Agency in September 2002. The plan encompasses the disassembly of the JACADS facility, the treatment of waste generated by the weapons destruction, and cleanup of the island. Relying on human health and ecological risk assessments, sampling and analysis, and quality assurance methods, the U.S. Army is required to certify that the atoll is safe before they depart. Once that assurance has been provided, the atoll will transfer into the custody of the U.S. Fish and Wildlife Service. Johnston Atoll, which was designated a National Wildlife Refuge in 1926, will then become a bird sanctuary.

K

KAFFA, SIEGE OF

The Mongol siege of the Crimean city of Kaffa in 1346 is often cited as one of the first recorded incidents of biological warfare—and perhaps even the cause of the spread of bubonic plague to Europe.

The city of Kaffa (or Caffa, now Feodosija, Ukraine), established in 1266 by agreement between the Mongols on the Black Sea and the Genoese, was an important trading hub between Genoa and the Far East. In 1289, the city fell under the suzerainty of the Khan (Toqtai) of the Golden Horde. The relationship between the Genoese and the Khan, however, was an uneasy one. Kaffa was first besieged in 1308 after the reported displeasure of Khan Toqtai over Genoese trading in Turkic slaves. (The sale of these slaves to the Marmelake Sultanate in Egypt reportedly upset the Khan by depriving him of an important source of foot soldiers for his own army.) The Genoese set fire to Kaffa and fled. After Toqtai's death, Khan Uzbeg allowed the Genoese to rebuild their trading colony in 1312.

In 1343, after a brawl between Christian locals and Muslims in the Italian enclave of Tana inflamed the ire of Khan Janibeg, the Italians fled from Tana to Kaffa, bringing the Khan's army to the gates of Kaffa behind them to besiege the city. In February 1344, the Italians managed to break the siege after killing 15,000 of the Khan's Tartars and destroying their siege machines. Janibeg renewed the siege the following year, but the residents of Kaffa were able to maintain their position because they retained access by sea to supplies.

In 1346, the Khan's army besieging Kaffa suffered a natural outbreak of plague. The Tartars catapulted the plague-infected corpses of their dead comrades over the city walls. According to one historical account, the Tartars' tactic finally broke the 3-year stalemate; the Genoese were crippled by the plague and fled Kaffa by sea—taking the disease to Europe with them.

The most contemporaneous account of the siege was written by Gabriele de' Mussi, a notary of the town of Piacenza, north of Genoa. There is some debate as to whether de' Mussi witnessed the events at Kaffa. Written in 1348 or 1349, the account describes the "mysterious illness" that struck the Tartar army besieging Kaffa. De' Mussi recounts how the Tartars, desperate from the devastation of the disease on their army, thought to kill the inhabitants of Kaffa with the stench of their diseased dead. According to the de' Mussi account, the people of Kaffa had no hope once the air and water had been contaminated, and only one in 1,000 was able to flee the city. Those that did flee took the plague with them as they left.

De' Mussi's account suggests that not only did the Tartars deliberately hurl their diseased dead over the city walls of Kaffa with the intent to kill their enemies, but those escaping Kaffa brought the disease into the ports of Europe. The disease was most likely brought within the walls of Kaffa through flea-infested rodents from the Tartar camps, or possibly through the transmission of the disease from direct contact with infectious body fluids from the Tartar dead.

Most scholars believe that the Genoans brought the plague with them to Naples, from where it then spread throughout Europe. Others have recently suggested that although the use of plague corpses against Kaffa was a true act of biological warfare, the siege had no significant impact on the spread of the Black Death through Europe. As Wheelis suggests, Kaffa was certainly not the only Tartar port that could have transmitted plague into European ports. Wheelis further argues that the rate and pattern of plague transmission suggests that it took 1 year to spread the plague into different European ports.

Though Kaffa may not have been the precise source of the Black Death that spread into Europe, the use of infected cadavers against its besieged inhabitants remains one of the most important instances of the intentional use of disease in warfare.

KOREAN WAR

The Korean conflict began as North Korean troops, aided by the former Soviet Union, launched an artillery barrage against U.S.-backed South Korea on June 25, 1950, in an attempt to unify the peninsula under Communist rule. Under United Nations command, United States and Republic of (South) Korea (ROK) forces managed to push the North Korean army back, and UN forces were able to get across North Korea as far as the Chinese border that winter. Faced with the prospect of losing Korea to the Western "Imperialists," Mao Zedong ordered a counterattack. Fortunes turned once again, as Chinese volunteer forces crossed the (now frozen) Yalu River and nearly overwhelmed UN forces. Finally, the belligerents reached a stalemate near the thirty-eighth parallel, resulting in *status quo antebellum.* Some 130,000 U.S. military personnel were killed or wounded by time of the Armistice in 1953. Perhaps as many as 2 to 3 million Koreans and 1 million (or more) Chinese people were killed during the conflict.

Allegations of Chemical Warfare

The Chinese government and military apparatus claim that the United States—presumably with UN connivance—used chemical weapons against North Korean and Chinese People's Volunteer Forces (CPVF) during the conflict. These allegations peaked in 1953 and were proven false, but the belief persists, at least within mainland China, that chemical weapons were used by UN forces. For example, a Chinese book on chemical weapons published in 1997 states that during the Korean War, the U.S. military used chemical weapons against the Sino-Korean forces on more than 200 occasions, and the book lists the following CW agents by name: mustard, cyanide (presumably HCN), chloropicrin, and chloroacetophenone (CN).

China first made formal chemical weapons charges during the Korean War on March 5, 1951. The Report on U.S. Crimes in Korea, compiled by the Communist front organization International Association of Democratic Lawyers, claimed that the United States used chemical weapons between May 6, 1951, and January 9, 1952. The UN ambassador from the former Soviet Union, Jakob Malik, repeated similar charges in February 1952. However, when the International Scientific Commission (a group of Sinophilic scientists, leftists, Marxists, and otherwise Maoist fellow travelers [communist sympathizers]) reported on the BW allegations (see below) in 1952, no mention was made of chemical weapons being used in Korea or China. Furthermore, in a 1998 book alleging that the United States conducted BW during the Korean conflict, authors Stephen Endicott and Edward Hagerman make no mention of chemical weapons being used (aside from some peripheral references to U.S. CW agents and chemical/biological warfare policy).

Perhaps the most dramatic testimony that undermined the Chinese allegations of CW during the Korean War is found in the Soviet archives. Lt. Gen. V. N. Razuvaev, former Soviet ambassador to North Korea and military advisor for the Korean People's Army, wrote the following to Levrenti Beria (Stalin's infamous henchman and chief of espionage) on April 18, 1953:

> The Chinese . . .wrote that the Americans were using poison gas in the course of the [Korean] war. However, my examinations into this question did not give positive results. For example, on April 10, 1953, the general commanding the Eastern Front reported to Kim Il Sung that 10–12 persons were poisoned in a tunnel by an American chemical missile. Our investigation established that these deaths were caused by poisoning from carbonic acid gas [i.e., CO_2] [released into] the tunnel,

The United States used napalm with great effect against communist forces during the Korean War (1950–1953). (Corbis)

> which had no ventilation, after the explosion of an ordinary large caliber shell. (Razuvaev, quoted in Weathersby, http://wwics.si.edu)

In retrospect, the Russian archives explain best why Chinese military leaders could have believed that the United Nations armies were using chemical warfare. The CPVF was torn apart by U.S. artillery and air strikes. (Even Mao Zedong's eldest son, Mao Anying, was killed during a U.S. napalm strike.) In addition to the devastating effects of these attacks, resultant off-gases from bombardments were no doubt responsible for respiratory distress and pulmonary edema among Chinese soldiers, symptoms that are largely indistinguishable from those caused by lung irritants found in chemical weaponry. For the Chinese leadership (namely Mao Zedong and Zhou Enlai), interested in propaganda to give a sense of being the victim of an "imperialist aggressor," it made practical sense to blame the deaths of the ill-equipped CPVF soldiers on phantom chemical weapons used by the "imperialists."

Allegations of Biological Warfare

In March 1951, Peking radio charged that the United Nations Command was manufacturing biological weapons for use against North Korea. In May of that same year, the North Korean Minister of Foreign Affairs protested to the United Nations that the United States had attacked Pyongyang with smallpox. Almost a year later, on February 22, 1952, North Korea made more detailed charges, claiming:

> The American imperialist invaders, since January 23 this year [1952], have been systematically scattering large quantities of bacteria-carrying insects by aircraft in order to disseminate infectious diseases over our front line positions and rear. Bacteriological tests show that these insects scattered by the aggressors on the positions of our troops and in our rear are infected with plague, cholera and the germs of other infectious diseases. This is

> irrefutable proof that the enemy is employing bacteria on a large scale and in a well-planned manner to slaughter the men of the [Korean] People's Army, the Chinese People's Volunteers, and peaceful Korean civilians. (van Courtland Moon, p. 55)

In response to these charges, General Matthew B. Ridgeway addressed the United States Congress, saying "no element of the United Nations Command has employed either germ or gas warfare in any form at any time" (Leitenberg, http://wwics.si.edu).

Nevertheless, by dint of their own writings and public pronouncements, the Chinese government still appears to believe that the United States employed biological weapons during the Korean War. Real Japanese BW atrocities that occurred in China during the 1930s and 1940s make these dubious Korean War allegations appear reasonable. During the first half of 1951, when the allegations first emerged, the Chinese media often referred to Japanese biological weaponeers, and on April 30, 1951, they even claimed, "the American forces are using Chinese People's Volunteers as guinea pigs for their bacteriological experiments" (Leitenberg, p. 174).

The United States has refuted the allegations concerning its use of chemical and biological weapons during the Korean War. Despite the paucity of real evidence to support such a claim, however, it would appear that these charges are etched upon the collective consciousness of the Chinese leadership. Unfortunately, Western collaborators with the myth of BW in the Korean War are often cited by the Chinese as further proof that the United States engaged in chemical and biological warfare against the Chinese.

LATE BLIGHT OF POTATO FUNGUS (*PHYTOPHTHORA INFESTANS*)

Late blight of potato is caused by the fungus *Phytophthora infestans,* which was most likely responsible for the Irish potato famine of 1845–1847. Isolated cases of potato crops with this fungus are still common around the world, and, once started, the plant disease is very expensive to treat. Lesions that form on infected plants can produce some 300,000 fungal spores each day, and when conditions are right, spores of this fungus (sporangia) can be spread for miles by flowing water or by the wind. Because of the importance of potatoes as a food staple and agricultural commodity, the potential consequences of an attack using this fungus in agroterrorism could be enormous. At the same time, experimental data show that it would be difficult to replicate natural disasters such as the Irish potato famine using deliberate introduction of the fungus to potato crops. Still, this fungus is among several agents of concern when considering food safety and potential vulnerabilities to bioterrorism or state-sponsored biological warfare (BW).

Many Americans and Canadians of Irish ancestry can trace their family histories back to the 1845–1847 Irish potato famine (also known as the Black '47). When, in 1845, Irish potatoes became infected with the *Phytophthora infestans* fungus, an entire crop of tubers was destroyed—as was a great source of nourishment. The unfortunate confluence of bad weather and colonial oppression exacerbated the crisis as the disease continued to affect potato crops throughout Ireland. Some 1.5 million people died of starvation, and a like number left the country, many choosing to emigrate to the United States.

During the mid-1800s, the great tragedy in Ireland piqued the interest of Dr. Miles J. Berkeley, who believed that a fungus was responsible for the potato blight. However, he could not find sufficient proof to support his notion, because it was still possible that the fungus only grew on the potato after the fact, and was not necessarily the original cause of death of the plant. In 1861, the German researcher Anton De Bary conducted his own experiments with potatoes and was able to conclude that, indeed, a parasitic fungus was responsible. He named it *Phytophthora infestans*—"the terrible plant destroyer." De Bary's work established an important foundation for the study of plant diseases as a discipline.

Later, in the 1900s, potato blight would haunt Germany during World War I. On the heels of spectacular potato harvests early in the Great War, in 1916, potatoes were soon rotting in the fields and creating a fulsome stench in German supply houses. *Phytophthora infestans* struck at a most inopportune moment for Germany. The subsequent loss of potatoes could have been averted were it not for the fact that copper, needed during the war for shell casings, electrical wire, and other war-related materiel, was therefore made unavailable for production of copper sulfate, a well-known antifungal used at that time. Seven hundred thousand Germans starved to death in this famine, and this may have contributed to Germany's defeat.

During World War II, French and U.S. officials noted how economically dependent the Axis powers were on potatoes as a staple food crop, particularly the German and Japanese reliance on sweet potatoes. During researches into potential BW agents in World War II, *Phytophthora infestans* was seen as a potentially effective weapon. Code named OL, late blight of potato was researched at the Main Agricultural Experiment Station in Orono, Maine. One method of delivery devised for potato blight involved the use of navy beans and specially made pellets to use as carriers to deliver the fungus to the target. Producing and storing this fungus in large quantities proved extremely difficult. Eventually, though, the United States developed a standardized arsenal of anticrop agents and continued its research in late blight of potato as part of its now-defunct biological weapons program (formally ended in 1972).

Today, unlike in nineteenth-century Ireland, industrialized countries do not depend upon a single source of calories. Because modern agriculture can produce an abundant and diversified food supply, it is unlikely that late blight of potato would cause severe hardship for most countries, and it would certainly not lead to starvation. Furthermore, genetically modified potatoes are being researched to develop a resistance to this fungus. This research holds the promise of helping to avoid both natural and deliberate outbreaks of late blight in the future. The economies of underdeveloped countries, however, may be more vulnerable to natural or possibly deliberate attacks on their food supplies.

LIBYA AND WMD

Since his successful coup against King Idris in September 1969, Colonel Mohamar Qaddafi has been the unchallenged leader of Libya. During Qaddafi's fulsome regime, the North African nation has gained pariah status among the nations of the world. Events in late 2003, however, may have changed this trend. In a startling announcement made on December 19, 2003, Qaddafi announced that his government will forgo its weapons of mass destruction (WMD) programs, presumably meaning activities related to the production of chemical, biological, or nuclear weapons.

During the 1970s and 1980s, Libya supported terrorist organizations such as the Irish Republican Army and the Palestinian Liberation Organization. Libya also was implicated in the bombing of a Berlin nightclub in 1986, intended to target U.S. military personnel. This attack killed two U.S. soldiers and one civilian, while injuring more than 250 people. Having determined that Libya was directly connected with the bombing, the United States responded in retaliation with an air raid against Tripoli. The Libyan government has also admitted that it was responsible for the downing of Pan Am flight 103, a civilian jetliner, over Lockerbie, Scotland, in 1988, and it has since paid billions of dollars to the victims' families in compensation.

During most of Qaddafi's rule, Libya has been considered a "rogue nation," developing chemical weapons as well as acquiring delivery systems such as the Scud B and C missiles. Although a member of the Nuclear Nonproliferation Treaty (NPT) and subject to International Atomic Energy Agency inspections, Libya may have as many as eleven nuclear-related facilities rather than the four that have been officially declared. An unconfirmed report from the 1970s alleged that Libya attempted—but ultimately failed—to purchase a nuclear device from China. Thirty years later, the scope of Libya's nuclear program is still unknown.

Some reports suggest that Libya may have pursued biological weapons development. There also are rumors that the former director of South African biological weapon activities, Dr. Wouter Basson, covertly assisted Libya in this pursuit during the mid-1990s.

Libyan Chemical Weapons

Countries such as Egypt and the former East Germany may have shipped chemical munitions to Libya during the 1970s. In its war with neighboring Chad, Libyan troops reportedly used chemical warfare (CW) agents in the late 1980s. As a response, the United States shipped some 2,000 protective masks to Chad. During this same time frame, Libya established a suspected CW agent production facility at Rabta (Pharma 150) using technology acquired from West Germany. However, the estimated quantity of CW agent produced at this facility was not a large figure, perhaps 100 tons.

In the early 1990s, after the United States hinted that a preemptive strike against Pharma 150 was possible, Libyan officials decided to build an underground chemical facility. Built inside of a granite mountain, the Tarhunah facility was described by the U.S. Central Intelligence Agency as the "world's

Artist's conception of the suspected Libyan chemical facility in Tarhunah. (Corbis/Sygma)

largest underground chemical weapons plant" (Rosenthal, p. A23). Qaddafi later announced that he would stop construction at Tarhunah after a diplomatic consultation with Egyptian president Hosni Mubarak. In the summer of 1996, U.S. Department of Defense (DoD) sources confirmed that the site appeared dormant. In March 1997, however, Israeli sources reported that construction at Tarhunah had resumed.

In 2003, Libya reportedly engaged in low-level negotiations with the United States and Great Britain over its WMD programs. According to published accounts, U.S. and British intelligence diverted a ship purported to have been carrying gas centrifuges to Libya in September 2003. On December 19, Libya announced that it would end its WMD programs and would subject itself to international inspections, which would include the full disclosure of its nuclear fuel cycle. Libya's decision was probably influenced by the interdiction of the dual-use gas centrifuges, as well as the success of the U.S. coalition's invasion of Iraq, which was ostensibly undertaken to rid Iraq of its WMD programs and of its dictator.

It is uncertain whether Qaddafi's recent turnaround with regard to WMD will result in a better understanding of Libya's chemical, biological, and nuclear weapons activities, or whether Qaddafi is fundamentally changing the course of his national policies. Qaddafi's constructive reengagement with the West may be signaling an end to Libya's marginalization in the global polity.

LINE SOURCE

A moving device or a linear series of stationary devices that disperse chemical, biological, or radiological (CBR) agents is known as a line source. (Two other common classifications of sources are point and area sources.) Typically, a line source constitutes a moving platform such as an aircraft, boat, or ground vehicle, which discharges a CBR agent as it moves. For example, between 1935 and 1936, Italian forces used aircraft to spray chemical agents, mainly mustard, on enemy forces in Ethiopia.

A moving platform, however, is not required for a line source. On April 22, 1915, outside the city of Ypres, Belgium, the Germans released chlorine gas from more than 5,000 cylinders, forming a 5-mile-wide toxic cloud. This cloud would best be classified as a line source despite the fact that it was produced from more than 5,000 point sources (*see* Point Source). As another example, artillery guns can deliver shells containing CBR materials along a wide front perpendicular to the wind direction. The cloud released from such an artillery barrage would be best modeled as a line source, although the source of the contamination is stationary. The classification of a source (as point, line, or area) depends on the spatial and directional characteristics of CBR contamination. This information is also used to develop vulnerability assessments and prepare emergency response plans.

An agent released into the atmosphere is affected by meteorological conditions: temperature, pressure, wind direction, and wind velocity. It is most effective to employ chemical weapons during an inversion, when the air temperature increases with altitude and the contaminant is therefore held close to the ground. Inversions normally occur at dawn, dusk, or night. Atmospheric releases of agents occur as either a continuous plume or an instantaneous discharge (puff). If the total duration of the release is much less than the transport time between the source and the downwind receptor, then the cloud is best described as an instantaneous release. Because the total amount of agent to be delivered is of limited quantity, the time of actual release will necessarily be of short duration. Line sources are most effective when the line along which they are employed is perpendicular to the wind. When employed in this way, a line source can contaminate a relatively large area, compared to a point source release of the same quantity and concentration of CBR agent.

Recent trends in research and development have focused on improving wide-area, long-range, standoff (that is, at considerable distance up to 50 km), and remote agent detection systems that can increase early warning time and assist in consequence management in the event of CBW. In the event of a line or point source delivery, it is possible that adequate standoff detection systems will provide adequate intelligence for authorities to take appropriate defensive measures—before the public is exposed to toxic or infectious aerosolized agents.

LIVENS PROJECTOR

Also referred to as an "8-inch chemical drum," the Livens Projector was one of the more effective means of delivering chemical warfare (CW) agents during World War I. Essentially, the Livens fired a large chemical artillery shell, the Livens projectile being launched from mortars set in the ground. Standing about 2 feet in height and about 7.5 inches in diameter, the Livens shell had a total weight (including the gas or explosive inside) of 60 pounds. The mortar was set into the ground at a 45 degree angle so as to maximize the range.

The device was named after the colorful and brilliant inventor Major William Howard Livens of the British army, whose wartime forays into the invention of early flamethrowers and other devices are the subject of legend. (Livens's superior officer, Foulkes, once wrote that, although he was duly impressed with the young man's ingenuity and enthusiasm for his work, Livens had "little use for factors of safety or correct official procedure" [quoted in Richter, p. 150].) A fellow officer, Harry Strange, collaborated with Livens on the overall design. The inspiration for the Livens Projector came from the use of oil cans to make Molotov cocktails. At first, the incendiary form of the early Livens Projector fired canisters filled with oil and were launched using modular sack charges. By adding additional explosives in measured amounts, as in traditional artillery, one could control the overall distance. But it soon became apparent that the Livens Projector had the potential for offensive CW applications.

Following the chlorine gas attack at Ypres in 1915, the Livens Projector was rigged to launch chemical agents. Its design could launch large volleys of chemical shells in rapid succession, making it the most efficient means of deploying gas during the war. The Livens Projector was particularly useful in launching phosgene canisters at distances of 1,700 meters, and German troops reported that it had significant impact on the battlefield: "The enemy has combined in this new process the advantages of gas clouds and gas shells. The density is equal to that of gas clouds, and the surprise effect of shell fire is also obtained. . . . Our losses have been serious up to now, as he has succeeded, in the majority of cases, in surprising us, and masks have often been put on too late" (Spiers, p. 25).

The Livens Projector also had its disadvantages. Although the main part of the firing base mortar was hidden by earth and relatively easy to conceal, the system could only be fired once.

Occasionally, Livens Projectors turn up in old sites among abandoned and obsolete munitions. In 1993, a construction worker discovered a Livens projectile at a site near American University, Washington, D.C., prompting a full-scale evacuation in Spring Valley, Washington, D.C. Some of the 200-

millimeter Livens projectiles found in 1993–1994 still contained some chemical agent. In April 1999, some children found a Livens projectile at Fort Ord, Monterey, California. Fortunately, this Projector the children found was originally used only for training and contained no explosives or toxic chemicals.

LYOPHILIZATION

Having been used for many years in biotechnology research and related applications, lyophilization—essentially, freeze-drying—can be utilized for research and development of biological warfare (BW) agents. Because one of the major obstacles to keeping biological agents in storage over long periods of time is the issue of water content, a way is needed to keep these agents stable by removing water without destroying the organism, destroying its enzymes, or denaturing proteins. By reducing the amount of water contained in biological materials through freeze-drying, the resultant product can remain in storage for long periods of time without losing biological activity.

When it comes to dealing with BW applications, essentially the problem is how to produce a storable agent that also remains viable—thus, the relevance of lyophilization in biological weapons development and production. Furthermore, once the given agent has been freeze-dried, further processing (such as milling) can be performed to create BW agents that can be aerosolized. Work conducted for the U.S. biological weapons program in the 1940s found that freeze-dried organisms could remain viable for extended periods of time. In this case, simulants—inocuous agents used to simulate the behavior of BW agents in this case—such as *Serratia marcescens* could be produced in dense liquid suspensions and then lyophilized to survive up to several weeks without losing very much in the way of viability. Similar techniques were utilized by both the United States and the former Soviet Union during the heyday of the Cold War in their respective biological weapons programs.

A lyophilizer is a dual-use item that has both civilian use and potential military use in developing biological weapons. As this technology is used widely for civilian pharmaceutical and other research, using this technology would not necessarily raise particular suspicions concerning possible offensive BW activities. Other information would be necessary to indicate that possession or use of a lyophilizer meant there was illicit biological weapons research at work. One significant factor to consider would be the overall production capacity of the equipment, as full-fledged BW programs would require more than the small quantities of material produced in single batches in laboratory settings. (During World War II, for example, the United States used lyophilizing equipment in its nascent BW program that could handle up to 2.5 liters or about 2.5 kilograms of material in a single batch.) Another consideration in determining the possibility of BW use would be the type of organism or biological material being processed, as well as the general scope of the activity.

M

MARBURG VIRUS

Marburg virus is named after the German city in which a laboratory outbreak of hemorrhagic fever occurred among the staff of a hospital in 1967, during which 31 people became infected and nine died. Marburg virus is a member of the Filoviridae family, the other known member being Ebola virus. According to Ken Alibek, former deputy of the Soviet Biopreparat biological weapons program, the Soviet Union had planned to weaponize Marburg just before Boris Yeltsin rose to power in 1991. It is unknown whether Russian scientists continued research with Marburg with the aim of using it as a biological weapon during the 1990s.

MELIOIDOSIS

Melioidosis is an infectious disease of humans and animals caused by the free-living (survives on its own) bacterium—once thought to be parasitic—*Burkholderia pseudomallei,* a natural inhabitant of soil and water in rice-growing regions of the world. The disease is concentrated in parts of northern Australia and southeast Asia, especially Thailand, Malaysia, and Singapore. Humans are usually infected by direct inoculation of the organism through breaks in the skin, less often by inhalation or ingestion of dust or aerosolized polluted water, and rarely by contact with infected animals or other humans.

The bacterium causing melioidosis was first isolated in 1912 from a morphine addict in Rangoon, Myanmar. *Burkholderia* (formerly *Pseudomonas*) *pseudomallei* is an aerobic (thrives in oxygenated environments) gram-negative (does not absorb gram's stain) rod-shaped bacterium. The disease-causing propensity, or virulence, of the organism is largely due to its ability to evade host defense mechanisms and to survive inside macrophages, the cells that defend the body from invaders, and other phagocytic cells of the host. Melioidosis, also known as glanders-like disease, is of current interest because *B. pseudomallei* has been studied in the past by bioweapons developers in the United States and other countries. *B. pseudomallei* could still potentially be developed as a weapon because it is relatively easy to grow, has prolonged survival in the environment, is infectious by aerosol, and has a high capacity to cause severe illness and death.

Melioidosis is endemic (occurring naturally and consistently) in tropical and subtropical regions of the world and is a common infectious hazard for rice farmers, travelers, and military troops. During the rainy season, the bacteria, normally associated with plant roots, rise from the clay layers of the Earth into the surface waters and multiply. Humans and animals are most vulnerable to acquiring infection in endemic areas during the monsoonal wet season. A few isolated cases diagnosed in the Western Hemisphere have been imported from the tropics by immigrants, travelers, and Vietnam veterans. Although a wide variety of mammals, birds, tropical fish, and snakes can be infected with *B. pseudomallei,* animals differ widely in their susceptibility to melioidosis. For example, although high mortalities are reported in sheep, water buffalo are remarkably resistant to the disease. Infected animals pass the organism in their feces and are a significant reservoir of infection in the environment.

Medical Aspects

Melioidosis has myriad clinical forms, depending on the site of original infection, the virulence of the infecting organism, and the host's immune status, making diagnosis difficult. Most infections with *B. pseudomallei* in endemic areas are asymptomatic or subclinical (does not rise to the level of noticeable disease symptoms), with the only sign of exposure being an antibody response detectable by serology. Melioidosis may be acute, with rapid progression and death, or it may run a chronic and relapsing course. Illness may develop after a latent period ranging from 2 days to 30 years and usually presents clinically with a fever and signs of sepsis. Upon infection, the bacteria can grow in number and release toxins, usually at a level too low to cause noticeable symptoms. Given enough bacterial growth in the body, however, more serious disease will result.

The most common form of the illness is acute pulmonary infection, which can vary from mild bronchitis to overwhelming necrotizing pneumonia. In the acute localized form, a nodule is found at the site of skin inoculation, and infection may progress rapidly to the bloodstream. Acute bloodstream infection is uncommon in an otherwise normal, healthy host, but it often develops in immunocompromised patients with chronic diseases such as HIV or diabetes, and it can progress rapidly to produce abscesses throughout the body, septic shock, and high fatality rates. Chronic suppurative forms with abscesses in deep organs of the body may also occur.

Melioidosis, like tuberculosis, can be reactivated years after the initial infection or can recur months or years after apparent cure. An estimated 225,000 Vietnam veterans in the United States are serologically positive for melioidosis, but disease reactivation is rare.

To diagnose suspected melioidosis, various laboratory tests are used. For rapid, presumptive diagnosis, gram stain and methylene blue (methods of staining cells and tissue for identification) can be used to visualize the distinctive safety pin staining pattern of the small gram-negative rod in patient specimens, particularly blood, sputum, abscess contents, and skin lesions. Diagnosis is confirmed by *B. pseudomallei* isolation on conventional laboratory culture media, which takes 48 to 72 hours to grow.

Not all strains of *B. pseudomallei* cause disease in humans and animals. *B. pseudomallei* is a frequent laboratory contaminant in endemic areas, and virulent biotypes found in clinical specimens can be differentiated from avirulent environmental biotypes based on the ability to metabolize arabinose (a type of sugar).

Various serological tests have been developed to aid in disease diagnosis, but they are of limited use in endemic areas because of high background positives due to previous exposure, thus have limited specificity. The promise of rapid molecular testing has not yet been fulfilled for diagnosing melioidosis. Currently, there is no immunization for melioidosis prevention, but many antigens found on the organism are possible candidates for a subunit vaccine that uses parts of the organism to develop an immune response. Early intensive intravenous antibiotic therapy with ceftazidine or imipenem is highly effective against acute bloodstream melioidosis, followed by several months of maintenance therapy for prevention of relapses.

MICROENCAPSULATION

Microencapsulation means producing extremely small droplets or tiny solid particles of a material, and covering these particles with a fixed protective membrane. Commercial examples of microencapsulation include dry toner for photocopiers and carbonless copy paper. The microencapsulation of very small particles is a technology that could maximize the effectiveness of chemical or biological warfare agents: Chemical warfare (CW) agents or biological pathogens or toxins could be encapsulated to enhance their survival in a weapon.

Chinese military experts in CW categorize potential applications of microencapsulation for chemical delivery as persistency encapsulation, seepage encapsulation, hydrophobic encapsulation, and time capsules. Persistency encapsulation increases the concentration of CW agents that would otherwise evaporate too quickly for effective use on the battlefield. For seepage encapsulation, the membranes around the particles would slowly release agent for use in contaminating areas or equipment. In the case of hydrophobic encapsulation, a membrane would help to protect the agent from hydrolysis (chemically broken down by water molecules) upon contact with water, enabling CW agents to remain potent for a longer period of time. Time capsules would delay release of the agent until after the membrane deteriorates. It is not known at this time whether any military CW programs have ever taken microencapsulation beyond the stage of basic research.

Microencapsulation also has many applications for biological weapons production. Most biological warfare (BW) agents are composed of microbes or protein-based toxins that are fragile and quickly decay in the open environment. By using special polymers or other biodegradable substances, BW microencapsulation would involve coating liquid or dry BW agents and toxins with materials designed to protect them during aerosolization. Also, when the particles reached the target (most likely lung tissues), the coating could protect the infectious agent from the body's defenses long enough for the agent to cause disease. Microencapsulation can also produce agent particles within a 1–10 micron diameter range, the size that is optimal for infection via aerosol.

For both chemical and biological agents, microencapsulation technology could also help defeat some detection schemes, particularly those that rely on direct contact with the agent in order to send warning signals. Chemical point detection is sometimes dependent on the presence of volatile compounds and their vapors; encapsulating the agent would limit the amount of agent in the immediate area for detection. Properly coated BW agent particles also may confound sampling detection devices that rely on immunodiagnostics, relying upon direct contact with specific biochemical constituents of the organism. But the use of microencapsulation is still a relatively new technique, and it requires an advanced research and development infrastructure. Although most of the publicly known terrorist organizations are unlikely to utilize such technology, state-level CBW programs could certainly employ microencapsulation to produce highly effective weapons of mass destruction.

MUSTARD (SULFUR AND NITROGEN)

Mustard (United States and NATO code HD for distilled mustard) usually refers to sulfur mustard, a classical vesicant (or blister) agent. It was first used by Germany in World War I, later by Italy during Mussolini's war against Ethiopia, and later by Iraq against Iran in the 1980s. Although not as toxic as the nerve agents developed in the 1930s, mustard is still regarded as a significant chemical threat due to its ability to cause mass casualties. As a consequence, especially during the World War I era, mustard was once known as the king of chemical warfare agents. In Germany, mustard was referred to as Lost (from the names of researchers Lommel and Steinkopf, who developed processes for its mass production), and France and Russia named mustard agent after its use at Ypres, Belgium (Yperite).

Other forms of mustard besides sulfur mustard include the nitrogen varieties, coded HN-1, HN-2, and HN-3 in the West. Although the nitrogen mustards differ in some respects from sulfur mustard, the basic mechanism and injuries that result from their exposure are largely the same. Whereas sulfur mustard played relatively important roles in World War I and the Iran-Iraq War (1980–1988), there is little information to suggest that nitrogen mustards have ever been used in battle. Mustard has been shown to be a highly effective casualty-causing agent, especially in military settings.

The effects of mustard agent reverberate in historical and modern contexts. In October 1918, German corporal Adolf Hitler was injured by Allied use

Iraqi 500kg mustard bombs were destroyed by international inspectors following the Gulf War (1991). (UN/Corbis/Sygma)

of mustard agent. Even after its use in World War I, injuries still occur from old munitions left in battlefields from China to Europe. In 1990, for example, a Frenchman suffered serious mustard burns on his hands and arms after he picked up a mustard shell in the old battlegrounds of Verdun.

Sulfur and nitrogen mustards are toxic via a number of routes, including the skin, eyes, and upper respiratory tract. Mustard, an oily liquid, is also more persistent than other true "gases" that were used in the beginning of World War I. (Because the first chemicals used in World War II were in gaseous form, such as chlorine and phosgene, subsequent uses of CW agents were often—and sometimes still are—referred to by the misnomer "gas.") Because of its persistency, opposing forces must wear not only protective masks but also complete protective clothing. Mustard's effects are likewise insidious. Itchy and painful irritation of the skin, leading to sometimes very large blisters (vesicles), occurs after a considerable delay (up to 24 hours).

The mode of mustard's action in the body appears to be cytotoxic—that is, it kills living cells. After coming into contact with living tissue, the mustard molecule forms a highly reactive ion called a free radical. This free radical combines with nucleic acids, cross-linking constituents of DNA by a chemical bond. Mustard then destroys cells from the inside by interfering with DNA synthesis, and it probably affects other important chemicals in the body as well. When these cells die, they release enzymes called proteases, breaking down tissues into liquid exudates (pus). This is the basic process through which blisters are formed. Being oil soluble, mustard readily penetrates the skin, and as it can dissolve through fatty layers, mustard attacks vital organs of the body.

Brief History of Sulfur Mustard

The Belgian Cesar-Mansuete Despretz first synthesized sulfur mustard in 1822, but he did not describe its qualities. The British scientist F. Guthrie repeated Despretz's experiments in 1860 and described mustard as "smelling like mustard, tasting like garlic, and causing blisters after contact with the skin" (quoted in Siddel, Urbanetti, Smith and Hurst, p. 198). Apparently, however, the new compound and its irritating effects did not receive much attention. In 1886, the German chemist Victor Meyer independently synthesized mustard, first by making thiodiglycol and then reacting this nontoxic chemical with chlorine. Surprisingly, this small change produced an extremely toxic chemical, later identified as sulfur mustard. According to Meyer: "The intended work with this chloride was not continued—on account of the extremely poisonous qualities of the compound. It is very striking that this apparently harmless substance which is only slightly volatile, is almost insoluble in water, and has a very slight odor as well as a perfectly neutral reaction, should exert a specific toxic effect. Its chemical constitution would never lead one to expect its aggressive properties" (quoted in Senior, p. 17).

By 1916, after using gaseous chemicals such as chlorine and phosgene, Germany found that both sides in World War I had discovered fairly effective defenses against chemical warfare (CW), primarily through the use of protective masks. After trying—with little success—to use irritating compounds such as diphenylcyanoarsine (DC) in fine dusts to force the enemy to remove their masks, German scientists then looked to mustard. Its attractiveness lay in not only being toxic, but also in its persistence in the field. Decisive animal experiments on mustard were conducted in September and October 1916. The military effectiveness of this agent was already known when the German High Command requested a new CW agent that could be used for the defense of the western front in the summer of 1917.

Sulfur mustard was first tested during the summer of 1916, and it was used at Ypres in July. Because of its persistency and its latency period, soldiers exposed to this chemical often did not know they had been contaminated until injuries manifested themselves later.

Although Germany had confidence that mustard could help turn the tide in World War I, Fritz Haber—chief of the German chemical weapons program—warned that the Western militaries would be able to respond using mustard as well. Haber was right. Corporal Hitler accurately described the effects of mustard: "During the night of October 13–14 [1918] the British opened an attack with gas on the front south of Ypres. They used the yellow gas whose effect was unknown to us, at least from personal experience.... About midnight a number of us were put out of action, some for ever. Toward morning I also began to feel pain. It increased with every quarter of an hour, and about seven o'clock my eyes were scorching as I staggered back and delivered the last dispatch I was destined to carry in this war. A few hours later my eyes were like glowing coals, and all was darkness around me" (Adolf Hitler, *Mein Kampf,* 1924, quoted in Marrs, et al., pp. 161–162).

Although it did not have the lethal effect of phosgene and other gases, mustard agent caused the greatest numbers of wounded throughout World War I. Statistics from the Great War showed that British casualties from CW increased dramatically following the use of mustard agent. With advances in protective gear, however, mortality rates due to mustard agent fell from 6 percent to 2 percent by war's end.

In World War II, CW was limited to the Chinese theater of operations during Japan's invasion of east Asia. Although Winston Churchill had been referred to as a mustard gas fiend, the European militaries and the United States refrained from using chemical weapons during the war. Japan, however, employed a large number and variety of CW agents in China from about 1930–1945. In 1940, Japanese troops used about 600 pounds of mustard against Mao Zedong's communist forces in Shanxi province.

During the Iran-Iraq War (1980–1988), Iraq became desperate to stave off massive attacks of Iranian foot soldiers. Iran had early on adopted a "revolutionary" battle strategy reminiscent of Mao Zedong's People's War—basically throwing bodies at the enemy with little equipment or preparation for battle—resulting in thousands of poorly trained and poorly equipped Iranian troops extremely vulnerable to chemical agents, especially mustard. Like the Germans during World War I, Iraq found value in the use of mustard in roles that could be described as defensive rather than offensive, especially in the later stages of the conflict, when Iraq feared that it could be overrun by Iran's superior numbers. In March 1984, the United Nations confirmed the use of chemical weapons, including mustard, by Iraq.

It is unknown how many Iranian casualties were caused by CW during the war. Figures of 50,000 or more casualties, mostly inflicted by mustard, are certainly possible. At first, Iraq was able to obtain chemical precursors from Western countries, including Europe and the United States. When cut off from these supplies during the war, however, Iraq turned to its domestic petroleum industry for alternative sources. By using oil and breaking it down into ethylene, Iraq found a relatively efficient means to produce mustard agent from indigenous materials. (*See* Iran-Iraq War.)

Nitrogen Mustards

Nitrogen mustards were first developed out of research into nitrogen-carbon compounds during the 1920s and 1930s. In 1931, a chemist by the name of Kyle Ward found that using nitrogen to link chlorinated carbon chains produced a highly potent vesicant. Although the United States Chemical Warfare Service was interested, code-naming the first of these nitrogen mustards as HN-1, it was not considered to be more effective than sulfur mustard. However, the German military found it to be of great interest. Variations on the nitrogen-carbon molecule generated different analogues, some of which were later coded by the U.S military as HN-2 and HN-3. Germany considered the nitrogen mustards to be highly effective for contaminating the ground for area denial and harassing the enemy, and produced some 2,000 tons of HN-1 during World War II. Allied forces destroyed these stockpiles at the end of World War II. Few nations appeared to have produced nitrogen mustard since World War II in large quantity, probably because sulfur mustard production was already in place, and offered many of the same advantages as nitrogen mustard.

Nitrogen mustards are generally more toxic than the sulfur variety and like sulfur mustard are easily manufactured. Both types of mustard cause injury with similar mechanisms. Because of mustard's well-known ability to kill cells, physicians theorized that it could help treat cancer. Experiments found that tumors shrank following treatment with a type of nitrogen mustard called HN-2, also known as mustine (Mustargenor mechloroethamine). Its high toxicity and the introduction of many other chemotherapy options make nitrogen mustard less attractive in medicine.

Mustards Today

Although terrorists might utilize mustard as a weapon of mass destruction, it is not as toxic as other compounds that are available. From a proliferation standpoint, mustard offers a "quick and dirty" option for less developed countries to obtain relatively inexpensive and highly effective chemical weapons.

Because the mustard agents produce blisters on the skin, casualties are at risk for secondary infections and systemic poisoning. By and large, however, injuries to the skin will heal, although there may be significant scarring due to changes in pigmentation. Exposure to mustard agent is particularly dangerous through the respiratory route. In these cases, dead tissue in the upper airways can form "false membranes" that may block the respiratory system, causing death by asphyxia. At present, the primary defenses against mustard are skin protection, taking casualties away from contaminated areas when exposed, and the rapid removal of agent from the skin. Medical treatment options are still limited to supportive therapy.

Although mustard has properties that could lead to the development of cancerous cells, for those who survive single exposures, the risks of cancer are not significantly elevated. Repeated contact with the agent has been shown to be carcinogenic, however, particularly for those employees who worked in mustard manufacturing plants during the world wars. Mustard has a severe injurious effect on the eyes, causing at the very least temporary blindness in low concentrations. However, most victims recover from mustard's effects on the eyes, although some may require corrective lenses or other interventions. In severe cases of exposure, however, permanent blindness is very possible.

MYCOTOXINS

Mycotoxins are poisonous chemical compounds that are produced as a by-product in fungal organisms. Mycotoxins are often produced by molds as well. Select toxins produced by fungi, that is, mycotoxins, are considered potential candidates for weaponization as biological toxins. The trichothecene mycotoxins, including T-2 toxin, are putative agents in the weapon known as yellow rain. U.S. allegations that the Soviet Union and its allies used T-2 and other trichothecene mycotoxins in southwest and southeast Asia during the 1970s and 1980s have not been confirmed.

Among all biological toxins that have been developed or proposed as candidate BW agents, the trichothecene mycotoxins (particularly T-2) stand out because of their intensely irritating effect upon the skin. During the 1980s and possibly the 1990s, Iraq researched and developed another mycotoxin for use in warfare: aflatoxin, a highly toxic compound in its own right and one of the most potent carcinogens known (see below).

Mycotoxins were first recognized as being associated with food-borne poisoning caused by moldy grains. In the early eighteenth century, for example, starving soldiers in the army of Peter the Great were forced to eat moldy cereals infected with ergot rust fungus (*Claviceps purpurea*), the same mold that causes a painful condition named St. Andrews Fire. The army was greatly debilitated by eating this moldy grain. In addition to a generalized illness, ergotism can lead to blood vessel constriction and gangrenous tissue. Interestingly, the chemical produced by the fungus, ergotamine, was utilized as a therapeutic agent in old pharmacopeia, especially as a means to control postpartum hemorrhage.

Natural outbreaks of alimentary toxic aleukia (ATA) in the former Soviet Union (especially in Siberia in 1942–1947) affected thousands of people (at least 10 percent of the population) after they ingested grain that was infected with *Fusarium,* a fungus that also produces T-2 toxin. Individuals suffering from ATA developed severe and painful irritation of the digestive tract, skin, bleeding, and suppressed immune systems leading to other disease processes. Similar conditions that gave rise to ATA from trichothecene have occurred in Japan (*akakabi-byo,* or red mold disease), the United States, and Canada. Another illness called cotton lung disease, caused by a fungus that infects cotton (*Dendrochium toxicum*), was described in Russia. More recently, *Fusarium* is reported to be a serious fungal infection and complication occurring in patients who are severely immunocompromised, including individuals undergoing aggressive chemotherapy.

Trichothecene Mycotoxins

Tricothecene (T-2) mycotoxin (i.e., toxin derived from fungi) is unique among the BW agents in that it is immediately active upon contact with the skin. There are a number of fungal genera that produce T-2 or similar toxins, such as *Myrotecium, Trichoderma,* and *Stachybotrys,* with the *Fusarium* species of mold being among the better-known sources. The T-2 toxin stops protein synthesis in cells. Although not nearly as toxic for the nervous system or muscles, T-2 targets those cells that are replaced rapidly, such as the skin, mucous membranes, and bone marrow. Because the *Fusarium* toxin's effects in animals and humans are quite similar to those of ionizing radiation (fever, nausea, vomiting, etc.), these compounds have been termed radiomimetic. The toxicity of T-2 is estimated to be ten to fifty times greater when inhaled as an aerosol than when introduced via injection. T-2 and related substances have been investigated for possible medical uses, including the treatment of some cancerous tumors. A mycotoxin from *Fusarium equiseti* (diacetoxyscirpenol, or DAS) was examined for one such antitumor drug formulation called anguidine. It was found to be far too toxic, however, for routine therapeutic use.

Effects on the human system by trichothecene mycotoxins depend upon the route of exposure. Generally, contact with T-2 aerosols cause severe nausea, vomiting, diarrhea, skin irritation, rash (including blisters), and breathing difficulty. Toxins like T-2 are unique among BW agents in that these toxins have high dermal activity. Severe cutaneous irritation occurs in those who are exposed to dusts generated from hay infected with trichothecene-generating molds. Inflammation of the skin in experimental animals was seen with as little as 25 nanograms of T-2 toxin dissolved in solvent. (A nanogram is one thousandth of a microgram, which is one thousandth of a milligram.) These toxins can also cause acute eye injury, as well as marked effects in the respiratory system.

Because there are no means of detecting the use of trichothecene mycotoxins outside a well-equipped laboratory, in warfare or terrorism, the symptoms of those exposed to the poison would be the primary means of determining that the weapons had been employed. James M. Madsen (2001) notes that clinical diagnosis "of T-2 use as a [weapon of mass destruction] rests on the basis of typical signs and symptoms in the setting of colored smoke, high attack and fatality rates, and dead animals of various species" (Madsen, p. 600). Casualty management is largely limited to decontamination, mostly soap and water, followed by supportive medical care.

T-2 would be a particularly effective casualty agent among unprotected civilians or military personnel, causing enormous pain, general discomfort, and, in large enough concentrations, agonizing death. Trichothecene mycotoxin would also present a contaminating hazard for clothing and equipment. Production of toxin is not considered very difficult, and the toxin could be produced under the guise of "single cell protein" (SCP) manufacture, an activity that under most circumstances would not draw much suspicion. Indeed, it is possible that Iraqi methods of fermenting biological products under the cover of SCP were designed for manufacture of mycotoxins as well as other BW agents.

The exact nature of yellow rain and its relationship to alleged biotoxin warfare by the Soviet Union and client states in southeast Asia remains a mystery. In September 1981, the United States charged that the Soviet Union and clients were using a form of biotoxin against anticommunist guerrillas in Laos, Cambodia, and Afghanistan. The trichothecene mycotoxins were the main component of what the U.S. government alleged was a toxin weapon referred to as "yellow rain." Although there is persuasive evidence to show that mycotoxins were used in southeast Asia in the late 1970s and early 1980s—including pathological samples containing the purported trichothecene mycotoxins—conclusive evidence has yet to prove that Soviet surrogates used trichothecene mycotoxins on the battlefield. Some experts in the U.S. defense establishment still desire more evidence before making a final determination of what occurred. Others state the case for yellow rain rather matter-of-factly and with remarkable detail. For example, in 1997, Robert Wannemacher (a researcher at the U.S. Army Medical Research Institute of Infectious Diseases) and Stanley L. Wiener wrote that trichothecene mycotoxins were involved in some of the following chemical attacks.

"From 1974 to 1981, toxic agents were used by the Soviet Union and its client states in such Cold War sites as Afghanistan, Laos, and Kampuchea (Cambodia). Aerosol-and-droplet clouds were produced by such delivery systems from the Soviet arsenal as aircraft spray tanks, aircraft-launched rockets, bombs (exploding cylinders), canisters, a Soviet hand-held weapon (DH-10), and booby traps (i.e., hidden improvised devices designed to injure or kill military personnel). Aircraft used for delivery included L-19s, An-2s, T-28s, T-41s, MiG-21s (in Laos), and Soviet MI-24 helicopters in Afghanistan and Laos. Attacks in Laos (1975–1981) were directed against Hmong villagers and resistance forces who opposed the Lao People's Liberation Army and the North Vietnamese. In Kampuchea, North Vietnamese troops used 60-millimeter mortar shells; 120-millimeter shells; 107-millimeter rockets; M-79 grenade launchers containing chemicals; and chemical rockets, bombs, and sprays delivered by T-28 aircraft (1979–1981) against Khmer Rouge [Cambodian rebel] troops. The chemical munitions were supplied by the Soviets and delivered by North Vietnamese or Laotian pilots" (Wannemacher and Wiener, p. 654).

Probably because Vietnam was supported by the Soviet Union and elements of the Khmer Rouge were supported by the Chinese government, experts in CW in the Chinese People's Liberation Army also seem to support the charges that yellow rain was used. However, they claim that it was, in fact, a noxious brew of old and new CW agents. Chinese authors Cheng Shuiting and Shi Zhiyuan suggest that "yellow rain claimed about 20,000 victims. Foreign observers believe that 'yellow rain' is a combination of World War I–era mustard gas, combined with a later-developed nerve-type poison that resulted in a third generation CW agent" (Cheng and Shi, p. 9).

Aflatoxin

In 1995, Iraq admitted to having produced mycotoxins, including aflatoxin, for use in biological warfare. Aflatoxin B_1, the most toxic of the aflatoxin analogues, is produced by various molds, most notably *Aspergillus flavus.* Although known for its potential to cause liver cancer in animals, aflatoxin itself has been recognized as a toxic poison. For example, in 1960 in Great Britain, some 100,000 turkeys were poisoned by aflatoxin from moldy grain meal. Although the toxicity of aflatoxin may have been the original reason for Iraq's selecting this BW agent, it is also possible that more mundane and bureaucratic pressures were at work. To demonstrate to their superiors in Baghdad that they were making progress in weapons development, Iraqi BW scientists may have attempted to weaponize aflatoxin because it is relatively easy to manufacture.

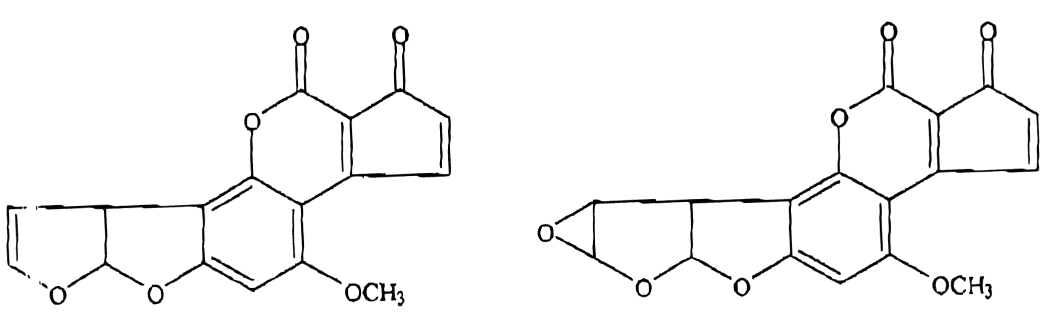
Iraq stated to UN inspectors in 1995 that its research on aflatoxin and other toxins began in 1988. Using the fungus *A. flavus* grown in 5-liter flasks, aflatoxin was produced originally at Al Salman. To step up biological weapons production, aflatoxin production was later moved to Al-Safah, otherwise known as Fudhaliyah, in 1989. According to Iraqi officials, approximately 1,850 liters of aflatoxin solution was produced from April to December 1990. Aflatoxin was then transferred to Al Hakam in January 1991.

From March 1988 to September 1990, Iraq sporadically tested a number of biological weapon delivery munitions, such as LD-250 and R-400 aerial bombs, as well as 122-millimeter artillery rockets. Among the BW agents used to fill these weapons was aflatoxin, probably weaponized in liquid suspension. Iraq also declared that Al-Hussein (modified Scud) missiles were armed with aflatoxin-filled warheads. Although Iraq declared that four of these "special warheads" were filled with aflatoxin, there is some question about whether these actually were filled with another toxin, such as botulinum. Iraqi BW scientists also tested aflatoxin and wheat cover smut (*Tilletia* sp.) spores with silica as a dry preparation.

Beyond the purpose of destroying crops, it is unclear why Baghdad developed these toxins. Iraq might have considered the use of aflatoxin for its long-term carcinogenic properties, especially as a means to attack Kurdish populations opposed to Saddam Hussein's regime, but this seems somewhat far-fetched. No further details of Iraq's work with these or other toxins emerged following Operation Iraqi Freedom (2003).

Aflatoxin can produce long-term effects (e.g., cancer) from repeated exposure, or in large enough quantities, it can cause acute toxicity. In the latter case, aflatoxin interferes with the cytochrome oxidase electron transport system—the essential part of energy utilization in the body—and in this sense it resembles the toxic mechanism of cyanide: The mitochondria (energy-producing organelles) of cells are damaged, resulting in liver damage and related pathologies such as Reyes syndrome, which also includes coma, brain damage, and possibly death. The cancer-causing mechanism of aflatoxin is the result of activation of its molecule by cytochrome P450—an enzyme in the liver that removes toxins—into a reactive epoxide, a chemical constituent containing a highly reactive and damage-causing oxygen group (see Figure M-1). This

Figure M-1: Aflatoxin B1 and Its Reactive Expoxide



Aflatoxin B_1

Reactive epoxide of aflatoxin B_1

can then form harmful chemical bonding with DNA and RNA to impede nucleic acid translation, leading to possible formation of cancer cells in the liver and elsewhere. Due to the carcinogenic properties of aflatoxin, various food grains and other food products, such as peanuts, are closely monitored by industrialized nations for public health purposes.

N

NAPALM

Napalm is technically an incendiary, that is, a weapon designed for destroying targets with high-temperature flame. The inclusion of napalm under the rubric of chemical warfare, while technically incorrect, occurs because it is often developed and handled by chemical warfare services. Napalm is basically a jellified liquid containing a fuel such as kerosene, combined with other components to give it persistence. By thickening flammable liquid in such a manner, napalm (or similar mixtures) becomes more practical to use in aerial munitions and in flamethrowers. The physical properties of napalm enable it to adhere to surfaces, be they materiel or individual soldiers. When delivered from combat aircraft, such as those employed against Japanese forces in World War II, Korea, and the Vietnam War, napalm proved to be devastating against troop concentrations caught in the open.

Napalm was first conceived as a jellied mixture of gasoline and rubber in 1942 when Professor Louis Fieser of Harvard produced a soap combining aluminum naphthenate and aluminum palmitate, the latter consisting of a number of fatty oils. This formula gave the world the name *napalm.* An incendiary bomb produced in 1942, the M-47, utilized gasoline jelly that was ignited by white phosphorus surrounding the TNT-tetryl burster, a high explosive charge. About 80,000,000 pounds of napalm were produced by the United States during World War II for incendiary bombs and flamethrowers. In response to the tenacity of Japanese soldiers, who often fought to the bitter end while ensconced in fortified redoubts, U.S. soldiers increasingly relied on napalm used from the air and in flamethrowers during the World War II island-hopping campaign in the Pacific. In Korea (1950–1953), plastic canisters, each containing 90–100 pounds of napalm, were dropped on North Korean and Chinese positions from the air.

Later, isobutyl methacrylate polymers were employed as thickeners to produce napalm. From 1965–1969, Dow Chemical mixed a polystyrene-gasoline-benzene fuel that was used primarily during the Vietnam conflict. Other applications for napalm included explosive devices attached to 55-gallon drums containing napalm, called fougasse (from the French *fougade,* referring to a type of land mine). These were employed in Vietnam for trip wire perimeter security at military bases.

The use of napalm was often a target of Vietnam War protesters during the 1960s, and it was often mentioned by international critics of U.S policy in Southeast Asia. A now-famous photograph of a young Vietnamese girl (Kim Phuc), who had been severely burned by a U.S. napalm strike, captured for many not only the unpopularity of the Vietnam War, but the perceived immorality of employing Napalm as a weapon.

In 1998, the United States undertook to destroy some 23 million pounds of stockpiled napalm, but this, too, was met with controversy when the napalm was transported across the United States by railcar. As of 2001, most, if not all, of the remaining napalm stores in the United States had been destroyed or recycled into furnace fuel. Although other incendiaries such as fuel-air (thermobaric) munitions have been used and developed for special combat roles, napalm is no longer included in U.S. military planning. Other militaries, such as the Chinese People's Liberation Army, continue to train using napalmlike mixtures for portable flamethrowers and larger devices in armored vehicles.

NERVE AGENTS

Any chemical compound that poisons the mammalian system by moderating nervous system impulses could technically be considered a nerve agent. In addition to the toxic organophosphates (those chemicals combining phosphorous with a carbon-based structure), other chemical classes such as the carbamates and various cyclic compounds could also potentially be used as nerve agents. Only organophosphorus (OP) compounds, however, have been used as chemical warfare (CW) nerve agents.

During the twentieth century, nerve agents such as tabun (GA), sarin (GB), soman (GD), and VX (or the Russian V-gas) have been weaponized. During the Cold War, both the United States and the Soviet Union maintained thousands of tons of nerve agents in stockpiles. These included sarin, soman, and VX (the Soviet version being a slightly different analogue than the U.S. formula). The U.S. chemical weapons program was halted in 1969, but it was revived temporarily in the mid-1980s by the Reagan administration to counter Warsaw Pact forces in Europe. Although several weapons systems were developed in the 1980s, the United States primarily integrated the binary 155-mm (GB) shell and the VX Bigeye glide bomb into its chemical forces. By 1989, however, the United States and the former Soviet Union had come to an understanding to stand down and disarm their respective chemical inventories. The 1993 Chemical Weapons Convention (CWC) later cemented this agreement in a multilateral disarmament treaty.

Nerve compounds are extremely toxic. In animal studies, the average lethal dose is used as a means for comparing the relative toxicities. The dose required to kill 50 percent of a given population is termed the LD_{50}. It takes more than a teaspoon of the blister agent sulfur mustard, for example, to produce an LD_{50} for skin exposure (percutaneous). The nerve agent VX, by comparison, is about 700 times as toxic as mustard. Nerve agents also have liquid properties that make them amenable to weaponization in artillery shells, rockets, and missile warheads.

Depending upon the operational mission, one nerve agent may be more effective against unprotected troops (e.g., sarin), while another excels at creating highly toxic contaminated areas that can prevent troop movement or deny forces access to materiel or logistics (e.g., VX). As in other types of chemical munitions, high concentrations in a given area can be created by using an aerosol, thereby maximizing the impact of nerve agents on the battlefield. More crude forms of delivery, however, can also be effective. Sarin, for example, forms toxic vapors at room temperature, and it thus could be applied grossly on targets, allowing its volatile fumes to do the rest of the work. A much more persistent nerve agent, VX, does not create appreciable amounts of vapor under normal conditions. However, its dermal (skin) activity and high persistency both make it a prime candidate for rendering areas uninhabitable for troops.

Due to tabun's relative ease of manufacture, it was used by Iraq during the Iran-Iraq War (1980–1988), particularly in the later years of that conflict. Iraqi military units, including its air forces, also mixed a precursor chemical (DF) with cyclohexanol and isopropyl alcohol, forming roughly an equal mixture of sarin and cyclosarin. This procedure was done just before loading the aerial bombs and other ordnance for delivery. Soman was apparently not produced in great quantity by Iraq, probably because Iraq was not able to obtain a key precursor, pinacolyl alcohol, on the open market. Most notoriously, Iraq reportedly used tabun, sarin, and soman against Kurdish populations in the northern part of Iraq, and VX may have been employed from 1987–1988. Some 5,000 civilians perished in the immediate aftermath of the Iraqi chemical attack on Halabja in 1988; nerve agents caused a substantial portion of these fatalities.

Terrorists have generally avoided the use of CW agents, including nerve compounds. However, Japanese cult operatives for Aum Shinrikyo used sarin on various occasions from 1994–1995. The cult also used VX in at least one assassination. There are suspicions that the Islamist organization al-Qaeda, in collaboration with Iraqi CW scientists, has researched the production of VX and other nerve agents for use in terrorist operations. The U.S. Central Intelligence Agency claimed in 1998 that it had obtained a soil sample in Khartoum, Sudan, revealing the existence of a VX precursor, EMPTA (ethyl methylphosphonothioic acid). This led to a U.S. cruise missile strike on August 20, 1998, destroying the Al Shifa pharmaceutical facility in the Sudan. Subsequent analysis has yielded only limited evidence pointing to a direct connection between Al Shifa, the manufacture of VX nerve agent, or Osama bin Laden's al-Qaeda organization. Nevertheless, the trace evidence of EMPTA found near the site does suggest that nerve agent synthesis was being performed at or near the Al Shifa building.

Background: Toxic Organophosphorus (OP) Compounds and Nerve Agents

In the mid-1850s, research chemists Wurtz and Clermont reported on their work with tetraethyl pyrophosphate (TEPP), an OP compound. TEPP (marketed under the German trade name Bladan) was the first widely used insecticide. It was later discovered that TEPP is toxic to mammals, although this toxicity went largely unnoticed until the twentieth century. (Its poisonous character was no doubt revealed when farmers used TEPP in large amounts during the 1930s.) The Russian chemist A. E. Arbuzov also performed groundbreaking work in OP chemistry by the early 1900s.

In the early twentieth century, most insecticides were petroleum based. In an effort to reduce foreign oil imports—as well as to improve its agricultural outputs—Germany undertook wide-ranging efforts to develop new insecticides. The large German chemical firm I.G. Farbenindustrie undertook research into phosphorus-based compounds. (One idea may have been inspired by the German production of synthetic lubricants from phosphorus trichloride.) In 1937, a laboratory team led by Gerhard Schräder synthesized tabun, an extremely toxic OP compound that had more relevance to military chemistry than agriculture. During its initial synthesis in the laboratory, tabun vapors produced characteristic symptoms of nerve agent poisoning among Schräder's laboratory staff. Later, another nerve agent analogue, called sarin, was discovered by the same German chemists. Due to the laws in effect at the time, these formulas were subsequently provided to Nazi Germany for possible military use. Research performed in England in 1941 also characterized the toxic nature of diisopropyl fluorophosphate (DFP). Although not nearly as poisonous as other nerve agents, it nonetheless had the same properties. In addition to possibly using DFP as a CW agent, Allied military chemists saw that it could be mixed with sulfur mustard to lower mustard's freezing point. The advantage of this was the agent could remain liquid even at low temperatures and could be used in winter fighting.

Tabun was manufactured by the German military during World War II at the Dyhernfurth plant in Silesia. Although Germany produced large quantities of tabun (as well as relatively limited amounts of sarin), none of these stocks were used in World War II. (There are suspicions of some use by Germany against Soviet Red Army troops, but these are not confirmed). The compound called soman, the more toxic of the so-called German series of nerve agents, was synthesized by Richard Kuhn in 1944. Soman was also the product of investigations into producing more effective insecticides.

By the early 1950s, the most successful insecticide ever used, DDT, began to wane in its effectiveness against certain pests, including lice. With a market ever widening for substitutes, Ranajit Ghosh, a British chemist at Imperial Chemical Industries Ltd., patented a number of new and promising OP compounds. Using a combination of phosphorus, sulfur, and nitrogen, Ghosh stumbled upon a chemical that was so toxic to mammals that that only the military would have any use for his discovery. Variations on Ghosh's formula would form the most toxic nerve agent to have been weaponized: VX. There currently exist many more analogues of the traditional nerve agents produced in military programs.

Medical Specifics

All known nerve agents possess the same toxicological properties and function in the same way. The OP molecule acts upon human enzymes, the one of most concern being acetylcholinesterase (AChE). The enzyme AChE normally functions as a regulator of the neurotransmitter acetylcholine, thus its name (-ase indicates an enzyme). Under normal circumstances, when a chemical-nerve impulse is generated by the interaction of acetylcholine with a nerve receptor, AChE "grabs" a molecule of acetylcholine and breaks it apart. This subsequently brings an end to the nerve transmission. However, OP nerve agents inhibit the normal activity of AChE. By attaching itself to the enzyme like a key fitting into a lock, the nerve agent stops the action of AChE. The body therefore loses its capacity to break down acetylcholine. This, in turn, brings about a crisis, because nerve receptors are now constantly being stimulated by ever-rising acetylcholine levels.

This ultimately generates life-threatening effects on the respiratory system as well as the central nervous system. Outward symptoms include miosis (constricting of the pupils), and twitching (fasciculation) in the skeletal muscle. More worrisome are copious amounts of secretions in the upper airways, caused by incessant stimulation of glands by high levels of acetylcholine. These fluids can asphyxiate victims of nerve agent exposure. Even if the airways allow for nominal breathing, the repeated nerve-muscular excitation can exhaust the diaphragm, leading to failure of the respiratory system. All of these effects, depending on the dose and route of exposure, can occur within a matter of minutes.

Nerve agent exposures can be dealt with by using (1) drug pretreatment (carbamates), (2) counteraction of increased acetylcholine levels (using atropine), or (3) restoration of impaired enzymes with oximes (e.g., 2-PAM chloride). Drug pretreatment involves ingestion of the drug before possible nerve agent exposure. In the West, pyridostigmine bromide (PB) has traditionally been used to prepare soldiers for combat in chemical warfare environments. Although they are a mild, reversible inhibitor of AChE, carbamates like PB are essentially nerve agents that hold AChE in reserve. Following nerve agent exposure, the subsequently reactivated enzyme then aids in the treatment and recovery of nerve agent casualties. The Chinese People's Liberation Army (PLA), for example, uses a variant of this scheme, prescribing a carbamate compound similar to huperzine, a naturally occurring drug that can cross the blood-brain barrier easier than PB. Although Chinese sources indicate that it is more effective than PB, it is uncertain how this Chinese carbamate might affect soldiers' ability to perform. Thus, the safety-efficacy tradeoff in using drugs for nerve agent exposure might be viewed differently by different national military programs.

Following poisoning with a nerve agent, the compound atropine—a belladonna drug that is related to BZ and that affects the body in a nearly opposite way—helps to restore some normalcy to the victim, drying up the secretions in the upper airways. Militaries usually employ a spring-loaded syringe (autoinjector) to administer atropine in 2-milligram doses, with additional injections called for depending on severity of exposure. In conjunction with atropine, oximes are also delivered by autoinjector. The North Atlantic Treaty Organization and other countries use 2-PAM chloride, and others use a variant for nerve agent casualties. Depending upon the type of nerve agent in question, as well as the time elapsed between exposure and treatment, the oxime is used to free AChE from its nerve agent "trap." Generally speaking, nerve agent casualties treated with atropine and oxime have better chances of survival than those treated with atropine alone. Brain damage and death can result from convulsions caused by exposure to nerve agents; administration of diazepam (Valium) or similar drugs helps to resolve seizures, and these can also be delivered in the field by means of an autoinjector.

Long-term health effects from exposure to toxic OP compounds vary depending upon exposure and the type of nerve agent. The long-tem effect of low-level exposure to these agents is also the subject of considerable controversy. There is not a unanimous opinion among researchers as to the long-term effects of low-level nerve agent poisoning in humans.

Some OP compounds, such as DFP or tri-ortho cresyl phosphate, require higher doses to cause fatalities but have a propensity to inhibit the neuropathy target esterase (NTE) enzyme, which is critical for maintaining proper neuro-muscular functions. This inhibition of NTE can generate a paralytic type of disability in the nervous system and musculature. This effect has been termed OP-induced delayed neuropathy (OPIDN). It is ironic that the toxic nerve agents used in warfare are not likely to produce such symptoms. This is partly because, even in small doses, the CW nerve agents actually cause the most long-lasting and permanent of medical conditions: death. These highly toxic CW nerve agents, however, do not appear to affect NTE levels, and if brain damage can be avoided from nerve agent-induced seizures, full recovery (albeit over weeks or even months) is normally expected, given proper medical care. Thus, survivors of even high doses of nerve agents used in the military context, given proper treatment and time to heal, are not likely to become permanently disabled. Data on voluntary as well as accidental exposures to nerve agents compiled by both British and U.S. chemical weapons programs bear out this finding.

Terrorist attacks involving chemical weapons are, of course, possible. Nerve agents such as DFP that have moderate toxicity and are relatively easy to manufacture may become a weapon of choice. Health care professionals need to be aware of both the short-term and the long-term consequences of OP intoxication.

NEWCASTLE DISEASE

Newcastle disease was identified in 1972 in domestic chickens in Newcastle upon Tyne, England. Newcastle disease virus (NDV), also known as fowl pest, is a contagious and fatal viral disease affecting most species of birds. NDV should not be confused with fowl plague. The disease, caused by an avian paramyxovirus—a type of virus similar to those causing rinderpest in ruminants and measles in humans—is so virulent that many birds die from it without showing any clinical signs of infection. Because of the devastating impact that the disease can have on unprotected flocks, NDV can cause significant economic damage.

Although Newcastle infection is transmissible to humans through contact with infected birds, the illness in humans is mild. However, because the virus can result in a death rate of nearly 100 percent in unvaccinated flocks and can affect even vaccinated poultry, Newcastle disease virus could be used as a biological weapon. It is believed that the Soviet Union had investigated the use of NDV as an agricultural weapon.

NDV has recently been investigated as a possible treatment for cancer. NDV appears to reproduce better in human cancer cells than in normal human cells. Lytic strains (those strains that damage the plasma membrane of infected cells) of NDV have been used to kill cancer cells directly in clinical studies. Both nonlytic (those strains that interfere with cell metabolism) and lytic strains of the virus have been used to produce vaccines intended to stimulate the immune system to fight cancer cells. The success of using NDV as a cancer treatment, though, is still unknown.

Newcastle disease virus is highly contagious and spreads primarily through direct contact between healthy birds and the secretions and droppings of infected birds. The virus can also be easily transported on fomites (items such as clothing or shoes that can carry infectious agents) from an infected flock to a healthy one. The virus is rather hardy and can survive for several weeks in a warm, humid environment or indefinitely in frozen material. The virus can be destroyed either through dehydration or through exposure to ultraviolet light. There is no known treatment for NDV, but general biosecurity measures can be used to prevent transmission from infected to healthy flocks.

NDV presents in four clinical syndromes: viscerotropic velogenic, neurotropic velogenic, mesogenic, and lentogenic. Vicerotropic velogenic Newcastle disease is the most severe strain and is often referred to as exotic Newcastle disease (END). Mesogenic is the most common variant found in the United States. Neurotropic velogenic and the lentogenic syndromes vary in their symptomology but are much less deadly forms of Newcastle disease (especially in the case of the latter).

In general, Newcastle disease affects the respiratory, nervous, and digestive systems. The incubation period for the disease ranges between 2 and 15 days, though some birds may never present clinical signs of infection. Symptoms, when they do present, can vary depending upon the viral strain, but they generally show some combination of sneezing, nasal discharge, coughing, shortness of breath, greenish and watery diarrhea, drooping wings, muscular tremors, circling behavior, complete paralysis, partial to complete drop in egg production and/or thin-shelled eggs, swelling of tissue around the neck and eyes, and sudden death. NDV causes only minor illness in humans, characterized by flu-like symptoms.

The END virus variant, which generally affects domesticated exotic caged birds, also affects chickens and other poultry. Although most poultry brooders will vaccinate against NDV, few vaccinate against END. In late 2002, an outbreak that began in California spread to Nevada and Arizona before it was contained. The outbreak was devastating—approximately 3.5 million commercial poultry were euthanized to contain the outbreak.

NEWPORT FACILITY, INDIANA

This U.S. Atomic Energy Commission heavy water production facility, used to produce the deuterium isotope in water for nuclear-related activities was later converted to a nerve agent factory. In 1953, the British government gave the United States access to a series of compounds discovered by a British chemical firm (Imperial Chemical Industries) that proved highly toxic to humans. Hardier and more toxic than previously discovered nerve agents, these compounds were further researched by the U.S. Chemical Corps, which decided to initiate large-scale production of one compound designated VX. The facility ultimately chosen to produce the compound had previously been home to an Atomic Energy Commission's heavy water plant in Newport, Indiana.

Completed in 1961, the Newport Chemical Plant operated for 7 years, during which time it was the sole producer of VX nerve agent in the United States (*see* Nerve Agents). As of 2003, the Newport Chemical Plant possessed 4 percent of the original U.S. stockpile in the form of 1,690 steel 1-ton containers containing VX. This agent will be destroyed via a process of neutralization followed by supercritical water oxidation, in which water is heated above 860° degrees Fahrenheit, converting the wastes generated by the neutralization of VX into distilled water and salt.

After original construction of the facility was completed in the 1960s, Newport produced VX in a four-step process. The agent was then used to fill a variety of munitions, including land mines, spray tanks, and rockets. After President Richard Nixon ended U.S. chemical weapons production in 1969 and froze movement of these weapons on U.S. soil, the VX remaining at the facility was placed in storage. At that time, the main plant was decontaminated, but it essentially remained intact. However, under the Chemical Weapons Convention, ratified by the United States in 1997, all former chemical weapons production facilities must either be destroyed or approved for conversion. The Tennessee Valley Authority is responsible for decontaminating and destroying the areas where the first three steps of VX production occurred. The part of the plant where the fourth step, the mixing of the VX precursors, took place is located inside the area where the agent is currently being stored. Destruction of that section of the facility is scheduled to take place once disposal of the agent stored at Newport is complete.

Decisions regarding how to safely destroy Newport's VX stocks took years of study and considerable debate. The U.S. Army finally chose neutralization over incineration as the preferred process. A new destruction facility is under construction and is scheduled to be completed in 2007. After some basic testing, the facility will begin operations. Destruction activities are expected to conclude in 2010.

NORTH KOREA: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

Suspicions of ongoing weapons of mass destruction programs in the Democratic People's Republic of Korea (DPRK or North Korea) have been a focal point of international security concerns since the 1990s. The Korean peninsula remains a volatile region decades after the Korean War, which ended in a cease-fire in 1953. Movement toward unification of North and South Korea has been very slow and fraught with tension. The parties to the conflict never signed a peace agreement and remain technically at war. As a result, one of the DPRK's long-standing aspirations has been to sign a peace treaty with the United States, distinct from any peace treaty involving the Republic of Korea (ROK or South Korea). Not without justification, such a separate peace without southern participation has consistently been rejected by South Korea and the United States, both militaries being partners in defense of the south by potential invasion by the north. This history has exacerbated the security threat posed by weapons of mass destruction in North Korea, for without a coming to terms as to the future of the Korean peninsula—not to mention and end to hostile posturing by the north—the threat of war will continue to persist.

Chemical Weapons

Although concerns about weapons of mass destruction in North Korea have focused on its nuclear weapons program, the country is also believed to possess a longstanding chemical weapons program and stockpiles of chemical weapons. According to various sources, the Korean People's Army developed chemical and biological units and received sarin nerve gas from the Soviet Union in the 1950s. The Soviet Union also reportedly provided small quantities of mustard and nerve agents to the DPRK in 1966. South Korean sources assert that the

U.S. military forces in South Korea train with nuclear, biological, and chemical defensive gear in the event of a North Korean attack. (Reuters/Corbis)

DPRK augmented these acquisitions with domestic production of chemical agents, including mustard and tabun, in the late 1970s. American defense and intelligence agencies have suggested that North Korea moved toward an offensive capability at that time and that it now has the capability to weaponize these agents.

By 2003, estimates of the North Korea stockpile of chemical weapons agents, including nerve, blister, and blood agents, ranged between 2,500 and 5,000 tons. North Korean officials consistently denied these accusations, but they have resisted pressure to join the Chemical Weapons Convention. South Korea alleged in a 1999 white paper that North Korea maintains eight chemical weapons production facilities, four research sites, and six storage facilities.

Biological Weapons

Although it acceded to the Biological and Toxin Weapons Convention in 1987, North Korea allegedly also maintains a rudimentary biological weapons program. At the Fifth Review Conference of the Biological Weapons Convention in 2001, the United States accused North Korea of violating its obligations under the treaty, a charge that North Korea has denied. Sources have reported that the DPRK began production of biological weapons agents, including anthrax bacteria, botulinum toxin, and possibly plague bacteria, in the 1980s. South Korea's Defense Ministry has suggested that North Korea has since then acquired several additional biological weapons, including smallpox, and that it has an ongoing program to weaponize these agents.

NOVICHOK

Novichok, or "New Guy," was a top-secret Soviet chemical weapons development program that extended well into the 1990s, even while deliberations continued over the Chemical Weapons Convention (CWC). In the view of some observers, the Novichok program threatened the validity of the CWC as an effective arms control verification regime because Novichok used chemicals not prohibited by the treaty. Novichok agents used precursors similar to those found in fertilizers or pesticides that can be disguised as relatively harmless common chemicals. Consequently, some have argued, even the most intrusive inspection would not be able to identify these agents as chemicals specifically used for weapons production. If the general-purpose criterion of the CWC is to be adhered to, however, any chemical used for toxic warfare is prohibited. Novichok agents, whatever their actual composition, are therefore no less prohibited than any other chemical warfare agents.

Vil Mirzayanov, a Russian émigré, was responsible for bringing the existence of the Novichok program to light. According to Mirzayanov, who was originally responsible for developing detection schemes for Novichok in the Soviet military, the filtration systems in Russia's production and testing sites were not adequate. In the interests of environmental safety, Mirzayanov and another chemist, Lev Fedorov, wrote an article for the weekly *Moscow News* titled "A Poisoned Policy." In this article, they exposed the open-air testing of chemical agents and the inadequate filtration systems that led to contamination of air, water, and soil surrounding the production and testing facilities. The authors accused the Soviet government of poisoning its citizens. Mirzayanov was subsequently jailed for divulging state secrets. He immigrated to the United States in the mid-1990s.

Novichok agents were developed at the Soviet State Scientific Research Institute for Organic Chemistry and Technology (GosNIIOKhT) as part of a third-generation chemical weapons program. Research efforts included methods of delivering these chemicals in unitary and binary form. (Binary agents are advantageous because they allow the chemicals to remain separated and nontoxic until the weapon is deployed, at which time the chemicals mix and become lethal). According to Mirzayanov, the Chemical Research Institute, located in Nukus, Uzbekistan, was a major research and testing site for Novichok. There was also a relatively small test area near Krasnoarmejsk, a Moscow suburb. The Nukus facility was built in 1986 to produce small batches of novichok agents for testing in binary weapons. According to Mirzayanov, testing demonstrated that novichok agents would be effective military weapons in both unitary and binary forms. Novichok agents can be dispersed as a liquid, aerosol, or gas, and they can be used in a variety of delivery systems (bombs, artillery shells, spray rigs, and missiles).

The actual chemical and physical characteristics of novichok agents are still unknown. According to Mirzayanov, novichok 5 is estimated to be five to eight times more toxic than VX, and novichok 7 is estimated to be ten times more toxic than soman. The effects of novichok agents are rapid, and the progression of symptoms is similar to that of other nerve agents (pinpoint pupils, runny nose, tightness of chest, nausea, vomiting, involuntary twitching of muscles, loss of consciousness, and, eventually, death). Despite the fact that they produce similar symptoms, the novichok agents are different in their chemical structure from the traditional G-series or VX nerve agents.

Media reports have indicated that novichok agents cannot be detected by Western technology, particularly those chemical warfare agent detection systems used by NATO militaries. Reportedly, should a chemical alarm be set off by the presence of a novichok agent, the substance would not be identifiable and would appear to be a false alarm. Apparently, the novichok class of compounds falls outside the identification range used in many chemical detection systems.

There is still much to learn about the Novichok program. The Russian government continues to withhold information regarding this secret weapon. Meanwhile, the Uzbek government is working closely with the United States to dismantle and decontaminate chemical weapons testing facilities within their borders. Soil samples and other tests may be able to provide more information on the physical makeup of novichok agents that were tested at the Nukus facility.

O

OKLAHOMA CITY BOMBING

On 19 April 1995, Timothy McVeigh—a domestic terrorist with antigovernment beliefs—drove a rented cargo truck to Oklahoma City and parked in front of the Alfred P. Murrah Federal Building. While driving to the intended target—the U.S. federal government and its enforcement agencies located there—he had already lit the fuse that protruded from the cargo hold into the cab of the truck. He parked the vehicle at a drop-off point near the building and walked away. Inside the truck were approximately 5,400 pounds of ammonium nitrate, 1,200 pounds of nitromethane, and a 350-pound high explosive charge. Diesel had also been added to some of the ammonium nitrate in the back of the cargo container. Essentially, the truck was an ammonium fuel oil (ANFO) explosive weighing about 7,000 pounds. Although McVeigh was wearing ear plugs and was at least two hundred yards away from the blast, the resulting explosion nearly deafened him. The bomb destroyed the building, killing 168 people, 19 of them young children.

The bombing at Oklahoma City was the second most devastating terrorist attack on American soil, eclipsed only by the attacks to come six years later on 9/11. But unlike the assault on the World Trade Center in New York, the origins of the Oklahoma City bombing were entirely domestic. Furthermore, it established a precedent for the U.S. Federal Bureau of Investigation to define a weapon of mass destruction along the following lines:

> Mass casualties and extensive property damage are the trademarks of weapons of mass destruction, making their detection, prevention, and destruction an FBI priority. A weapon of mass destruction (WMD), though typically associated with nuclear/radiological, chemical, or biological agents, may also take the form of explosives, such as in the bombing of the Alfred P. Murrah Federal Building in Oklahoma City, Oklahoma in 1995. A weapon crosses the WMD threshold when the consequences of its release overwhelm local responders. (FBI, 1999)

In 1997 McVeigh was convicted of murder and employing a weapon of mass destruction (WMD) "to kill and injure innocent persons and to damage the property of the United States." (Quoted in Michel and Herbeck, p. 347). Finally, after waiving his right to appeal the death sentence verdict, McVeigh was executed by lethal injection on 11 June 2001. Another co-conspirator, Terry Nichols, was convicted for the Oklahoma City bombing on 26 May 2004, but on 11 June 2004 he was spared execution by a deadlocked jury during his sentencing. He will spend the rest of his life in prison.

The timing of the Oklahoma City bombing was to protest—as well as to dramatically commemorate—the U.S. government's actions at Waco, Texas, in 1993. On 28 February 1993, federal agents from the Bureau of Alcohol, Tobacco, and Firearms (ATF), while serving a firearms violation warrant, raided a compound at Waco that housed members of a cult (Branch Davidians) led by David Koresh. It led to a shootout and siege that continued for over a month. McVeigh had even driven to Waco in March 1993 in order to witness the spectacle but was denied entry to the area by local law enforcement. On 19 April 1993, a fire consumed the Branch Davidian compound, killing more than 80 of the people inside, including 21 children. Later investigations showed that the use of CS riot control agent by Federal agents—as well as actions taken by David Koresh and his followers—contributed to the final death toll.

By the time he heard of the tragic aftermath at Waco, McVeigh, a former U.S. Army soldier and a

Gulf War veteran, had already developed antigovernment sentiments. Loosely associated with the militia movement in the Western United States, McVeigh intended to retaliate against these federal agencies by destroying the federal building in Oklahoma City. On 18 April, with assistance from Nichols, McVeigh assembled the truck bomb at Geary Lake State Park in Kansas. A day later, McVeigh drove the truck to Oklahoma City, timing the attack to ensure the building was full of federal workers, including federal agents of the ATF—the same agency that McVeigh blamed for the conflagration at Waco, Texas. An hour outside of the city McVeigh was pulled over by Oklahoma highway patrol for driving without a license plate, leading to his arrest.

ORGANOPHOSPHATES

Many important chemical substances can be categorized as organophosphates. These chemicals possess a structure that is composed of carbon-hydrogen bonds linked in some fashion (often via an oxygen atom) to a phosphorus atom. Since their discovery in the nineteenth century, organophosphates have found many uses.

Organophosphate (OP) synthesis begins with phosphorus, often in the form of phosphorus trichloride, phosphorus oxychloride, or phosphorus pentasulfide. Although the process chemistry to produce OP compounds is not exceptionally difficult, the challenge for some countries or groups might be finding a source of phosphorous itself: a more difficult undertaking, as there are limited producers. Although many of these OP compounds have useful roles in agriculture and modern industry, the development of OP compounds for use as insecticides in the 1930s led to the development of the military nerve agents, which are also OP compounds. These compounds top the list of chemical threats that could be used in modern weapons of mass destruction (WMD), including for purposes of terrorism.

Background

The chemist Wurtz discovered a chemical compound known as tetraethyl pyrophosphate in the mid-1800s but did not report on its toxicity. It is now known as a relatively potent nerve agent. In the nineteenth century, the German chemist Carl Arnold August Michealis worked with phosphorus-related compounds as a focus of his research. In the 1920s, the Russian scientist A. E. Arbusov published his own work on phosphorus. In 1932, German research chemists Lange and von Krueger reported on toxic properties of some OP agents. They noted that upon exposure, a fluorinated OP chemical they synthesized caused breathing difficulties, and "glare phenomena with painful hypersensitivity of the eye to light" (Franke, p. 201). During the course of research into producing new insecticides without using scarce petroleum, German chemists in 1937 found some OP compounds that were highly lethal to mammals and therefore had no useful role in agriculture. But these chemicals had obvious military applications. Gerhard Schräder's team would eventually discover the more potent chemical compounds tabun and sarin.

At the start of World War II, research in the United Kingdom independently discovered the toxic properties of a nerve agent, diisopropyl fluorophosphate (DFP). But knowledge of the much more toxic analogues, including tabun and sarin, would have to wait until war's end and the fall of Berlin. In 1945, British and U.S. intelligence organizations were quite surprised at the extent of Germany's research and development of OP compounds for military use.

Medical Aspects

The nerve agents inhibit the work of the body's enzymes—most critically that of acetylcholinesterase (AChE), but they will also interfere with other enzymes. The toxic nature of these OP compounds is due to their affinity for AChE. This enzyme controls the amount of acetylcholine in the nervous system by catalytically breaking it down into its constituent parts. Too much acetylcholine causes hyperstimulation of the nervous system, including important glands and the musculature.

Nerve agents work on the body and its enzymes by acting like neurotransmitters. Toxic OP agents like sarin, tabun, and VX possess a phosphorus atom that bonds with a chemical group on the enzyme. The other part of the OP molecule mimics the properties of acetylcholine, a neurotransmitter in the nervous system. The analogy of a lock and key is apt: normally, acetylcholine is the perfect key for the AChE lock, fitting nicely and allowing the continuation of normal operation. The OP chemical, however, is a pseudokey that finds its way into the enzyme (lock). Like a poorly copied key that gets stuck in the mechanism, the OP compound can render the lock useless—sometimes the key even breaks off inside, and it now becomes a hopeless task to repair it. (This process of binding with the enzyme, sometimes reversible but at a slow rate, is often referred to as phosphorylation.) With no enzyme to control the amount of acetylcholine, excessive stimulation leads to crisis and death of the body. Some chemicals can be used to help repair AChE, such as oximes. In the case of soman poisoning, however, the bond is basically irreversible within minutes of exposure, and in these cases oxime therapy is not as effective.

Other Uses for Organophosphates

Besides nerve agents, another role for OP compounds is in removing or chelating heavy metals, such as uranium, for extraction and purification. Tributyl phosphate (TBP) is an essential chemical used in the processing of plutonium (plutonium uranium recovery by extraction or PUREX) and uranium for nuclear weapons development. TBP is the workhorse for extracting plutonium from irradiated fuel rods. Another OP compound used in uranium extraction is trioctylphosphine oxide (TOPO), often used with bis(2-ethylhexyl) phosphate (DEPA), another organophosphate. The DEPA-TOPO process removes uranium, which is then extracted from a solvent (such as kerosene).

Although infamous for their role in weapons chemistry, OP compounds also contribute to very useful and lucrative chemical markets in a variety of other applications, including pesticides, herbicides, antivirals, lubricants, flame retardants, and plasticizers (see below).

Some of the first OP compounds to be successfully marketed included the triphenyl (generally referred to as triaryl) phosphates and the tri-cresyl phosphates. These chemicals were useful as plasticizers, making substances such as celluloid and vinyl more flexible, while also adding a flame retardant effect. Other uses included treatment of

TOCP POISONING: OR THE HAZARDS OF UNREGULATED BOOZE

One OP compound that targets the body's enzyme function and causes devastating effects on the nervous system is tri-ortho cresyl phosphate (TOCP). During the 1930s, some 50,000 people in the United States unwittingly ingested TOCP while drinking "ginger jake" tincture. Due to the prohibition of alcohol enacted at that time in the United States, those who desired alcoholic beverages had to resort to improvised sources. One such source was a ginger extract that contained 70–80 percent alcohol. Originally conceived as a tonic and a purgative, "jake" was sold for 50 cents per bottle, and although still somewhat expensive for the day, it was a cheaper option than bootleg liquor.

One businessperson who produced and sold this concoction, Harry Gross, president of the Hub Products Corporation, decided to cut manufacturing costs by adulterating jake with cheaper solvents. It was suggested that a varnish component marketed as LINDOL could be added. The main component of this varnish was TOCP. More than 640,000 bottles of jake were produced with this adulturant in Boston, Massachusetts, and were eventually distributed by American pharmaceutical companies.

At that time, TOCP was deemed "presumably nontoxic," but soon after the shipments of jake were sold on the street there appeared cases of "Jake walk" or "Jake leg," described as a characteristic foot- and wrist-drop symptomatic of a serious motor paralysis. It is now known that TOCP and/or its toxic metabolite targets the enzyme neurotoxic esterase (NTE) in the nervous system, resulting in a severe and debilitating nerve dystrophy. When taken in only small quantities, symptoms were relatively minor and usually resolved themselves. Others who consumed more of the product suffered chronic partial or even complete paralysis. Even as late as 1978, survivors continued to display typical polyneuropathies of TOCP poisoning.

The individual responsible for this "mass poisoning," Harry Gross, received a two-year jail sentence (suspended) and a $1,000 fine a few years later, but none of his victims received anything in the way of compensation.

leaded gasoline to cut down on premature firing, although this is no longer needed with the advent of unleaded fuels. Because they are not as flammable as oil mixtures, OP compounds are also being used as hydraulic fluids and lubricants in gas turbines and other platforms.

By far, the largest group of OP compounds used commercially is the pesticides, including insecticides and herbicides. Although DDT was effective and relatively safe to use, insects quickly developed a resistance to this and other chlorine-based organic chemicals. As the German chemists noted early in the 1930s, the OP nerve agents were highly effective against insect pests. The challenge was to find those OPs that did not kill animals (and humans) as well. Since then, a number of highly successful OP insecticides have been marketed and are still used today, including malathion and chlorpyrifos. It has been found that although flies and mosquitoes develop a resistance very quickly against chlorinated organic pesticides—say, within a dozen generations or so—it takes much longer for the same insects to develop resistance to OP compounds. A further advantage to OP pesticide chemicals is that they quickly hydrolyze (are broken down by water) in the environment. Hazards of using OP insecticides most often occur when farmers use these chemicals without strict adherence to labeled instructions, as these insecticides are sold in bulk form at high purity for agribusiness.

The development of glyphosate (sold as a product called Roundup) herbicide is another example of a very successful OP chemical whose markets for use continue to expand. This is especially true with the recent introduction of genetically modified crops that tolerate the chemical ("Roundup Ready"). The agrichemical giant Monsanto, for example, has developed Roundup Ready soybeans for use in tandem with glyphosate, for more efficient use of the herbicide and for increased yields.

OP compounds also account for nearly 25 percent of the market for flame-retardant chemicals. These substances provide a chemical buffer between the flame source and the fabric, allowing fibers to char but not burn. In pharmaceutical applications, drugs such as Foscarnet (antiviral) and other promising compounds are being used in microbial chemotherapeutics. These are also based on OP chemistry.

OSAMA BIN LADEN

Osama bin Laden is the leader of the global Islamic terrorist organization al-Qaeda (*see* al-Qaeda), which was responsible for perpetrating the September 11, 2001 attacks against the United States. Bin Laden has openly stated that he and his followers wish to acquire weapons of mass destruction (WMD) and to use them against American and other Western interests.

Bin Laden was born July 30, 1957 in Riyadh, Saudi Arabia. His mother, Hamida, was originally from Damascus, Syria. His father, Muhammad bin Awdah bin Laden, was originally from Yemen and had four wives and many concubines. Bin Laden was the seventeenth of fifty-two siblings. His father is founder and owner of the Saudi bin Laden Group, a respected construction firm in Saudi Arabia and the Middle East.

Bin Laden was raised in Medina, Saudi Arabia and attended primary and secondary schools in Jeddah, Saudi Arabia. Bin Laden attended King Abdulaziz University for three years, where he studied economics and management but did not graduate. At the university, he also studied Islam with Muhammad Qutb and Abdullah Azzam, both important Islamic fundamentalist thinkers. Bin Laden went to Afghanistan in 1979 following the Soviet invasion of that country, serving as part of the mujahideen (holy warriors) resistance. His motivation—as it was for the rest of the mujahideen—was the desire to expel atheistic Russians from a Muslim state. In Afghanistan, he became even closer to Abdullah Azzam. In 1984, the two formed the Afghan Service Bureau (MAK) to recruit and train mujahideen fighters. Although bin Laden played

Osama bin Laden may have begun serious efforts to acquire WMD while in the Sudan. (Reuters/Corbis)

mainly a support role during the Afghan conflict with the Soviet Union, he did take part in a handful of battles. In 1988, bin Laden reportedly formed the "base" organization formed by mujahideen and other radical Islamists, called al-Qaeda. By 1989, however, a growing rift between Azzam and bin Laden over the future direction of MAK led bin Laden to sanction the assassination of his former mentor and partner. In November 1989 a bomb killed Abdullah Azzam and two of his sons in Peshawar, Pakistan; the perpetrator is still unknown, although bin Laden is suspect.

After the Soviet withdrawal from Afghanistan in 1989, bin Laden returned to Saudi Arabia, where he helped Saudi intelligence found a jihad group in southern Yemen to oppose the communist government in that country. After the Iraqi invasion of Kuwait in August 1990, bin Laden proposed that he and the Saudi government form an Arab, anti-Saddam Hussein group made up of 5,000 Afghanistan veterans to guard Saudi Arabia against a possible Iraqi invasion. The Saudis rejected his proposal and invited the United States military to Saudi soil instead, a move that angered bin Laden. When the Saudi government broke its promise to him to bring about an immediate U.S. withdrawal after the war, bin Laden became very outspoken in his views against the Saudi government.

Fearing assassination by the Saudi government, bin Laden left Saudi Arabia in April 1991, moving his base of operations to Sudan. In 1994, Saudi Arabia revoked bin Laden's citizenship. In retaliation, he formed the Advice and Reformation Committee, which proceeded to agitate within Saudi Arabia against the Saudi royal family. Later in 1994, the Saudi government attempted to assassinate bin Laden. In response, bin Laden ordered the bombing of targets within Saudi Arabia, including the National Guard Building in 1995 and the Khobar Towers in 1996, the latter killing nineteen and wounding over 500 American military personnel. In response to growing international pressure, Sudan expelled bin Laden in May 1996.

Bin Laden then moved his headquarters to Afghanistan, where he developed a relationship of mutual cooperation with the ruling Islamic fundamentalist Taliban regime. During 1997 and 1998, bin Laden worked to form an international Islamic fundamentalist coalition. In February 1998, he announced the formation of a larger umbrella organization, with Al-Qaida ("the base") leading the World Islamic Front for the Jihad against the Jews and the Crusaders (*Al-Jabhah al-Islamiyyah al-`Alamiyyah li-Qital al-Yahud wal-Salibiyyin*), saying that it was the duty of all Muslims to kill Americans.

As a result of bin Laden's 1998 U.S. Embassy bombings in Kenya and Tanzania, the U.S. government tried to kill bin Laden and weaken his network by carrying out cruise missile strikes against training camps in Afghanistan and against the alleged chemical weapons production facility at the Al Shifa pharmaceutical factory in Khartoum, Sudan (*see* Al Shifa). Bin Laden was not killed by the U.S. strikes but was instead vaulted to further preeminence as an Islamic fundamentalist figure in the Muslim world, partly as a result of the U.S. military response.

According to some reports, bin Laden has used his inheritance from his father's business, estimated at between $25 million and $300 million, to fund al-Qaeda's operations. However, other recent stories in open sources have concluded that bin Laden has long since spent his fortune and now relies on foreign assistance and donations. Due to his previous dealings with Abdullah Azzam, bin Laden has been described as duplicitous. Although not known as an original thinker himself, bin Laden is a competent manager and businessman who surrounds himself with talented advisors. He has also been described as an opportunist, given his willingness to ally himself with those who can contribute to his success, even if these allies do not completely support his ideological vision.

Bin Laden first expressed an interest in acquiring and using weapons of mass destruction while in Sudan. During that time, he began his network's WMD research with the help of the National Islamic Front (the ruling regime in Sudan) and the Sudanese military. Bin Laden has been very open about his desire to acquire and use WMDs. He has stated publicly his belief that acquiring WMDs is a Muslim duty and even that the failure to acquire WMDs is a sin.

OXIMES

In the treatment of nerve agent casualties, oximes are a category of therapeutic compounds used to help restore acetylcholinesterase (AChE) enzyme function (*see* Nerve Agents, Atropine). In the battlefield, oximes can be administered with the use of a spring-loaded syringe for self administration (autoinjector), along with atropine and anticonvulsant (diazepam) therapy. Civilians also may require oxime therapy in the occasional case of poisoning by organophosphate insecticides (*see* Organophosphates).

The general approach to nerve agent antidote regimens includes an injection of atropine to counter the immediate effects of the nerve agent. Next, the administration of oximes helps the body to restore the balance of its nervous and muscular function by "repairing" enzymes that are blocked by the nerve agent. By speeding up the process of hydrolysis (cleaving off the nerve agent with water molecules), oximes provide more leverage to separate AChE from the nerve agent.

Atropine can counter the effect of dangerously high levels of acetylcholine, which otherwise would overstimulate glands and cause respiratory crisis. Oximes help to restore AChE enzyme to normal function, but it does not appear to treat chemical imbalances in general. The chances for survival are much better when antidotes combining both atropine and oximes are used. Along with atropine, oximes are fielded in autoinjectors that can be carried by each soldier and by emergency medical personnel. One treatment called TAB has been a long-standing mixture for bolus administration, consisting of trimedoxime (TMB4), atropine, and benactyzine (the latter serves the role of a carbamate to help protect AChE).

Some oximes work better than others, depending on the type of nerve agent that may be encountered. Soman, for example, is a nerve agent that is notoriously difficult to reverse, and standard pralidoxime chloride (2-PAM-Cl) therapy has shown little or no reversing effect. In the case of tabun, the oxime TMB4 (the acronym for N,N'-trimethylene bis-[pyridine-4-aldoxime bromide]) is more effective against tabun than is 2-PAM-Cl, for example. Other oximes are being studied that can make up for deficiencies, depending upon which nerve agent is encountered. Following nerve agent exposure and immediate treatment, follow-up care may be necessary to prevent long-term neurological damage, and anticonvulsants (such as diazepam) are often prescribed in such cases.

There are several types of oximes that have been developed by militaries around the world. Which oxime is used depends on each country's view of risk versus benefit among the different compounds that are available. In the U.S. military, 2-PAM-Cl is the standard drug used to treat chemical weapons casualties. It is also the treatment of choice for organophosphate insecticide poisoning. A pralidoxime called P2S is employed by the British armed services, and obidoxime and TMB4 are used in other European nations. As seen in the Table O-1, hagedorn (HI-6 and HS-6) oximes appear to be at least marginally effective in experimental studies of soman poisoning. However, this may be due to factors unrelated to the inhibited enzyme.

Table O-1: Comparison of Oximes and Their Effectiveness in Countering Nerve Agent Poisoning

Oxime	*Sarin*	*Tabun*	*Soman*	*VX*
2-PAM-Cl	+	+	0	+
Obidoxime	+ + +	+ +	0	+ + +
HI-6	+ + + +	0	+ +	+ + + +
HS-6	+ + +	0	+	+ + +

(Plus signs indicate relative effectiveness, while 0 means no appreciable effect)

Oximes and "Aging"

Oximes are only effective if administered promptly after nerve agent exposure. In the case of soman poisoning, the effective oxime treatment window may be a matter of minutes. As a consequence, if U.S. troops are thought to be facing a threat from soman nerve agent, pretreatment with a carbamate (e.g., pyridostigmine bromide) has been recommended (*see* Carbamates).

The chemical process that leads to enzyme aging depends largely upon the type of nerve agent encountered on the battlefield. In the case of soman, cyclosarin, and some others, the aging depends upon a large functional group (the esteric portion made of an alcohol such as isopropyl in the case of sarin) attached to the molecule of the nerve agent. Once the first leaving group, the portion that first dissociates from the phosphonic ester (such as fluorine in the case of sarin or soman) is removed through hydrolysis (cleaving with water), the molecule with the active phosphorus entity will then phosphorylate AChE—that is, the nerve agent molecule bonds with the enzyme, effectively inhibiting its function. At this point, there is a chance that hydrolysis—either by itself or with an assist from an oxime (such as 2-PAM-Cl)—could take place. However, at some point (quickly, in the case of soman), the large structural unit also leaves the phosphate structure of the nerve agent molecule. Now, the phosphorous atom is highly resilient to hydrolysis, basically repelling water molecules away. This is now a so-called "aged" enzyme and cannot be practically restored to normal function.

Studies suggest that therapy using atropine (or similar drugs) together with oximes offers better therapeutic success than atropine alone. Without oximes, the natural course of events may allow for hydrolysis and dephosphorylation of nerve agent to take place, albeit at a very slow rate, thereby reversing AChE inhibition. If this process fails, however, oximes come to the rescue. In certain cases, however, as in the aforementioned problem with soman poisoning, the enzyme may "age." If this occurs, there is no hope of hydrolysis to restore the enzyme—with or without oxime therapy—lessening the chances of survival or vitiating fast and full recovery.

P

PARASITES—FUNGAL

Although many disease-causing microbes are obligate parasites—requiring a host to survive and duplicate, such as viruses and most rickettsial bacteria—the term *parasites* generally refers to eukaryotic (unicellular parasites such as fungi, protozoa, nematodes) rather than prokaryotic (not having a distinct nucleus, such as bacteria) organisms. By virtue of their capacity to infect via aerosol, some fungal pathogens, such as *Coccidioides immitis* (the causative agent of coccidioidomycosis or valley fever) and *Histoplasma capsulatum* (histoplasmosis), have been studied for potential use in biological weapons.

Fungal organisms that could have potential as biological warfare agents include:

- *Blastomyces dermitidis* (also known as *Ajellomyces dermatitidis*)
- *Cladophialophora bantiana* (formerly known as *Xylohypha bantiana, Cladosporium bantianum*)
- *Coccidioides immitis*
- *Coccidioides posadasii*
- *Histoplasma capsulatum* (incl. var. *duboisii*)
- *Histoplasma capsulatum* var. *farcinimosum*
- *Paracoccidioides brasiliensis*
- *Penicillium marneffei*

During World War II, *C. immitis* was studied at the Stanford University School of Medicine for the U.S. War Research Service. Because African Americans have traditionally shown susceptibility to coccidioidomycosis, this disease was of concern to the U.S. military during the war. After the war, some experiments were conducted that violated legal guidelines for such research: In 1951, U.S. Army scientists carried out studies of this pathogen using a relatively innocuous fungus, *Aspergillus fumigatus,* exposing a disproportionate number of African Americans as test subjects without their prior consent. Between 1943 and the end of the U.S. offensive biological weapons program in 1969, ten researchers at Fort Detrick, Maryland, became infected (presumably by accident) by fungal organisms during research into their potential as biological warfare (BW) agents. Nine of these infections were caused by *C. immitis,* the other being caused by blastomycosis (*Blastomyces dermitidis*).

Fungi offer potential as antihuman agents primarily because of their natural propensity to disperse as small particles in aerosols. Fungal organisms such as *C. immitis* can be carried long distances in the air, causing numerous infections every year. Diseases such as valley fever and histoplasmosis are prevalent from the southwestern to the central and eastern parts of the United States and are a serious public health issue. When compared to a number of other pathogens that could be used in BW, however, it is not clear that their potential to cause widespread disease is sufficient to warrant much concern.

Another possibility exists that molds such as *Fusarium* sp. could be utilized to produce mycotoxins (*see* Mycotoxins) for use in warfare.

Fungi and other parasites also may be used as an anticrop weapon. The real threat these agents pose to modern agricultural industries is not clear, but the following pathogens are included in some lists for purposes of biological arms control:

- *Bipolaris oryzae* (also called *Helminthosporium oryzae, Cochliobolus miyaeanus*), brown spot of rice
- *Colletotrichum coffeanum* var. *virulans* (also known as *Colletrichum kahawae*)
- *Deuterophoma tracheiphila* (also known as *Phoma tracheiphila*), mal secco disease

- *Dothistroma pini* (also known as *Scirrhia pini*), needle blight on/of pine
- *Microcyclus ulei* (also known as *Dothidella ulei*), South American leaf blight
- *Moniliophthora rorei* (also known as *Monilia rorei*), cocoa moniliasis
- *Phytophthora infestans,* late blight of potato
- *Puccinia erianthi* (also known as *Puccinia melanocephala*), orange rust of sugar cane
- *Puccinia graminis* f. sp. *tritici,* rust fungus
- *Puccinia striiformis,* wheat yellow rust (*Puccinia glumarum*)
- *Pyricularia grisea* (formerly known as *Pyricularia oryzae,* also *Magnaporthe grisea*), rice blast fungus
- *Sclerotinia sclerotiorum,* Sclerotinia rot
- *Ustilago maydis,* corn smut
- *Tilletia* sp., wheat cover smut

As for protozoans, nematodes, or even insects that can cause significant disease in humans, few if any known military programs have seriously investigated or developed such organisms as biological warfare agents. However, some negotiators of a verification protocol to the 1972 Biological and Toxin Weapons Convention have included parasites in suggested pathogen lists for arms control. Past experience also suggests that bioterrorists, or perhaps criminal saboteurs, might consider using these pathogens as a weapon. Although it is difficult to foresee a significant threat from these parasitic organisms, the following agents may pose a threat if used for sabotage or purposeful contamination:

- *Echinococcus granulosus*
- *Echinococcus multilocularis*
- *Echinococcus vogeli*
- *Leishmania brasiliensis*
- *Leishmania donovani*
- *Naegleria fowleri* (naegleriasis, or amoebic meningoencephalitis)
- *Plasmodium falciparum,* malaria
- *Taenia solium,* pork tapeworm, cysticercosis
- *Trypanosoma brucei rhodesiense*
- *Trypanosoma cruzi*

Two additional parasites (more precisely referred to as protozoa), *Giardia lamblia* and *Cryptosporidium parvum,* also pose a public health hazard today. For example, a scientist who belonged to the Rajneeshee cult in Oregon (1984) reportedly considered using *Giardia lamblia* as a weapon. This parasitic organism causes giardia, a serious but usually self-limiting (resolves on its own) infection with symptoms mostly consisting of diarrhea. The idea apparently came to the attention of the cult scientist because beavers, common to the Pacific Northwest United States, are a well-known carrier of the parasite. One plan may have included finding an infected animal, putting tissues such as certain organs in a blender, and collecting the protozoa.

Deliberate spreading of giardia to humans could be accomplished by adulterating food or water. The practicality, however, of isolating, growing, and preparing a concentrate of this protozoan is hard to assess. In the 1984 case, the Rajneeshees instead chose the *Salmonella typhimurium* bacterium and used it to contaminate salad bars throughout The Dalles in north-central Oregon, hoping to change the outcome of local elections. They failed to influence the election, but (despite the fact that the bacterium was a nonlethal pathogen) 751 people became ill, making this thus far the largest bioterrorist attack on record.

In the United States and elsewhere, *Cryptosporidium parvum,* the causative agent in cryptosporidiosis, also causes severe diarrheal symptoms in humans. As in giardia infections, cryptosporidiosis also can lead to death in the severely immunocompromised, especially those affected by HIV/AIDS. This protozoan is transmitted in the form of oocysts: very tiny egglike structures containing four sporozoites (young parasites) each that attach themselves to the epithelial mucosa (tissue coating the surface) of the small intestine. The oocyst itself is somewhere between 4 and 7 microns in average diameter. Thus, most modern filtration schemes may not adequately screen these out of city water systems. Even more problematic is the fact that this organism is resistant to chlorine (chlorination is a common water purification technique).

Oregon experienced another outbreak of diarrheal illness in 1992, this time due to a natural outbreak of cryptosporidiosis. Some 15,000 people were affected in Jackson County, Oregon. The largest recorded outbreak of this disease, however, occurred in 1993, when 403,000 people became infected with the *Cryptosporidium* organism in Milwaukee County, Wisconsin. Some seventy people died from the infection, most of these being HIV-positive individuals. This outbreak was caused by a large quantity of the parasite being drawn through the water treatment facility of the Milwaukee Water Works. Its exact source is still not known, although it is suspected that a large runoff containing waste from cattle, slaughterhouses, and humans flowed into Lake Michigan. From there, this contaminated water found its way to the water works, overwhelming its water treatment capacity.

Bioterrorists could possibly utilize a parasite such as *Cryptosporidium* to sabotage drinking water. The process involved in growing this organism and utilizing it as a BW agent, however, is probably too problematic to be worthwhile—either for a military or terrorist organization.

PARATHION (METHYL AND ETHYL)

By 1944, the German chemist Gerhard Schräder and his team had already synthesized a number of organophosphates that had potential for commercial use as insecticides, but some (e.g., tabun and sarin) were so toxic to mammals that these were given to the Nazi military authorities for development as chemical warfare (CW) agents (*see* Organophosphates). One particular type of OP compound, an organothiophosphate called parathion, was also synthesized in Schräder's laboratory. Since that time, parathion has been used as the generic name for the insecticide ethyl parathion (O,O-diethyl O-p-nitrophenyl phosphorothioate). Another closely related insecticide, methyl parathion (O,O-dimethyl O-p-nitrophenyl phosphorothioate) has been marketed under a number of trade names, including Parathion-Methyl, Bladan, and Metafos. Ethyl parathion has been trade named Parathion, E-605, Etilon, Fosferno 50, and Panthion in the United States, and it was trade named Thiophos in the Soviet Union.

Both the methyl and ethyl analogues of parathion inhibit the functioning acetylcholinesterase and are relatively toxic in mammals, but they require larger doses to cause injury or death when compared to the military nerve agents (e.g., sarin or VX). Due to safety concerns, ethyl parathion has been phased out in the United States since October 31, 2003, per agreement between its manufacturer Cheminova and the U.S. Environmental Protection Agency. The use of methyl parathion in the United States is, as of this writing in 2003, restricted to only selected applications for outdoor crop protection. Parathion has also been restricted or outlawed in several countries that once manufactured it in large quantities, including Russia, China, and India. Still, there is a risk that remaining and obsolete stocks of parathion might be used by terrorists or criminals in some sort of improvised weapon.

During the apartheid era in South Africa, parathion may have been utilized as an assassination weapon against political targets. In 2003, the U.S. Central Intelligence Agency (CIA) mentioned parathion among other possible toxic chemicals that could be utilized by terrorists, including al-Qaeda. A CIA pamphlet notes: "Organophosphate pesticides such as parathion are in the same chemical class as nerve agents. Although these pesticides are much less toxic, their effects and medical treatments are the same as for military-grade nerve agents" (CIA, p. 4). Although essentially this statement is true, caregivers should be aware that the treatment for insecticide poisoning is actually somewhat different from those of military nerve agents. For example, in the case of insecticide poisoning, the required dosages of atropine can be substantially higher and longer term than, say, for sarin. As with other toxic OP compounds, exposure to significant amounts of parathion can lead to dizziness, sweating, blurred vision (pinpoint pupils), respiratory distress, nausea, convulsions, and possibly death.

PERFLUOROISOBUTYLENE (PFIB)

Perfluoroisobutylene (PFIB) is an industrial gas, most often produced as a by-product from the production of Teflon (polytetrafluoroethylene). PFIB has also found uses as an intermediate in some industrial processes, including etching for semiconductor fabrication. The cause of "polymer fume fever," PFIB has the potential to be an asphyxiating weapon, causing pulmonary edema even at very low concentrations. The high toxicity profile of PFIB (about ten times as toxic as phosgene) and its wide availability have made this compound a Schedule 2 toxic substance (an industrial chemical controlled to prevent its proliferation) in the Chemical Weapons Convention (CWC).

Like phosgene gas (carbonyl chloride), PFIB has a latency period between exposure and symptoms. Although toxicity data are sparse, in humans this latency period is estimated to be between 1 and 4 hours before signs of pulmonary edema manifest themselves. Because of PFIB's high toxicity and the fact that it could "break" protective filters used by military forces, some have speculated that the Soviet Union (and perhaps other countries) once weaponized PFIB. It was therefore brought to the attention of the Conference on Disarmament in 1989 by the United Kingdom, and PFIB was subsequently entered into the CWC. PFIB produced as an off-gas from incendiary fires or other heat sources is also a potential hazard, as militaries around the world often employ Teflon in fibers, tarpaulins, and other materiel.

PHOSGENE GAS (CARBONYL CHLORIDE)

Not to be confused with phosgene oxime, phosgene gas (carbonyl chloride) is a classic lung irritant (choking gas) first used in World War I. The British chemist John Davy (1790–1868) is credited with having synthesized phosgene by combining carbon monoxide and chlorine in the presence of light, hence the name (*phos* = light, *gene* = born of).

Because of Germany's rapidly growing chemical industry, which existed well before World War I, there was already large capacity for phosgene production as a dye intermediate. The first known battlefield use of phosgene occurred on 19 December 1915 at Nieltje, in Flanders (Belgium). Here the German military combined phosgene and chlorine gas, releasing 88 tons of these from cylinders. Augustin Prentiss reported that this attack caused 1,069 wounded and 120 fatalities (Prentiss, p. 155). Used throughout the remaining years of World War I, with the advent of protective masks (respirators) phosgene became less and less effective.

The typical course of phosgene poisoning is delayed up to 24 hours. Phosgene, upon being inhaled, reacts with vital proteins, setting off a chain of events that disrupt the delicate tissues in the lungs. Battlefield injuries caused by phosgene were often insidious, as the following description by a World War I contemporary relates: "There are records of men who have undergone a phosgene-gas attack and who seem to have suffered slightly, but have died suddenly some hours later upon attempting physical effort" (Prentiss, p. 156).

Phosgene has a toxicity about ten times that of chlorine gas. Of the chemicals used during World War I, phosgene was particularly deadly, killing some 80 percent of its victims. However, it did not prove to be nearly as effective as mustard for causing large numbers of casualties (that is, dead and wounded) across the board.

A Schedule 3 industrial chemical regulated by the Chemical Weapons Convention (CWC), phosgene continues to be produced in large quantities (millions of tons per year) in the modern chemical industry. The diversion or sabotage of phosgene could pose a risk by its use in chemical terrorism. In 1994, there was an instance in which terrorists of the

Aum Shinrikyo attempted to assassinate a Japanese reporter (Shoko Egawa) by piping phosgene through the mail slot in her apartment door. The victim of the attack suffered no permanent injury, however, due to an insufficient concentration of gas.

PHOSGENE OXIME (CX, DICHLOROFORM OXIME)

Phosgene oxime (CX) appears often in the military chemistry literature, but in practice it is a relatively obscure chemical warfare (CW) agent. Phosgene oxime (not to be confused with phosgene gas, that is, carbonyl chloride) is also known as dichloroform oxime. Not to be confused with phosgene gas (carbonyl chloride), the basic formulae for phosgene oxime and related compounds were first discovered in 1894 by R. Nef and J. U. Scholl. Phosgene oxime was also synthesized by German chemists in 1929. Although the Soviet Union and Germany had researched this compound for possible use in chemical weapons before World War II, the United States military was largely uninterested, as its scientists (incorrectly) believed it had little to offer as a CW agent.

Phosgene oxime generally falls into the category of vesicants or blister agents, but this is mostly out of convenience. In contrast to sulfur mustard, another vesicant, phosgene oxime has little or no latency period, and its mechanisms of injury are not well understood. Small amounts of phosgene oxime cause painful irritation 5–20 seconds after exposure to unprotected skin. Perhaps phosgene oxime is better thought of as an urticant or nettle gas, having an effect similar to the painful effects of the stinging nettle plant. Although its structure is different from phosgene gas, phosgene oxime does share some of its properties as a lung irritant, in addition to its extremely irritating effect on the skin. According to Siegfried Franke, a "rash appears on the skin without the whole body's having come into contact with the substance. It is very intensive, unpleasant, and distracts the victim completely from his tasks. In general the itching effect of the aerosols begins on the hands and face and then spreads over the whole surface of the body" (Franke, p. 165).

A colorless, crystalline solid, phosgene oxime would likely be delivered as a thermal fog for battlefield use. There are no confirmed reports, however, of phosgene oxime ever having been used in warfare. In the chemical weapons literature, phosgene oxime has been used with other chemicals, including mustard or perhaps VX, to give these agents an increased penetrative ability. Phosgene oxime is also noteworthy for its ability to penetrate protective clothing—including rubber—faster than other CW agents.

There are probably few substances in organic chemistry that exert such a violent effect on the human body as phosgene oxime. Although not a true blister agent in the sense that its effects on the skin are different from mustard or lewisite, phosgene oxime produces an almost immediate and extremely painful irritation to the skin, eyes, and respiratory system. Some sources indicate that a full body rash can result from even limited contact with phosgene oxime, including the production of wheals. Sores and necrotic lesions on the skin require extensive time to heal, and, as with other blister agents, skin damage done by phosgene oxime can serve as focal points for opportunistic infections. Long-term effects of phosgene oxime have also been described, with injuries to the skin lingering for up to a year. As in the case of vesicants such as mustard, there is no prescribed regimen for treating exposure to phosgene oxime other than decontamination, antibiotics to stave off infections, and other supportive care.

PINE BLUFF, ARKANSAS

The chemical warfare arsenal established in 1941 in southeastern Arkansas, 8 miles northwest of the city of Pine Bluff, was originally a site for the manufacturing of magnesium and thermite (a metallic-based incendiary) munitions. Pine Bluff's mission expanded to include extensive production of chemical agents, storage for a portion of the U.S. chemical weapons stockpile that was manufactured off-site, and production of biological weapons and munitions. After the termination of the U.S. offensive chemical weapons program, Pine Bluff Arsenal became Pine Bluff Chemical Activity, a storage site for approximately 12 percent of the original U.S. chemical weapons stockpile. Construction of an incinerator to destroy those weapons was completed in 2002. Disposal of agent and munitions was slated to begin in April 2004 after a period of testing of the disposal process.

Pine Bluff Arsenal produced both conventional and chemical munitions. Chemical agent production and weapon filling capabilities were quickly added, allowing the facility to produce and weaponize millions of pounds of the blister agents mustard and lewisite. In addition to the mustard agent stored on-site, Pine Bluff's storage igloos (large, reinforced storage structures covered with earth) also include 90,000 M55 rockets filled with sarin, almost 20,000 M55 rockets containing VX, and some 10,000 VX mines. These had earlier been transferred from other military storage locations during the 1950s and 1960s, before President Richard Nixon halted the transport of chemical weapons in 1968. The Pine Bluff Chemical Disposal Facility will use the army's baseline incineration method to destroy 3,850 tons of chemical warfare agents. In addition to the agent production facilities located at Pine Bluff, the arsenal also produced a variety of chemical weapons-related equipment, munitions, and protective material. This mission eventually expanded until Pine Bluff became the sole location for repairing and rebuilding several types of gas masks as well as one type of breathing apparatus.

In 1978, the U.S. government chose Pine Bluff as the location for research into and production of binary chemical weapons. After Congress authorized the production of this new type of chemical weapon in 1985, the M-687 binary projectile was produced at Pine Bluff, and one of the two canisters used in the projectile was filled at Pine Bluff. (The other canister was filled at the Louisiana Army Ammunition Project.) When the United States signed the Bilateral Destruction Agreement with the Soviet Union in 1990, the Department of Defense discontinued the program.

Pine Bluff was also a central part of the U.S. biological weapons program. Originally called the X-201 Plant, the biological facility at Pine Bluff was finished in 1954 and renamed the Production Development Laboratories. Later, a virus and rickettsia production plant was added. Between 1954 and 1967, at least seven different biological agents were produced: *Brucella suis* (brucellosis), *Francisella tularensis* (tularemia), *Coxiella burnetii* (Q-fever), Venezuelan equine encephalitis (VEE) virus, *Bacillus anthracis* (anthrax), botulinum toxin (botulism), and staphylococcus enterotoxin B. Pine Bluff also produced and filled many of the munitions used in the U.S. biological weapons program.

In the 1960s, U.S. offensive biological weapons activities included not only antipersonnel weapons but also antiagriculture weapons. Wheat stem rust and rice blast disease were among those agents produced at Pine Bluff Arsenal. When the United States discontinued its biological weapons program after President Richard Nixon renounced these weapons in 1969, Production Development Laboratories became the National Center for Toxicological Research. It now conducts research to support the regulatory activities of the Food and Drug Administration. All the antipersonnel biological agents at Pine Bluff Arsenal were destroyed between 1971 and 1972. Biological antiplant weapons were destroyed in 1973.

PLAGUE

Plague is one of the oldest diseases known to humankind. The first documented plague epidemic occurred in 542 B.C. in Egypt, and it spread worldwide within four years. This plague lasted 50-60 years, and probably led to the death of 100 million people. The second epidemic was from 1346 to 1356, causing 13 million deaths in China and 20–30 million deaths in Europe. The most recent plague epidemic began in 1894; it started in China and spread to Hong Kong, affecting 26 million people. The common name of the plague is "black death" because cyanosis (a bluish or purplish discoloration due to lack of oxygen in the blood) causes the victim's skin to darken during the terminal stage of the sickness.

There are two forms of the disease found in humans as well as animals: classic bubonic plague and pneumonic plague, the inhalation form of the disease. Bubonic plague occurs from an infectious flea bite, while person-to-person spread of plague is possible through infectious aerosols (such as those produced by coughing or sneezing). In a biological warfare context, pneumonic plague would present the greatest threat.

The bacterium that causes plague is *Yersenia pestis* (formerly *Pasteurella pestis*), a gram-negative (so-called because it does not absorb gram's stain) bacterium. Virulent plague bacteria secrete a variety of substances that protect them against the body's defenses, and are triggered with elevated temperature found in the body (37 degrees C). These so-called virulence factors include F1 and VW.

In bubonic plague, the disease begins with a flea and host life cycle. In total, about 340 species of mammals can be hosts for fleas, and thirty varieties of fleas can be transmitters of *Y. pestis.* Animals such as squirrels, prairie dogs, and other rodents can harbor plague. Fleas feed on infected animals, taking in a blood meal. Infectious material containing *Y. pestis* bacteria clog the upper gut (proventriculus) of the flea. When this occurs, the flea can no longer take in nourishment. Now desperately hungry, it attempts to bite other animals, including those usually not typically associated with fleas (including humans). In the course of biting, the flea may disgorge the bacteria-laden material into the wound, infecting

Plague has struck down whole populations since at least 430 B.C. (Corbis) the animal. When a host (such as a rat) dies, its infected fleas move to other, living rats and pass the disease along. When infected fleas bite a human, bacteria enter the dermal lymphatics (the draining system that handles foreign matter, including pathogens). The plague bacteria eventually reach the nearest lymph node, frequently in the groin due to the fact that fleas often bite at the lower extremities. This route of infection results in bubonic plague, presenting with swelling of the lymph nodes such as those in the groin after a 1–8 day incubation period. The term bubonic comes from the Latin and Greek derived term for groin (bubo). However, bites that occur in other parts of the body may result in swelling of the nodes found in the armpit or neck. Headache, chills, sudden fever and vomiting often follow. Without medical treatment bubonic plague has a mortality rate of 50 percent. Left untreated, bubonic plague may develop into systemic infection of the blood (septicemic plague), then to the pneumonic form (100 percent fatal without treatment). In the latter case, bacteria seed the lung, forming infectious material that can be exhaled as aerosolized particles.

When a person inhales *Y. pestis,* it becomes pneumonic plague. Infection by inhalation occurs between humans in natural conditions, but it is more rare than bubonic plague. This infection route is caused by sneezing and coughing with bloody sputum. Pneumonic disease has an incubation period of two to eight days. The onset of the symptoms includes malaise, high fever, chills, headache, and myalgia (muscle pain). Pneumonic plague usually causes more severe sickness than bubonic plague. Death from this form of plague is due to respiratory failure and septicemic shock.

Early diagnosis of the plague is important because early treatment is critical in saving the patient's life. Extreme caution must be exercised by caregivers because the plague is highly infectious.

Plague can be treated with antibiotics. Without treatment, the pneumonic plague mortality rate is almost 100 percent; thus early treatment is especially critical for pneumonic plague. Bubonic plague usually responds well to antibiotic treatment. Vaccines can also help in defending against plague. The vaccine made from killed plague cells is not considered to be highly effective against the pneumonic form of the disease. It is important to prevent the spread of plague at the source, notably through control of rodents and using insecticides such as DDT to kill the vector (fleas).

The Plague as a Biological Weapon

Yersenia pestis is one of the strongest candidates for biological weapons because it is easy to culture and therefore can be mass produced. Additionally, *Y. pestis* can form an aerosol, and infection by inhalation causes the deadliest form of plague, pneumonic plague. From the 1930s until 1945, the Japanese, under the command of General Shiro Ishii, developed plague as a biological weapon. They devised a porcelain bomb that contained many infected fleas. When the bomb hit the ground, the porcelain shell was shattered and the fleas were released into the surrounding environment to spread the disease. According to some reports, these bombs offered an 80 percent survival rate for the fleas loaded inside the munition. Until President Richard Nixon announced the termination of biological weapon preparation in 1969, the United States was also engaged in defensive as well as offensive research of plague as a biological weapon. In former Soviet days, several thousand scientists were involved in a plague project at ten different institutes. By the 1980s the Soviet Union had weaponized a so-called "super plague." American scientists, on the other hand, failed to successfully weaponize *Y. pestis* during the 1950s–1960s.

The inhalation route is a good means for spreading biological weapons. Pneumonic plague is contagious and can easily spread from person to person. According to a World Health Organization (WHO) estimate, there would be 5 million people infected and 150,000 deaths if only 50 grams of *Y. pestis* were spread into the air as an aerosol over a major metropolitan city. As previously mentioned, unless it develops into pneumonia from the septicemic form of the disease, bubonic plague is typically spread by flea bites.

In the United States, there is naturally occurring plague, with ten to fifteen cases every year, mainly in the southwest. The last urban plague epidemic occurred in the United States in 1924 in Los Angeles. Since then, plague cases have usually been sporadic and have mainly occurred in rural areas of the country. Therefore, any modern-day plague epidemic is likely to be a result of bioterrorism, not a naturally occurring outbreak.

Detection of the exact strain of plague used in cases of bioterrorism is extremely important. Naturally occurring plague is mainly studied at the Centers for Disease Control (CDC) Division of Vector-Borne Infectious Diseases in Fort Collins, Colorado. To deal with the eventuality of a bioterrorist attack, the CDC lab is making genetic maps of more than 1,000 plague strains. The plasmid (bacterial DNA) profiles on the map could be compared with intentionally released plague to facilitate the identification of the source and origin of any plague used. The effect of plague on people during a bioterrorist attack would vary depending on conditions such as weather, time of day, topography of the area, and delivery system (sprayed from an airplane or sprayed on the ground) at the time of release.

Countries—or plausibly terrorist organizations—could bioengineer plague bacteria to make them resistant to antibiotics and able to lodge deeper in the lungs, making the new strains more lethal than the normal plague. With the advancement of biotechnology, it is relatively easy to make antibiotic-resistant plague by inserting antibiotic-resistant genes into the plague bacteria.

One problem in combating bioterrorism is that the release of plague is not immediately detectable. One or two days after a terrorist attack, however, patients with pneumonic plague would start appearing. The incubation period for pneumonic plague is one to eight days. Therefore, if a large number of pneumonic plague victims were observed within a short time span, a bioterrorist-related outbreak could be suspected. Alternatively, if it were a natural epidemic outbreak, the occurrence of the disease would usually spread over a longer period of time.

To improve consequence-managing capacity in the event of an attack, the U.S. Department of Justice conducted a simulated exercise of plague outbreak due to bioterrorism in Denver, Colorado, from May 20 to 23, 2000. The exercise gave valuable lessons, and the following conclusions were reached:

1. Political leadership in the decision-making process was critical. The process of decision making by conference call was highly inefficient and led to indecision and significant delays in taking action.
2. Assignment of priorities for the use of scarce resources and implementation is important. An antibiotic distribution plan should be improved in case of bioterrorism attack.
3. Facilities for drugs and medical equipment were inadequate and should be expanded.

PLASTICIZED EXPLOSIVES

Plasticized explosives (or simply plastic explosives) is the term that describes the formulation of high explosive compounds—such as RDX (Royal demolition explosive)—in a form that is easily shaped for a variety of civilian and military uses. Some of the more popular forms of plastic explosives, such as C-4 and Semtex (made in the Czech Republic), have been widely used in terrorist attacks since the 1960s. With regard to weapons of mass destruction, as we have seen in the Oklahoma City bombing (1995), cheaply and mass-produced explosives such as ANFO or TNT (trinitrotoluene) could be used to kill large numbers of people and destroy entire buildings. Due to their relatively high expense and more specific roles, plastic explosives are therefore more likely to be found as triggering mechanisms or in smaller-scale attacks.

POINT SOURCE

A device that disperses chemical, biological, or radiological (CBR) contamination from a single stationary location is known as a point source, the other major form of delivery being known as a line source. CBR agents are typically disseminated as an aerosol, gas, powder, liquid, or vector. Dissemination can be achieved by a variety of delivery mechanisms, including sprayers, bombs, bomblets, and missiles.

The term *point source* is generally associated with CBR agents that are released into the atmosphere as an aerosol or gas, but it can be applied to any combination of dissemination modes and mechanisms. For example, a bomb might explode, releasing an agent in the form of an aerosol into the atmosphere. Or, a 55-gallon drum may discharge a slow, steady stream of agent into a reservoir. In both of these cases, the agents have been dispersed from point sources. The motivation for classifying a source as point, line, or area arises from the need for understanding the spatial and directional characteristics of CBR contamination. This information is further used to develop vulnerability assessments and prepare emergency response plans.

There are numerous historical examples of CBR agents being deployed from a point source. One of the earliest recorded uses of CBR agents occurred in the fourteenth century when Tartar warriors launched plague-infected corpses over the city walls of Kaffa during a siege of the city. Although it is likely that infected rats were the likely cause, the plague-infected corpses were intended as a vector to disseminate the disease. As this strategy was employed at a single, confined geographic location (Kaffa), in a sense the entire city became a point source for the plague (*see* Kaffa, Siege of). As another example, in 1979, the Soviets accidentally released anthrax from a military compound in Yekaterinburg (this was known as Sverdlovsk incident). Again, as the agent was released from a single, confined, geographic location, the military compound is considered to be a point source for the anthrax (*see* Sverdlovsk Anthrax Accident).

An agent released into the atmosphere is affected by meteorological conditions: temperature, pressure, wind direction, and wind velocity. Atmospheric releases are either a continuous plume or an instantaneous discharge (puff). Most releases will be of a short duration because of the constraints on the total available mass of the CBR agent. If the total time of release is much less than the transport time between the source and downwind receptor, then the cloud is best modeled as an instantaneous release. Atmospheric effects diffuse a CBR cloud as it moves downwind from the source and generally form a cloud that is roughly one-third as wide as it is long. The cloud is carried downwind, spreading at a 30-degree angle to either side of the wind direction. Average casualty rates for unprotected populations can be predicted if information on the agent, distance from the point source, and wind speed are known. The exposure hazard is a function of both the CBR agent's concentration and the duration of exposure to the agent.

Recent trends in research and development have focused on improving wide-area, long-range, standoff, and remote agent detection systems that can increase early warning time and assist in consequence management.

PORTON DOWN, UNITED KINGDOM

The Chemical and Biological Defence Establishment of the British Ministry of Defence (MoD) is situated at Porton Down, a 7,000-acre site on the Hampshire-Wiltshire border in the Test Valley and Salisbury districts of southern England. Porton Down was established in 1916 as a top-secret chemical weapons test center. During World War II, its scientists began researching biological weapons, which became top priority during the Cold War. The United Kingdom relinquished its offensive chemical and biological weapons (CBW) capability in 1956 due to cost considerations and publicly admitted its existence in the 1960s. Since the end of World War I, over 23,000 people have taken part in experiments at Porton Down, some of these including human volunteer experiments involving chemical and biological agents. More than 300 ex-servicemen claim to have suffered disabilities, ranging from breathing difficulties to kidney complaints, as a result of tests carried out at the center.

Today, Porton Down conducts research and development on CBW defensive measures in four areas: hazard assessment, detection/identification, protection/decontamination, and medical countermeasures. It also provides expert advice to the United Nations, including the UN Special Commissions on Iraq. Current research includes biochemistry and inhalation toxicology (toxicity of gases, vapors, and aerosols of chemicals); full facilities for histopathology, including light and electron microscopy; drug evaluation; vaccine research; physiology; surgical and materials specialization; biological containment suites for dangerous pathogens (airborne infections); containment facilities for toxicological studies; an outdoor laboratory licensed for chemical trials; chemical laboratories for hazardous and supertoxic chemicals; vapor and particulate filter testing and evaluation; ultra-trace analysis of organic materials in media; and biological and chemical munitions disposal.

With 3,000 employees, Porton Down was retained as a government agency and was renamed the Defence Science and Technology Laboratory (DSTL) following government restructuring in 2001. It was empowered to develop and evaluate new technology to provide solutions for civil and military customers worldwide. In this capacity, it manages chemical and biological defense research programs as well as carrying out key functions relating to the overall integration of the results of the U.K.'s defense science and technology programs. DSTL Porton Down conducts research at the defense systems level and conducts management of international research collaboration. At the height of the U.K. foot-and-mouth disease epidemic in 2001, Porton Down also provided fast-track advice on cull disposal options for infected carcasses.

Porton Down is one of twelve laboratories worldwide designated to analyze chemical samples collected by inspectors implementing the 1997 Chemical Weapons Convention (CWC), the first arms control treaty that introduced a verifiable ban on an entire class of weapons of mass destruction. In other activities, the DSTL Porton Down Balkans Operation Support Group helped the scientific community to support the military during the conflict in Kosovo in 1999. Research agreements with the United States account for around one-half of Porton Down's collaborative research and development work. This collaboration includes the Atmospheric Dispersion Model for risk analysis of chemical and biological terrorism. In collaboration with Australia, DSTL Porton Down also developed and deployed support security operations for the 2000 Olympic Games in Sydney.

The Porton Down Biomedical Sciences Department provides the U.K. MoD with the science base for the development of effective medical countermeasures for chemical and biological agents, as well as ballistic countermeasures for military personnel. Its research efforts focus on expedient surgical approaches; vaccine development; and the fields of microbiology, biochemistry, genetic manipulation, and microbiological containment. Other developing capabilities include drug evaluation, toxicology, pharmacology, physiology, behavioral sciences, trauma and surgery, and animal breeding.

The environmental sciences department provides a science and technology platform to enable the Ministry of Defence to manage, monitor, and control biological, chemical, and radiological hazards and to dispose of abandoned chemical weapons safely through secure transport and storage. It also plays a key role in providing a nuclear accident response capability. Porton Down serves as the U.K. authority in radiation physics, dosimetry (radioactive detection metrics), and measurement. It can conduct environmental assessments and surveys of chemical, biological, and radiological (CBR) contamination. It conducts range trials capability for testing and evaluation of defenses against CBR agents. The energetics (physics) department and detection department conduct research and development of sensors and systems for detection of chemical and biological (CB) agents and explosives, along with CB hazard assessment and consequence management.

Porton Down is the U.K.'s designated laboratory under the CWC and the national laboratory for CB attack confirmation. Its capabilities include physicochemical techniques through the use of chemistry and solid-state sensors for detecting CW agents, microbiological sensing techniques, and CB hazard assessment. Facilities at DSTL Porton Down include exposure chambers, and its scientists study bioremediation dispersion modeling and validation. Porton Down also evaluates the role of public health, environmental protection, and nongovernmental organizations in reducing the CBW threat.

There is an integral radiological protection service within Porton Down that is the prime source of radiation protection advice for the Ministry of Defence. This Demil section conducts research into the protection of individuals involved with radioactive materials, such as routine protection of patients in hospitals and during dentist surgeries from radiation sources (tracers and X-rays), surveying battlefields for depleted uranium (DU) munitions, and establishing the whereabouts of counterweights used as ballast in aircraft (also made of DU) following plane accidents.

The Demil section is also responsible for the assessment of highly contaminated environments and for the sampling, analysis, removal, transport, and disposal of extremely hazardous and toxic materials and for the Ministry's chemical weapons demilitarization. It is thus involved in environmental monitoring in Russia; the disposal of hazardous chemicals in the Far East; and battlefield cleanup in Europe. The knowledge services department provides information products to support the defense community. Its publications include Defence Reports Abstracts and Defence Technology Alerts (the latter being classified), which comprise three-quarters of a million reports dating back to World War II.

PRECURSORS

Compounds that precede the final product in a chemical reaction are called precursors. In the case of preparing toxic chemicals such as chemical warfare agents, chemical precursors are usually easier to obtain than the final toxic compound itself. To control the distribution of a particular toxic compound (such as VX nerve agent), it is essential to ban the sale of its precursors too, especially those chemicals that are closest in the chemical reaction steps to the final product.

This can be problematic, however. For example, sarin, a potent nerve gas, can be prepared from phosphorous trichloride, or PCl_3, which is usually the starting compound. PCl_3, however, has many other commercial uses, so authorities would not necessarily be alerted by its purchase. The 1993 Chemical Weapons Convention (CWC), therefore, puts PCl_3 lower on the list as a Schedule 3 precursor for regulation of export and manufacture. A Schedule 1 precursor, on the other hand, such as difluoromethylphosphonate (DF) is a key precursor to producing nerve agent (sarin or soman). As there is no industrial use for DF, and it is a highly useful substance to form the final nerve agent itself, the CWC has essentially outlawed its production (except in small quantities for defensive or peaceful purposes).

As in the case of PCl_3, some chemicals are easier to regulate than others as potential precursors for chemical weapons. Isopropyl alcohol, for example, when added to DF forms sarin nerve agent. However, isopropyl (rubbing) alcohol is found nearly everywhere, from industrial processes to the bathroom medicine cabinet. Little good would come of over-regulating this useful chemical that is sold and produced nearly everywhere. As a consequence, isopropyl alcohol is nowhere to be found in either the CWC schedules of precursors or the Australia Group (AG) list of chemical substances for export control. However, another chemical, pinacolyl alcohol, is listed in the CWC as a Schedule 2 precursor, as well as in the AG list of controlled chemicals. This is because pinacolyl alcohol has been used in the past to produce soman nerve agent, and in the commercial industry pinacolyl has very few common uses other than specialized research or in certain specialty areas (such as in pharmaceuticals). Therefore, it was easier to regulate this chemical without having to overburden the industry.

PROTECTIVE MEASURES: BIOLOGICAL WEAPONS

Biological agents are difficult to defend against, primarily because this form of attack is difficult to detect before exposure. Most biological agents have a delayed manifestation of symptoms, ranging from hours in the case of toxins to days or even weeks for bacterial and viral threats. During this delay, in the case of contagious diseases such as smallpox, airborne pathogens are possibly being passed from one person to another. Although protective suits and masks can prevent infection from biological agents, it is difficult to detect biological agents with sensors or alarms that give enough warning for personal protective measures to be put into place. It is therefore important to adopt protective measures in advance if there is a known chance that a biological agent is present. Employing protective measures before a biological attack occurs, however, will depend heavily on intelligence assessments. Ultimately, advanced research and development in the area of immunotherapy—that is, vaccines—as well as antimicrobial medications will provide the most effective protection against biological attacks.

Protecting against biological agents rests primarily upon protecting the airways from infectious particles. In a purely biological threat environment, covering the mouth and nose with any barrier to keep out particles of a size roughly between 1 and 10 microns is usually sufficient. The biological toxin of the trichothecene mycotoxin family is dermally active; however, all other biological threats are posed mainly by inhalation or ingestion, in which case the protective mask alone can prevent biological casualties.

Laboratory personnel have depended on protective clothing and equipment for years. The military has also been perfecting its defenses ever since the threat of biological weapons became a serious concern during Operation Desert Storm in 1991. The infection risk for nonmedical and nonmilitary personnel is greater because they do not operate in a controlled environment and they do not possess the advance warning devices that may be available to militaries. Still, unless humans or sentinel animals show obvious signs of infection, even military personnel still find it difficult to reliably detect biological warfare agents. Even when detected, some infections could be mistaken for naturally occurring diseases rather than recognized as a planned attack. Therefore, considerable time may elapse before it is realized that a biological attack has occurred.

Immunizations and prophylactic medications (such as antibiotics for bacterial agents) are the first line of defense available to both civilians and military personnel. For immunizations to be effective, the threat or agent must be known, there must be a vaccine available to fight off infection, and there must be time for the vaccine to take effect. (Time is also important because some vaccines must be administered in stages.) Providing vaccines to military personnel is much easier than providing the inoculations to civilians: The armed services are a relatively small and intensely observed population, and it is therefore easier to keep track of immunizations and to update shot records. The civilian population must usually take it upon themselves to seek out available vaccines and to maintain their personal health. For the armed services or civilians, however, personal health maintenance is necessary to improve the survivability of a biological attack, and up-to-date immunizations reduce the chances of becoming a casualty of a biological attack. It is important to understand what diseases or viruses are prevalent in areas of concern, and intelligence assessments should warn the armed services of biological hazards that they may come into contact with. There are many biological warfare agents, however, that have no cure or vaccine.

Collectively, buildings can be protected to a degree from a biological attack. Physical security is important; however, if an attack were to occur, special airflow and filtration systems can limit the number of people infected. HEPA (High Efficiency Particulate Air) filters capture 99.97 percent of particles 0.3 microns in diameter or larger. ULPA (Ultra Low Penetration Air) filters capture very small particles, 99.999 percent of particles 0.12 microns in diameter or larger. In the case of biological threats, the particles of most concern are usually those between about 1 and 10 microns in diameter, sometimes larger. Adequate filtration systems, together with increased physical security, can make a building a less attractive target for biological attack because the success of the attack would be minimized.

Finally, before an attack occurs, one should be aware of local response procedures for a biological attack and should have a plan, just as one would for a fire or a medical emergency. A rapid response to a biological attack will limit the amount of casualties and increase the chances for those infected to be treated promptly.

Provided that civilian and military personnel had knowledge that a biological hazard existed and knew the type of biological agent, personal protective equipment could prevent contamination and infection. Most biological weapon agents are not easily spread from person to person; the more contagious agent threats are smallpox, plague (pneumonic), and some hemorrhagic fevers. By contrast, anthrax bacteria are not likely to be contagious unless there is gross contamination.

Protective Clothing and Equipment

There are four types of biological safety postures, which differ based on the type of agent present and its virility. At a minimum, those who first come into contact with victims of a biological attack should use impermeable (surgical type) gowns, oral-nasal masks, face shields or goggles, and surgical gloves. It is important to wear a protective mask, to keep the clothing buttoned, and to treat any unknown agent as if it were a chemical agent requiring the highest degree of skin and respiratory protection. The types of suits and masks and the levels of protection they provide follow.

Biosafety levels describe the type of protective clothing worn and the equipment and room attributes that must be present to provide that level of protection from biological agents. Biosafety level 1 (BL 1) provides the lowest level of protection. It provides a basic level of containment and can be effective when the microorganisms present are not known to cause disease in human beings and when the potential hazard to laboratory personnel or the environment is minimal. Gowns and gloves are used, and eye and face protection may be required if there is a splash potential. There should be a sink for washing hands in a laboratory environment, and work areas should be kept sanitized. When a sink is not available, some other method for washing hands should be employed.

Biosafety level 2 (BL 2) is required when there is a moderate potential hazard to personnel and the environment. Immunization or antibiotic treatment should be available for the infectious agent. Gloves and lab coats should be used, mechanical devices should be used to prevent contact with blood or other bodily fluid that may hold the infection, and care should be used to not injure oneself with sharp needles, broken glass, or other sharp objects that may be contaminated. Immunizations are important for protecting against infection from level 2 agents. Equipment such as safety cabinets and eye and face protection should be used for protection against splashes and aerosols. (A safety cabinet is a work area that is usually attached to a ventilation system and is enclosed on all sides except for the front to limit splashing and spills.) An eye wash station and equipment to sterilize protective clothing, such as an autoclave, should be available. (An autoclave uses pressurized steam to sterilize equipment and clothing.)

Biosafety level 3 (BL 3) is required when the potential hazard is an infectious agent that can cause serious or lethal disease from inhalation of the agent. A mask that provides respiratory protection is necessary in addition to face protection, as well as coveralls for the body and gloves for the hands. To the extent possible, it is necessary to seal off the contaminated area using double-door entries and other secondary barriers. Safety cabinets or glove boxes (fully enclosed work areas attached to a ventilation system) should be used as work areas. For glove boxes, protective gloves are built into the work area so that work can be done with level 3 biological agents.

Biosafety level 4 (BL 4) is required for work with dangerous and exotic agents that pose a risk of being transmitted by aerosol and are life-threatening, and for which there is no available vaccine or reliable treatment in the case of infection. The BL 4 suit provides complete isolation from the infectious material. It is a full-body suit including gloves, boots, and protective mask that is airtight with a positive pressure air supply, ensuring that any potentially hazardous particles will be expelled outward from the wearer. The air supply may be an individual tank or may be sourced from a wall unit. Containment of the infected area is most important when level 4 agents are present. In addition to the equipment used for BL 2 and BL 3 facilities (safety cabinets and glove boxes), work areas should be sealed with double entry doors, and these should be airlocked (sealed with air pressure). There should be dedicated HVAC (heating, ventilation, and air conditioning) and air filtration units. The walls and floors should be nonporous and water-resistant, and a shower and changing room should be attached to the contaminated area. When work is being done outdoors, every effort should be made to replicate these laboratory conditions with modular units constructed around the contaminated area.

Actions Following a BW Attack

Once an attack has occurred, determining what level of protection is needed is vital. The infectivity, virulence, and toxicity level of an agent will determine what types of protective measures should be taken to prevent the spread of disease after an attack. Not all biological agents pose a threat of being transmitted to another individual; however, workers should still take precautions such as barrier nursing (wearing protective clothing and never coming directly into physical contact with an infected person) and isolation (separating nonaffected individuals from contaminated victims of a biological attack).

Decontamination is an integral step in preventing further contamination after a BW attack. All contaminated clothing should be placed in an airtight, impermeable bag until the clothes are laundered in hot water and bleach or until they are autoclaved. Soap and water or a solvent should be used to wash away the biological agent from the victim's body. Ideally, all equipment or surrounding objects should be washed with soap and water or solvent as well. Some environmentally safe chemicals may be used to disinfect biological toxins.

Some medical procedures can be taken after an attack, depending on the type of biological agent used. Specific therapy can be used for many biological agents, with drugs that diminish, alter, or reverse the agent's effects. General supportive measures are used to make a victim comfortable; these do not cure the victim, but they can help ameliorate symptoms. For instance, a biological agent may cause respiratory distress; artificial ventilation is a supportive therapy that may even be crucial for survival after some attacks, such as botulinum toxin poisoning.

Advance Warning

With regard to advance warning and preparedness against a biological weapon attack, intelligence is the key. Medical countermeasures are not always available or effective. Communication networks and response plans must be in place to maximize early warning. Good intelligence must alert populations to specific threats so that personal protective measures can be employed. Information on specific biological threats can be the greatest protective measure; when the threat is known, personal protective measures and medical countermeasures become most effective.

PROTECTIVE MEASURES: CHEMICAL WEAPONS

No longer a threat limited to the battlefields of foreign conflicts, chemical and biological weapons now present a threat to civilians and government personnel as well as to the armed services. At varying levels of sophistication, terrorist organizations, state actors of concern, and even certain individuals may develop chemical warfare (CW) agents and the munitions to deliver them. By leveraging modern information technology and widening trade routes to smuggle chemical precursors—even the chemical weapons themselves—terrorists and rogue states are able to move these items across borders without much likelihood of being detected. It is therefore necessary to understand CW protective measures, both personal and collective, that can be used in the event of a chemical attack.

The first basic concept is contamination avoidance. By means of reconnaissance and through the use of detection devices, personnel are naturally less likely to become chemical casualties by avoiding toxic exposures in the first place. Should these measures fail, a range of personal protective equipment has been developed to prevent chemicals from coming into contact with the body through inhalation or exposure to skin. Finally, decontamination through the physical and/or chemical neutralization of agents can be used to mitigate chemical threats.

Types of Protective Suits

There are different levels of protection available. In the civilian context, Level A suits provide the greatest level of protection. A Level A suit is airtight and covers the entire body. It includes boots and gloves, a pressure-demand (use of air pressure to create a better seal) full-face mask with a self-contained breathing apparatus (SCBA), and a communication system (usually a two-way radio) that are all contained within the suit. This ensemble protects against vapors and should therefore be used when the highest level of protection is needed to protect the skin, eyes, and respiratory system, especially when the chemical agent is unknown. Level A protection is needed when there are high concentrations of vapors, gases, or particles and should be used when the possibility of exposure to skin is great and the contaminated environment is poorly ventilated.

The Level B suit offers high protection for the respiratory system but less in the way of skin protection. This suit will have the pressure-demand full-face mask with SCBA, but it includes only chemical-resistant clothing rather than an airtight suit. The chemical-resistant clothing consists of coveralls, gloves, boots, and sometimes a hard hat, as well as two-way radios. The Level B suit should be used when the chemical is known and is not harmful or absorbed through the skin, or when the concentration requires respiratory protection but only limited skin protection. The Level B suit is usually sufficient for these chemicals, whether in liquid, gas, or vapor form. Emergency teams that deal with hazardous materials (hazmat) incidents most often use Level B suits.

A Level C suit is used when a substance has been identified and it is known that air-purifying respirators alone will provide adequate protection. A Level C suit will have a full-face shield or a half mask, and requires only an air-purifying respirator (no SCBA), and hooded, chemical-resistant clothing such as coveralls, gloves, boots, and sometimes a hard hat and two-way radios. The Level C suit can be used when direct contact with the chemicals will not affect the skin, or when the chemicals will not be absorbed into the skin.

The Level D suit provides only minimal protection. This type of suit is worn when there are no known atmospheric hazards, but when work-related activity could produce splashes, immersions, or the potential for chemical inhalation. The ensemble in this case might consist of coveralls, a lab coat or other outer layer for minimal protection, and possibly a face mask such as a surgical mask to minimize inhalation of nonlethal but hazardous chemicals.

Chemical protective clothing is designed to prevent chemicals from coming into contact with the skin. It is made from special materials and can be either permeable or impermeable. Impermeable suits are used for hazardous materials situations when the airtight feature of the Level A suits is required. Permeable suits have a charcoal lining to provide added protection. Military-issue protective clothing is usually permeable. Impermeable suits are less costly than permeable suits, but they are often disposable and only intended for one-time use. They are also extremely uncomfortable when worn for long periods of time in the field. Permeable suits can be used again, depending upon the overall quality of the garment and the nature of the activated charcoal layer. Impermeable suits have an increased level of heat buildup inside the suit, whereas permeable suits allow for some air transfer and are generally cooler to wear. Impermeable suits, however, can be exposed to water and can be used during decontamination operations, whereas water can decrease the overall effectiveness of permeable suits. The latter are more durable than impermeable suits, however, and are used for tactical operations and when extreme physical conditions are present, such as high temperatures.

There are several types of masks that can be used for respiratory protection in the case of a chemical attack. Escape masks have a hood and filter or air supply and are used to provide respiratory protection for a short duration, usually only long enough to evacuate from a suspected contaminated area. There are several problems with escape masks, however: It is difficult to communicate when wearing one, the face piece causes claustrophobia in some individuals, and it is difficult to maintain a tight seal around the face, allowing contaminants to enter the mask.

A negative-pressure respirator is the most common type of "gas mask." It provides Level C protection but is not recommended for situations in which the agent contaminant is undetermined or the concentration of agent in the air is unknown. Most importantly, there must be an oxygen level of at least 20 percent in the atmosphere in order to use a negative-pressure respirator. Communication will still be limited when wearing this type of mask, but voice amplification adaptors can be installed to enhance the ability to communicate.

Powered air-purifying respirators (PAPR) are similar to negative-pressure respirators, except air is supplied by a battery-powered pump that forces air through the filter in the face mask. This type of mask makes it easier to breathe and reduces heat buildup because of the stream of cool air filtering into the mask. However, there are several disadvantages: The hose that connects the blower to the filter can get in the way and may easily get caught on something, pulling the mask away from the face. The hose could also be damaged and the air supply cut off. This type of mask is heavy, the blower is loud, and the wearer's communication capability can be reduced.

A self-contained breathing apparatus provides the greatest level of respiratory protection. A SCBA uses a clean air supply from a tank or from a stationary oxygen source located near a work station. Although SCBA provides the greatest level of protection, the self-contained air supply does run out and must be changed. This can significantly disrupt operations. The SCBA units are also costly to purchase and expensive to maintain.

In most respects, respiratory exposure to chemical agents is usually more dangerous than skin exposure. However, in the case of some threats (e.g., VX nerve agent), skin exposure can be just as deadly. The overgarment/suit, gloves, and boots provide protection for the skin. There are different types of overgarments (one-piece, two-piece, hooded, etc.). A suit's level of protection is determined by whether or not it is fully encapsulating or non-fully encapsulating. Level A overgarments are airtight and fully encapsulating. Level B and C overgarments are non-fully encapsulating and offer less skin protection. Gloves capable of protecting against chemical agents should be made of butyl rubber or a similar substance, and the thickness of the glove will offer added protection but with a trade-off in hand dexterity. There should always be a balance between effective protection and maintaining the ability to perform daily activities in protective gear. When contamination is possible, individuals should err on the side of increased protection.

There are two types of footwear for chemical protection: booties that are part of the overgarment, or full boots that can be worn over shoes. Full boots worn over shoes provide the greatest protection. They are usually made out of a thick rubber and cover the foot and the bottom part of the leg. When worn with protective pants or coveralls, there is less chance for leaks to enter at the opening of the boot.

U.S. Military Force Protection

In the U.S. military, the doctrinal approach to chemical defense equipment in the field is referred to as the mission-oriented protective posture (MOPP). Defense levels are rated from MOPP I to MOPP IV, depending upon the severity of the threat. For example, at MOPP I, a battle dress overgarment (BDO) is worn to serve as some barrier against most agents, and M9 chemical detection paper is worn on the sleeves and near the ankles. Such a posture is for a chemical threat whose nature or severity is not yet determined. At MOPP IV, the entire body must be covered, using a protective mask, hood, and rubber gloves. The newer Joint Service Lightweight Integrated Suit Technology (JSLIST) protective overgarments incorporate a fabric surface layer that beads off liquid threats, and an advanced, activated charcoal layer using tiny beads to absorb toxic agents before they reach the skin. The M40 chemical-biological field mask, currently being used in the U.S. military, is another advancement, with improved fit, a seal around the face, and better visibility. The C2A1 filter canister consists of charcoal, filter elements to remove small particles (greater than 3 microns in diameter), and zinc to inactivate chemicals.

Personal protective equipment should be put on in a specific order so that the most critical areas are protected first. When first alerted to a contamination, the face mask and respiratory apparatus is donned first. The body's respiratory system should be protected first because chemicals have the greatest and most rapid effects when inhaled. Next, the greatest surface area of the body should be covered by putting on the overgarment. Then, the boots and gloves are put on, making sure that the overgarment's sleeves and legs are on the outside, so that chemicals cannot easily fall down into the boots and gloves. Finally, a hard hat or extra protection such as a splash guard apron can be put on for further protection.

Collective protection equipment will allow groups of people working in a chemical-contaminated environment to receive protection while limiting the need for personal protective equipment. Collective protection is necessary when an area is exposed to contamination for an extended period of time. There are modular rooms that can be assembled with filter units to eliminate contaminated particles and vapors from entering the room. There also are hybrid systems that use positive pressure and ventilation. Positive pressure reduces the amount of vapor contamination that enters a vehicle or room, and protective entrances on modular rooms provide separation between a contaminated and a protected environment. Decontamination procedures must be used before entering a protected environment. Chemical detection and monitoring alarms are another form of collective protection. They warn when an area has a significant level of contamination so that personal protective measures may be employed.

Decontamination

Decontamination is a secondary protective measure used to prevent the spread of contamination to others. Both equipment and personnel should be decontaminated. Chemicals can be removed physically or chemically (using other, nontoxic chemicals to deactivate harmful agents). Physical methods involve washing with soap and water or a solvent, vacuuming, brushing and scraping, absorption, and disposal of contaminated clothing and material used in the decontamination process. Physical methods can be used whether the chemical has been identified or not. Chemical methods are primarily used on equipment. This process uses some type of chemical reaction to render an agent ineffective and less harmful to the environment through disinfecting, sterilization, neutralization, solidification, or degradation.

When decontaminating people, all gross signs of contamination should be removed first by scraping, sweeping, or blotting, and then all clothing should be removed. Clothing that needs to be removed over the head should simply be cut off. Next, the person should remove all watches, eyeglasses, or other items and flush the eyes with large amounts of water. Next, the face and hair should be washed with soap and water and thoroughly rinsed. The person should then begin to wash the rest of the body starting at the neck and working down, so that any remaining chemicals will not be spread to the face and eyes, which have already been decontaminated. Personnel can then change into uncontaminated clothing.

Both personal and collective protective measures are essential to maintaining a protected environment. Familiarity with equipment and protective procedures can dramatically reduce the number of chemical casualties in an attack. Knowing, understanding, and training with personal protective equipment and collective protective equipment can truly be an effective defense against the use of chemical weapons.

Franz, eds., *Textbook of Military Medicine, Part I: Warfare, Weaponry, and the Casualty: Medical Aspects of Chemical and Biological Warfare* (Washington, DC: Borden Institute, Walter Reed Army Medical Center, 1997), pp. 361–396.

PSYCHOINCAPACITANTS

As chemical warfare (CW) agents and potential mass casualty weapons, psychoincapacitants are designed to render military personnel and other targeted individuals incapable of performing even the most basic tasks. The ideal psychoincapacitant does not cause death or permanent damage, and its effects are temporary, lasting long enough for the attacker to achieve tactical advantage on the battlefield. BZ (3-quinuclidinyl benzilate) was the only psychoincapacitant standardized by the U.S. military (1962). Other militaries, including Iraq and the former Yugoslavia, are also suspected of having developed BZ or similar agents. The Iraqi version was called Agent-15. The use of such CW agents is outlawed by the 1993 Chemical Weapons Convention (CWC), and the United States was thereby obligated to destroy all of its remaining stocks of psychoincapacitants.

A 1956 working paper written at the Operations Research Office at Johns Hopkins University identified several targets as being vulnerable to psychoactive chemical attack:

a. Attacks on key personnel to impair their judgment and lead to poor decisions at a critical time
b. Psychochemical attacks on the population of a city prior to attack by other means, to destroy effective protective measures and/or resistance
c. Attack on [Strategic Air Command] or other military organizations to impair or destroy effectiveness (Gardner, p. 2)

Unlike other CW agents, whose purpose is solely to injure and kill, a true psychoincapacitant does not cause significant harm among targeted individuals. Being nonlethal, psychoincapacitants can offer more flexibility in operations against enemy troops intermixed with civilians. To achieve a balance between potent action and low toxicity in humans, the chemical compound used must be safe enough to be absorbed in large doses without fatal consequences. Maintaining this margin of safety has proved to be extremely challenging during the course of research and development (R&D) of psychoincapacitants. Arguably, no "perfect" incapacitating agent has yet been discovered.

The United States Army, for example, researched many potential candidate psychoactive chemicals during the Cold War before finally settling on BZ (agent "buzz"). Even this compound had its limitations. Its effects were by no means immediate, requiring up to a few hours to manifest themselves following exposure. Like other compounds studied, BZ was to be delivered as an aerosol, in a device similar to military-type CS tear gas (riot control agent). This generated a large pall of smoke that was clearly visible to the enemy, and thus little tactical surprise could be achieved. And although it was decidedly less deadly than other CW agents in the U.S. arsenal, the side effects from large doses of BZ could be dangerous.

Finally, one has to consider the end result when considering use of a psychoincapacitant: will enemy personnel affected by a psychoactive drug become less or even more dangerous and unpredictable following intoxication? How will this affect operations to secure enemy prisoners of war (e.g., will prisoners become more violent, unruly, and unresponsive to commands)?

Background

Modern R&D efforts into utilizing psychoincapacitants as a means of warfare began mostly in the 1950s, a time when chemotherapy for psychological disorders was widely studied. Earlier examples of the use of psychoincapacitating agents in war go back almost 1,000 years. In his study on atropine—a chemical long known for its effects on both body ("dry as a bone, hot as a hare") and mind ("mad as a hatter")—a U.S. Army chemical researcher by the name of E. Goodman (1961) found that in 1040, Scottish armies "used wine dosed with 'sleepy nightshade' against the troops of Sweno, King of Norway" (quoted in Ketchum and Sidell, p. 289). Goodman also describes a battle during which belladonna (i.e., atropine and related substances) was used by the Bishop of Muenster during a 1672 siege of Greningen. In this case, however, unfavorable winds caused the belladonna (delivered in the form of grenades and other pyrotechnic projectiles) to blow back onto the attacking forces. Other examples from modern history include the inadvertent consumption of Jimson's weed, a plant that has belladonna properties, leading to delirium among troops.

From 1953 to 1973, the U.S. Army investigated the use of a number of chemicals that had potent but largely transient effects on human cognition and behavior, including the following:

- Depressants (barbiturates, opiates)
- Diliriants (BZ, other belladonna-like drugs)
- Stimulants (amphetamine derivatives, nicotine, etc.)

Many of the chemical substances in these categories seemed at first to hold promise as potential incapacitants. After all, most are used in medicine without excessive risk (albeit under controlled conditions), and some are used recreationally (with much less attention to their possible dangers). After these chemicals were studied in experimental animals (as well as human subjects), however, most were eliminated as viable candidates due to the fine line between their desired effects (temporary incapacitation) and permanent incapacitation (i.e., death). Lysergic acid diethylamide (LSD-25) at first seemed a promising psychoincapacitant because it had a thousandfold spread between what was needed for incapacitation and the lethal dose. However, its possible effect on the enemy might have been unpredictable, and in ways that may have been undesirable. (Would enemy soldiers not only manage to fire their weapons under the effects of LSD, but also become better shots?) Also, some individuals have had serious side effects (such as epileptic seizures) from relatively small doses of LSD.

Other chemicals investigated as possible psychoincapacitants included MDMA (popularly known on the street as ecstasy), technically a stimulant but having potent hallucinogenic properties. Phencyclidine (PCP or "angel dust"), tetrahydrocannibol (THC), and psilocybin have also been investigated for use in warfare or sabotage. But the anticholinergics, such as belladonna drugs (including atropine and scopolamine) traditionally derived from nightshade and Jimson's weed (among others), are the only drugs reliably causing sufficient delirium to incapacitate enemy troops while still being reasonably nonlethal.

Generally, the delirium induced by BZ involves hallucinations, including impairment of perception in terms of size and shapes; delirious "woolgathering" behavior (the pulling at clothing, real or imagined); and delusions played off others who also are affected by the drug. The psychological impact can be long-lasting (a day or longer) but resolves on its own. As with the other belladonna drugs, widened pupils, rapid heartbeat, flushed skin tone, and visual impairment are hallmarks of BZ intoxication. Administering a carbamate (e.g., physostigmine) can at least temporarily diminish the effects of belladonna-induced delirium, and such treatment can be used as a means to diagnose what is happening while reassuring the patient that the effects will eventually go away. Because these belladonna drugs shut down the sweat glands, the potential for hyperthermia—especially in stressful conditions of combat and field operations—is considerable, and body temperature should be closely monitored.

Another category of compounds, the opiates, has already been utilized in at least one recent counterterrorism operation in Moscow in 2002 (*see* Fentanyl). Although they are nominally included in the category of psychoincapacitants, it is uncertain whether opiates are safe enough to use in military-style operations. One advantage they have is that an antidote (Nalaxone or Narcan) is available to treat opiate intoxication. Although considered unfit for large-scale production or weaponization, opiate drugs such as fentanyl may in the past have had some applications in specialized warfare or covert operations. For example, the military use of fentanyl or similar drugs was considered for tactical roles in Vietnam. The intention was to isolate high-ranking individuals and temporarily knock them out while scattering away irrelevant logistical support personnel. The army could then bring these officers in for questioning. One of the plans was to utilize something along the lines of a tranquilizing dart with fentanyl or a related substance. In the end, however, the science advisor to General Westmoreland (commander of U.S. troops in Southeast Asia) did not approve of this venture, and only CS (a riot control agent) was ever employed in Vietnam.

In October 1997, the Israeli Mossad used fentanyl in what was either an assassination attempt or a snatch-and-grab operation that subsequently went awry. In this case, Israeli intelligence operatives (including one physician) traveled to Jordan. There, they followed Khalid Mishal, a Jordanian-based Hamas leader. The plan was to deliver fentanyl in a spray that would be absorbed through Mishal's ear, but Khalid Mishal was able to escape. Following the event, he was reportedly affected by the drug, requiring significant medical attention.

Current Uses of Psychoincapacitants

In the twenty-first century, the potential always exists for the use of psychoincapacitants in warfare (in 1995–1999, for example, Serbian armed forces allegedly used BZ against Bosnian Muslims, but this allegation has yet to be fully evaluated). The use of these potent chemicals in terrorism is also a possibility, but it is unlikely. It is much more likely that terrorists, if they were to go the trouble and expense of developing weaponized CW agents at all, would choose deadlier and more persistent chemicals (e.g., VX).

The CWC clearly prohibits the use of psychoincapacitants like BZ in war. Interest in so-called nonlethal warfare has triggered a response from critics in the arms control community that this will lead to CW under a different name. For example, a 2001 article from the Chinese military newspaper *Zhongguo Guofangbao* (*China National Defense*) refers to the cholinergic compound EA3834, which was researched by the U.S. military as an anticholinergic incapacitant. Its authors then decry so-called nonlethal weapons chemicals as being "inhumane." Although some have recently called for further clarification as to the legality of using nonlethal chemicals, the U.S. government believes that the current language in the CWC is sufficient. (BZ, for example, is explicitly scheduled as a proscribed chemical under the CWC lists of toxic chemicals, and its precursors are also controlled.) The U.S. government is not against banning psychoincapacitants, but is concerned that the prohibition might later be extended to tear gas. Thus, the U.S. government resists what it sees as a political movement toward outlawing the use of riot control agents (RCAs). Since 1975, the United States has reserved the right to use CS tear agents, for example, during combat operations under special conditions.

The Russian use of fentanyl (or a related compound) in 2002 against Chechen terrorists barricaded in a Moscow theater, although conducted as a domestic police action, highlights the problem of prohibitions on psychoincapacitants. On October 23, 2002, in the middle of an evening performance at a Moscow music theater, some fifty Chechen terrorists equipped with firearms and large quantities of explosives suddenly seized the venue, taking hostage 800 people inside. The terrorists threatened to kill the hostages unless Russia ended the war in Chechnya. Although the Chechen militants agreed to release some of the hostages during the first couple of days, their negotiations with the Russian authorities eventually stalled. Just before dawn on October 26, Russian special police units used an incapacitating gas based on the drug fentanyl to end the crisis. All of the Chechen militants were shot and killed as they slept, and most of the civilian captives survived. But although the operation was largely a success, at least 117 of the hostages died from the effects of the gas.

The fact that so many died because of poisoning from the gas has been the source of some controversy about how the entire operation was handled. But even while acknowledging that mistakes were made by the police, most Russians supported the action taken by Moscow authorities. The international community (including the executive body that governs the CWC, the Organization for the Prohibition of Chemical Weapons in the Hague) has not formally contested the Russian use of chemicals against terrorists on legal grounds.

PYRIDOSTIGMINE BROMIDE

Pyridostigmine bromide (PB) was given as a prophylactic tablet during the 1991 Persian Gulf War to protect U.S. military personnel and some other allied forces in the event that Iraqi forces attacked them with the chemical nerve agent soman. The U.S. Food and Drug Administration had approved PB in 1955 for treatment of myasthenia gravis, a neuromuscular disease that causes muscle weakness and fatigue. However, when U.S. authorities approved PB for use in the Gulf, the approval was qualified as an investigational new drug: PB had not been formally approved for general commercial marketing as a nerve gas antidote. Since the war,

Pyridostigmine bromide (PB) can be used as a pretreatment for nerve agent exposure. (Orban Thierry/Corbis Sygma)

thousands of American, British, and Australian veterans of the conflict have reported health problems such as joint pain, headache, sleep disorder, memory loss, and fatigue. The veterans report these problems more frequently than those who were not deployed, raising the possibility that PB may be linked to Gulf War illnesses.

During the Persian Gulf War, coalition forces recognized that Iraq possessed nerve agents, including sarin, and had prepared them for use in rockets, bombs, and missile warheads. Recalling that Iraq had previously employed chemical weapons against Iran and the Kurds, coalition governments anxiously tried to prepare their forces to fight in a chemical environment, something they had not done in earnest since the First World War. It was not known whether Iraq had militarized the nerve agent soman, but because the Soviet Union had produced soman during the Cold War, and because of fears that Iraq may have acquired soman from Russian sources after the breakup of the Soviet Union, coalition troops were given PB to use for protection when the threat of chemical warfare was deemed high. After the Gulf War, Iraq was discovered to have weaponized the nerve agents sarin, cyclosarin, and perhaps tabun and VX, but it probably did not possess soman.

The Defense Department estimates that approximately 250,000 personnel took at least some pyridostigmine bromide pills during the Gulf War. (All U.S. troops were supposed to receive packets containing PB pills.) The PB was intended to be self-administered upon a unit commander's order. In some units, PB administration was carefully monitored, but in others, it was not. Troops generally did not receive adequate information about the possible side effects of the drug. Actual administration of the pretreatment was decentralized and not under direct medical supervision, so accurate assessments of actual PB use are difficult to obtain, because no specific records were kept of self-administered medications.

Medical science has not yet been able to explain many Gulf War illnesses; thus, some people wonder if troops were exposed to an agent or combination of agents that caused these illnesses. In addition to PB, the men and women who served in the Gulf War theater faced exposure to a wide variety of chemical and biological agents including smoke from oil fires, paints, solvents, insecticides, petroleum fuels, organophosphate nerve agents, depleted uranium, anthrax and botulinum toxoid vaccinations, and infectious diseases, in addition to psychological and other physiological stress. Authoritative studies have concluded that there is inadequate evidence to determine whether pyridostigmine bromide is associated with chronic adverse health effects.

Q

Q-FEVER

Q-fever is a common global disease of wild animals and domestic livestock, especially sheep, cattle, and goats, caused by the bacterium *Coxiella burnetii.* Humans are usually infected with *C. burnetii* by inhalation of aerosols from infected animal products or of dust particles containing the spore form of the bacterium. In natural settings, the organism has low virulence (that is, produces less serious disease) for humans, with only half of all infected humans developing signs of illness. When disease develops, Q-fever has both acute and chronic forms, and the predominant clinical symptoms vary widely, making diagnosis difficult. The onset of acute Q-fever usually takes 10 to 40 days following exposure and typically begins with sudden high fever and flulike symptoms. Rarely, a few individuals develop a chronic illness with liver or heart complications, which is frequently fatal.

Background and Military Applications

Research on the military use of *C. burnetii* began in Russia before World War II. According to Ken Alibek (Kanatjan Alibekov), a former senior scientist in the Soviet biowarfare program, an outbreak of Q-fever among German soldiers in Crimea in 1943 may have resulted from intentional dissemination of the agent by the Russians. The United States Army studied experimental *C. burnetii* infections in soldiers, using vaccines, antibiotic treatment, and prophylaxis protocols in the mid-1950s and 1960s.

The exceptional infectivity of *C. burnetii* aerosols was observed in volunteers in open-air tests at Dugway Proving Ground, Utah. Inhalation of a single organism could cause infection in a susceptible person 40 days after exposure. A single dose of an inactivated whole-cell *C. burnetii* vaccine provided greater than 90 percent protection for 5 years against aerosol exposure.

C. burnetii is potentially dangerous as a weapon because it can be stored and disseminated as an aerosol or dry powder over a wide range of temperatures (–52° to +40°C, –60° to +104°F). Generally, the organism is hardy and survives in the environment in a spore form that allows significant spread of the agent by wind. Although culture is difficult and dangerous for laboratory workers, the organism can be grown to very high densities in live chick embryos. The organism can be transmitted by ticks, and it infects many animals that are usually asymptomatic carriers of the disease. A World Health Organization committee estimated in 1970 that if 50 kilograms (110 pounds) of a virulent *C. burnetii* strain were released upwind of a city of 500,000, it could incapacitate 125,000 people and kill 150.

Biological weapons stockpiles, including Q-fever bacteria, were destroyed by the United States upon signing the Biological and Toxin Weapons Convention of 1972, when other countries also agreed to end state-sponsored offensive biowarfare programs. The Soviet Union, however, continued biological weapons development into the early 1990s, including work with the Q-fever agent. As of 2003, it was not known if other countries were still producing the Q-fever agent as a biological weapon, but the Japanese religious cult Aum Shinrikyo attempted to weaponize the agent in the 1990s. Several cult members were reported to have been infected by the agent as they worked on it. In the United States, Q-fever was made a notifiable disease to public health authorities in 1999 because of increasing concerns of bioterrorism.

Q-fever (named after "query" fever when the cause of the unknown disease was first being investigated) was first described as a blood-transmissible disease in Queensland in 1937 by Edward H. Derrick, who was investigating a cluster of febrile illnesses of unknown origin among Australian abattoir workers. At about the same time, researchers in the Rocky Mountain Laboratory in Montana were studying a febrile illness transmitted by ticks. The causative agent, *Coxiella* (formerly *Rickettsia*) *burnetii,* was named for both MacFarlane Burnet (Melbourne, Australia) and Herald R. Cox (United States Public Health Service), who isolated and characterized the new pathogen in the late 1930s. Q-fever is colloquially known in different parts of the world as nine mile fever, north Queensland fever, and Balkan grippe.

Q-fever occurs on five continents, but the true incidence of Q-fever infection worldwide is unknown because a disease presenting as fever of unknown origin is hard to diagnose, many cases are mild or asymptomatic, and reporting is not required in many countries. It has infected military troops of all nations who have camped in endemic areas or near infected livestock, particularly goats and cattle. In Australia, about 500 cases of Q-fever occur annually in the meat processing industry, with younger workers and new recruits frequently being affected. In Europe, seroprevalence (evidence of exposure by testing blood) studies indicate that between 5 and 30 percent of the general population have antibodies to *C. burnetii.* A higher incidence is seen in rural areas with, occasional pet-associated outbreaks of human Q-fever in urban areas. About one-half of all people infected with *C. burnetii* have no sign or symptoms of clinical illness.

Medical Aspects

C. burnetii is a very small, gram-negative (does not absorb gram's stain) organism classified in the rickettsial family of bacteria, a group that includes the Rocky Mountain spotted fever and typhus agents. Rickettsia are often propagated in fertilized chicken eggs in the laboratory and require an intracellular environment in animal and arthropod hosts to grow and reproduce. Remarkably, *C. burnetii* lives and multiplies inside host cells, an environment that destroys most life forms. The organism has two distinct antigenic phases in animals and humans and in which antibodies are produced. Using serum antibody determinations one can determine the nature of the disease. Phase I antigens, for example, are indicative of chronic infection, while the presence of Phase II antigens usually shows acute onset of disease.

A dormant sporelike form of *C. burnetii* exists and is excreted in milk, urine, feces, and especially in the birth products (amniotic fluid and placental tissues) of infected animals. The spore is extremely hardy and can survive for long periods (weeks or months) in the surroundings of infected animals. Inhalation of the spore in contaminated dust up to one-half mile from the source may cause infection. The spore is not readily killed by sunlight, drying, or many common disinfectants. Sodium hypochlorite, formalin, ethanol, glutaraldehyde, gaseous formaldehyde and gamma irradiation can destroy *C. burnetii.* The ability to destroy the spore stage of *C. burnetii* is the current standard for adequate pasteurization of milk: 145° F (63° C) for at least 30 minutes, or 161° F (72° C) for 15 seconds.

C. burnetii is carried by a variety of birds, ticks, and mammals, including wild goats, cattle, sheep, kangaroos, wallabies and bandicoots, and other domestic and wild animals. Although it can cause abortion and stillbirth in goats and sheep, most animals infected with *C. burnetii* are healthy (asymptomatic). The organism may be transmitted by aerosols from animal excretions, contaminated straw, wool, hides, and clothing; ingestion or inhalation of raw milk or goat cheese; blood transfusions; and tick bites. Ticks are an important vector for maintenance of *C. burnetii* in the wild. Q-fever is an occupational hazard of persons working with animals or animal products and of laboratory workers who work with *C. burnetii.* Because the organism accumulates to high levels in birth products, people who assist at the birth of farm animals (such as animal husbandry workers and veterinarians) are at extremely high risk of infection. Other people at high risk are sheep, dairy, and meat processor (abattoir) workers, livestock farmers, and visitors to high-risk environments. Person-to-person spread is rare, but bone marrow- and blood transfusion-related transmission has occurred.

Q-fever has both acute and chronic disease forms. Acute Q-fever has a wide range of clinical symptoms, with no characteristic clinical picture. When symptomatic, the onset of Q-fever is usually 10 to 40 days after exposure, depending on the infecting dose. Early acute Q-fever is often characterized by a sudden onset of high fever (up to 105° F), with or without a flulike illness, pneumonia, or hepatitis. The most common symptoms are high fever, chills, sweating, severe headache, and malaise. Patients also frequently complain of muscle pain, fatigue, anorexia, weight loss, chest pain, and cough.

The disease normally resolves on its own without medical intervention, lasting up to 3 weeks, although recovery may be delayed in persons with hepatitis and pneumonia. Up to 15 percent of patients develop a post-Q-fever chronic fatigue syndrome that may last many months. Most people will recover within 60 days, even without treatment. However, prompt antibiotic treatment with a tetracycline can be helpful (see below). The antibiotic chloramphenical may be used in young children. Only 1 to 2 percent of people with acute Q-fever die of the disease. In general, recovery confers lifelong immunity against reinfection.

Attempted antibiotic prophylaxis of fever with tetracyclines has produced mixed results. Initiation of the antibiotics early in the incubation period (24 hours after exposure) prolonged the incubation period, but initiation of therapy late in the incubation period prevented disease development. Although the disease usually resolves without treatment, initiation of antibiotic treatment within the first few days of clinical illness shortens the course of the disease and can prevent progression to a chronic disease form.

Chronic Q-fever is uncommon, but it may result from *C. burnetii* infection that persists for more than 6 months, or it may develop from 1 to 20 years after initial infection. Rarely, chronic *C. burnetii* infection of the liver can lead to cirrhosis (chronic liver disease). The most serious complication, endocarditis (an inflammation of the heart valves), is difficult to diagnose. About 75 percent of such patients are male, over 40 years old, and have preexisting valvular heart disease or other risk factors (prosthetic heart valves, previous transplants, cancer, and chronic kidney disease). Chronic Q-fever is difficult to treat and is fatal in as many as 65 percent of cases.

Q-fever is difficult to diagnose without appropriate laboratory testing. A major clue to suspecting acute Q-fever infection is a history of contact with farm animals, animal by-products, birthing animals and their newborns, or tick bites. The diagnosis is proven by clinical suspicion and serology. Specific antibodies to the two antigenic phases of *C. burnetii* (phase I and phase II) can be measured in a blood sample taken at the onset of disease and during recovery by a variety of serological tests, including complement fixation testing (CFT), immunofluorescent antibody (IFA) testing, and enzyme-linked immunosorbent assay (ELISA). The indirect IFA is the most widely used method. *C. burnetii* may also be identified in infected tissues by using immunohistochemical (testing blood for exposure) methods and DNA detection methods such as the polymerase chain reaction test, or PCR, that can take very small amounts of genetic material from an assay, multiply them, and record the material's unique characteristics. Although it is possible to grow *C. burnetii* in fertilized chicken eggs, culture is difficult and dangerous for laboratory workers. Most infections are asymptomatic, or present as a flulike illness with no diagnosis. Atypical pneumonia is the most common diagnosis made.

Q-fever is a vaccine-preventable disease, but vaccination during the incubation period does not prevent the disease. Tetracyclines, as mentioned above, are the best prophylaxis for those exposed. A formalin-fixed (live cells killed with formaldehyde) whole-cell vaccine for Q-fever is commercially available in Canada and Australia and has protected humans in high-risk occupational settings. Individuals who have previously been exposed to *C. burnetii* should not receive the vaccine, because severe local skin reactions, including necrosis, can occur at the site of the injection. Persons wishing to be vaccinated must therefore first be screened for immune status with a skin reaction and complement fixation test (CFT). Protection depends primarily on cell-mediated immunity (response by lymphocytes). In the late 1970s, a nonhuman primate model was established to test experimental Q-fever vaccines at Fort Detrick. Vaccines for use in humans and animals are not commercially available in the United States. A Q-fever investigational new drug vaccine can be obtained from the United States Army Medical Research Institute of Infectious Diseases (USAMRIID) in Frederick, Maryland.

QL

QL is the code used by United States and the North Atlantic Treaty Organization (NATO) for the immediate precursor to VX nerve agent. It possesses a chemical structure that is still far removed from VX. As such, QL is a relatively nontoxic compound that, following a reaction with sulfur, isomerizes (changes the structure but not the essential elemental make-up) into a toxic VX molecule.

QL served as the basic component in the former U.S. chemical weapons stockpile, especially in the binary VX Bigeye glide bomb. Developed as part of a U.S. Navy program, the Bigeye munition used liquid QL and powdered elemental sulfur that would combine in a chemical reaction as the bomb flew over the target, releasing VX nerve agent. QL was also a key chemical component in the manufacturing process of the U.S. chemical weapons stockpile. QL was first produced in large batches. The product was then heated to accelerate the rearrangement of the molecule to form VX nerve agent.

The United States is currently destroying its chemical weapons stockpile, including remnants of QL that it produced during the Cold War. It is unknown whether foreign countries possess QL in any militarized quantities, or if they possess binary weapons utilizing this VX precursor.

R

RICIN

Ricin is a potentially lethal proteinaceous toxin found in the seeds of the castor bean plant, *Ricinus communis.* Upon entering the body, the toxin is strongly cytotoxic, killing most cells that it contacts by rapidly and irreversibly inhibiting protein synthesis. Entry into the body can be via injection, ingestion, or inhalation, with the lethal dose for the average person varying by route of entry.

The toxin's effects also vary depending on the route of entry. Based on a historical case study, injection of a lethal dose causes generalized weakness, fever, vomiting, dysphonia (difficulty speaking), and lymphadenopathy (swelling of lymph nodes) proximal to the site of injection within 24 hours, followed by symptoms of shock over the next 1–2 days and ultimately ending in circulatory collapse, diffuse hemorrhaging, and death on day three.

Following ingestion, symptoms of abdominal pain, vomiting, and (at times bloody) diarrhea appear within a few hours. Severe dehydration ensues over the next several days, leading to decreased urine output and blood pressure. If a lethal dose is consumed, death results in 3–5 days due to massive gastrointestinal hemorrhaging. If the patient survives past this time, however, he or she usually recovers.

Inhalation of a lethal dose leads to symptoms of cough, chest tightness, dyspnea (difficulty breathing), nausea, and myalgia (muscle aches) within approximately 3 hours. As the dyspnea worsens due to severe inflammation of the lungs and airways, cyanosis (bluish skin tone due to oxygen deprivation) rapidly develops. Death occurs 36 to 48 hours after initial exposure, as a result of either respiratory failure or circulatory collapse (stop of blood flow).

A high index of suspicion on the part of the health care practitioner and laboratory worker is required to identify ricin intoxication. Diagnostic confirmation is acquired via enzyme-linked immunosorbent assay (ELISA), a very specific test that uses enzyme reaction. Although a formalin-treated toxoid (toxin made harmless by treating with formaldehyde) with a proven safety record in animal studies has been submitted to the FDA for approval as an investigational new drug, treatment currently remains limited to supportive care. Promising research on the development of a newer toxoid incorporating only a small component of the toxin is ongoing. No antitoxin has been developed.

Ricin is listed in Schedule 1 of the Chemical Weapons Convention (CWC), meaning it is a toxic chemical banned by international law. It also falls under the purview of the Biological and Toxin Weapons Convention (BWC).

Ricin as a Biological Weapon

In addition to its high lethality, ricin is relatively inexpensive and easy to acquire and produce, and it is therefore considered by many analysts to be the present-day biological weapon of choice for actors with limited funds or technical expertise. Castor beans, though no longer grown in the United States, are widely available on the international market. The subsequent extraction of ricin is relatively straightforward and poses little danger to the handler. Approximately 1 million tons of castor beans are processed for the production of castor oil each year, yielding a waste product that is 5 percent ricin by weight.

The ease of acquisition and production of ricin is offset by the fact that it is easily affected by environmental factors as well as physical stress, making it very difficult to deliver as an aerosol. Thus, ricin is generally considered an excellent assassination weapon—especially given that it is tasteless, odorless, and very difficult to detect both pre- and postmortem—and a potentially dangerous food or

North London police raided a mosque in January 2003. Seven people were arrested under suspicion of manufacturing ricin toxin. (Reuters/Corbis)

water contaminant, but not a large-scale airborne threat. It also might be effectively delivered as part of a fragmentary device (a weapon that breaks up into smaller projectiles to create wider coverage) by coating explosive shrapnel with it.

Military History

The potential of ricin as a weapon of war has been evaluated since the beginning of the twentieth century. In early animal experiments performed by the U.S. Army, the results of which were first published in the *Journal of the American Medical Association* in 1903, bullets laced with the toxin were used to inflict poisoned wounds with firearms. Ricin was further investigated by the U.S. Army's Chemical Warfare Service (CWS) late in World War I, but the toxin was never deployed.

During World War II, the United States, along with Canada and Great Britain, again looked at ricin as a potential biological warfare (BW) agent. Called Agent W in the Allied arsenal, ricin was thoroughly explored by scientists at Edgewood Arsenal, and by the end of the war more than 1,700 kilograms of the toxin had been produced (Great Britain also conducted pilot-plant development of ricin). The toxin was processed into a liquid suspension and then incorporated into high-explosive shells and bombs, as well as into cluster bombs and plastic containers specially designed for its dispersal. Dubbed the W bomb, each cluster bomb was comprised of 500 pounds of independent 4-pound bomblets.

Field testing suggested that under appropriate weather conditions, the contents of just one W bomb distributed over 80 percent of a 100 x 100-yard target area would kill more than half of the area's population. Extrapolating this calculation, a 1-square-mile target required approximately 90 tons of weaponry, far less than the 600 tons required for phosgene bombs (the representative respiratory-effect chemical agent at the time), and thus it was deemed that the "W bomb" was worth pursuing. Ricin's lack of odor also suggested that its detection would be difficult, and its low persistency made it unlikely to hinder Allied advances after its delivery. It has been reported that the Allies did, in fact, consider using ricin against Japan, but the agent was never deployed in either the European or Pacific theater during World War II.

Human experimentation with ricin was performed within the confines of Japan's BW program during World War II, albeit indirectly: castor beans were placed in food that was then provided to prisoners of war over 2-week periods. Whether killed by the toxin or systematically executed to maintain secrecy about the tests, these test subjects invariably died as a result of their involvement in the experiments. Soviet researchers have performed similar experiments since World War II. Varied amounts of ricin and other poisons were added to the food of unsuspecting prisoners at Laboratory no. 1, a covert KGB facility. If the amount given did not prove lethal, more was injected with a syringe until death occurred.

In September 1978, Bulgarian dissident Georgy Markov was assassinated with ricin. While Markov awaited a bus on Waterloo Bridge in London, a Bulgarian secret service agent covertly fired a steel pellet filled with the toxin through the tip of a pneumatic umbrella into Markov's leg. Markov died 3 days later. A second Bulgarian, Vladimir Kostov, was targeted with a similar device in Paris but survived. Both the toxin and the umbrella designs used against Markov and Kostov were Soviet-made and had been provided for the operation by the KGB.

Following the 1991 Persian Gulf War, it was learned that Iraq had considered ricin as a potential BW agent in 1989 and had produced approximately 10 liters of concentrated ricin solution. All of this was used in field tests of 122-millimeter artillery shells, according to Iraqi declarations to the United Nations Special Committee (UNSCOM). Syria also is believed to have produced an unknown quantity of the toxin. In the early 1990s, Iran allegedly procured 120 tons of castor beans, possibly with the production of ricin in mind.

Ricin and Terrorism

In March 1991, four members of the American antigovernment group the Minnesota Patriots Council purchased castor beans through the mail after reading an advertisement in the right-wing *CBA Bulletin:* "Silent Tool of Justice . . . Castor Beans . . . Silent Death . . . Including instructions for extracting the deadly poison 'Ricin' from castor beans." Upon receiving the beans, these men extracted 0.7 grams of 5 percent ricin despite a lack of education and expertise. They plotted to kill law enforcement officials with the toxin but were discovered. In 1994 and 1995, they became the first persons to be convicted under the U.S. Biological Weapons Anti-Terrorism Act of 1989.

The extraction process for ricin for assassination purposes is described in the al-Qaeda training manual, and the Kurdish group Ansar al-Islam, which has known ties to al-Qaeda, has reportedly tested the toxin on animals and possibly even a man in northern Iraq. During the post-September 11 U.S. military action, instructions for the preparation of ricin were discovered in the basement of two Arab doctors connected to al-Qaeda, and trace amounts of ricin were detected at 5 or 6 of the approximately 110 sites searched throughout Afghanistan. But the quantity was too small to make any definitive assessment that ricin had been produced in the area.

In January 2003, the search by authorities of a London apartment uncovered castor beans and equipment for the extraction of ricin, leading to multiple arrests. Subsequent forensic analysis identified traces of ricin itself. Allegedly, four of the men arrested in the sweep—one of whom had been in contact with persons employed on a British military base—were linked to al-Qaeda.

In March 2003, two vials of ricin were discovered in a locker at the Gare de Lyon railway station in Paris. To date, no arrests have been made in the case.

Ricin and Crime

Ricin has been the agent of choice in numerous criminal plots over the past two decades.

In 1982, for example, Texas attorney William A. Chanslor was arrested for attempting to acquire ricin, which he claimed had been sought so that he could assist his wife in committing suicide. He was found guilty of conspiracy to commit murder, but the conviction was overturned on appeal. Before he could be retried, Chanslor pled guilty and was sentenced to probation.

In 1985, Montgomery Todd Meeks was convicted of the attempted murder of his father. Meeks purchased what was apparently a vial of ricin toxin itself and poured the contents of the vial into his father's water glass (and water pitcher). Before the tainted water could be consumed, however, Meeks's father was alerted to the plot by the county sheriff's office.

A decade later, cardiologist Michael Farrar discovered a supply of castor beans in the purse of his estranged wife, Debora Green. Farrar had been suffering from unusual symptoms that had left him hospitalized on three separate occasions earlier that year, and it was soon determined that ricin had in fact been the cause of his illness in each instance. Less than a month later, Green set fire to her own home, killing two of her children. She was arrested and in April 1996 pleaded no contest to charges of murder and attempted murder.

In 1997, authorities responding to an emergency call entered the residence of one Thomas C. Leahy, who after a night of drinking had shot his son in the face. Investigation of the crime scene revealed approximately 0.7 grams of 4 percent ricin in his home. Leahy's wife later testified that Thomas Leahy had planned to poison his mother and former wife with the toxin. He was ultimately sentenced to 6 and one-half years in prison.

Medical Applications

Given its cytotoxic (cell-killing) effect, ricin has been pursued as a potential therapy for cancer for the past half-century. To be used to inhibit tumor growth, however, the toxin must be delivered in such a way that it targets cancerous cells without affecting normal cells. In recent years, scientists have accomplished this feat by conjugating the active component of ricin with tumor-specific monoclonal (very specific and uniform) antibodies to create "immunotoxins" capable of selective cell destruction. Preliminary studies with a number of different immunotoxins have shown significant promise.

RIFT VALLEY FEVER

Rift Valley fever (RVF) is a viral disease transmitted to humans by contact with infected animals or through the bite of infected mosquitoes. In a majority of cases, RVF is transmitted by contamination of broken skin during animal handling or by inhalation of infected fluids (aerosols). This can occur during the slaughter of infected livestock. Infection of health workers may occur during careless handling of patients' blood or other body fluids. Proven to be highly infectious under natural circumstances as an aerosol, RVF is an excellent candidate for deliberate dissemination in biowarfare. In mild cases, RVF symptoms are similar to the common flu with chills, fever, and muscle aches, but in 1 to 2 percent of cases, complications of eye inflammation, brain infection (encephalitis) or liver damage, and abnormal bleeding (hemorrhagic fever) can be serious or fatal. Domestic sheep, cattle, camels, and goats are susceptible to RVF; abortion among pregnant animals is a common outcome. Sheep are particularly vulnerable; in fact, the virus was originally isolated from a newborn lamb in 1930.

RVF was discovered in eastern Africa as a disease of sheep and other domestic livestock. Mosquitoes of many species are the source for natural disease transmission among animals. Infected eggs of female mosquitoes also can carry RVF through successive insect generations. In central Africa, an increase in mosquito populations after heavy rains or flooding often precedes livestock outbreaks, and a sudden increase of abortions or deaths of newborn lambs may presage human outbreaks. In 1977, an epidemic of RVF in Egypt heralded the spread of RVF to livestock in relatively dry regions of north Africa, where channels of irrigation water or flooded fields offer hospitality to mosquitoes. In 2000, RVF caused local epidemics for the first time outside of the African continent (in Saudi Arabia and Yemen). Thus, the virus has adapted to new environments.

Technical Details

The virus of RVF is midsize (0.1 micron in diameter) and belongs to the family of bunyaviruses, genus *Phlebovirus.* It is consists of protein-coated helical RNA enclosed within a fatty envelope that aids virus entry by targeting receptors on the host cell. In the first round of virus multiplication, RNA fragments provided by the host cell enable expression—that is, the initial blueprint—of the virus's genetic information. Eventually, the virus becomes self-replicating and produces the proteins needed for the maturation and release of infectious particles.

Initially, the virus multiplies in white blood cells at the site of a mosquito bite. After a latent period of 2–6 days, it spreads through the bloodstream to multiply into other tissues and organs. A symptomatic phase then lasts 4–7 days. On days two or three after infection, a heavy load of virus is released into the bloodstream (viremia). This is an optimal interval for isolation of the virus by infecting mice with blood from the patient or by using tissue cultures, or for detection by newer molecular methods of polymerase chain reaction (PCR). Prior to the existence of PCR, diagnosis usually depended upon detection of protective antibodies that increase for 1–2 weeks after infection. Signs of liver damage and bleeding from the gums, under the skin, or into the intestinal tract can be seen at 2–4 days after infection. Up to 50 percent of patients with these "hemorrhagic fever" complications may die. Complications of encephalitis or eye disease may be delayed for 1–4 weeks after the onset of fever but are rarely fatal. The overall death rate of RVF is about 1 percent.

In sheep, vaccination with a live attenuated strain of RVF can produce long-lasting immunity, but vaccination of cattle depends upon a killed virus that is less effective and requires regular follow-ups to ensure immunity. Human vaccination is not yet feasible. Control of mosquito populations is the basic public health measure to limit RVF spread. Treatment of human RVF addresses the symptoms only; however, in severe cases, the antiviral drug ribavirin, administered intravenously, may be life-saving.

RFV has been tested for use in biowarfare by the U.S. Army. The results of these tests are classified. This agent was not reported to be a major consideration in the Soviet bioweapons program; however, a potential for criminal abuse exists. Military or civilian populations exposed to RVF aerosols could be out of action for several days.

RIOT CONTROL AGENTS

A riot control agent (RCA) is any nonlethal, nonpersistent substance used to disperse a crowd and move its members in a specific direction, normally away from a key area. Riot control agents have a long history of use by law enforcement agencies to break up mobs, protests, looting, or other activities without using lethal force.

In 1912, Parisian police used "hand bombs" filled with ethyl bromacetate, an early lacrimator or tearing agent, against rioters and looters. French soldiers used this same agent against German soldiers in World War I, and more irritating substances were also synthesized for use on the battlefield. Following World War I, the continued development of RCAs as war gases waned with the development of more toxic chemicals. Although the United States used RCAs to clear tunnels in Vietnam (mostly CS agent), the use of RCAs by the U.S. military today is generally limited to confidence training with protective masks and to law enforcement functions such as riot control, internment and resettlement operations, and military corrections. Today, police worldwide use RCAs for law enforcement, corrections, and crowd control activities.

Agents used for riot control should meet two criteria: (1) they must be able to irritate and disable their human targets, and (2) they must inflict only temporary effects that will not require medical treatment. Traditional RCAs include the World War I-era chemical CN, or chloroacetophenon (also known commercially as Mace), which was commercially developed in the 1920s by the British and used in the United States to protect banks and armored cars from robbery in the 1930s. The British also used CN in post-WWII civil disturbances in Cyprus, and the United States used this agent against rioters and criminals in the 1960s and 1970s. CS gas has replaced CN in most police and military uses. The advantage of CS agent (delivered as a powder or in a thermal fog) is that it is much more intense in causing pain to the eyes, nose, and throat, while being less toxic than CN.

Water, either dispersed with a high-pressure hose or a water cannon, can also be used as an RCA and is especially effective in cold weather. Water was used against civil rights activists in the United States in the 1960s and is being used today in countries such as Indonesia, South Africa, and Israel. Government officials in the United States, however, normally avoid using firefighting equipment in riot control, in order to maintain these units' reputation for community assistance.

Technical Details

The most common RCAs used today are CS gas and oleoresin capsicum (OC or "pepper spray"). CS, named after its manufacturer, Corson and Stoughton, which developed the chemical in 1928, is shorthand for the chemical name O-chlorobenzylidine malononitrile. It emits a pepperlike odor and causes burning and tearing in the eyes, shortness of breath, tightness in the chest, coughing, wheezing, and stinging of exposed skin. When a person is exposed to CS in effective quantities, he or she loses the ability to communicate with others or coordinate his or her actions. The effects of CS typically wear off after 5–10 minutes in fresh air. During the siege of the Branch Davidian compound at Waco, Texas, in 1993, large quantities of CS agent mixed in solvent were used in an attempt to resolve a standoff. Unfortunately, the use of CS in this instance probably helped create an uncontrollable fire that left 80 people dead.

The naturally occurring substance oleoresin capsicum (OC or "pepper spray") is extracted from various types of pepper plants and is used widely by the United States military and police. OC was introduced to United States law enforcement agents and mail carriers in aerosol form to repel animals and humans in 1973, and its usage spread during the 1980s. By dint of its "natural origin," OC is generally considered a safer alternative to other RCAs. Some law enforcement personnel consider its overall effectiveness in crowd control, however, to be weak when compared to other RCAs such as CS agent. It creates sensations of burning in the eyes, involuntary closing of the eyelids, coughing, gagging, loss of breath, a burning sensation on exposed skin, and loss of strength and coordination. Like CS, OC will incapacitate a targeted person, leaving him or her unable to coordinate actions. The effects of OC typically wear off after 30–40 minutes in fresh air.

A third riot control agent, used less often today, is CR, known chemically as dibenz-(b,f)-1,4-oxazepine or dibenzoxazepine. CR was synthesized in 1962 and approved for use by the U.S. Army in 1974. CR is more irritating than CS and also more persistent. CR liquid can be dispersed from a portable dispensing device that can be carried on the back by a law enforcement officer. Although some studies suggest that CR is even more effective and less toxic than CS tear agent, there is a paucity of human data with regard to the use of CR, and thus it has not found widespread application as an RCA.

The impact of RCAs is measured as a function of concentration and time, also known as the Haber Product. One such measure of severity is the intolerable concentration, or IC_{50}. The IC_{50} is the concentration of an irritating substance, such a tear gas, that 50 percent of a given population (human or animal) find intolerable after one minute. CS, for example, has an IC_{50} of 3.6 milligrams per minute per meters cubed (in aerosol form).

Some experiments for determining IC_{50} have been designed using human test subjects, including those conducted by the United Kingdom. In one trial, volunteers were brought into a room and told that a 5-pound Sterling bank note was hidden inside. As the subjects looked for the phantom bill, CS agent was poured into the room. The amount of time it took before subjects gave up the fruitless search due to intense discomfort caused by the RCA was used to calculate the overall effectiveness of CS agent in humans.

The concentration of CS that would cause death to 50 percent of the population is represented by LCt_{50}, where L stands for lethal, C is concentration and t is the exposure time. Although RCAs are intended to be nonlethal, they can cause serious side effects, including bronchitis, asthma, lung damage, eye damage, and skin inflammation. Death may occur from large exposures to CS in older populations, children, and those with respiratory conditions. First aid for RCAs includes moving to uncontaminated areas; allowing powdered agents to blow off of clothing and skin; not touching one's eyes, mouth, or other mucous membranes; and showering.

Operational Aspects

Riot control agents can be dispersed by pyrotechnics, canister burst, aerosol, fogging, and grenades. The effective use of a riot control agent depends on the area and the weather. An agent is normally released 15 to 100 meters from the target, depending on wind speed. As wind speed increases, the distance to the target needs to be shortened to be effective. The employing force should only use RCAs when the target population has an escape route, as panic and additional injuries could result from a trapped crowd. As an alternative, high-pressure water can be used in confined areas (e.g., alleys) or narrow fronts (e.g., a roadblock). Those who employ RCAs will usually need personal protection via protective masks, except when using high-pressure water or water cannons. The employing force needs to be prepared to further break up remaining groups, prevent illegal activities, and assist the injured or unconscious. Riot control agents, if unsuccessful at convincing people to move away from the area, have the potential to incense an already motivated crowd to inflict more violence or property damage.

Currently, the use of RCAs by the United States is limited by two documents, one international and one domestic. The 1993 Chemical Weapons Convention (CWC) bans the use of riot control agents as a method of warfare. Riot control agents, defined as "any chemical . . . which can produce rapidly in humans sensory irritation or disabling physical effects which disappear within a short time following termination of exposure" (CWC, Article II, Sec. 7) are not prohibited, however, when used for law enforcement, including domestic riot control purposes.

The United States has further limited its use of riot control agents by Executive Order 11850, signed by President Gerald Ford in 1975. In this order, the United States renounced first use of riot control agents in war except in defensive military modes to save lives. The order specified four classes of events where riot control agents can be used with prior presidential approval: (1) in a riot control situation in an area under U.S. military control (e.g., to prevent riots at an enemy prisoner of war camp); (2) when civilians are being used to "mask or screen attacks and civilian casualties can be reduced or avoided"; (3) rescue missions; and (4) in rear echelons to "protect convoys from civil disturbances, terrorists and paramilitary organizations" (Executive Order 11850). Much of the rationale for the United States to maintain the exception for the possible use of RCAs in warfare goes back to the Vietnam War, when U.S. forces used CS tear agent to suppress enemy fire in order to undertake search and rescue missions for missing pilots and air crews.

Employment of RCAs should be guided by a priority of force. The United States military, for example, suggests the use of chemical irritants only after verbal persuasion and show of force, but before the use of physical force, presentation of deadly force, or use of deadly force. In most cases, law enforcement officials weigh the benefits of using nonlethal tactics such as riot control agents against possible injuries and further inflaming the crowd.

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF) is a potentially severe, arthropod-borne rickettsial infection endemic to most of North America and parts of South America. The disease is caused by the bacterium *Rickettsia rickettsii* and is spread to humans by the bites of ixodid (hard-bodied type) ticks. Early infection is difficult to diagnose because of nonspecific symptoms (fever, headache, muscle and joint pain). The lack of a prompt diagnosis and the resulting delay in treatment can greatly increase the severity of the disease.

The first description of RMSF appeared following a case in south-central Idaho, in the Snake River Valley in the late 1800s. The appearance of a characteristic rash first led to the disease to be described as black measles. The name Rocky Mountain spotted fever later supplanted this early terminology, due to the geographic distribution of infections that first came to the attention of medical care providers. The leading medical researcher in the field was Howard T. Ricketts, after whom this entire class of organisms was named. He and his colleagues not only identified the infective agent of RMSF, but they also described in detail the role of the tick vector and the life cycle of the organism.

The natural hosts of *R. rickettsii* include the common dog tick (*Dermacentor variabilis*) in the eastern United States and the Rocky Mountain wood tick (*D. andersoni*) in the intermountain west and Pacific coast. The microorganisms propagate within a host and can be transmitted to humans in saliva released from a feeding tick. Ticks may feed for hours on a host, and long feeding periods are necessary to transmit *R. rickettsii* bacteria. General symptoms (fever, headache, nausea, and muscle pain) can appear 7–10 days after exposure. A rash can begin 3–5 days after the onset of symptoms and may develop into a characteristic pattern of dark red spots that occur on the extremities (arms, legs, ankles), including the palms of the hands and soles of the feet in most infected individuals.

Among other microbial pathogens, RMSF has been studied by U.S. scientists as an offensive weapon. Between 1943 and 1969, five researchers at Fort Detrick, Maryland, became infected with RMSF while conducting research on the pathogen.

The United States also conducted field aerosolization tests during the Cold War. RMSF can also be delivered as a biological agent, using infected ticks as the disease-carrying vector.

Rocky Mountain spotted fever is the most commonly reported rickettsial infection in the United States. Although prompt and efficacious antibiotic treatment has significantly reduced the mortality of infection, approximately 5 percent of individuals infected with *R. rickettsii* die from the disease. One set of data showed that when treated within 5 days of symptoms, most survived, while those who received antibiotics within 7 days died. Prior to the widespread use of antibiotics to treat the disease, a 30 percent case fatality was not uncommon. The U.S. Centers for Disease Control and Prevention report that children are at greatest risk for the disease, accounting for more than 60 percent of all cases reported in the United States. Antibiotics such as doxycycline and chloramphenicol are effective in treating RMSF. Left unchecked, RMSF causes damage to the tissues vital for proper circulation, leading to hemorrhage and sometimes formation of blood clots (thrombosis).

Rocky Mountain spotted fever is difficult to diagnose, and the consequences of delayed treatment are significant. Improved diagnostics are in development, as is a standard case definition to help physicians identify and report RMSF to state public health officials. There are no vaccines approved for human use for protection against RMSF.

RUSSIA: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

Russia inherited the largest stockpile of chemical and biological agents in the world from the former Soviet Union (FSU). Even after signing the Chemical Weapons Convention (CWC) and the Biological and Toxin Weapons Convention (BTWC), Russia continued to develop chemical and biological weapons in secrecy. In 1992, President Boris Yeltsin claimed that the CBW programs in Russia had been abandoned and that Russia was committed to destroying its stockpiles of chemical and biological weapons and operating within the framework of the CWC and the BTWC. Some observers believe, however, that Russia still has an offensive CW and BW program today, despite promises to the international community that their research and development in this area are strictly for defensive purposes.

Russia also continues to have financial problems that directly affect the demilitarization and disposal of its current stockpiles. Whether the nation is fully committed to the elimination and nonproliferation of CBW or not, Russia's legacy as a chemical and biological superpower continues to have an effect on global security.

All aspects of Russian CBW programs must be safeguarded to prevent other groups and nations of concern from obtaining CBW capabilities, whether through theft, black market sales, or unauthorized technology transfer. Protecting the remaining stockpiles while awaiting demilitarization is a costly venture for Russia because it lacks the resources to keep its scientists employed. The United States, however, has worked with Russia through threat reduction initiatives to redirect their scientists and illicit programs toward legitimate research and development. CBW programs in Russia were quite extensive, and the breakup of the Soviet Union has made it difficult to maintain physical security for the materials and equipment associated with the programs. The dual nature of chemical and biological technology also makes it difficult to maintain the type of export controls needed to keep other nations from transferring legitimate chemical and biological research and development technology to clandestine operations.

Historical Background

Chemical and biological weapons use in Russia dates back to at least the sixteenth century, when Russian troops allegedly used plague-infested corpses against the Swedes. Until the end of World War II, however, Russia was more often the victim of CBW attacks. During World War I, the Germans—in a sabotage operation conducted in the United States and possibly elsewhere—infected with glanders and other diseases livestock bound for Russia, and Russia also suffered more than 60 percent of all the chemical-related casualties in that conflict. In 1919, during the Russian Civil War, the British used

Chemical weapons storage, Sartov region. Destruction of Soviet-era chemical weapons in Russia has been painfully slow. (Reuters/Corbis)

adamsite against the Bolsheviks. In 1939, the Japanese poisoned Soviet water supplies along the Mongolian border with intestinal typhoid bacteria.

Russia's history of foreign invasion and CBW attacks contributed to a feeling of distrust of others that led to an aggressive offensive CBW doctrine, even after the use of such weapons was determined to be inhumane by the international community. The Soviet-era CBW programs officially began with a 1967 decree by the Communist Party Central Committee and the U.S.S.R. Council of Ministers, which directed the preparations for chemical and biological war. The 1967 decree established the program that the West codenamed the F programs (Flute, Fouette, Fagot, Flask, Ferment, Factor, and Flora).

Russian CBW programs were an even more closely kept secret than their nuclear program; Soviet offensive CBW programs were well hidden behind legitimate bioscience and chemical industry covers. Most of what is known about their efforts comes from former Russian scientists like Ken Alibek, who immigrated to the United States after the end of the Cold War. He was the former Deputy Director of Biopreparat, the principal Soviet government agency responsible for biological weapons research and development (*see* Biopreparat).

Biological Weapons

The Soviet BW program involved thousands of personnel from the military, education, and civilian sectors. The Soviets compartmentalized sensitive aspects of the program so that very few people had knowledge of the program as a whole and its intended military applications. Although Russia produced tons of agents such as anthrax, smallpox, plague, tularemia, glanders, Venezuelan equine encephalitis, Q-fever, and Marburg, research was also conducted on many more types of agents and organisms.

In 1946, an army biological research facility was built at Sverdlovsk; Soviet scientists used data culled from germ warfare documents taken from the Japanese in Manchuria. In 1953, another bacteriological facility was built at Kirov. Both Sverdlovsk and Kirov suffered serious accidents. In 1953, a leak occurred at the Kirov facility in which anthrax was released into the city's sewer system. The West remained unaware of this incident, and when a rodent was found a few years later in the sewer system with a more virulent strain of anthrax, the Soviets were able to further their BW program using this new strain.

In 1979, there was an anthrax release at Sverdlovsk that apparently occurred when a technician forgot to replace a clogged filter that had been removed. The plant released a cloud of anthrax that allegedly killed hundreds of people. The Soviets were unable to keep this incident out of the public eye and, for the first time, the West had clear evidence that the Soviet Union was in violation of the BTWC. Moscow officials denied the incident and said that it was a naturally occurring outbreak of anthrax among domestic animals and that all the patients had been treated successfully. Eventually, however, Moscow admitted that 96 people had been infected and that 66 of those infected had died. The Soviets then launched a major cover-up to protect their BW program. Unfortunately, residents continued to get sick; anthrax spores can survive in a dormant state for years. The Sverdlovsk incident became known as the biological Chernobyl, and to this day, Moscow claims that the outbreak was due to contaminated meat.

Subsequent Western focus on the incident at Sverdlovsk meant that continued operations there would be difficult. Four facilities had originally been established under the Ministry of Defense; however, research and development (R&D) was carried out within institutions under the Ministry of Defense, Ministry of Agriculture, Ministry of Health, Academy of Sciences, and Biopreparat. Eventually, between forty and fifty different institutions were involved in some aspect of the BW program, an organizational network that led to the continued secrecy of the program. Not all were engaged in microbiology or weapons R&D. Some were cover operations to further secure the program. Others supported fermenter design and the construction of test chambers. Because of its geographic isolation, Vozrozhdeniye Island was used as a test site in the Aral Sea where open-air testing of BW agents took place.

Biopreparat took advantage of the pressure that was put on the Ministry of Defense and pushed to become the main developer of new biological weapons using agents such as tularemia. Because Biopreparat was a civilian organization, it was easier to conceal its activities from the West under the guise of medical research. The Ministry of Defense, the Military Industrial Commission, and other state organs, all the way up to the Central Committee and the Office of the President, ultimately controlled the programs undertaken by Biopreparat. Eventually, all biological weapons-making equipment and materials were transferred to Stepnogorsk, a Biopreparat-controlled research facility. The Ministry of Defense facilities continued research, but the small scale of this research meant that they were effectively in charge of storage.

The first mission of Stepnogorsk was to take the virulent strain of anthrax that had been discovered in Kirov in 1953, Anthrax 836, and develop a technique for reproducing it on a massive scale. Anthrax 836 was considered to be the most suitable for mass production because it could be transported without losing its virulence. Stepnogorsk created an assembly line for mass production of weaponized anthrax, a capability previously unavailable to the Soviet military.

The success of the BW program also led the Soviet Union to develop a coherent BW employment doctrine. Biological weapons were considered strategic or operational weapons, meaning that they were not meant for tactical operations on the battlefield. Strategic agents were to be targeted against the continental United States for use in all-out war, and operational agents were to be used against North Atlantic Treaty Organization staging and logistic areas in the event of war in Europe. Strategic agents were typically lethal and included smallpox, anthrax, and plague. Operational agents such as tularemia and glanders were intended to incapacitate soldiers and overwhelm medical services. The overall goal of Soviet doctrine was to create mass casualties and disrupt critical civilian and military infrastructures. The Soviets worked continuously to make this doctrine a reality by improving the effectiveness of biological agents through genetic engineering and improved delivery systems.

R&D and production were concealed within the legitimate biotechnology and pharmaceutical industries. Genetic engineering produced a new generation of BW agents. Chimeric agents were developed; this genetic alteration of infectious organisms caused victims to display symptoms of several infectious organisms. Chimeric agents also shortened the time between infection and the onset of symptoms and caused symptoms to reveal themselves at noncharacteristic times. What resulted were biological agents with increased virulence, improved resistance to antibiotics, longer shelf life, and more ease of dissemination. The new agents could survive environmental effects that greatly reduced the virulence of naturally occurring organisms.

Two biological agents within the Russian arsenal, smallpox and Marburg, were especially dangerous. The World Health Organization (WHO) announced in May of 1980 that smallpox had been eradicated from the planet. Ironically, by its membership in the United Nations and its large vaccine production capacity, Soviet science and medicine had played a large role in the worldwide eradication of natural incidence of smallpox. When the WHO named the Centers for Disease Control in Atlanta and the Ivanovsky Institute of Virology in Moscow as the only two sites where limited stockpiles of smallpox could be held for research purposes, however, Moscow saw this as an opportunity to exploit smallpox as a weapon. In the 1981–1985 Five-Year Plan, Moscow listed smallpox as a virus targeted for improvement for military purposes. The Soviet program worked to shorten the time it takes smallpox symptoms to occur and to strengthen its virulence so that any vaccine would be ineffective. This was quite different from the West's policy, which only sought to weaponize agents for which there was a cure. A strong and stable strain of Marburg was also produced by Soviet researchers. The Soviet Union and Russia continued on this path into the early 1990s.

Equally important to the Russian BW program was the development of effective mechanisms for delivery of biological agents. At the Institute of Ultra-Pure Biopreparations, one of the major projects was the modification of cruise missiles to deliver BW agents. Soviet SS-11 and SS-18 missiles were equipped with biological weapons to attack strategic targets within the United States.

Chemical Weapons

The Soviet Union produced thousands of tons of chemical weapons at multiple facilities. The Soviet arsenal included nerve (sarin, soman, and Russian VX) and blister agents (mustard and lewisite). Vil Mirzayanov, eventually a Russian émigré to the United States, had worked for more than 25 years in the Soviet chemical weapons program and helped develop a new series of extremely lethal third-generation nerve agents under the Foliant program. These were binary agents—ones that were nontoxic by themselves but became lethal when mixed together. He also worked to develop agents that were not detectable by Western early warning systems.

Beginning in the 1920s, the Military Chemical Complex (MCC) of the Soviet Union secretly developed, produced, and stockpiled chemical weapons. At a 1957 meeting of the Communist Party, Defense Minister Marshal Georgi K. Zhukov said that the U.S.S.R. would assume that future war would include nuclear, chemical, and biological weapons. The MCC went through a series of changes as the CW program evolved. Today, military chemical affairs are handled by the Radiation, Chemical, and Biological Protection Forces (RCB), which have their own research, academic, and testing organizations.

Under the Soviet system, chemicals were divided into three categories based on their combat effectiveness. First-generation chemical weapons were those World War I vintage agents, including persistent toxic chemicals that produce a skin-blistering or general toxic effect (mustard, for example), nonpersistent toxic chemicals (such as phosgene), and irritants (riot control agents) such as adamsite and CS gas. Second-generation chemical weapons were organophosphorus toxic chemicals that cause a paralytic nerve action, including tabun, sarin, soman, and Soviet V-gas. Sarin, soman, and Soviet V-gas were produced on a large scale to be included in the army arsenal. Third-generation chemical weapons encompassed new types of toxic chemicals and more effective means of delivery during combat. The Foliant program produced several of these agents, of which A-232 and novichok-5 became the most useful for combat operations. Not much is known about these third-generation chemical weapons.

Soviet CW testing was conducted near the Caspian Sea, near Lake Baikal, and even in cities close to Moscow. Some of the most prominent testing facilities were Kuzminki and Kuntsevo in Moscow, Shikhany Central Military Chemical Proving Grounds on the banks of the Volga River, and Nukus, located on the Ustyurt Plateau in Karakalpakia, Uzbekistan. Chemicals needed to be tested in different areas to demonstrate their battlefield effectiveness in various climate conditions.

Until the early 1980s, chemicals were even tested during training exercises and on humans, although it is not known if these tests were performed with the consent of the participants. The Soviet program has received much domestic criticism because of the legacy of reported environmental damage produced by CW testing, although the type and extent of this purported damage are still unclear.

Although chemical weapons production facilities were numerous, they were concentrated in the Volga basin. The experimental plant Volsk, for example, produced various toxic chemicals and their precursors, including irritants and incapacitants. The S. M. Kirov Chemical Plant in Stalingrad produced large-scale quantities of yperite and phosgene. V-gas and other toxic agents were produced near the city of Novocheboksarsk.

Under the U.S.-Soviet Wyoming Memorandum of 1989 in which the United States and the U.S.S.R. exchanged information on their military chemical facilities, the Soviet Union identified locations where chemical weapons were stored. Some of the storage sites include the Shikhany Central Military Chemical Proving Grounds, Gornyy, and Kambarka. Under the Chemical Weapons Convention, Russia made further declarations that included civilian entities; however, there are still questions as to whether full declarations and disclosures have been made by Russia.

Russia inherited an extensive chemical arsenal from the Soviet Union. First-generation weapons (e.g., lewisite and sulfur mustard) were deployable from 122-millimeter and 152-millimeter artillery shells, 100-kilogram aircraft bombs, and 500-kilogram and 1,500-kilogram aircraft spray rigs. Second-generation chemical weapons (e.g., sarin and soman) were deployable in 122-millimeter, 130-millimeter, and 152-millimeter nonrocket artillery shells; 122-millimeter, 140-millimeter, and 240-millimeter rocket artillery shells; 250-kilogram aircraft bombs; and 350-kilogram aircraft spray rigs. Third-generation chemical weapons (e.g., VX) were deployable in 130-millimeter and 122-millimeter nonrocket artillery shells and 540-millimeter and 884-millimeter nose sections of tactical missiles.

CBW Arms Control Efforts

Currently, Russia openly supports nonproliferation regimes and arms control treaties. Russia does, however, export missile and nuclear technology and dual-use biological and chemical technology to nations of concern (e.g., Iran and North Korea). Because of the dual-use nature of chemical and biological weapons technology, countries like Iran could divert imported equipment or expertise for clandestine purposes. Russia has sought to strengthen its export controls and physical security of stockpiles in recent years; unfortunately, the dual-use nature of these programs makes foolproof safeguards virtually impossible. Russia has worked closely with the United States and other parties to the CWC and BTWC to improve its nonproliferation controls.

The most effective method for securing the Russian CW and BW programs would be destruction of current stockpiles, conversion of former production facilities, and the provision of peaceful work for former weapons scientists so that they are not lured into illicit programs in nations of concern. Russia has run into several problems in achieving these goals. Destruction of current stockpiles, for example, imposes an economic burden on Russia that it can ill afford.

Although former Soviet republics such as the Ukraine, Kazakhstan, and Uzbekistan have abandoned and closed the BW facilities located within their territories, Russia has not taken such broad steps in the area of verifiable biological weapons destruction. The BTWC does not have requirements or provisions for verification to regulate the destruction process. The CWC, however, has the most stringent verification requirements of any arms control treaty and commits its parties to destroy their chemical weapons. In addition, the Bilateral Destruction Agreement between the United States and Russia sought to further eliminate the chemical stockpiles and chemical weapon production facilities.

The legal and organizational framework for chemical weapon destruction is the bill entitled "On the Destruction of Chemical Weapons," which was approved by the Russian Parliament and signed into law on May 2, 1997. This document establishes the basis for destruction, and Government Order no. 305 sets up the timeline and priority for chemical weapon destruction. Russia still argues, however, that legitimate chemical industries are tied to plants that manufactured CW agents and that destruction of these facilities would directly affect the legitimate business conducted within the Russian chemical industry. Russian officials also argue against complete destruction because chemical weapon production facilities can safely be converted to civilian industrial use. There need to be strict verification measures, however, to ensure that these facilities cannot be redirected to weapons production. U.S. officials are concerned that converted chemical weapons production facilities could still be mobilized for production in times of war and could continue to act as covers for clandestine operations.

The United States has cooperative programs with Russia to assist with the destruction process. In addition to cooperative threat reduction programs, Russia is also seeking to engage in joint ventures with Western chemical and pharmaceutical companies to generate revenue and to create transparency within their legitimate research, development, and production facilities. Unfortunately, financial hardship and political instability in Russia do not make it an attractive place for foreign investment.

Due to the financial and ecological burden of chemical weapon destruction, Russia has missed CWC deadlines for destruction of its most dangerous chemical weapons. It has requested extensions, but with a deadline of 2007 for destruction of all chemical weapons stockpiles, Russia will most likely not be able to destroy all of its chemical stockpiles in time. Russian officials have already stated that they will request a 5-year extension until 2012 to meet the goal of destroying all of the chemical weapons within the former Soviet Union.

SABOTAGE

Sabotage is a word used to describe attacks against selected targets (usually one's own organization, employer, or military) to damage property or personnel. Sabotage can be conducted in a variety of forms, including the use of weapons of mass destruction in terrorism or war. In a military context, sabotage is a set of actions designed to harass, ruin, or otherwise interfere with the normal operations of the enemy. An agent already inside the targeted organization is often used to commit sabotage, or special operation forces are sent behind enemy lines in an attempt to cut communications, destroy logistical nodes, or set off explosions to degrade the enemy's ability to fight.

The origin of the word *sabotage* has been linked to French activists during the Industrial Revolution, who struck against modern industrial facilities. According to this version, workers put a wooden shoe (*sabot*) into the workings of a labor-saving machine, wrecking the device and preserving their jobs. This story is probably apocryphal, as *sabot* probably referred to a wooden pin that connected train tracks; when the pin was removed, the tracks would fail, setting the stage for a catastrophic train derailment.

In chemical and biological warfare, the primary routes of potential sabotage include the release of toxic industrial chemicals. The Bhopal, India, tragedy in the early 1980s is considered by many to be the worst case of industrial sabotage ever committed by a disgruntled employee (*see* Bhopal India: Union Carbide Accident). Sabotage can also take the form of deliberate contamination of food or beverages with pathogens, toxins, or highly poisonous chemical compounds. Militaries and terrorist organizations could both use chemical or biological sabotage as a part of, or prelude to, organized campaigns. Sabotage need not be directly targeted against people but perhaps could also target the economic well-being of a particular industry. The release of an animal or plant disease could be part of sabotage operations, causing considerable financial losses to the agricultural sector. Although it would be difficult to achieve mass casualties through this means, the threat alone of food or beverages being adulterated with chemical or biological agents can result in immediate loss of revenues, stock valuations, and confidence in the food industry. The public can quickly grow to doubt their government's ability to protect its food supply and public health following an incident of sabotage using chemical or biological agents.

In World War I, German agents led by Anton Dilger infected Allied horses, mules, and cattle with disease-causing bacteria, including *Burkholderia mallei* (glanders) and *Bacillus anthracis* (anthrax). Although the ultimate results of these operations are unknown, these German operations suggest that sabotage using biological agents is within the realm of possibility.

Modern saboteurs would have to find chemicals or organisms that are potent enough to cause damage while also being effective under various conditions. Chemicals in the water system, for example, quickly become diluted, causing little or no harm. Similar challenges exist in terms of using pathogenic microbes or toxins. Cholera, for example, usually requires at least thousands of bacteria to be ingested in order to cause infection.

Despite the difficulties of using chemical or biological agents to conduct acts of sabotage, the threat of such an event occurring remains significant. On February 20, 2002, for example, Italian police arrested four Moroccan nationals for allegedly plotting a chemical terrorist attack on the U.S. embassy in Rome. The suspects were apprehended with approximately 9 pounds of a cyanide compound and with maps identifying the locations of the water pipes that served the U.S. embassy. The substance reportedly in the possession of the would-be attackers was potassium ferrocyanide, a chemical commonly used as an anticaking agent and food additive. Because of its low toxicity in mammals and humans, ferrocyanide was an unlikely choice to cause poisoning, especially in a water system. It is likely the would-be saboteurs simply misunderstood that ferrocyanide would be far less toxic than other cyanide salts.

During the Cold War, both the United States and the former Soviet Union expended great energy and financial resources examining the problem of CBW, particularly the threat of introducing infectious or toxic agents into a water supply. Neither found many candidate agents capable of causing mass casualties, because water treatment reduces the effectiveness of virtually any effort to poison water supplies.

The intentional release of toxic or infectious substances has been of heightened concern since the September 11, 2001, tragedy. Most industrial chemicals are not toxic enough to wipe out whole communities, but under certain circumstances, a sudden release of volatile chemicals near densely populated areas could result in significant casualties. The U.S. government is looking into ways of improving security at industrial sites and defending them against potential sabotage by terrorists, criminals, or other malefactors.

Other forms of sabotage could include the use of radiological materials. Although it is not a very likely prospect, insiders at nuclear power facilities could try to circumvent safety measures and intentionally cause a reactor core to overheat. The disaster at Chernobyl in 1986, for example, was the inadvertent result of engineers attempting to complete a hastily conducted experiment. It ended in an explosion and an intensely radioactive fire. Some 4,000 people died, mostly firefighters who extinguished the burning graphite and others who assisted with the cleanup operations.

Less dramatic and not as effective are sabotage operations involving the contamination of food or beverages with radioisotopes. Here, too, the ultimate danger would be reduced by dilution of the agent in the food, and by the fact that many heavy metals that are radioactive (such as plutonium-239) will pass through the human digestive tract without causing much harm. Other radioisotopes, such as strontium-90, however, pose particular risks because they mimic the properties of calcium and can insinuate themselves into bone tissue. No data thus far have demonstrated that terrorists are contemplating such attacks, although al-Qaeda is reported to be interested in developing so-called dirty bombs (radiological dispersal devices).

SALMONELLA

Salmonella is a genus of disease-causing bacteria that could be used as a weapon for sabotage or to produce mass casualties. One species of *Salmonella* in particular—*enterica*—often results in significant disease affecting the gastrointestinal tract. Although the disease-causing *Salmonella* bacteria were recently grouped into the species *enterica* to simplify matters, the nomenclature is still confusing, especially for health care professionals. This species of bacterium, *Salmonella enterica,* is comprised of three main subcategories of distinct organisms, which cause the most significant numbers of illness associated with *Salmonella.* These three serovars (denoted by the capitalized, nonitalicized names following the species designation) are (1) *Salmonella enterica* Typhimurium, (2) *Salmonella enterica* Enteritidis, and (3) *Salmonella enterica* Typhi.

These *Salmonella* bacteria cause disease primarily via ingestion and are not known to spread via aerosols. Therefore, from a weapons of mass destruction (WMD) threat perspective, the only practical manner in which a bioterrorist could use *Salmonella* to cause significant casualties is through the deliberate contamination of food or water. This has been done before, notably in 1984 in Oregon (see below). Still, diseases caused by *Salmonella* have a low mortality rate. In the event of a bioterrorist attack using these types of bacteria, with modern antimicrobial therapy, death rates from *Salmonella* infections should be well below 1 percent.

Among the three *Salmonella* serovars of concern are *S. enterica* Enteritidis and *S. enterica* Typhimurium, the ones that cause salmonellosis (often referred to generically as food poisoning), and *S. enterica* Typhi, the one involved in cases of typhoid (or enteric) fever (not as common, with about 500 cases per year in the United States).

Salmonellosis (Food Poisoning)

S. enterica Typhimurium and *S. enterica* Enteritidis are the most common causes of food poisoning in the United States. Contaminated food and water, particularly as a result of unsafe food handling practices, are the typical sources of these infectious bacteria. Of these two serovars, the Typhimurium serovar is responsible for most cases of food poisoning in the United States. Unlike *S. enterica* Typhi (the cause of typhoid fever), *S. enterica* Typhimurium is also found in domesticated animals, especially those raised for food. This disease is typified by diarrhea, fever, and abdominal cramps, usually occurring within 1–3 days of infection. The course of illness may last up to a week, but in most cases the illness resolves without medical intervention, and diagnosis is not specific enough to warrant antibiotics. Those in risk groups—the elderly, immunocompromised patients, and infants—may, however, develop serious complications that require timely administration of antibiotics. In this group of individuals, the disease may be life-threatening.

If the bacteria spread outside the intestinal tract, antibiotics such as ampicillin and trimethoprim/sulfamethoxazole can be used. As in other common diseases, increased antibiotic resistance in *Salmonella enterica* bacteria can complicate public health efforts. Although some have blamed this on the use of antibiotics in growth feed supplements in agriculture, not all support this view (Hancock et al., 2000).

There are few known cases of individuals or groups deliberately using *S. enterica* Typhimurium as a biological weapon, although one rather spectacular bioterrorist incident involving sabotage using this organism did occur in the United States. In 1984, cult members of the Bagwan Shree Rajneeshee deliberately sickened 751 people with *S. enterica* Typhimurium by contaminating salad bars at local restaurants. None are known to have died as a direct consequence of this attack.

Salmonella Enterica *Typhi*

By 1898, military physicians were among the first to recognize *S. enterica* Typhi as the cause of an insidious infectious disease that could be spread in asymptomatic carriers. (Mary Mallon—pejoratively known as Typhoid Mary—was such a carrier, infecting more than fifty people in New York City during the early 1900s.) Typhoid fever is a serious illness that is only found in humans. As in other types of *Salmonella* infections, typhoid fever is spread via contaminated food or water. Secondary spread is often through the fecal-oral route (e.g., as a result of insufficient hand sanitation, etc.).

Following ingestion of sufficient *S. enterica* Typhi organisms, there is an incubation period of about 1–2 weeks. During this time, the intestinal infection migrates and becomes a systemic disease (bacteremia). High fever, stomach pains, headache, and sometimes a red rash may appear. Unless treated (with antibiotics), typhoid fever can result in death (at a 1–2 percent rate), often due to perforations in the bowel. Traditionally, antibiotics such as chloramphenicol, amoxicillin, and co-trimoxazole have been used to treat typhoid fever. With increased antibiotic resistance found in some *S. enterica* Typhi strains, however, ciprofloxacin and third-generation cephalosporins are currently recommended.

Due to its prevalence around the world, especially before the antibiotic era, typhoid fever has been a dreaded disease. Biological warfare (BW) programs around the world, including those initiated by the United States during World War II, have investigated typhoid fever as a potential threat to military forces. Avner Cohen has made the claim that an Israeli special BW detachment (Hemed Beit) poisoned wells in Palestinian villages with *Salmonella enterica* Typhi (typhoid) and *Shigella dysenteriae* (dysentery) bacteria during the 1948 War of Independence. Data are incomplete to adequately evaluate this allegation. According to the Monterey Institute of International Studies database on terrorist incidents involving chemical and biological agents (1998), in 1972, a group of college students produced 60–80 pounds of typhoid bacteria (*Salmonella enterica* Typhi) culture with the intent to contaminate the water supply in Chicago, St. Louis, and other Midwestern cities. None of these plans was carried out.

The modern threat of *Salmonella*-based weapons is difficult to assess. Factors that aid against mass casualties are increased public health surveillance, ample supplies of antibiotics, as well as the difficulty encountered by the would-be terrorist in culturing and delivering the agent to the intended target(s). Furthermore, even the most serious form, typhoid fever, has an untreated mortality rate of less than 2 percent, which in terms of BW is hardly devastating. At the same time, one cannot discount the possible use of *Salmonella* bacteria by saboteurs as an incapacitating agent, perhaps through the deliberate contamination of food or beverages.

SARIN

Sarin (NATO code GB from the first generation "German" nerve agents) was the second deadly G-series nerve agent discovered by the German chemist Gerhard Schräder and his colleagues in 1938. The name *sarin* is attributed to its discoverers—Schräder, Ambrose, Rudriger, and van der Linde. Germany tried to produce the agent on a large scale, but several technical and logistical hurdles prevented it from doing so. Only small quantities were produced by Germany in 1944. The sarin production process is more complicated than the one for tabun, partly due to the use of corrosive agents in sarin's manufacture. Techniques for mass production of sarin were later perfected by the major powers in the years following World War II.

Following inspections by the UN Special Commission in Iraq (UNSCOM) during the 1990s, Iraq claimed to have produced 790 tons of sarin, 30 tons of which were destroyed by UNSCOM, the remainder reportedly having been destroyed by the Iraqis. Sarin was also employed by the Japanese cult Aum Shinrikyo in 1994 at Matsumoto, where 7 people were killed, and during the 1995 Tokyo subway attack, which killed 12 people and injured about 1,000.

Sarin is an odorless, colorless liquid and is highly lethal. Its primary precursors include isopropyl alcohol, hydrogen fluoride, hydrochloric acid, and phosphorus trichloride. Sarin is not a very persistent agent (evaporating very quickly) and it is miscible (soluble) in water as well as organic solvents.

Like other nerve agents, sarin inhibits the action of the acetylcholinesterase enzyme, resulting in the production of excessive secretions, including mucous in the upper airways, and loss of muscular functions. Death may occur either due to respiratory paralysis or asphyxiation from fluid in the upper respiratory tract.

SEMTEX

Semtex is the brand name of a high explosive produced in the Czech Republic. The primary ingredient is pentaerythritol tetranitrate, with a plasticizer additive. Semtex was probably the explosive used to destroy the Pan-American Boeing flight over Lockerbie, Scotland, in December 1988.

SHIKHANY

Shikhany, located on the Volga River about 50 miles from Saratov, was selected in 1924 to become a center of Soviet chemical weapons activities. In 1926, a secret facility was established under the code name Tomko to conduct chemical warfare agent work under a secret Soviet-German agreement on chemical weapons production. The Germans used the site to circumvent the provisions of the Treaty of Versailles, which forbade Germany to produce, among other kinds of munitions, chemical weapons. Former chief of the Soviet chemical troops, Major General Nikolai S. Antonov, described the origins of Shikhany and the "Tomko" agreement in this way:

> The military-chemical test facility, "Tomko," was organized in cooperation with Germany in 1926. The creation of these schools and the military-chemical testing facilities took place under conspiratorial conditions. The Soviet-German agreement on joint activities within the framework of "Tomko" was signed in the name of fictitious joint stock companies. For Russia, the joint stock firm was signed as carrying out the "struggle against agricultural pests and the use of artificial fertilizers," while Germany's side of the bargain was described as "the use of raw materials." In the agreement text, howitzers were called "Metal devices," projectiles were called "balls," etc. German personnel were prohibited from making acquaintance with the local population, Soviet military personnel, or other foreign nationals. Nor were Germans allowed to leave the Shikhany region without the agreement of Soviet administrative leadership of Tomko. They were even forbidden to leave for the town of Volsk, located a mere 25 kilometers from their quarters in Shikhany (Antonov, p. 19).

The proving ground continued to conduct joint experiments until 1933, when the Germans stopped collaborating with Soviet scientists. After World War II, two chemical facilities used the same place name: Shikhany 1 officially conducted industrial hazardous chemical work for the State Institute for Organic Synthesis Technologies under the Industry Ministry, but may in fact have been engaged in chemical agent research. Shikhany 2 housed a research lab, included a chemical proving ground, and conducted defensive chemical warfare work. These closed cities, also referred to as Volsk-17 and -18, are about 2.5 miles apart. In 1992, chemical munitions were destroyed at both sites. Western suspicions about clandestine activities at these two facilities were raised, however, when President Boris Yeltsin closed the cities in 1997, denying Western observers access to the area.

Shikhany 1, together with two other sites at Novocheboksarsk and Volgograd, carried out all chemical weapons research in the Soviet Union. Shikhany 2, together with Turkus in Kazakhstan, was the main chemical weapons proving ground in the old Soviet Union. For reasons that included an effort to show Soviet willingness toward transparency during discussions on chemical disarmament with the West, a public demonstration to Western observers of twelve chemical weapons in the Soviet Army's inventory took place on October 3–4, 1987. The Soviet Union declared 40,000 metric tons of chemical agents when it became party to the Chemical Weapons Convention and was to begin destruction of these weapons in 1989. However, lack of funding has cast into doubt how far Russia has been able to proceed with the destruction of its Cold War surplus chemical munitions.

A current controversy tied to Shikhany is Western concern about the pilot production of third-generation nerve agents that many believe was undertaken at the site. Some believe that the Soviet Union produced both unitary and binary third-generation chemical nerve agents. Western press speculations focused on allegations in the Russian press that chemical weapons production and research had not ceased as President Yeltsin claimed in 1990. Shikhany 2 continues to undertake research, development, and testing of chemical agent detection and protection equipment for Russia.

SIMULANTS

Simulants are chemicals or microbes used in simulations to study the physical properties of chemical and biological warfare (CBW) agents. Whether for offensive or defensive applications, simulants have been employed for the research and development of methods in the production, dissemination, defense, detection, and decontamination of CBW agents. By their nature, simulants are nearly always non-hazardous substances that are useful for modeling the behavior of real CBW agents.

In most industrialized nations, CBW simulants are currently being used to prepare and exercise defensive measures, which is considered legal activity. This is in contrast to using CBW simulants to develop offensive delivery systems, which is now illegal per international and domestic legislation in most countries. The line, however, dividing offensive and defensive research when using CBW agent simulants can be blurry indeed.

By using nontoxic CBW simulants, laboratory or even open-air testing can be performed without unnecessary risk to workers or the environment. During the Cold War, the United States, the former Soviet Union, and probably other countries conducted CBW research using both live (that is, real chemical agents) and simulated CBW agents to pursue offensive and defensive research. Sometimes tests using simulants were done with the prior knowledge of the human participants. Other tests—such as vulnerability tests in urban cities—were conducted without the knowledge of test subjects. As both Russia and the United States have agreed to abide by prohibitions on chemical and biological weapons (the 1993 Chemical Weapons Convention and the 1972 Biological and Toxin Weapons Convention), both countries now are permitted to use simulants for defensive purposes only.

Today, there are strict guidelines concerning the permissibility of using simulated CBW agents even under controlled laboratory conditions. The challenge faced by researchers working on defensive systems is to find the appropriate chemical or biological agent to simulate a hazardous material, while ensuring that the simulant is safe for use around humans. Other hurdles also include choosing substances that accurately mimic certain chemical or biological signatures to evaluate more and more sophisticated CBW agent detection schemes.

Chemical Warfare (CW) Agent Simulants

Certain chemical compounds, such as riot control agents, have relatively low toxicities, and some of these agents can be used in their actual form to test gas masks and to conduct CBW defensive training. Experimenting on or near humans using other toxic chemicals—particularly the highly potent nerve agents such as sarin and VX—is now out of the question. In 1961, however, Secretary of Defense Robert McNamara led a review of U.S. military defense posture with regard to CBW, under the rubric of Project 112. This program included the testing of both real and simulated CBW agents. For more than a decade (1962–1973), about 150 separate live agent and simulant tests were conducted on U.S. land- and ship-based personnel (equipped with protective clothing and masks). One program that was part of Project 112 was Shipboard Hazard and Defense (SHAD), conducted on ships in open water.

Some chemicals, such as a radioactive tracer element (phosphorus 32, or P32), were used to track simulants as they were delivered and spread. Similarly, zinc cadmium sulfide (FP) was used to track how other simulants performed as aerosols. In a test named Flower Drum I conducted in 1964, the U.S. military experimented with sulfur dioxide and methylacetoacetate (MAA) as simulants for sarin nerve agent, settling upon the latter for further testing. For VX nerve agent, bis(2-ethylhexyl) hydrogen phosphate (BIS) and diethylphthalate (VX simulant) with fluorescent dye tracer were used, presumably because these chemicals behaved like VX. Similarly, tri(2-ethylhexyl) phosphate or trioctyl phosphate (TOF) were used in later testing as VX simulants. The threat from thickened CW agents, preparations that would increase the viscosity and persistence of nerve agents such as soman, was also addressed by the use of dimethyl methylphosphonate (DMMP) thickened with about 2 percent polymethyl methacrylate colored with 0.5 percent oil red dye. Sarin was also simulated by spraying trichloropropane with pneumatic atomization nozzles.

Today, DMMP is one of the more commonly used nerve agent simulants. DMMP closely resembles actual nerve agent for detection and decontamination tests, without possessing any significant toxicity in mammals. Work being done by the U.S. Department of Energy at Sandia Laboratories in New Mexico includes defensive research in CW agent detection using simulants for G-type nerve agents, VX, and sulfur mustard.

Biological Warfare (BW) Agent Simulants

Because of the requirement to generate aerosols when delivering BW agents, particles of many types of materials including flour, talc, oils, and the like have been used in simulating dissemination patterns. For more realistic testing, however, it has often been necessary to use living, noninfectious agents to simulate aerosol density, decay, and viability of organisms over time.

The more commonly used BW agent simulants have included common and innocuous bacteria such as *Bacillus subtilis* var. *niger*—formerly known as *Bacillus globigii* (BG)—and *Bacillus thuringiensis* or Bt. These bacilli have been used for many years, particularly for simulating *Bacillus anthracis* (anthrax) bacterial spores. Between 1949 and 1968, the U.S. government surreptitiously disseminated BW simulants such as *Serratia marcescens* over a number of American cities, including San Francisco and New York, to test for vulnerability to biological attack as well as to experiment with possible weapons and delivery systems. In 1950, the U.S. military spread BG over about 100 square miles in the United States as part of a vulnerability test. The bacteria causes no infections in people, and can be tracked by collecting spores on culture plates. In 1955, American scientists and military experts began using human volunteers to test the effect of various BW simulants including BG. *Serratia marcescens* (SM) was used in San Francisco during this same period. SM was later implicated in hospital-acquired infections, and its use was discontinued in 1969. Project SHAD also included the use of the common bacterium *Escherichia coli* (*E. coli*), as well as BG and SM in the Half Note test (1966). In the face of the modern threat from bioterrorism, research and development in detection technologies requires extensive use of BW simulants (including the standard *Bacillus subtilis*) in controlled laboratory as well as open-air experiments. U.S. government agencies will likely continue such defensive tests using BW simulants as part of a defensive program for the foreseeable future.

SINO-JAPANESE WAR

From approximately 1930 to 1945, Japan engaged in a series of military actions against China known as the Sino-Japanese war. After December 1941, China became an ally of the United States and Britain, and the fighting in China technically became part of World War II. However, the character of the fighting in China differed in some respects from that elsewhere in the Pacific: there was much deliberate cruelty against civilians, and the Japanese conducted chemical and biological warfare.

The Japanese conquest of China was often horrifically cruel and destructive, even when using only “conventional” weapons. During a 6-week period in Nanjing in 1937, for example, the Japanese army killed several hundred thousand civilians and Chinese prisoners of war and raped tens of thousands of Chinese women. Urban areas were subject to aerial bombardment with incendiaries.

Japan had adopted an expansionist policy in China following the first Sino-Japanese war in 1895, which led to the colonization of Formosa (Taiwan). The Russo-Japanese War of 1905 further extended Japanese influence into areas of northeastern China (Manchuria) and led to the annexation of Korea. In a series of fabricated “incidents,” Japanese military forces extended overt Japanese rule throughout Manchuria in 1933, and after 1937 throughout much of coastal China.

Japan did not ratify the 1925 Geneva Protocol that outlawed biological warfare (BW) and chemical warfare (CW). In 1930, Japanese military forces used an irritating agent chloroacetophenone (CN) during its suppression of a Formosa-based indigenous rebellion. Especially after 1933, Japan pursued the development of both CW and BW. In hundreds of separate incidents from 1937–1943, the Japanese military forces fighting in China used chemical weapons of the types developed in World War I. These included mustard, lewisite (often in mixtures), and another irritating substance, diphenylcyanoarsine. Chinese military forces lacked gas masks, and so they typically fled when gas was used. Although the United States later assisted in some areas to provide a defensive and offensive capability in CW, for the most part the Chinese lacked an effective chemical arsenal. Thus, the Japanese were able to use CW without having to endure retaliation in kind.

After China became a U.S. ally after the Japanese attack on Pearl Harbor (December 1941), President Roosevelt issued a warning in 1942 to the Japanese that further use of CW against China would be considered a use against the United States and that the U.S. military might retaliate in kind. Fearing the large chemical arsenal held by the Americans, Japan began to limit its use of chemical weapons against the Chinese after U.S. entry into the war in the Pacific.

As Japan faced an onslaught of both Allied and Soviet forces bent on liberating China, Japanese military forces buried up to 1 million or more chemical munitions, mostly along the Sino-Soviet border, in anticipation of warfare with the Soviet Red Army. As a result, the ongoing disposal of chemical weapons abandoned by Japan in China during the 1940s remains a problem today. Pursuant to the 1993 Chemical Weapons Convention (CWC), Japan has agreed to fund, and provide destruction technologies to rid China of, these abandoned chemical weapons.

Biological Weapons Research

In a well-funded program that lasted from approximately 1932 to the Japanese surrender in 1945, Japan researched, developed, and employed biological weapons while occupying mainland China. The primary research organization was called Unit 731, ostensibly a "sanitation" unit located near Harbin, Manchuria. The leader of this program was an ambitious Japanese military officer and microbiologist, Ishii Shiro. In addition to Unit 731, there were multiple satellite BW facilities located in most major occupied Chinese cities.

The program committed horrific crimes against humanity, including deliberately lethal testing on human captives. Field trials against civilians were conducted within these biological weapons research facilities, where victims (usually prisoners of war, or others taken from local villages) were sometimes vivisected. At least 3,000 innocent victims were murdered during biological experimentation by Japanese BW scientists in China. The weapons developed included plague-infected fleas dropped from airplanes over Chinese cities; bombs containing anthrax; and various waterborne pathogens (cholera, typhoid, paratyphoid, dysentery, and glanders), some of which were released into rural Chinese water supplies. Several cities and scores of villages in Zhejiang province in the summer of 1942 were subjected to BW attack with multiple pathogens, resulting in thousands of deaths. As a consequence of Japanese BW activities, infectious disease persisted in some Chinese villages long after the war was over.

Another branch of the Japanese military BW program included a veterinary research and development organization called Unit 100 that did work in agricultural BW. Unit 100 worked on antianimal diseases such as anthrax and glanders, as well as anticrop agents. Following the U.S. warning regarding the use of CW, Japanese use of biological weapons in China became less frequent.

After the Japanese surrender, the Soviets captured some Unit 731 scientists and related personnel. A dozen of these individuals were tried and convicted of war crimes at a court held in Khabarovsk in 1949. These individuals, however, were not executed but given various jail sentences, and most of them returned to Japan by the late 1950s. Other principal Japanese scientists and staff involved in the BW activity were granted amnesty for their war crimes by the United States in exchange for their technical data of BW effects on humans. At the time, concerns regarding the Soviet Union and its possible development of biological weapons were an important factor in this controversial decision.

Although technically not part of the Sino-Japanese War, the Japanese also mounted a BW attack during a short but vicious border war at Nohoman in 1939. This attack had the aim of contaminating water supplies used by Soviet forces. This was perhaps the first tactical antipersonnel BW attack of modern times. The effect on the Soviet forces is unknown, but the attack did not prevent a rout of the Japanese forces, and apparently it caused many unintended casualties among the retreating Japanese army.

SKATOLE

Skatole is an olfactory agent. Hardly a weapon of mass destruction, olfactory agents nonetheless continue to be researched for their possible role as crowd control agents and in combat. Olfactory agents produce foul odors to harass the enemy; in civilian contexts, they could be used by authorities to persuade unruly mobs to disperse.

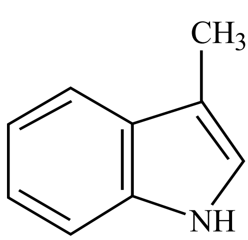
Military manuals dating back at least to the nineteenth century European militaries include stinkball recipes calling for a mixture of sulfur, horse hooves, and other materials that produced a stench. In World War I, foul-smelling substances were investigated to mask the odor of truly toxic chemical warfare agents such as mustard, so as not to alert the enemy to the presence of the toxic agents. These olfactory agents were also used simply to cause distress for the opposing forces, by causing panic about the possible presence of more lethal gases or to force troops to put on protective gear and masks.

N-butyl mercaptan—the essence of skunk—is one such compound mentioned in literature on chemical warfare (CW) during World War I.

During the now-defunct offensive U.S. chemical weapons program, nasty-smelling compounds including derivatives of skatole (3-methyl 1H indole), a foul-smelling substance akin to feces or rotting offal, were investigated. The relative ease of protecting against such odors (e.g., wearing masks) and the fact that motivated opponents would not be deterred by aversive odors alone led planners to abandon research into olfactory agents.

In the United States, there have been hundreds of recent cases involving "noxious chemical vandalism" on abortion clinics or other targets by activists. In most, if not all, of these, butyric acid was used. Butyric acid is the active compound that produces the foul odor in rancid butter, and it can be irritating to the skin and eyes in high concentrations.

Figure S-1: Skatole olfactory agent



Generally speaking, however, butyric acid and other olfactory agents are not very toxic.

SMALLPOX

Smallpox is a contagious, infectious viral disease of humans that causes death in about 30 percent of its victims. (*Contagious* refers to a disease that is communicable through contact, whereas *infectious* is defined as "capable of causing infection." Therefore, some organisms can be infectious but not contagious, i.e., not capable of being passed from person to person.) Motivated by hundreds of millions of smallpox deaths in the twentieth century, the World Health Organization (WHO) initiated a worldwide vaccination campaign that continued through the 1970s. In 1980, the WHO officially certified the elimination of smallpox from the globe (the last case of smallpox in the United States occurred in 1949). This was due to the fact that smallpox is a viral disease that only infects humans. There are no other animals known to carry or suffer from the disease.

Although the disease was officially eliminated in 1980, concerns have emerged about state or terrorist use of smallpox as a weapon. It is known that the Soviet Union ran a program to weaponize smallpox, and it was reported in the fall of 2002 that Iraq, North Korea, and France may also retain samples of the virus. In addition, terrorists are known to be interested in biological weapons. As a result, the United States government has stockpiled enough vaccine to immunize the entire U.S. population; however, due to the potential for side effects from the vaccine and the need to have health care workers available to combat smallpox in the event of an

Some first responders in the United States received the smallpox vaccine in 2003. (Kim Kulish/Corbis)

attack, the current U.S. vaccination policy is to vaccinate only selected health care workers.

Medical Aspects

The Variola virus, a member of the poxvirus family, causes smallpox. A virus is essentially a package of genetic material in a shell made up of protein, which may be surrounded by a protein envelope. Viruses cannot reproduce on their own and must invade another organism to reproduce and grow. Smallpox can take two forms: Variola major, the predominant form, and Variola minor, a less common and less severe form that causes death in less than 1 percent of cases.

A Variola major infection can manifest in four ways. In 90 percent or more of cases, patients experience "ordinary" infection (see below). Other types include modified (a milder infection that normally occurs in previously vaccinated individuals), a malignant form (flat), and hemorrhagic, a particularly dreadful outcome involving bleeding in skin tissues. Both the malignant and hemorrhagic forms of smallpox are nearly always fatal. As with many viruses, there is no specific treatment for smallpox, although prompt administration of vaccine before symptoms appear can prevent the disease.

In the past, natural smallpox was usually spread through close contact of less than 6 feet, with an infected individual spreading aerosolized viral particles, or through contaminated clothing or bed linens. There were occasional cases of transmission over larger distances. The average patient (ordinary infection) developed a fever, experienced severe aches, and became completely exhausted within 12–14 days (within a range of 7–17 days after infection). One to three days after the onset of fever, a rash consisting of small, solid, raised lesions developed on the face and extremities, and to a lesser extent, on the trunk. As the rash progressed, the small lesions filled with fluid and became inflamed, pus-filled, blisterlike, and typically extremely painful. Eventually, the lesions crusted over and formed scabs, which often scarred the patient severely. Death generally occurred during the second week in about 20 to 30 percent of cases, depending on the strain and whether good supportive care was given.

Smallpox as a Weapon

In the second half of the twentieth century, the Soviet Union weaponized Variola major. The collapse of the Soviet Union has caused concern that unsecured stores of biological (and other) weapons might be stolen or sold to terrorists, or that former Soviet scientists who are now out of work might share their expertise with other countries or terrorist organizations for pay.

Smallpox is of particular concern because of the lethality of the disease and the historic development of Variola major as a weapon by the Soviets. Smallpox was chosen as a viable biological weapon because it is a hardy virus, it is highly infectious through the air, it can survive explosive delivery, and it causes a debilitating, disfiguring disease with high mortality. One strain chosen by the Soviets, known as India 1967, was particularly virulent. It killed more than 30 percent of those infected, retained virulence when stored for long periods, and was extremely stable in aerosol form. Additional stabilizers, filling agents, and chemicals extended the shelf life of weaponized smallpox.

The Soviets are said to have stored some twenty metric tons of weaponized smallpox, although all but a few samples stored in Russia (and some kept by the Centers for Disease Control in Atlanta) are said to have been destroyed. There is no evidence in the unclassified literature that other countries or any terrorist groups have developed or acquired a smallpox weapon, and smallpox has not been used as such in modern times. Except for a possible outbreak caused by Soviet weapons testing in the 1970s (Aralsk), there is no experiential data on the course of a man-made smallpox epidemic. Discussions on the course of a smallpox epidemic thus reflect the characteristics of a natural epidemic, which may or may not be different from the effects a smallpox attack would have, especially with a weaponized form of the disease.

Complications in the Event of an Attack

If smallpox were used as a weapon, issues that may arise include recognition and diagnosis in infected patients; a lack of laboratory capacity to test samples; the severity of adverse reactions to the preventive vaccine; the low level of population immunity in the United States; and the difficulties in mounting a quick, widespread vaccination campaign.

Recognition and diagnosis of smallpox may be difficult because many health care workers have little experience with smallpox. In addition, the medical community is unsure about smallpox severity and presentation in individuals vaccinated more than 10 years ago. Smallpox can be confused with other diseases and has been confused with chicken pox in the past. Smallpox lesions develop on the same timeline and appear identical on all parts of the body at a given time; however, they are deeper than chicken pox lesions, and smallpox typically appears on the face and extremities whereas chicken pox lesions are usually concentrated on the trunk.

Atypical presentations of smallpox present additional problems. Malignant (flat) smallpox may occur in about 5 percent of patients, and was 95 percent fatal in non-vaccinated persons. It presents with an insidious, more velvety type of rash. The hemorrhagic form appears in about 3 percent of smallpox cases. In the past, all hemorrhagic cases, which occur more frequently in pregnant women, have resulted in death. The incubation period in these cases is somewhat shorter, and the patient is likely to die by the fifth or sixth day after onset of rash.

Laboratory confirmation of smallpox infection can only be done in a few locations in the United States due to the need for specialized equipment and personnel. Definitive testing may take time. Smallpox infection can be rapidly identified in the laboratory using electron microscopy; however, definitive identification and characterization requires growth of the virus in cell culture or on an egg membrane followed by characterization with biologic assays. The specialized equipment and personnel must be contained in biosafety level 4 facilities (*see* Protective Measures: Biological Weapons). There are only five such facilities in the United States: the Centers for Disease Control and

Prevention in Atlanta; the United States Army Institute for Infectious Disease at Fort Detrick, Maryland; the National Institutes of Health in Bethesda, Maryland; Southwest Research Institute in San Antonio, Texas; and the University of Texas Medical Branch in Galveston.

Vaccination side effects can be severe, and because the risks of a natural outbreak of smallpox are negligible, routine administration of Vaccinia is now only given to U.S. military personnel and certain health care professionals. The smallpox vaccine is made up of live Vaccinia virus. Although this virus is not normally deadly for humans, because the vaccine virus is alive, it can cause severe complications. On the positive side, immunization before exposure and up to 5 (or possibly 7) days after exposure will almost certainly prevent death, and early vaccination—within 1 to 4 days following exposure—will prevent the disease. Expected complication rates are commonly quoted at between one and three deaths and approximately fifty side effects per 1 million people vaccinated; however, based on U.S. surveillance, the actual death rate was five per million and as high as eight per million during vaccination campaigns in previous smallpox outbreaks.

Severe side effects from smallpox vaccination, although rare, may include postvaccinal encephalitis (swelling of the brain) and progressive vaccinia (spread of the vaccination lesion to surrounding tissue). In the past, postvaccinal encephalitis impacted three people per million first-time vaccinees and resulted in death in 40 percent of those cases. Those who survived often experienced permanent neurological damage. Progressive vaccinia occurs among those who are immunosuppressed. A passive form of vaccination using Vaccinia immune globulin (VIG) can be used to treat complications caused by the active Vaccinia inoculation.

In addition to the danger posed by the vaccine to the person receiving the vaccine, there is a period of about 2 weeks during which a newly vaccinated individual can transmit the Vaccinia virus to unvaccinated individuals, with the immunocompromised being the most vulnerable to this.

In addition, because the vaccine has not been commonly administered in the United States for the past 30 years, the effect of the health status of the population on the number and severity of side effects is unclear. There has been a significant increase over time in the number of immunocompromised people, such as those with HIV/AIDS, people undergoing chemotherapy, the elderly, and others who are more likely to experience more severe side effects. The stocks of VIG are very low, reportedly only enough to treat 700 people in 2002.

The United States has a very low level of herd, that is, collective immunity because childhood vaccination was stopped in 1972. Therefore, most individuals in the United States are either unvaccinated or were vaccinated more than 30 years ago. In the past, vaccinations for those working with smallpox were recommended once every 3 years, and the general population was instructed to receive boosters each decade. The efficacy of the vaccine after time periods longer than 10 years is not well studied, but experts generally agree that people vaccinated more than 10 years ago may be more likely to experience a milder atypical form of smallpox and are less likely to die from the infection.

Smallpox vaccination normally takes effect in about 80 percent of the recipients. Repeat administration may be required to ensure that the vaccine "takes," that is, elicits sufficient immune response for protection against smallpox exposure. Vaccination logistics are complicated because vaccination requires special bifurcated needles and the expertise to use them. Because the disease resulting from the live vaccine can be transmitted for 2 weeks, newly vaccinated individuals should not expose themselves (without specific protections including carefully applied bandages) to those who are immunocompromised, to pregnant women, or to people with eczema for at least 2 weeks after vaccination, because these individuals are at risk for developing severe complications from secondary infection with the Vaccinia virus. In an actual event of a smallpox outbreak, however, the risks of acquiring the disease are obviously much greater. For people with eczema and pregnant women, if suspicions are well-founded that either group were exposed to Variola major, combined vaccination of these individuals with Vaccinia and VIG would be indicated.

The Threat

Although there is great concern about a potential smallpox attack, the likelihood of a smallpox attack by terrorists or a state is extremely low—though not zero. There are several reasons for this. First, the virus causing smallpox is difficult to obtain. Starting in 1975, the Smallpox Eradication Unit of the WHO attempted to identify all laboratories that held samples of smallpox by (1) contacting every country and territory and requesting a list of laboratories that maintained stocks of the virus, (2) searching the literature, and (3) contacting laboratories directly. As a result, there are only two remaining known stocks of smallpox in the world. One is located at the Centers for Disease Control and Prevention (CDC) outside of Atlanta, Georgia, and the other is at the State Research Institute of Virology and Biotechnology (VECTOR) near Novosibirsk in Russian Siberia. It has been suggested that no state would want to give a weapon such as smallpox to a terrorist group because of its potential to have unplanned effects, such as killing unintended victims.

Second, the virus is not easy to grow and weaponize. It is a lethal virus, making it dangerous to work with. Any terrorists attempting to weaponize it would have to be immunized against smallpox, a practice stopped in most countries in the late 1970s and early 1980s, with a few exceptions for researchers and others. Therefore, terrorists would first have to acquire some of the vaccine. Also, terrorists capable of growing and weaponizing smallpox would be a very unique commodity. At a bare minimum, the terrorists would need special equipment to work with such a pathogen, and for most terrorist organizations, it would take some effort to acquire the equipment (although less effort than obtaining the virus itself).

Third, terrorists tend to prefer predictable results, and the consequences of releasing smallpox are not well understood. It has been decades since such a virus was released in such a naïve (unimmunized) population, and the population health and demographics have changed in other ways as well since the smallpox vaccine was widely used. The United States is one of the healthiest countries on Earth, and releasing the virus against it might have a boomerang effect, impacting more on the countries of origin of the terrorists than on the United States and its allies. Finally, terrorists or an enemy state may not want to provoke the likely complete and devastating reaction that the United States might have to such an attack.

SOMAN

Soman is a lethal nerve agent also referred to as GD for the "German" series of first-generation nerve agents. It was synthesized by Richard Kuhn in 1944 and had undergone laboratory experimentation by German military chemists by the end of World War II. Being more fat soluble and able to penetrate the skin, soman is far more lethal than sarin or tabun. Soman has been thickened in the past by U.S. and Soviet militaries (resulting in a product called TGD) to improve its dissemination properties as a liquid, as well as increasing its persistency. Soman is a colorless liquid with a "fruity" odor, sometimes described as resembling that of camphor.

Soman is produced in a similar batch process to sarin. The lack of ready precursors prevented Iraq from weaponizing this nerve agent, and thus it turned to others such as tabun (GA) and sarin (GB). Soman is less stable in storage than tabun or sarin but is much more rapid in its lethality: Death can occur within 15 minutes of exposure. Upon exposure to soman, some antidotes (such as selected oximes) are not as effective as they would be for other nerve agents.

Like other nerve agents, soman works by inhibiting acetylcholinesterase (AChE), resulting in the production of excessive secretions and loss of muscular function. Death may occur either due to respiratory paralysis or asphyxiation from fluid in the upper respiratory tract.

SOUTH AFRICA: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

Toward the end of 1981, the South African regime established a covert chemical and biological weapons program code-named Project Coast (later Project Jota). The project was ostensibly created for defensive purposes, in response to reports that government and Cuban military forces in Angola were possibly using chemical weapons against South African Defense Force (SADF) troops and their allies. The program, however, also had offensive features and capabilities. The apartheid-era government viewed itself as the target of a "total onslaught" by Soviet-backed Marxist guerrillas and regimes in neighboring states as well as by black nationalists at home, and to meet this all-encompassing "red-black danger," it was willing to use any means at its disposal to defend itself. It was in this highly charged political and military context that Project Coast was secretly initiated under the aegis of SADF Special Forces (SF).

Project Coast, like the foreign CBW programs upon which it was supposedly modeled, included both a chemical warfare (CW) component and a biological warfare (BW) component. Both the CW and BW programs in South Africa consisted of one principal production facility and several other facilities that, for administrative, security, or technical reasons, carried out specialized research, testing, or production tasks. Although these two main production facilities (one for CW and one for BW) were ostensibly private companies that did commercial contract work for industry—a "cover" that facilitated their recruitment of top scientists and their acquisition of materials overseas—they were in fact SADF front companies that worked primarily on "hard" (military) projects and only rarely on "soft" (commercial) or in-house (researcher-generated) projects.

The primary CW facility was Delta G Scientific (Delta G), a large research and production complex located in Midrand. Its staff of about 120 had the ability to make virtually any synthetic chemical, but their efforts were focused on various military projects geared toward the preservation of public order. These included (1) the large-scale production of chemical irritants and incapacitants used for crowd control, such as CS and CR tear gas; (2) the relatively small-scale production of various illegal mind-altering narcotics in an effort to develop and test their potential viability as "calmatives"; (3) a peptide (complex of amino acids) synthesis program, which was apparently working to enhance the physiological effects of bioregulators, novel agents that could induce dramatic changes in victims; and (4) a CW research and analysis program, which manufactured small quantities of toxic substances on demand.

The main BW facility was Roodeplaat Research Laboratories (RRL), a large, sophisticated research, testing, and production complex located north of Pretoria. Its staff of around 70 worked primarily on three types of military projects: (1) a toxin R&D program headed by Managing Director André Immelman, whose goal was to develop and test lethal BW and CW agents that were untraceable; (2) a fertility program, headed by Dr. Riana Borman, whose purpose may have been to limit the growth of the black population; and (3) a BW program linked to new developments in the genetic engineering field, headed by Dr. Mike Odendaal, whose aim was to develop antibiotic-resistant strains of pathogens by combining different biological agents.

Although there was no large-scale production or weaponization of either offensive CW agents at Delta G or offensive BW agents at RRL, a plethora of toxic substances were acquired, researched, tested, or prepared at these facilities. At Delta G, these substances included BZ and mustard and a wide array of other toxic chemicals, whereas at RRL they included anthrax bacterium, botulinum toxin, *Brucella* bacteria, cholera bacterium, *Clostridium perfringens, Escheria coli,* plague bacterium, *Salmonella* bacteria, HIV-infected blood, and snake venom, as well as small quantities of CW agents such as mustard, sarin, tabun, VX, and various other toxic chemical compounds. Some of the two firms' products were then reportedly tested at the pyrotechnical labs at Special Forces (SF) headquarters, the South African Police's (SAP) Forensic Sciences Laboratory, or other facilities at various state companies, partially state-run companies, private companies, and universities.

The apex of the official chain of command for both the CW and BW components of Project Coast was the president of the Republic himself (P. W. Botha), who, under the militarized National Security Management System established in August 1979, exercised his authority primarily through the State Security Council rather than the cabinet. The entity that officially managed Project Coast was known as the Coordinating Management Committee (CMC), which typically met two to four times per year and normally comprised the SADF chief, the Surgeon-General (who was also the head of the South African Medical Services [SAMS]), the Chief of Staff (COS) for Intelligence, the COS for Finance, representatives from the state armaments corporation, personnel from the Auditor-General's office, and a CMC secretary. Directly under the auspices of the CMC, three ad hoc "work groups" were formed to deal with specialized technical, financial, and security matters.

The Project Officer (Dr. Wouter Basson), who operated under the control and direction of these "work groups," had as his appointed task acting as an intermediary between the CMC and the directors and scientists at the various CBW facilities.

Project Coast may well have had some sort of parallel, unofficial command structure that operated alongside the official CMC chain of command. Former Surgeon-General Niel Knobel claimed that Basson was often either doing things on his own initiative or, as Basson himself later acknowledged, being given operational instructions directly by other parties, including the Defence Minister, the head of the SADF, the Commanding Officer of the SF, the COS Intelligence, the Director-General of the National Intelligence Service, the Commissioner of the SAP, and possibly members of the State Security Council or cabinet whom he encountered while providing them with medical treatment. After receiving at least some of his orders from these powerful figures, Basson then passed instructions on—always verbally—to Project Coast scientists and select members of covert SADF or SAP units with a need to know, frequently without informing his nominal superiors on the CMC.

On two or three occasions, SF elements may have used conventional CW or BW agents, such as BZ, against Mozambican soldiers and cholera to poison Namibian water supplies. The most characteristic feature of the South African CBW program, however, was its development, testing, and use of a wide array of hard-to-trace toxic agents to assassinate individual "enemies of the state." As insider testimony and the notorious RRL "sales list" of 1989 indicate, several of the highly toxic substances produced at both Delta G and RRL were apparently deployed by clandestine SADF and SAP "death squads," mostly the SF's Civil Co-Operation Bureau (CCB) and the SAP Security Branch's Counterinsurgency section (later renamed C10) housed at the Vlakplaas base, in covert assassination operations.

Members of certain elite Rhodesian counterinsurgency units who had previously deployed toxic chemicals or biological agents against guerrillas during the Rhodesian civil war were later incorporated into SADF special operations units (such as the SF and its Delta 40 and Barnacle "hit teams," the predecessors of the CCB) or the SAP's counterinsurgency forces (such as the Koevoet [Crowbar] unit). There is no doubt that high-ranking officers within the SADF and SAP, and other "securocrats" within the government, were generally aware of these murderous activities, many of which they in fact authorized.

On the verbal instructions of Basson, RRL's research and development director secretly transferred a host of highly toxic chemicals and freeze-dried pathogens that had been produced at either Delta G or RRL—and thereafter stored in a refrigerator inside a fireproof and bomb-proof walk-in safe in his own office—to military and police personnel through various channels. The actual substances included lethal chemicals such as Aldicarb, brodifacum, cantharidin, colchamine, cyanide, digoxin, methanol, monensin, paraoxon, paraquat, phencyclidine, phosphide, silatrane, sodium azide, thallium, and Vitamin D3; biological agents such as anthrax spores, botulinum toxin, *Brucella* bacteria, *Salmonella* bacteria, mamba venom, and bottles of cholera bacterium; and a wide variety of foodstuffs, beverages, household items, and cigarettes that had been contaminated with these poisons. The evidence suggests that several of these toxic materials, items, or devices were used to murder or sicken troublesome prisoners, guerrillas in neighboring countries, untrustworthy members of the security forces, or activists in the African National Congress (ANC) and other South African opposition groups.

Later, in the course of the extraordinary political transition of the early 1990s during which the apartheid regime reluctantly but peacefully ceded power to a new ANC-led government, the activities of Project Coast were gradually phased out and exposed. In January 1997, Basson was arrested in a sting operation for possessing thousands of capsules of the illegal drug MDMA (Ecstasy) that had apparently been manufactured at Delta G, ostensibly for use as a potential "calmative." Following Basson's arrest, the police discovered several trunks full of project documents that he had secretly whisked away and stashed with friends or in storage facilities, a small but important portion of the corpus of documents that was supposed to have been physically destroyed after being copied onto secured CD-ROMs.

Basson was indicted by the state for murder and a host of other crimes that he had allegedly committed during the period when he served as project officer for Coast. During the course of this trial, as well as at the earlier hearings held by the Truth and Reconciliation Commission, a wealth of detailed information emerged regarding the true scope and nature of South Africa's CBW program. To the astonishment of most observers, however, Basson was acquitted in April 2002 of all the charges filed against him, and disillusioned government prosecutors now appear to have abandoned their plans to file an appeal for a new trial.

While some analysts regard South Africa as a model for other states that might decide to dismantle their WMD programs, the termination of the country's CBW program was by no means as transparent as that of its nuclear program. Basson's assurances that the remaining stocks of Coast-related CW and BW agents were destroyed were never independently verified, virtually everyone responsible for the crimes associated with the program escaped punishment, and, as recently as 2002, at least one former Coast scientist was involved in a scheme to sell lethal BW agents to foreign parties.

SOUTH KOREA: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

Although it exists in uneasy armistice with North Korea, a proliferator of nuclear, biological, and chemical weapons, South Korea has foresworn weapons of mass destruction. In the 1970s, South Korea flirted with, then abandoned, a nuclear weapons program, but it retains the technical capacity to produce nuclear, as well as chemical and biological, weapons. South Korea is a signatory to several major nonproliferation treaties, including the Nuclear Nonproliferation Treaty (NPT), Chemical Weapons Convention (CWC), and Biological and Toxin Weapons Convention (BTWC). South Korea has adopted a policy of a "nuclear-free Korean peninsula."

In 1991, President Roh Tae-Woo ruled out South Korean acquisition of chemical and biological weapons and pledged to participate in international efforts to eliminate these weapons. After ratifying the CWC in 1997, South Korea acknowledged possessing a chemical weapons production facility as well as several tons of chemical weapons. Honoring its CWC obligations, South Korea is currently investigating means of destroying chemical munitions at a disposal site in Yongdong

South Korea joined the Australia Group in October 1995, and ratified the CWC in April 1997. Due to the threat of North Korean biological weapons, South Korea conducts research and development for defensive biological warfare and possesses vaccines against anthrax and smallpox. Although South Korea possesses a well-developed pharmaceutical and biotechnical infrastructure, there is no evidence that Seoul has an offensive biological weapons program.

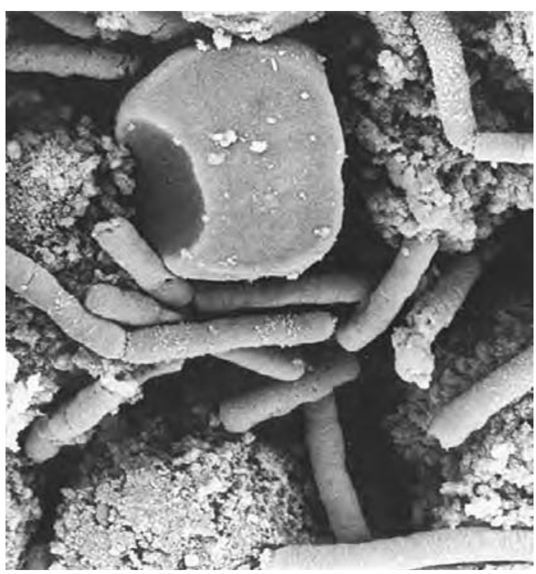
SPORE

Some bacteria convert to a dormant and inactive form called a spore under anaerobic (lacking in oxygen) conditions or when little nutrition is available. Usually, a spore is stable and is resistant to heat, drying, freezing, chemicals, and radiation because it is protected by an exosporium (an outer envelope), a spore coat, and a skin coat. Spores are metabolically



Bacillus anthracis (anthrax) under electron microscopy. (Ant/Corbis Sygma) inactive, which makes it unlikely that they will ingest poisonous materials.

The anthrax (*Bacillus anthracis*) spore has several qualities that make it an ideal biological weapon. When anthrax is converted to a spore, it becomes an extremely stable particle, resistant to many chemicals and environmental stress factors such as heat, moisture, and extremely cold weather. In the nineteenth century, cattle were imported from India to Australia for beef consumption, but anthrax disease broke out among them. These cattle were slaughtered and buried. After 130 years, the ground in that area was broken for construction purposes, and anthrax disease spread again, illustrating the extreme stability of spores.

When dormant and inactive, spores of anthrax enter a person or an animal through inhalation, through wounds in the skin, or orally. Once inside the body, the spore converts into the active form of anthrax bacteria, causing infection in humans or animals.

STABILIZERS

Due to the inherent chemical and physical properties of some chemical and biological warfare (CBW) agents, stabilizers are sometimes used to prolong shelf life, enhance dissemination patterns, and increase the overall effectiveness of these agents when deployed in weapons systems.

In the case of chemical warfare (CW) agents, the primary technical hurdles faced by weapons engineers have involved problems caused by acidic by-products and chemicals spontaneously combining into unwanted byproducts (polymerization). Overly high or low pH levels in a variety of CW agent mixtures can not only degrade the agent, but can corrode vessels in both storage and weapons platforms. In the case of polymerization, molecules can spontaneously attach themselves to one another, changing the properties of the agent or even causing an explosion. Sulfur mustard is notorious for its ability to polymerize, as is hydrogen cyanide. Nerve agents—particularly the G-series agents that contain fluorine (e.g., sarin and soman)—can be prone toward this same instability. Other agents are relatively stable and require little additional processing.

Chemical stabilizers such as neutralizing compounds can prevent the degradation of CW agents. In 1995, for example, Iraqi Scud warhead fragments showed degradation products of VX and dicyclohexyl carbodiimide, a well-known stabilizer for munitions containing VX. Other compounds such as trimethylamine can be used for acidic nerve agents. For the first mass-produced nerve agent, tabun, German chemists added chlorobenzene to increase its storability.

Biological warfare (BW) agents are biologically active but for the most part chemically inert substances or living organisms. In most cases, when it comes to stability of biological agents, water is the main culprit, causing physical manifestations (caking) and allowing other microbes and enzymes to spoil the product. Freeze-drying (or lyophilization) and the addition of certain neutral stabilizers have been used in the past to help correct this problem. Anti-caking agents (silicon dioxide-based powders) and other compounds to maintain loose particles have also been employed in certain BW preparations.

Although only indirectly related to the problem of stabilizing CBW agents, liquid rocket propellants also sometimes require the addition of chemicals to maintain the structural integrity of storage vessels as well as rocket components. In the case of the oxidizer (the oxygen containing part of the fuel mixture) called inhibited red fuming nitric acid (IRFNA), hydrogen fluoride (and other compounds) has been used to keep the acid from decomposing its metal containers. It is thought that hydrogen fluoride forms an insoluble metal complex that prevents corrosion of the inner wall of the vessel.

STAPHYLOCOCCAL ENTEROTOXIN B

The bacterium *Staphylococcus aureus* produces a number of toxic proteins that are considered exotoxins because they are excreted from the cell. These proteins generally act on the intestines and are thus also referred to as enterotoxins. Natural exposure to *Staphylococcus* toxins generally results in food poisoning or nonmenstrual toxic shock syndrome. Due to their profound effect on the immune system, these proteins are commonly referred to as superantigens.

Of these toxic proteins, staphylococcal enterotoxin B (SEB) is the most studied for its ability to achieve the desired effect at very low quantities. The offensive biological weapons program of the United States pursued SEB as an incapacitant in the 1960s. SEB proved to be stable, easily aerosolized, and able to cause systemic damage including multiorgan failure. Furthermore, the agent was more attractive than chemical equivalents because a smaller amount was necessary to get the desired effect. Although exposure to this agent most frequently results in a temporary incapacitating illness, inhalation of very high doses can lead to shock or death.

Most cases of ingested toxin can be linked to improperly handled food products and often traced back to a specific setting where contaminated food was consumed. In the 1960s, research was conducted by the United States at Camp Detrick (now Fort Detrick), Maryland, which included offensive use of SEB (code-named PG) as an incapacitant. These stockpiles were destroyed between May 1971 and May 1972 when other U.S. chemical and biological agents were destroyed. It has been reported that Russian biological weapons programs involved research into using SEB as a toxic agent.

Technical Details

Staphylococcal toxins can cause classic food poisoning. These toxins are produced by *Staphylococcus aureus* bacteria present in unrefrigerated meat, dairy, and bakery goods. When ingested, the toxins are usually confined to the intestines and cause diarrhea and vomiting. When present systemically, or throughout the body, toxic shock syndrome can result.

SEB is a relatively stable compound that is easily soluble in water, is resistant to temperature fluctuations, and can withstand boiling for several minutes. The toxin can be produced by bacteria cultivated in culture media, where the toxins can be excreted and harvested. When freeze-dried, SEB can be stored for more than a year.

SEB is classified as an incapacitating agent, as most cases are not lethal but cause profound illness within a short incubation time. The incubation time after ingestion of SEB varies from 1 to 8 hours (rarely, up to 18 hours) and results in the abrupt onset of acute salivation, intense nausea, vomiting, cramping abdominal pain, and diarrhea. Fever and upper respiratory distress are not seen in ingested cases. These symptoms are usually self-limiting and resolve in about 8–24 hours, but high levels of exposure can lead to septic shock and death if left untreated. Treatment consists of administration of antihistamines, and antibodies (gamma globulin) may also increase survivability.

Aerosol exposure manifests itself in a different manner. The incubation time from airborne exposure is 1–6 hours. After 3–12 hours, a high fever (103–106° F), chills, headache, myalgia (muscle aches), and nonproductive cough may appear. Shortness of breath and chest pains may appear in some patients. The fever can last 2–5 days, and the cough may persist up to 4 weeks. Supportive therapy (in addition to the use of antihistamines and passive antibodies) is recommended.

Diagnosis of SEB exposure can be challenging, as the early symptoms mimic many naturally occurring diseases such as influenza, adenovirus or parainfluenza. Additionally, early clinical manifestations can be similar to those of inhalation anthrax, tularemia, plague, or Q-fever. However with SEB, the respiratory signs and symptoms generally become stable more rapidly as the toxin is cleared from the system.

There are a number of laboratory tests to determine exposure that can be used during the first 6–12 hours. Nasal swabs, induced respiratory secretions, and blood or urine analysis can be useful. Most patients will develop a significant antibody response by 6 days after exposure.

Treatment for enterotoxin exposure is limited. Generally, supportive care and close attention to oxygenation and hydration are adequate. In severe cases, breathing assistance may be necessary. No vaccine is available.

There are no known stockpiles of weaponized *Staphylococcus aureus* toxins. Incidences of ingested toxins due to improperly handled food, however, are common.

An attack with an aerosolized SEB weapon would be unlikely to lead to significant mortality, but 80 percent or more of those exposed to the toxin could be incapacitated for 1–2 weeks. This ability to cause casualties, even if nonfatal, makes the toxin a candidate for weaponization. Additionally, SEB could be used to sabotage food or small-volume water supplies.

STEPNOGORSK

Stepnogorsk was a key Soviet military center that housed the largest biological weapons production complex in the world. Stepnogorsk, established in 1964 in northern Kazakhstan, never appeared on any Soviet maps. It has been referred to as Makinut-2, Tselinograd-25, or Aksu. The area around Stepnogorsk includes the Tselinny Gorno-Khimichskii Kombinant (TGK) mines and refinery, facilities for the extraction of uranium ore, and the Scientific Experimental and Production Base (SNOPB).

SNOPB, the most strategically important of all the facilities near Stepnogorsk, was a biological weapons facility ostensibly constructed as the commercial biotechnology plant Progress in 1982. This facility played an important role in the Soviet Union's plans for the mobilization of "total war." SNOPB was under the authority of Biopreparat and was designed to be one of the six plants in the Biopreparat system for large-scale production of biological weapons, should the Soviet Union decide to mobilize for total war. The facility specialized in the production of anthrax and might have been able to produce anthrax at the rate of 300 metric tons over 10 months. In 1988, a research team at SNOPB led by Kanatjan Alibekov discovered the Soviet Union's most lethal weapons-grade anthrax. However, anthrax was not the only agent produced at SNOPB. The facility also produced *Staphylococcus* toxin, Marburg viral vaccines, diagnostic tools, herbicides, and medicines.

The SNOPB facility was designed to incorporate the latest developments in biotechnology. Its construction was aided by access to an abundant amount of power, heat-generating facilities, and skilled construction specialists. When finally constructed, the facility consisted of twenty-five buildings

The facility was connected by a series of pipes to ease the production and transportation of biological agents. Building 211, which produced nutrient media, was connected by pipes to building 221, the production plant. Cultures were placed in fermenters. Selected strains of biological agents were then collected and taken to a Biosafety Level 3 laboratory in building 221. The laboratory contained all of the necessary equipment to cultivate the biological agents, including submarine doors. Cultivation took place in small fermenters, which used gravity to make the selected strain of biological agents descend into larger production fermenters. The solution was then sent to centrifugal separators located on a lower floor. Once the biological agents were separated, they were inserted and sealed into bomblets.

SNOPB, as mentioned previously, specialized in the production of anthrax. After the accidental release of anthrax spores from Sverdlovsk (1979), the West began to suspect that the Soviet Union was building a clandestine biological weapons program. Due to the inherent risks of both human safety and military secrecy, in 1984, the Soviet government began to transfer equipment and personnel from Sverdlovsk to Stepnogorsk.

SNOPB had a 350-person staff in 1984; that number increased to 800 personnel by 1991. The facility was able to attract the most talented Soviet biotechnology scientists, and specialized courses at leading Russian institutions were established for new personnel. SNOPB exchanged technical expertise with Ministry of Defense (MOD) facilities as an equal partner, even though SNOPB was technically subordinate to Biopreparat. The facility had staff from Sverdlovsk and the Kirov MOD research cen-

Andrew Weber led the U.S. effort to rid Kazakhstan of its Soviet-era biological weapon infrastructure. July 2000. (Reuters/Corbis)

ter. Additionally, SNOPB maintained numerous links with important research institutions such as the Institute of Bioorganic Chemistry.

In 1989, SNOPB began to move away from the production of biological agents toward civilian production of vaccines and diagnostic tools. SNOPB worked closely with Progress, and the Soviet authorities decided that SNOPB should now produce human insulin and remove all unnecessary equipment. Following the collapse of the Soviet Union, however, this decision was never implemented.

Today, under a cooperative threat reduction agreement, the United States has supplied funding to dismantle military facilities inside the former Soviet Union related to the production of weapons of mass destruction. Stepnogorsk has been included in an effort to engage the affected facilities personnel in defensive and peaceful scientific work. In 1998, the U.S. Civilian Research and Development Foundation made three project awards that included scientists from the Stepnogorsk facility. Additionally, the U.S. Department of State is providing $210,000 to support projects at the Stepnogorsk facility.

SVERDLOVSK ANTHRAX ACCIDENT

The April-May 1979 accidental outbreak of anthrax in Sverdlovsk (now known as Yakaterinberg), Russia provides a telling example of the dangers that are posed by biological weapons programs. In addition to highlighting the nature of the biological agent anthrax and possible distribution methods (i.e., aerosolization), the Sverdlovsk accident also brings to light the ease with which a clandestine biological weapons program can be constructed, operated, and maintained.

Anthrax is an acute infectious disease caused by the spore-forming bacterium *Bacillus anthracis.* Anthrax most commonly occurs in wild and domestic lower vertebrates (cattle, sheep, goats, camels, antelopes, and other herbivores), but it can also occur in humans when they are exposed to infected animals or tissue from infected animals.

Anthrax infection can occur in three forms: cutaneous (skin), inhalation, and gastrointestinal. *B. anthracis* spores can live in the soil for many years, and humans can become infected with anthrax by handling products from infected animals or by inhaling anthrax spores from contaminated animal products. Anthrax can also be spread by eating undercooked meat from infected animals.

Sverdlovsk was home to a secret Soviet government facility known as Compound 19, which manufactured weapons-grade anthrax and other biological agents. Although U.S. intelligence long suspected the existence of the Sverdlovsk biological research facility, it held no corroborating evidence to prove its suspicions that Compound 19 served as a biological weapons facility.

On or about April 2, 1979, millions of anthrax spores escaped from the secret facility. How this happened is still yet to be explained fully by Russian officials. One rumored explanation cites a missing air filter as the culprit for the leak.

Prevailing wind currents carried the escaped spores through a narrow zone extending from the compound all the way to the southernmost part of the city. Those in the immediate path of the spore cloud were at the greatest risk, having been exposed to the highest concentration of spores. As the spore cloud dissipated, its strength began to dwindle. Cattle as far away as 30 miles south of the city, however, were still found dead due to anthrax exposure, a testament to the efficiency with which the agent dispersed.

By all official Soviet accounts, this accidental release of a highly contractible aerosolized strain of anthrax in the working-class city of Sverdlovsk claimed the lives of sixty-four men and women in the spring of 1979. Some reports place the number of fatalities at closer to 100, and some earlier intelligence estimates placed casualty estimates into the thousands.

Immediate word of what happened in Sverdlovsk was scarce, even within the city and surrounding territories. Rumors were rampant of a strange disease that wasted healthy people away in a matter of days. No articles, television reports, or government statements were made, and aside from the random attempts by citizens to sanitize their homes against the invisible danger, there was little in the way of outward appearance which would have indicated any trouble at all. Local medical staff were only informed of the possibility of an outbreak "of some kind" and were given no further advice or support.

Initial U.S. intelligence reports regarding the outbreak relied upon second- and third- hand word of mouth. Word of the outbreak did not reach Western media sources until early 1980. As word of the outbreak finally began to surface in the West, the Soviet government hatched an outbreak scenario to explain the incident while protecting Compound 19's existence.

To conceal the true nature of the outbreak, Soviet officials first attributed the disease to the consumption of contaminated meat. Articles began to appear in Soviet medical, veterinary, and legal journals reporting on an anthrax outbreak that occurred in Sverdlovsk-area cattle. These articles implicated the consumption of this contaminated meat as the cause of the outbreak of the disease in the local community. Russian officials even went as far as to state that the reason why the majority of victims were middle-aged males was that males, as the typically dominant meat consumers in a working-class town such as Sverdlovsk, were far more likely to come into contact with contaminated meat.

U.S. agencies, however, citing epidemiological evidence showing a clear pattern of infection synonymous with inhalatory anthrax, concluded that the agent was aerosolized and most likely linked to the suspected Sverdlovsk biological research facility.

The source of the outbreak became a matter of intense international debate: Authorities knew that if the outbreak were proven to be of other than natural origin, it would be evidence of actions prohibited by the 1972 Biological and Toxin Weapons

Convention. In 1986, after a number of previous efforts had failed, a team of independent investigators was sent to Moscow for discussions with the four primary physicians directly responsible for dealing with the outbreak. Two years later, two of the primary physicians were invited back to the United States, where they provided formal presentations outlining the official Soviet stance on what occurred.

Although U.S. officials agreed that the evidence provided suggested the possibility of a gastrointestinal anthrax outbreak, they concluded that they required additional forensic evidence to reach a definitive conclusion about the origins of the disease.

In 1990, several articles about the epidemic surfaced that questioned the original Soviet explanation of the outbreak. As pressure mounted on the new post-Communist Russian government, President Boris Yeltsin (who, in 1979, was the chief Communist Party official for the Sverdlovsk area), directed his Counselor for Ecology and Health to determine the origin of the epidemic. In May 1992, Yeltsin was quoted as stating: “the KGB admitted that our military developments were the cause.” The Russian government has provided no further information regarding the outbreak. Subsequently, the chairman of the committee to oversee biological and chemical disarmament expressed doubt that the biological agent originated at Compound 19. The committee then conducted its own investigation into the outbreak, but has yet to provide the results of its investigation.

SYRIA: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

Although constrained by limited resources, Syria reportedly possesses an active chemical warfare program and a limited biological warfare program. Syria has also acquired a substantial force of ballistic missiles capable of delivering chemical munitions to targets throughout Israel. Syria views Israel as its primary external threat and sees its chemical weapons, and possibly its less advanced biological warfare capabilities, as a means to counter Israel's qualitative military superiority.

Syria's initial interest in chemical and biological weapons probably dates back to the 1970s, when it reportedly received chemical warfare technology and materials, including chemical agents, from Egypt in preparation for the 1973 October War against Israel. With the demise of the Soviet Union, Damascus has placed even greater emphasis on the development and acquisition of unconventional weapons to make up for the loss of Soviet conventional military support and for Syria's growing military asymmetry with Israel.

Chemical Weapons

Syria has not acceded to the Chemical Weapons Convention and has had a chemical warfare program for many years, although it has never used chemical agents in a conflict. According to a 2001 U.S. Department of Defense report, “Damascus already has a stockpile of the nerve agent sarin that can be delivered by aircraft or ballistic missiles. Additionally, Syria is trying to develop the more toxic and persistent nerve agent VX. In the future, Syria can be expected to continue to improve its chemical agent production and storage infrastructure. Damascus remains dependent on foreign sources for key elements of its chemical warfare program, including precursor chemicals and key production equipment. For example, during 1999, Syria sought chemical warfare-related precursors and expertise from foreign sources” (U.S. Department of Defense, 2001, p. 45). Media sources—including the Arabic newspaper *Al Hayat* (London) and *Washington Times,* among others—have reported that Damascus has received direct assistance from Russia (and formerly the Soviet Union), Iran, and North Korea in developing its CBW and missile programs.

The U.S. Central Intelligence Agency confirmed that in 2003 Syria continued to seek CW-related expertise from foreign sources: “Damascus already held a stockpile of the nerve agent sarin, but apparently tried to develop more toxic and persistent nerve agents. Syria remained dependent on foreign sources for key elements of its CW program, including precursor chemicals and key production equipment" (CIA, p. 6). Syria's motivation to acquire chemical warfare agents and ballistic missiles appears to be a response to Israel's superior conventional military capabilities. Insufficient public information exists to determine whether Syria plans to use CW primarily on the battlefield or if this capability is reserved for employment as a counterforce deterrent against potential Israeli attack.

Biological Weapons

Syria signed the Biological and Toxin Weapons Convention in April 1972, but since that time it has refused to ratify the treaty and has given no indication that it might do so in the near future. Although there is very little hard evidence in the public domain, both government and media sources (e.g., *New York Times* and *Jane's Defence Weekly*) suggest that Damascus is pursuing the development of biological weapons. Israeli sources (such as Dany Shoham) have asserted that Syria possesses *Bacillus anthracis* (which causes anthrax), botulinum toxin, and ricin. Other independent assessments (such as those published by the Nuclear Threat Initiative), however, maintain that there is no evidence that the country has progressed past the research and development phase of a BW capability. Syria has a pharmaceutical infrastructure that could support a limited BW program, and it engages in extensive trade of dual-use equipment and goods with companies in western Europe, Russia, and North Korea.

According to the 2001 U.S. Defense Department document, *Proliferation: Threat and Response,* "Syria's biotechnical infrastructure is capable of supporting limited agent development. However, the Syrians are not believed to have begun any major effort to put biological agents into weapons. Without significant foreign assistance, it is unlikely that Syria could manufacture significant amounts of biological weapons for several years" (p. 45). In a more recent assessment, however, the CIA reported in 2003: "it is highly probable that Syria also continued to develop an offensive BW capability" (CIA, p. 6).

Ballistic Missiles

As mentioned above, Syria's missile program began in the early 1970s as a means to counter Israel's superior military capabilities. Because Syrian defense planners have no illusion about the effectiveness of their own air force against Israel's air defense network, Damascus has made its missile development program a top priority. Today, Syria's arsenal of ballistic missiles, consisting of hundreds of Scud-derived missile systems, is one of the largest in the Middle East. Syria is believed to have chemical-filled warheads available for a portion of its Scud missile force.

In the 1970s and 1980s, the Soviet Union provided Syria with technology and support for its missile program and transferred to Damascus the Soviet FROG-7, Scud-Bs, and the solid-fueled Scarab SS-21 missile systems. In the 1990s, Syria looked to other states to supply it with missile technology and found willing partners in Iran and North Korea. Iran provided Syria with technical assistance for solid-fueled rocket motor production, and North Korea supplied it with equipment and technical assistance for liquid-fueled missile production. Syria, however, has had difficulty creating an indigenous production capability and has had to rely on continued imports from countries such as North Korea, China, and Russia. Syria reportedly purchased 150 Scud-C missiles from North Korea in 1991. In September 2000, Syria tested a North Korean 700-kilometer-range Scud-D missile, revealing its continued commitment to expanding its missile capability. All of Syria's missiles are mobile, that is, are transportable on vehicles, and can reach much of Israel and large portions of Iraq, Jordan, and Turkey from launch sites well within Syria.

In addition to its ballistic missiles, Syria has a variety of Soviet-made land- and sea-launched short-range antiship cruise missiles and air-launched short-range tactical missiles, which have the potential to deliver chemical and biological weapons. Syria also has numerous fighter aircraft, helicopters, artillery, and rockets available.

T

TABUN

The first of the G-series ("G" for German) nerve agents, tabun was discovered in 1936 by Gerhard Schräder and his colleagues at the German firm I. G. Farben while conducting some agricultural research on pesticides. Shortly thereafter, Germany undertook efforts to produce large quantities of tabun, but due to various logistical and technical hurdles, production did not begin until 1942. Tabun was intended to be disseminated as a deadly aerosol by the German military, but despite their having produced 12,000 pounds of tabun, the agent was never used. Half a century later, Iraq declared that it had developed about 210 tons of tabun, most of which was believed to be of poor quality. Thirty tons of Iraqi tabun were destroyed by the UN Special Commission (UNSCOM) in the 1990s, while the remainder is still unaccounted for.

Tabun is a cyanide-containing organophosphate that is much less volatile than other G-series agents. It is only slightly soluble in water but can dissolve more easily in fat-soluble solvents. Tabun can be stored (in steel containers) up to several years at ordinary temperatures. Described as having a slightly "fruity" smell, pure tabun is actually an odorless, brownish liquid.

Tabun production is quite simple, requiring only four primary precursors: sodium cyanide, dimethylamine, phosphorus oxychloride, and ethyl alcohol. Its relative ease of production was probably the reason Iraqi scientists chose to manufacture tabun as a significant part of the country's chemical weapons program. Like other nerve agents, tabun prevents the enzyme acetylcholinesterase (AChE) from hydrolyzing (breaking apart with water molecules) acetylcholine (an essential neurotransmitter), eventually leading to nervous system failure. Initial symptoms of exposure include breathing difficulty, nausea, headache, drowsiness, twitching, and loss of muscle control. Depending on the lethality of the agent and the mode of delivery, tabun can kill a human being within 15 minutes to a few hours.

TERRORISM WITH CBRN WEAPONS

Terrorist use of chemical, biological, radiological, and nuclear (CBRN) weapons and devices is considered the most likely form of future "unconventional" warfare. In this next phase of "asymmetrical" warfare, terrorist operatives will exploit the latest technological advances, albeit through relatively crude or unsophisticated means, to inflict catastrophic harm against much more powerful adversaries. This forecast is not intended to imply that conventional terrorist warfare will not remain the most pervasive form of warfare facing the world—and that it will not become increasingly lethal and

Firefighters practice decontamination measures in a WMD terrorism exercise. Cambridge, MA, May 2004. (Jim Bourg/Reuters/Corbis)

damaging in its own right—but that as terrorist groups, especially the al-Qaeda network, escalate the lethality of their warfare, CBRN weapons (i.e., in terms of agents, devices, and delivery systems) are likely to play a larger role among terrorists' weapons of choice.

The world already confronts the specter of CBRN terrorism. With regard to biological weapons, in late January 2003, al-Qaeda operatives arrested in Great Britain and in Spain were suspected of plotting biological attacks using the deadly toxin ricin against a major European city. Al-Qaeda's British cell had reportedly plotted to employ ricin to lace the food supply at a British military base. Following al-Qaeda's simultaneous suicide aircraft attacks of September 11, 2001, which represented the most catastrophic terrorist operations to date but which still employed conventional means, an unknown perpetrator launched a poisonous anthrax letter campaign that killed five persons and terrorized the entire United States. The anthrax attacks represented the second largest biological terrorist operation in the United States. In 1984, the Bagwan Rajneeshee cult carried out a *Salmonella* food poisoning of the salad bars of several Oregon restaurants, which fortunately did not lead to any deaths, but made at least 750 people ill.

In terms of chemical weapons, in February 2002, a plot by an al-Qaeda cell to poison Rome's water supply with cyanide-based chemicals was thwarted by Italian authorities. (It is likely that this apparent plan would not have succeeded, as the chemical chose, ferrocyanide, has a very low toxicity profile.) This was followed in August 2002 with the CNN television network running a series of reports on captured al-Qaeda documents and training films that demonstrated the magnitude of al-Qaeda's interest and training in employing chemical weapons. Al-Qaeda's intention to carry out CW attacks was further confirmed in November 2002, when British police arrested three al-Qaeda operatives who had plotted to release cyanide gas on the London Underground.

The first major international chemical operation by a terrorist group was the March 1995 sarin nerve agent attack by the Japanese cult Aum Shinrikyo on the Tokyo subway system, killing 12 people and wounding 3,796 others. The group's first major sarin attack occurred in 1994 against the Japanese town of Matsumoto. According to testimony by Dr. Ikuo Hayashi, a cult member, the group had also plotted to release nerve gas in the United States in 1994, but the plan was never carried out.

Palestinian terrorist groups have also exhibited some interest in acquiring a CBW capability. According to the Israeli media, members of Hamas's military wing have been collecting information to carry out CBW attacks. In 2002, Israeli security forces arrested members of a Hamas cell who admitted that the group was gearing up for attacks involving unconventional weapons. In late 2002, Israel's media also reported a Hamas plan to poison the food supply in a Jerusalem restaurant. In January of 2003, Walid al-Ara, an owner of a computer store in Gaza and a member of Hamas's military wing, was indicted for allegedly researching the subject of BW on the Internet on behalf of a top Hamas operative. Israel claims that evidence of Hamas's interest in biological weapons has also been discovered in one of the group's explosives laboratories in the West Bank. Another group, Palestinian Islamic Jihad, had reportedly planned to poison the water supply of a Jerusalem hospital. Israel's media also carried a story claiming that a Palestinian al-Qaeda operative had planned to poison the entire country's water supply.

There are also precedents for concern about terrorists' use of radiological dirty bombs. In 2001, for example, Russian authorities uncovered a container filled with 2 kilograms of a "radioactive substance" in Shali, Chechnya. In May 2002, Jose Padilla, an al-Qaeda operative, was arrested at Chicago's O'Hare International Airport and charged with plotting to detonate a radiological dirty bomb in the United States.

Although there are no precedents for nuclear terrorism, in November 2002, a Tunisian man with links to al-Qaeda, who had been arrested in Belgium the previous year, claimed that he was part of a plot to attack an air base in that country where U.S. nuclear bombs were stored.

As indicated by these plots and thwarted operations, the al-Qaeda terrorist network, with its worldwide logistical reach, is considered the most likely terrorist candidate to employ CBRN weapons against the United States and its allies.

Whether actually executed, thwarted, or nascent plots, these efforts by terrorist groups have cumulatively crossed the threshold from conventional to CBRN terrorism, about which terrorism experts have been warning with increasing frequency since the mid-1990s. As a result, the U.S. government, as well as its allies, has been expending several billion dollars annually in homeland security-related protective training, technologies, new organizational structures, and preemptive strategies.

A New Terrorist Paradigm

The specter of CBRN terrorism (and the conventional catastrophic terrorism of September 11) has transformed the previous paradigm about the magnitude of terrorist warfare. Thus, the famous maxim formulated by Brian Jenkins of the RAND Corporation, a public policy think tank, that "terrorists want a lot of people watching, not a lot of people dead," has been replaced by the dictum that, today, "terrorists want a lot of people watching, *and* a lot of people dead."

The breaking of the previous taboo by terrorist groups against mass casualty attacks has ushered in a new era of catastrophic terrorist warfare in which CBRN are likely components in the terrorists' modus operandi and weapons arsenal.

Despite the presumed imminence of terrorist use of CBRN, the majority of today's terrorist incidents still involve conventional weapons and devices. Conventional devices still remain the terrorists' weapons of choice, although they have evolved into highly lethal weapons. For example, although suicide bombings have become the tactic of choice for today's most lethal groups, replacing the previous modus operandi of "attack and escape," their explosives belts are still conventional in nature. The concern, however, is that in the future the weapons in these explosives belts will be laced with various poisons that will infect and kill a much larger circle of victims than conventional explosives will affect.

Because the transition from conventional to unconventional terrorist warfare is still largely incomplete, a comprehensive threat assessment is required to forecast whether or not a terrorist group is likely to embark on conventional or unconventional warfare. In assessing the likelihood of CBRN terrorist warfare, six questions need to be answered. Within these questions are a multiplicity of accelerators and triggers, and internal and external hurdles that need to be overcome for a group to mount a CBRN terrorist operation.

Assessing the Likelihood of CBRN Terrorism: Six Questions

First, what acquisition costs would influence a terrorist group to acquire the capability to employ CBRN weapons and devices? In terms of the financial considerations involved in acquiring CBRN weapons, devices, and delivery systems, significant financial resources are required for terrorist groups to be able to develop an indigenous CBRN operational capability unless a group succeeds in obtaining such a device from a state sponsor or in stealing or hijacking such a device. In general, a range of costs are involved in acquiring, weaponizing, stockpiling, and deploying CBRN weapons of varying levels of sophistication and lethality. As a result, financial considerations play a role in deciding whether a group will choose single or multiple CBRN weapons, what types of dispersal systems they will use, and whether these weapons will be indigenously developed, obtained from an external source (whether legally or through smuggling, hijacking, or theft), or provided by a state sponsor.

CBRN weapons for use in terrorist attacks vary greatly in their cost. For example, acquiring, or producing and developing, an operational capability to deploy chemical or biological weapons and devices involves relatively small financial resources and is within the means of many terrorist groups. Far more significant financial resources, which only a few groups possess, are necessary to acquire tactical nuclear weapons, such as suitcase nuclear devices. Nevertheless, some terrorist groups, such as Aum Shinrikyo in its heyday, the al-Qaeda network, or Colombian narcotics traffickers, could potentially acquire a crude nuclear weapon because of the vast financial resources accruing from their multiplicity of legitimate and criminal business enterprises.

The second question concerns the goals of a group in acquiring CBRN weapons and what they hope to achieve in their use. Thus, in terms of biological weapons, a group might choose to employ agents and toxins that can cause mass destruction, such as the highly contagious smallpox biological agent, which has the potential to kill tens of thousands of victims across a wide geographical region. Some biological attacks may not inflict massive casualties but may instead cause massive economic costs. For example, in the case of the anthrax letter attacks, although there were few deaths as a result, the economic toll was significant, including several hundred million dollars in cleanup costs, the forced relocation of U.S. Senate offices, an overhaul of U.S. postal security, and the closure of the Brentwood postal facility. Chemical weapons such as sarin nerve gas can kill tens or hundreds of victims yet remain contained geographically. The contamination effects of radiological dispersal devices are likely to far outweigh their direct physical impact in an explosion. Thus, even after decontamination, people would be reluctant to return to the previously affected areas, and property values would be depressed for lengthy periods if the neighborhoods were perceived as being radioactive. Nuclear weapons, however crude or miniaturized, would inflict tens of thousands of deaths and widespread radioactive contamination on the affected areas.

Another important consideration for terrorists is whether the chosen CBRN weapons would cause immediate medical health effects vs. delayed effects, short-term vs. long-term effects, mass casualties vs. death, or contamination of areas resulting in short- vs. long-term economic damages.

Third, how technologically feasible is it for a terrorist group to deploy CBRN weapons and devices? In this sphere, the specialized training of members and/or recruitment of individuals with CBRN-related skills is one of the most crucial indicators demonstrating that a group is embarking on CBRN warfare.

Fourth, would such weapons and devices be indigenously developed, acquired in the black or "gray" markets, or provided by a state sponsor? State sponsors provide terrorists with funds, arms, training, documentation, and other types of operational support; obtaining the sponsorship of a state with CBRN resources is a major indicator that a terrorist organization is attempting to carry out catastrophic warfare. There are a number of motivations and strategic and bureaucratic considerations involved in the relationship between terrorist groups and potential state sponsors regarding possible cooperation in catastrophic warfare. An important indicator for cooperation is whether a potential state sponsor is undergoing a profound crisis that would drive it to subcontract a catastrophic operation to a terrorist group.

However, obtaining the support of a state sponsor is not automatic or inevitable. Potential state sponsors would have to weigh the costs and benefits involved in sponsoring CBRN operations by terrorist groups, including providing assistance in the phases of research, development, production, and operations planning. Other issues concern the conditions and arrangements for providing the terrorist group with CBRN weapons, devices, and delivery systems, as well as training, logistics, diplomatic cover, and deniability.

Thus, a number of cost/benefit factors are involved in the relations between state sponsors and surrogate terrorist groups. For both, there are advantages and disadvantages. For terrorist groups, state sponsorship can provide the crucial assistance they require to launch a catastrophic attack. For example, attaining the support of a state sponsor with nuclear capability (such as Iran, Iraq, Pakistan, or North Korea) would shortcut the process of fabricating a high-grade nuclear bomb with weapons-grade material. The latter is an undertaking that would be extremely difficult, although not impossible, for most terrorist groups to successfully complete without assistance. Such a nuclear weapon, however, would likely be smaller in terms of its explosive yield (in kilotons) versus strategic nuclear weapons (megatons).

Fifth, given the technological feasibility of a group's employing CBRN weapons and devices, what human or physical targets (e.g., "trophy" buildings and landmarks, or a critical economic sector, such as agriculture), would these weapons be used against? Would they be employed indoors or outdoors, or against civilian or military targets? In the case of radiological or nuclear warfare, what types of targets would such weapons be employed against, or would conventional means be used to target nuclear power plants or facilities that store radiological devices, thereby inflicting a Chernobyl-type radiological event on the nearby population?

Sixth, what ideological or religious motivations and strategic objectives would drive a terrorist group to employ CBRN, especially given the risk that the use of unconventional weapons could generate an especially massive response from a targeted state? A group that demonstrates a willingness to take high risks in its warfare might be attracted to these types of attacks. Organizations intent on completely destroying a government might also consider a mass casualty event as something that would further their cause. According to terrorism expert Bruce Hoffman, religious groups are the most likely candidates to carry out CBRN terrorism because they are at once activists and constituents engaged in what they see as a total war. Moreover, their terrorist acts are executed for their own audience or constituency, not to influence the behavior of outsiders and nonbelievers. Thus, the restraints that may exist on catastrophic violence by "secular" terrorists—such as political or ethnic identity-based separatism—are not necessarily relevant to religious terrorists.

How likely would it be for terrorist groups to launch a successful CBRN attack? A group would have to attain proficiency in developing and deploying such weapons, but terrorists' probable inexperience in many of the technical tasks involved in CBRN use would make them continuously liable to make mistakes. In the technical realm, for example, untrained people may have difficulty integrating biological agents with munitions or disseminating agents against open-air targets. They may experience numerous testing failures, their facilities may catch fire, or there might be accidental leaks in their facilities. In terms of personnel, counterterrorism and intelligence agencies may succeed in influencing some of their operatives to defect, leading to exposure of a group's CBRN program. Moreover, a group's attempts to recruit foreign technical and warfare specialists may fail or may be reported to intelligence and law enforcement authorities. As a result of the clandestine nature of their operations and of constant surveillance of their activities by government agents, their group might be overcome by internal paranoia, causing them to embark on hasty actions and make mistakes.

THICKENERS

Used in chemical warfare (CW) agent preparations, thickeners increase the persistence—that is, their ability to remain potent in certain environments—of toxic chemicals in warfare. As with napalm—which is essentially a liquid incendiary (petroleum) made more persistent—some CW agents such as soman, VX, lewisite, and mustard have been thickened with several different compounds. By increasing the viscosity of a given CW agent, thickeners increase droplet size during delivery, increasing the amount of contamination reaching the target. Although CW agents such as VX are already highly persistent, Soviet scientists thickened soman and V-agent used to fill their munitions with polymer thickeners.

The medical consequences of exposure to thickened CW agents can be severe and highly complex. Dr. Charles G. Hurst, former commander of the U.S. Medical Research Institute of Chemical Defense, has warned: "Casualties with thickened nerve agents in wounds (e.g., from pieces of contaminated battle dress uniform or protective garment being carried into the wound tract) are unlikely to survive to reach surgery. Thickened mustard has delayed systemic toxicity and can persist in wounds even when large fragments have been removed" (Hurst, p. 356). For current chemical demilitarization programs under way, thickeners have also presented different problems. For example, the use of thickeners by the Soviet Union in its V-gas stockpile has complicated the neutralization process, requiring an additional solvent to to break the polymer matrix.

TNT

TNT is the acronym for the high explosive trinitrotoluene, one of the most important military explosives. Other names include trotyl, tolite, triton, tritol, and trilite. The chemist Joseph Wilbrand first synthesized the compound in 1863, and large-scale production of TNT began in Germany in 1891. Although TNT was significant in its military applications during World War I, production quantities were limited at the time due to a shortage of one of the critical precursors, toluene, which was only found in coal tar derivatives. However, when petroleum and synthetic processes were developed before World War II, the supply of toluene could be nearly limitless, raising the U.S. production capacity of TNT, for example, from 350,000 tons to 1.8 million tons per year during the 1940s.

Terrorists have been known to employ TNT in large casualty attacks. On August 7, 1998, two U.S. embassies in East Africa were targeted by al-Qaeda suicide bombers—one in Nairobi, Kenya, and the other in Dar es Salaam, Tanzania—driving trucks carrying approximately 2,000 pounds of TNT. At Nairobi, 213 were killed including a dozen Americans, with over 4,500 injured, while 11 people and 85 were injured minutes later at Dar es Salaam. As in the Oklahoma City bombing in 1995, and although conventional explosives were used, the scale of murder and devastation rises to the level of a weapon of mass destruction. The large market for high explosives, especially in areas of construction and engineering, ensures that a large supply of TNT will be available for diversion for use by terrorists or criminals.

TOBACCO MOSAIC VIRUS

Tobacco mosaic virus (TMV) is a plant virus infecting tobacco plants and other vegetable plants such as beans. TMV attracted scientists' attention in 1930 when it was shown that a crystalline preparation of TMV was infectious. This discovery had a far-reaching effect on concepts regarding viruses in general: it indicated that TMV without a host cell was a benign material but that in the presence of host cells, TMV was infectious. This discovery suggested that viruses—previously considered to be microorganisms like bacteria only too small to see with the microscope—were more like complex proteins (actually, they were proteins making up the nucleic portion of the virus) that showed living activity only when the host organism was infected with the virus.

Many plant bacteria and viruses are considered to be potential biological weapons, but these are mainly targeted to destroy staple crop plants such as rice, wheat, corn, and potatoes. TMV's destructive scope is more limited to beans, tobacco plants, and possibly tomatoes. Therefore, if TMV were used for biological terrorism, it would be aimed toward damaging the agricultural economy rather than the food supply.

TOOELE, UTAH

The Deseret Chemical Depot located at Tooele Army Depot in Utah once stored almost 45 percent of the U.S. chemical weapons stocks, the largest percentage by far of any of the original eight storage sites maintained by the United States (the other seven are Anniston Chemical Activity, Alabama; Blue Grass Chemical Activity, Kentucky; Edgewood Chemical Activity, Aberdeen Proving Ground, Maryland; Newport Chemical Activity, Indiana; Pine Bluff Chemical Activity, Arkansas; Pueblo Chemical Depot, Colorado; and Umatilla Chemical Activity, Oregon).

From completion of the Tooele Chemical Agent Disposal Facility in 1996 until 2003, close to half that amount, or 11 million pounds of these chemical agents, was destroyed by the army's baseline incineration process (*see* Demilitarization of Chemical and Biological Agents). Disposal efforts are scheduled to conclude in 2008.

Tooele Army Depot was established in 1942 as an ordnance depot. In 1949, it also assumed command of the Deseret Chemical Depot, maintaining the ordnance depot in the north area of the installation while operating the chemical depot in the southern area. Early efforts to find methods to destroy chemical weapons included the construction of the Chemical Agent Munitions Disposal System at Tooele in 1979. On a pilot-scale, or small-scale, demonstration capacity, this facility was designed to test and evaluate equipment and processes for destroying chemical agents and munitions. From 1981–1986, this system expanded to test and evaluate incineration as well as processes for decontamination of metal parts and containers.

When Congress ordered the destruction of all U.S. chemical agents and munitions in the Defense Authorization Act of 1986, plans were made to begin building on-site destruction facilities at the various storage locations because of the increased risks presented by the transport of chemical weapons. Incineration, as tested at the Tooele Chemical Agent Munitions Disposal System, became the U.S. Army's baseline method of chemical weapons disposal.

Unlike some of the other U.S. chemical weapons storage sites, Deseret Chemical Depot contained not only ton containers of chemical agents in bulk storage, but also millions of various types of munitions, including cartridges, projectiles, land mines, spray tanks, and rockets. Some of these munitions still contain explosive components, but others do not. There are also a variety of chemical agent types stored at Tooele: blister agents such as mustard, and nerve agents such as sarin and VX (*see* Nerve Agents; Vesicants). Munitions are kept in storage igloos buried underground in a secure section of the depot. Destruction of all sarin gas weapons at the depot was completed in March 2002.

The Tooele Chemical Agent Disposal Facility was the first full-scale destruction facility constructed in the continental United States. During the course of operations, there have been minor leaks reported from the facility. However, none of these have resulted in any types of injuries or have required emergency responses.

—Claudine McCarthy

TOXINS (NATURAL)

There are many animals, plants, fungi, and bacteria that contain different types of toxins or that release toxic substances. The term *toxin* is used widely, yet its definition is ambiguous. In many contexts, all toxic substances are called toxins regardless of whether they are naturally occurring substances or human-made ones.

Table T-1: Toxins Ranked According to Toxicity

Natural Toxins	*Origin*
Botulinum Toxin D	Bacteria
Palytoxin	Coral
Tetrodotoxin	Puffer Fishes
Human-Made Toxins	
Hydrogen Cyanide	Inorganic Compound
Carbon Tetrachloride	Inorganic Compound

Some animals possess special ducts or organs that release toxic substances called venoms. Plants do not release toxic substances as such; instead, toxic substances are present within a particular part of the plant. In this case, toxic substances are called toxins.

Natural toxins can be grouped as protein or nonprotein toxins. This is a convenient way to classify toxins because the two types of compounds have distinct properties. Toxins are also grouped into high molecular weight and low molecular weight classes. The high molecular weight toxins are usually proteins, and low molecular weight toxins are usually nonproteins. There are also many toxins whose molecular weights are intermediate in size.

Of all the ways toxins are classified, classification based on biological activity may be the most important. Toxins are classified as neurotoxins, necrotic toxins, cardiotoxins, cytotoxins, nephrotoxins, and hemorrhagic toxins. Of these, the neurotoxins are the most germane to potential use in WMD, and have been most often researched as potential toxin weapons in biological warfare.

Neurotoxins

For neurotoxins, the functional area of the toxin itself and the site of action on the body can be different for each toxin. There are two types of neurotoxins: central neurotoxins (affecting the central nervous system), and peripheral neurotoxins (affecting the peripheral nerves). Apamin, for example, is a bee venom component with twenty-two amino acid residues. It is a central neurotoxin. Morphine and codeine, isolated from poppy seeds, are also central neurotoxins. There are also many different varieties of peripheral toxins affecting various parts of the peripheral nerves. Usually, small-size toxins can be central neurotoxins because they can penetrate the brain-blood barrier, the membrane that prevents most large molecules from entering the neural tissues.

Snake neurotoxins contain presynaptic, postsynaptic, and other types of neurotoxins. They all affect the neuromuscular junction. A presynaptic neurotoxin causes spontaneous release of the neurotransmitter acetylcholine. The result is a spasm of the muscle. After all acetylcholine molecules are released from the vesicle at the nerve ending, however, muscle paralysis eventually occurs. Presynaptic toxins are found in krait (genus *Bungarus*) venom, mamba (genus *Dendroaspis*) venom, and all Australian snake venoms (genus *Notechis, Pseudechis, Austrelaps*).

Postsynaptic toxins are common in snake venoms such as those of the cobra (*Naja*) and sea snake (family Hydrophiidae). At the muscle site of the neuromuscular junction, there is a special acetylcholine receptor. Normally, the receptor accepts acetylcholine, transmitting the nerve signal to the muscle, enabling the muscle to contract. Snake postsynaptic toxins attach to the receptor at the same site where acetylcholine attaches, thereby blocking the receptor. The result is paralysis of the muscle. When the muscles at the end of the diaphragm succumb to this postsynaptic neurotoxin action, the diaphragm stops moving, which can cause respiratory arrest and death.

Botulinum toxins (BT) are the most toxic substances in the world. It is estimated that 1 microgram of the toxin can kill 20 million mice. Botulinum toxin, which comes from the *Clostridium botulinum* bacterium, is a presynaptic toxin that causes muscle paralysis by stopping the release of acetylcholine from the nerve ending.

Natural toxins are potential biological weapons because of their extremely high toxicity. Some toxins are attractive candidates for biological weapons because they can form a stable aerosol, poisoning the body through the lung by inhalation. Usually, pneumonic route poisoning is much more severe than poisoning from oral or dermal routes of entry.

TOXOIDS AND ANTITOXINS

As a prophylactic against infectious disease, toxoids are toxins that have been rendered harmless, usually by chemical treatment, and then administered to cause the body to produce antibodies to protect against future infection. In addition to their role in reducing the incidence of childhood diseases, toxoids have been developed for use against biological warfare (BW) agents, especially against botulinum toxin. Passive antitoxins—that is, toxin-specific antibodies utilized to treat diseases such as botulism—are being developed in the United States and elsewhere to respond to a bioterrorism incident.

How toxoids are administered depends upon the nature and process of the infectious disease being combated. Toxoids are usually administered to combat bacteria that produce toxins. Examples of these are classic childhood illnesses such as whooping cough (*Bordetella pertussis*), diphtheria (*Corynebacterium diphtheriae*), and tetanus (*Clostridium tetani*). Thus, it has become standard practice to vaccinate against diphtheria, pertussis, and tetanus (DPT) by using their respective toxoids or in combination with other vaccine techniques. Toxoids were also produced during World War II against a relatively new threat—the specter of BW—when early intelligence indicated that Nazi Germany was planning an attack using botulinum toxin.

Development during War and Peace

If disease has influenced the course of peoples, civilization, and warfare, then it has often been the exigencies of war that determined the course of modern vaccine development. Despite the scientific advancements in the nineteenth century that promised to lower childhood mortality from disease, it was military demands that drove those advancements' early applications.

Although not all early vaccines were successful (some, in fact, did more harm than good), by 1914, effective and safe vaccines were available for smallpox (vaccinia), rabies, anthrax, and whooping cough (*pertussis* toxoid). The use of tetanus antitoxin saved countless lives during World War I: Tetanus, along with gas gangrene (caused by the toxin-producing bacterium *Clostridium perfringens*), was especially common as an illness acquired from battlefield injuries.

Toxoids were produced during World War II to defend against a possible BW attack by Germany. Allied intelligence indicated that Germany was planning to use botulinum toxin against the troops ready to land on Normandy's beaches in 1944. Although the details were sketchy, botulinum toxin was notorious for being highly lethal in extremely small quantities. (Produced by the bacterium *Clostridium botulinum,* the toxin produces a flaccid paralysis in the body. Ingested amounts of botulinum as small as 1 microgram are deadly in humans.) This intelligence information led to a rush production of botulinum toxoid for the troops gathering in England. As the official history of the U.S. BW program in World War II notes, however, the British had no toxoids available, but the American and Canadian troops were well supplied. In the end, none of the troops were inoculated against botulinum toxin, the British having decided (based on decrypts of German communications) that the original intelligence was faulty. U.S. officials followed the British lead and came to doubt that botulinum toxin would be an effective agent for aerial dissemination.

During the Gulf War (1990–1991), some 8,000 U.S. troops were administered the botulinum toxoid out of fear that Iraq would use its biological weapons. This turned out to be an unnecessary (albeit prudent) measure.

Currently, the United States has in its inventory a botulinum toxoid that protects against A through E types, and a botulinum antitoxin derived from horse sera under Investigational New Drug (IND) status (2003). The antitoxin is produced by generating antibodies to botulinum toxin in a live horse. This is accomplished by administering small doses of botulinum toxin to the horse, and these antibodies are separated from the horse blood products. These antibodies are then treated with enzymes that remove the "horse" component, so that the active portion of the antibody should be safer to use in humans.

Another toxin that is considered a significant threat in BW or bioterrorism is ricin, a highly poisonous lectin, a protein-containing substance derived from the castor bean. Not nearly as toxic as botulinum, ricin is nevertheless relatively easy to produce from commercially available materials. Research in the United States is underway to develop prophylaxis for ricin, and an IND toxoid is under evaluation. Although ricin is not suspected to form a significant threat in a military context, it is known that al-Qaeda operatives are interested—and have received rudimentary training—in the production of ricin toxin in makeshift laboratories. Ricin's potential use as a terror weapon was confirmed when it was discovered in powder form in some envelopes sent to U.S. Senate offices in February 2004.

Staphylococcal enterotoxin B (SEB), produced by the bacterium *Staphylococcus aureus,* is a highly potent toxin that was weaponized by the United States during the Cold War. The toxin could pose a threat from bioterrorists interested in sabotaging food or beverages, and its aerosolization is another possible route of attack. A formalin-treated (toxin is rendered harmless by adding formaldehyde) SEB toxoid has demonstrated some degree of efficacy in animal trials but has not yet been approved for human use.

Numerous toxoids and antitoxins have been developed for clinical use against snake venom, conotoxins (Pacific cone snails), and other poisonous substances produced in living organisms. Some countries, such as Australia, have sophisticated public health responses to naturally caused incidences of poisoning by these toxins. The BW threat posed by these toxins, however, is probably low.

TULAREMIA

Tularemia is an infectious disease of small mammals caused by the bacterium *Francisella tularensis.* Humans usually acquire *F. tularensis* from the bite of an infected insect or from contact with infected wild animals. Less often, tularemia results from inhalation or ingestion of contaminated dusts, food, or water. The onset of tularemia in humans is usually 3–5 days following exposure, and the disease usually begins with fever and flulike symptoms, including headache, chills, fever, and cough. Multiple tularemia syndromes can occur, including pneumonia and "typhoidal" tularemia (an infection throughout the body), which can be fatal. About 75 percent of all tularemia cases present with skin lesions and swollen lymph nodes (ulceroglandular), and 4 percent of these patients die without treatment. The remaining 25 percent, typhoidal, has a mortality rate of about 35 percent without treatment. With the use of antibiotics, the disease (encompassing both syndromes) has a death rate between 1 and 2.5 percent.

The organism is dangerous because it can be released as an aerosol to cause large tularemia epidemics in both human and animal populations at the same time. *F. tularensis* is extremely infectious in humans, requiring inhalation of only ten to fifty organisms to cause severe, incapacitating, and sometimes fatal results. Tularemia can also infect a wide variety of small aquatic and terrestrial mammals, insects, birds, fish, amphibians, amoeba, and other invertebrates, which then act as carriers for the disease. Generally, the organism is hardy and is tolerant of cold temperatures, and it persists in the environment in water, moist soil, hay, straw, and decaying animal carcasses. A World Health Organization committee estimated in 1970 that if 50 kilograms (110 pounds) of a virulent strain of the bacterium were sprayed over a metropolitan area with a population of 5 million, it could incapacitate 250,000 people and kill 19,000. Respiratory failure or shock would cause most of the fatalities.

Tularemia occurs only in the Northern Hemisphere, with naturally occurring outbreaks being most frequent in Scandinavia, Japan, Russia, and North America. Recently, tularemia was reported in southern European nations including Spain, Switzerland, Turkey, and Kosovo. Dozens of biting and bloodsucking insect vectors, especially ticks and tabanid flies (horse flies and deer flies), can transmit the disease. In Europe, mosquitoes and ticks are particularly important disease vectors. Tularemia is primarily a disease of wild rabbits and rodents (mice, rats, lemmings, voles, squirrels, groundhogs, prairie dogs, and beavers). Other mammals that act as carriers for the disease include opossums, sheep, coyotes, and domestic dogs and cats. Tularemia is spread among animals by predatory feeding, cannibalism, insect vectors, and exposure to mud and water contaminated with animal urine and feces.

In the United States, cases of tularemia have been found in all states except Hawaii. It is most commonly transmitted by tick bites or by contact with infectious tissues of wild rabbits. Direct human-to-human transmission of tularemia does not occur, but indirect transmission from wild rabbits to humans (such as through the bites of pet dogs or cats that have been in contact with diseased rodents) has been reported. Hunters, trappers, fur handlers, taxidermists, game wardens, farmers, forest workers, butchers, wildlife veterinarians, and laboratory workers are the people most commonly infected.

Historical Background

Research on the military use of *F. tularensis* to spread disease began in the 1930s in Japan and Russia. During World War II, the U.S. War Research Service noted the extremely high infectivity of this organism and developed the highly virulent Schu-4 strain for weaponization (U.S. code UL). The Soviet Union acquired the Schu-4 strain in the 1950s (apparently obtained from the United States) for its own biological weapons program. Its extremely high infectivity via inhalation makes *F. tularensis* one of the most potent germ warfare agents. In the U.S. biological warfare (BW) program, tularemia bacteria were freeze-dried and milled to a fine consistency to deliver as an aerosol. A live vaccine, effective antibiotic treatment, and prophylaxis protocols that can prevent the development of significant disease in exposed persons were developed by the United States military during the 1950s and 1960s.

Biological weapon stockpiles, including tularemia bacteria, were destroyed by the United States upon signing the Biological and Toxin Weapons Convention of 1972, when many other countries also agreed to end their state-sponsored offensive biowarfare programs. The Soviet Union, however, continued its biological weapons development well after signing the accord and further increased its range of biological warfare agents. Russia finally acknowledged its program in the early 1990s and admitted that genetically engineered vaccine- and antibiotic-resistant *F. tularensis* strains were still being produced as weapons in the former Soviet Union. As of 2003, however, it is not known whether Russia still maintains an offensive BW program.

Tularemia was first described in Japan in 1837 and in Russia in 1926. The organism, renamed *Francisella tularensis* in 1974, was originally isolated in 1911 from ground squirrels with a plaguelike illness in Tulare County, California. It was not until 1921 that Dr. Edward Francis of the United States Public Health Service established that the bacterium was the cause of deerfly fever. Tularemia is also colloquially known in different parts of the world as rancher's fever, rabbit fever (yatobyo in Japan), hare plague, and lemming fever.

Medical Aspects

The bacterium *F. tularensis* can invade and multiply within host cells and can survive inside cells for long periods. There are two major biotypes of *F. tularensis* found in nature, usually referred to as type A and type B. Many type A strains are highly virulent for humans and are found mainly in rabbits, rodents, and ticks throughout North America, and recently in Europe (1998). Type B strains produce a milder and benign, often unnoticed, infection in humans. Type B strains, common in parts of North America, Europe, and Asia, do not cause disease in rabbits but are usually associated with waterborne disease of rodents and mosquito vectors.

The epidemic potential of tularemia became known in the 1930s when large waterborne outbreaks occurred in Europe. Outbreaks of tularemia in wild animals are often harbingers of outbreaks in humans. In Sweden and the former Soviet Union, human outbreaks of tularemia have been linked to ground vole die-offs. Tularemia is predominantly a rural disease, and large outbreaks occurring in war zones are associated with the breakdown of public health and with surging rat populations that carry the disease. An outbreak of a mild form of the disease in Kosovo in early 2000 was due to an increase in the population of infected rats, which was a result of the breakdown of garbage collection after the war of separation from Yugoslavia.

During World War II, a tularemia epidemic affected many thousands of German and Russian soldiers on the European eastern front at the Battle of Stalingrad in 1941. The possibility that this epidemic may have resulted from intentional dissemination of *F. tularensis* by the Russians against German troops was raised by Ken Alibek, a former senior scientist in the Soviet biowarfare program. A more mundane explanation was later offered, however: Tularemia was already widespread in the local populace of the Volga region well before German armies had made their approach. Meanwhile, fighting had essentially destroyed the local public health infrastructure while also preventing the harvesting of crops. As vermin consumed this uncut grain, the rodent population subsequently exploded, widening the focus of disease. Together, these circumstances cleared the way for an epidemic. Many infections among Russian and German troops occurred from inhaled dust from straw used for bedding.

Tularemia is not a notifiable disease to the World Health Organization, so its worldwide incidence is unknown. The frequency of tularemia in the United States, however, has dropped markedly from thousands of cases reported in the 1930s to several hundred cases reported annually through 1994, when it was removed from the list of notifiable diseases. Only in 1999, with increasing concerns of bioterrorism, was tularemia reinstated as a notifiable disease in the United States.

Reasons given for the apparent rarity of tularemia today include decreased rabbit hunting, and therefore reduced opportunity to come into contact with infectious rabbit tissues, as well as the probability that many infections are undiagnosed, misdiagnosed, or unreported due to the relatively benign nature of the disease in some cases. Also, because many people are presumptively treated with antibiotics, that is, no specific pathogen is identified—and because laboratory testing for tularemia bacteria can be difficult—this disease is much less commonly reported nowadays in North America.

Six clinical tularemia syndromes are recognized, depending largely on the route through which the bacterium enters the body (inoculation, inhalation, or ingestion). Typically, 90–100 percent of those exposed to the bacterium develop disease. All forms usually begin with the sudden onset of flulike symptoms: fever (103° to 104° F), chills, headache, generalized joint and muscle aches, cough, and lethargy. Symptoms usually develop within 3–5 days of presumed exposure to *F. tularensis.* The disease course is influenced by host and bacterial factors, including the virulence of the infecting organism, the amount of bacteria introduced, the route of entry, and the host's immune status.

In the most common form, ulceroglandular tularemia (about 75 percent of recognized cases), the bacterium is acquired through a tick bite. An ulcerative skin lesion is found at the site of inoculation and may persist for several months. In hunters and trappers, the organism usually enters the body through a scratch or microabrasion on the hands while skinning or cleaning an infected wild animal. The bacterium spreads to the local lymph nodes, and onset of flulike symptoms is accompanied by painful swollen lymph nodes resembling the buboes associated with bubonic plague. If the organism enters the bloodstream, it may spread to distant organs (lungs, kidneys, spleen, liver, intestines, central nervous system, and skeletal muscles). Recovery can be protracted (from 3 weeks to several months), but this form of the disease is rarely fatal even without treatment. (A second form of this ulceroglandular syndrome, glandular tularemia, has similar symptoms without the characteristic skin lesion.)

Oculoglandular tularemia (1 to 2 percent of cases) may result if the organism enters the conjunctiva due to splashing or rubbing of the eyes after contact with infectious material. Usually only one eye is affected, with painful ulcers and nodules on the conjunctiva. Without treatment, the infection can spread to the local lymph nodes, developing into the glandular form. Rarely, oropharyngeal or gastrointestinal (GI) tularemia is acquired from drinking contaminated water or eating inadequately cooked rabbit meat. Following this type of infection, the tonsils enlarge and dead tissue may form in the oral and throat cavities (pseudomembrane) resembling that found with diphtheria. Patients usually experience sore throat, abdominal pain, nausea, vomiting, diarrhea, and, occasionally, GI bleeding. Depending on the infecting dose, clinical severity ranges from mild but persistent diarrhea to an acute fatal disease with intestinal ulcerations.

Typhoidal (septicemic) tularemia once accounted for up to 25 percent of tularemia cases worldwide but is now rare in the United States. In most cases, the route of entry is unknown but is most likely the result of inhalation of contaminated environmental dusts or aerosolized bacteria. This form is often associated with a huge inoculum or a preexisting compromising condition; patients with this form of the disease experience severe bacteremic disease, septic shock, and, frequently, atypical pneumonia that can be fatal.

Tularemia pneumonia is uncommon but may result from the inhalation of aerosolized bacteria. It also may spread to the lungs as a complication in 10 to 15 percent of ulceroglandular cases, and in about half the cases of typhoidal tularemia. This form of the disease may occur in laboratory workers. Naturally acquired cases occur occasionally from handling infected birds and animals, as well as from other activities such as mowing grass or handling hay that generates dusts from infected rodent nests. Patients with this form usually complain of dry cough and shortness of breath. If untreated, this form of tularemia could progress to respiratory failure, shock, and death.

The mortality rate for severe untreated infections (including all cases of untreated tularemia pneumonia and typhoidal tularemia) is about 35 percent. In the United States, recent mortality rates have been 1–2.5 percent with treatment. Poor outcomes are often associated with long delays in diagnosis and treatment. Early antibiotic therapy is effective, and if started within 24 hours of exposure, may even prevent disease. A variety of antibiotics have been used with success, including aminoglycosides (streptomycin and gentamicin), macrolides, chloramphenicol, tetracycline, and fluoroquinolones (ciprofloxacin). Lifelong immunity is widely reported to follow recovery from infection with *F. tularensis.* There are cases, however, of reinfection.

Early diagnosis of tularemia is difficult because a patient does not usually seek medical attention for a small skin lesion, and at the onset of disease, the clinical picture is typical of other illnesses. Culture and isolation (careful handling is required) of *F. tularensis* is usually done in reference microbiology laboratories, specially equipped with technology and expertise to make a definite identification. Recovery of the bacterium from a patient's ulcer scrapings, lymph node biopsies, sputum, and, rarely, blood is diagnostic but difficult. *F. tularensis* is fastidious and grows very slowly in culture. The diagnosis of tularemia is usually confirmed by blood testing, and *F. tularensis* antigens may be detected in the blood and urine of patients. An antibody response to *F. tularensis* infection is detectable around 2 to 3 weeks after infection. A fourfold increase in antibody levels at 4 to 6 weeks after infection is considered diagnostic. Molecular tests, such as the polymerase chain reaction (PCR, which can multiply small amounts of genetic material into detectable quantities), have been useful to detect *F. tularensis* DNA.

Vaccines to prevent tularemia were developed and used in humans in the Soviet Union in the 1940s and 1950s. A live, attenuated vaccine using a *F. tularensis* type B strain called Live Vaccine Strain (LVS) is currently available as an Investigational New Drug from the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID). The LVS was demonstrated to protect human volunteers against an aerosol attack with virulent *F. tularensis.* An analysis of laboratory-acquired infections showed that LVS prevents the typhoidal form (inhalational route of infection) of the disease and lessens the severity of ulceroglandular forms (cutaneous) of tularemia. The LVS is recommended for people who work in occupations with a high risk of contracting tularemia.

TUBERCULOSIS (TB, MYCOBACTERIUM TUBERCULOSIS)

Tuberculosis (TB) is a bacterial infection caused by the bacterium *Mycobacterium tuberculosis* that can affect many areas of the body, primarily via the lungs, causing fatigue, weight loss, fever, night sweats, chills, chronic cough, and coughing up of blood or sputum. Although tissue samples from 5,400-year-old graves have tested positive for *Mycobacterium tuberculosis,* it was not until 1882 that Robert Koch discovered the tuberculosis-causing bacteria.

The TB bacterium is spread through aerosolized infectious droplets that enter the lungs, multiplying to cause disease locally and then spreading to other parts of the body. With an intact immune system, TB can often be controlled. The bacterium may persist, however, in a latent, noninfectious, asymptomatic form for a lifetime, becoming active upon weakening of the immune system. The disease is particularly serious in the elderly, those who are immunocompromised (especially HIV-infected people), young children, and babies.

Previous military research by the United States and Japan has involved TB mainly for use in studying the dynamics of disease transmission. Because of its known ability to infect via inhalation, biological weapons programs—including that of the United States during World War II—researched the possibility of using *M. tuberculosis* bacteria as a biological warfare agent. It was quickly discounted as a plausible weapon, primarily because TB was not as infectious as other pathogens. Nor were symptoms from TB disease fast-acting or dramatic enough to make a difference on the battlefield.

Although TB is very contagious—it was once the number-one killer in the United States—it is not considered an immediate biological threat, because infection can be prevented, cured, and detected using the tuberculin skin test. The general U.S. population is not vaccinated with the TB vaccine (Bacillus Calmette-Guerin or BCG) in part because this can confound the tuberculin skin test, and currently is not viewed as being worth the risk for infant inoculations. Although many children and infants in developing countries are vaccinated, TB is increasing globally, killing approximately 2 million people per year. This is partly due to the emergence of multi-drug-resistant strains that pose a higher mortality rate and require more aggressive treatment.

TYPHUS (RICKETTSIA PROWAZEKII)

Typhus (caused by *Rickettsia prowazekii*)—not to be confused with typhoid fever (caused by *Salmonella typhi*)—is an infectious disease caused by a rickettsial pathogen, bacteria that usually need a host to survive and reproduce. It is considered a potential biological warfare (BW) agent. Some other forms of rickettsial illness, including scrub typhus (*Rickettsia tsutsugamushi*), are also mentioned in BW defense literature as potential BW agents. The classic, epidemic form of typhus is transmitted by the human body louse *Pediculus,* and reservoirs for the pathogen include rats and other rodents such as the flying squirrel. Although it is no longer considered a significant threat today, biological warfare (BW) programs in the past have investigated typhus as a potential biological weapon, including the United States (during World War II) and the former Soviet Union.

Natural outbreaks of typhus are occasionally seen in developing countries, but the classic (louse-borne) epidemic typhus has not been seen in the industrialized world for decades. In the classic form of the illness, *R. prowazekii* organisms multiply at the focus of the insect bite. These parasitic bacteria grow within the cellular tissue, causing infected cells in the host to rupture. The organisms are then released and migrate to the regional lymph nodes. Systemic infection follows, producing sudden onset of chills, fever, headache, and other flulike symptoms 1–3 weeks after the bite. A rash appears after several days during the course of the disease (thus the name spotted fever). Stupor and delirium eventually set in, sometimes leading to serious complications such as gangrene.

If the disease is left untreated, the death rate from epidemic typhus is approximately 10 to 50 percent, but timely administration of antibiotics should bring about full recovery. The most effective measures to prevent typhus have included rodent control, as well as insect abatement through the use of insecticides (particularly DDT). Although some have claimed that typhus vaccines contributed to the eradication of the disease from the developed world, no vaccine has yet found widespread acceptance.

Background

Especially in the preantibiotic era, disease played a major role in military conflict. Of all diseases affecting troops and civilians in times of war, typhus probably claimed the most lives. The Greek historian Thucydides, for example, wrote about the "plague of Athens." Although the etiologic agent has yet to be identified, what he described closely matches the description of typhus, which probably spread to the civilian population by Peloponnesian troops in about 425 B.C.E. Typhus also probably played a major role in defeating Emperor Napoleon's campaign in Russia. In 1812, France lost up to 80,000 men from disease, especially from epidemic typhus (*R. prowazekii*). Tight living quarters and poor hygiene contributed to lice-infested conditions. Napoleon's subordinates reported that their comrades were swarming with lice, and not long after, many came down with spotted fever, the old name for typhus.

Later, in the formative years of the Soviet Union, epidemic typhus was rampant. From 1918 to 1921, as many as 30 million people were affected, and 10 percent of these died. Dr. Kenneth Alibek, former deputy director of the Soviet biological weapons program, suggests that it was this experience that helped convince Red Army commanders to pursue biological weapons development, including the use of typhus as a biological weapon. In 1928, military biologists in the Soviet Union grew *R. prowazekii* in chicken embryos and rats. Using industrial-grade blending equipment, the animals' infected tissues were liquefied into crude BW agent preparations. Also, according to Dr. Alibek, by the 1930s, the Soviets had produced both liquid and dried forms of typhus for use in biological weapons.

Although there is no evidence of deliberate use of BW agents by either side during World War II, Soviet officials suspected that Germany deliberately infected Red Army troops with typhus. According to one Soviet retrospective on the Battle of Stalingrad, the retreating German army purposefully left behind foci of infectious disease: "the fascists imposed distinctive, epidemiological diversities aimed at injuring our troops: they threw across the front line the lice-ridden victims of spotted fever [that is, typhus] and prior to their back off dissolved the camps of war prisoners and civilian population infected by spotted fever" (Agafonov and Tararin, p. 7). It cannot be proven that the German military purposefully spread typhus in this manner. (During the Battle of Stalingrad, the number of German casualties due to typhus nearly equaled the number of battlefield injuries.)

Although a typhus vaccine was available during World War II, its real efficacy has always been in doubt. By far the greatest factor in the reduction of typhus was the introduction of DDT to kill its main vector, lice. The United States Typhus Commission, formed in December 1942, was established in the War Department. In early 1943, Merck & Company produced about 500 gallons of DDT, which was immediately sent to Naples, Italy, for use in delousing. This proved to be an effective demonstration of how the application of DDT could halt a fast-growing typhus epidemic. Following the war's end, DDT was instrumental in processing many German prisoners of war, many of whom were infected or were vulnerable to infection by typhus. Few, if any, of this population had been vaccinated for typhus, and many German soldiers were ridden with lice. Since World War II, DDT has saved untold lives, not just from of typhus but from many other arthropod-borne diseases.

In 1965, the Indian intelligence apparatus became suspicious during the Indo-Pakistan war following an outbreak of scrub typhus in northeast India, raising the possibility that Pakistan was using some sort of biological weapon. Caused by the organism *Rickettsia tsutsugamushi,* scrub typhus had first been introduced to the American hygiene lexicon during Commodore Matthew Calbraith Perry's visit to Japan in 1853, and it became a problem later during the Pacific campaigns of World War II. In the preantibiotic era, fatality rates from scrub typhus reached 35 percent. Despite India's suspicions, the presence of scrub typhus during the Indo-Pakistan war was undoubtedly a natural consequence of the war's disruption of hygiene and displacement of people.

UNIT 731

Unit 731 was the first modern biological weapons unit. It was organized by Japanese troops and conducted heinous crimes in China during World War II. Unit 731 was also referred to as "General Ishii's Unit" because it was organized by Japanese Lieutenant General Shiro Ishii, a military surgeon.

In 1930 or 1931, General Ishii proposed to the Japanese Army that pathogenic bacteria could be used as a weapon. In August 1932, the Laboratory of Preventive Medicine was set up within the College of Military Medicine. In 1933, a Unit of Preventive Medicine in the Kwantung army was set up in the city of Harbin, Manchuria. The name was eventually changed to Kwantung Army Institute of Preventive Medicine. General Ishii was given formal command of the Kwantung Army Institute of Preventive Medicine, including its 1,300 military personnel, in 1936. In the Institute, the Japanese tried to weaponize plague, cholera, anthrax, *Shigella dysenteriae*, typhoid fever, tularemia, botulism, brucellosis, gangrene, glanders, influenza, meningococcus, *Salmonella*, smallpox, tetanus, tick encephalitis, tuberculosis, and typhus. Some toxins such as puffer fish (*Fugu*) toxin (i.e., tetrodotoxin) were also investigated. Tsutsugamushi fever, which is caused by rickettsia, and epidemic hemorrhagic fever were also studied.

Personnel under Ishii's command used Chinese prisoners, dissidents, and spies as human specimens to study the effects disease and biological weapons. Altogether, about 3,000 people were sacrificed to obtain firsthand knowledge of the effects of different bacteria on humans. Despite the large scale of its biological warfare research, the identity of the Institute was kept secret.

Weaponization of bacteria was not an easy task, and General Ishii's goal was to develop a bomb that could be delivered from an airplane to cause massive outbreaks of deadly diseases. He found that the bacteria alone were not suitable for spreading disease; he thought that fleas carrying plague were the most suitable vector for a biological weapon attack. Therefore, mass breeding of disease-carrying fleas was undertaken, using rats as hosts. Eventually the Japanese developed a porcelain bomb that incorporated a minimum amount of explosive (in order to protect the viability of the insects inside) to attack targets with plague-carrying fleas. Upon impact, the bomb's porcelain shell was to break, and fleas were to be released, eventually reaching and biting humans. One bomb of this type carried 30,000 fleas. The survival rate of fleas when the bomb exploded was perhaps as high as 80 percent. Porcelain bombs also were made for anthrax, typhoid, and dysentery.

For the anthrax bomb, Ishii used the spore form of anthrax because of its extreme stability. When the bomb exploded, shrapnel fragments were to cause wounds through which anthrax spores entered the body. Modern-day biological weapons makers prefer to develop aerosol weapons, as the inhalation route of infection typically causes more severe disease.

At the end of World War II when Soviet Union troops invaded Manchuria, the Japanese destroyed the buildings and facilities of Unit 731 and returned all its personnel to Japan before they could be captured by advancing Soviet troops. Even so, some personnel associated with Unit 731 were arrested by the Soviets. In December 1949, these persons were trotted out in a show trial, and given sentences ranging from 3 years to 25 years by the Soviet Military Court. However, most of them were sent back to Japan without serving the full terms of their prison sentences.

The U.S. Army was surprised to see the advanced stage of the Japanese biological weapons program and tried to learn from General Ishii's group in Japan. Instead of punishing them as war

Chinese protestors claimed their relatives were killed by Unit 731 BW scientists (2002). (Reuters/Corbis)

criminals, the United States protected them in an effort to obtain the information generated by Unit 731's experiments.

UNITED KINGDOM: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

The United Kingdom's chemical and biological warfare programs developed in response to the perceived threat posed by other nations' efforts to develop chemical and biological weapons. The development of British chemical weapons, for example, followed German attacks on elements of the British Expeditionary Forces in 1915. The biological program started shortly after the beginning of the Second World War in response to concerns about possible Nazi interest in germ warfare.

Chemical Warfare

During World War I, chemical agents—sulfur mustard, chlorine, phosgene, and chloropicrin—were developed and manufactured at a new facility at Porton Down, while substantial progress was being made in protection against chemical attack through the development of gas masks. In addition to the battlefields of the western front, German cities were also considered as targets for chemical attacks. But this option was not taken, and the British limited their use of chemical weapons to the western front. Overall, the British suffered about 185,000 casualties from gas attacks during World War I.

During the interwar period, British opposition to the use of chemical and biological weapons grew. Successive British governments supported the idea of banning chemical weapons, and Great Britain signed the 1925 Geneva Protocol upon its conception, and ratified it in 1930. Britain, however, refused to completely abandon its chemical warfare capabilities; it accepted in principle the no-first-use concept but insisted on maintaining a deterrent. In the years preceding the Second World War, extensive preparations were made for civil defense based on the assumption that Germany, Italy, and Japan were likely to use chemical weapons against British forces in the field and that a threat existed to the civilian population.

During the Second World War, research at Porton Down was expanded and production was increased to ensure that sufficient chemical deterrent stocks were available in all theaters of war. In addition to experiments with the new insecticide DDT, the British discovered compounds that could be used as nerve agents, but they failed to realize these compounds' significance. Nevertheless, the toxic organophosphate nerve compound diisopropyl fluorophosphate (DFP) was developed, and, although less deadly than tabun or sarin, it significantly enhanced the effect of mustard gas when the two were mixed together. The new compound produced a dual effect from both blister and nerve agents in terms of causing casualties, and the mixture could remain a liquid under colder temperatures than mustard agent alone. Although U.S. and European armies used no chemicals during World War II, the production of chemical weapons on both sides—the Axis and the Allies—was considerable. In 1944, after the Germans started using V1 and V2 ("Vengeance") cruise missiles and ballistic rockets against London, the British came close to a preemptive use of mustard and other chemicals against German cities.

In the immediate postwar world, the British, in conjunction with the United States and Canada, pooled their knowledge of the German nerve gases tabun, sarin, and soman and conducted tests with these agents. With funding being short, however, the British government placed greater emphasis on its nuclear and biowarfare programs and less on its chemical program. As a result, the United Kingdom never went into full-scale production of the new nerve agents before deciding in 1956 to renounce the offensive use of chemical weapons under any circumstances.

Since 1956, all British chemical warfare research has focused on providing for defensive equipment. The United Kingdom has become a world leader in protective gear, including the use of ion mobility spectroscopy—the use of measuring ionized particles to determine the identity of a substance—in hand-held chemical agent detection systems. The United Kingdom also signed the 1993 Chemical Weapons Convention (CWC) as part of general efforts to eliminate chemical arsenals worldwide.

Biological Warfare

In Britain, fears about biological warfare first became public in 1934 in the Wickham Steed Affair, when claims were made that German spies had tested biowarfare agents on the London Underground and Paris Metro. Within a year of the outbreak of the Second World War, a new biology department was set up at the chemical warfare establishment of Porton Down to develop a bioweapon that could be used to retaliate against a German biological weapons attack. The department focused its efforts on anthrax bacterial spores and botulinum toxin (derived from *Clostridium botulinum* bacteria).

Two weapons were developed. The first consisted of 5 million linseed cattle feed cakes filled with a slurry of anthrax spores and stockpiled as an antilivestock weapon ("Operation Vegetarian"). These cakes were to have been dropped over livestock grazing areas in Germany by aircraft, but the operation was never carried out. The second weapon was a prototype antipersonnel anthrax bomb that was tested on Gruinard Island off the coast of Scotland. After 50 years of isolation due to safety concerns about the possibility of lingering anthrax spores, this island has now been decontaminated and returned to its previous owner (*see* Gruinard Island).

With the end of the Second World War, the government gave the biowarfare program equal priority with the atomic program, and a series of tests were undertaken with the pathogens responsible for diseases such as brucellosis, tularemia, and plague. British interest in biowarfare receded with Britain's first atomic test in 1952. In 1972, the United Kingdom signed the Biological and Toxin Weapons Convention, ending research into offensive biological warfare. A pool of British scientists, however, remains engaged in developing protective equipment and treatments for defense against biological attack.

UNITED NATIONS MONITORING, VERIFICATION, AND INSPECTION COMMISSION (UNMOVIC)

In 1999, the United Nations Security Council, acting under Chapter VII of the UN Charter, established the United Nations Monitoring, Verification, and Inspection Commission (UNMOVIC) to undertake the responsibilities of the UNSCOM (United Nations Special Commission on Iraq). (*See* United Nations Special Commission on Iraq [UNSCOM].)

In response to Iraqi insistence, UNSCOM withdrew its staff from Iraq on December 16, 1998, and ceased to function. United Nations Security Council Resolution 1284 (December 17, 1999) created UNMOVIC to replace the former UN Special Commission. The commission had been assigned to dismantle Iraq's program to acquire weapons of mass destruction (chemical and biological weapons, and missiles with a range of more than 150 kilometers) and to operate a system of ongoing monitoring and verification along with the International Atomic Energy Agency (IAEA). UNMOVIC was to check Iraq's compliance with its obligations not to develop or possess weapons prohibited to it by the UN Security Council. From its creation until November 27, 2002, however, UNMOVIC carried out no inspections, due to Iraq's refusal to cooperate with inspection teams.

On September 16, 2002, following UN Resolution 1441, which was introduced by the United States and found the Iraqi government to be in material breach of its obligations to verifiably disarm, the foreign minister of Iraq informed the UN secretary-general that Iraq had decided to allow the return of UNMOVIC and IAEA inspectors without conditions. Inspections resumed on November 27, 2002. UNMOVIC took over UNSCOM's assets, liabilities, and archives and was required to report to the UN Security Council every 3 months. Dr. Hans Blix of Sweden served as UNMOVIC's executive chairman, and sixteen other individuals served on the College of Commissioners that provided advice and guidance to Blix in the execution of his duties. UNMOVIC's staff included weapons specialists, analysts, scientists, engineers, and operational planners. It was financed from a small portion of the monies raised from the export of oil from Iraq (the "oil-for-food" program, allowing purchases of items for humanitarian purposes, such as food and medicine, in exchange for crude oil). Unlike UNSCOM, all the staff of UNMOVIC were employees of the United Nations.

UNMOVIC comprised four divisions (Planning and Operations, Analysis and Assessment, Information, and Technical Support and Training) and an administrative service, headquartered at the UN in New York. On resumption of inspections, a transport and supply system was established in Cyprus with regular flights to Baghdad, where more than 100 inspectors operated daily along with IAEA inspectors. Their duties included interviewing Iraqi scientists; UNMOVIC personnel also held consultations with interested IAEA member states on revisions to the list of dual-use goods and chemical, biological, and missile equipment to which the UN-monitored export/import mechanism applied. It submitted these modified lists of contraband materials to the Security Council.

UNMOVIC produced an interim report to the Security Council on January 9, 2003, after completing 250 inspections. In making the report, Blix noted that Iraq's most recent declaration to UNMOVIC was incomplete and left many questions unanswered. UNMOVIC evacuated its staff from Iraq on March 17, 2003, following Iraq's rejection of President Bush's ultimatum to disarm. On March 19, a U.S.-led coalition invaded Iraq, intending to once and for all eliminate suspected Iraqi WMD and missile programs. The UN Security Council will now determine UNMOVIC's future mandate.

UNITED NATIONS SPECIAL COMMISSION ON IRAQ (UNSCOM)

In addition to its work to disarm chemical, biological, and missile-related technologies in Iraq's known weapons of mass destruction (WMD) program, the United Nations Special Commission on Iraq (UNSCOM) was formed to assist the International Atomic Energy Agency (IAEA). The latter's mandate was to provide evidence of the destruction, removal, or demilitarization of Iraq's nuclear facilities and ballistic missiles with a range greater than 150 kilometers, including the launchers, production, related major parts, and repair facilities of such missiles. UNSCOM was also charged with undertaking a monitoring program to ensure that Iraq could never reconstitute its chemical, biological, and nuclear arsenal.

After losing the 1991 Gulf War, Iraq agreed, as a condition of surrender, to declare within 15 days all of its WMD and the means (rockets, artillery shells, etc) to deliver them, and then to destroy them. This obligation was reinforced by U.N. Security Council Resolution 687 on April 3, 1991, which formed UNSCOM to monitor and verify Iraq's compliance with its undertaking not to use, develop, construct, or acquire chemical, biological, and nuclear weapons.

Under the terms of the resolution, Iraq was barred from selling oil until UNSCOM verified the destruction of its prohibited weapons. The nuclear inspection teams were organized by the IAEA, with the assistance and cooperation of the Special Commission. UNSCOM commenced its first missile inspection on June 30, 1991. Iraq consistently tried to evade its responsibilities, and following Iraqi efforts to deter its mission, UNSCOM withdrew its entire staff from Iraq on December 16, 1998.

Iraqi Long-Range Missiles

On April 18, 1991, Iraq provided an initial declaration that it possessed fifty-three al-Hussein and Scud-type long-range ballistic missiles. From September 21 to 30, 1991, IAEA inspectors first found large amounts of documentation relating to Iraq's efforts to acquire nuclear weapons. Following this, the IAEA, with the assistance and cooperation of UNSCOM, undertook fifty-three ballistic missile and thirty nuclear inspections. UNSCOM supervised the destruction of forty-eight operational long-range missiles, fourteen conventional missile warheads, six operational mobile launchers, twenty-eight operational fixed launch pads, thirty-two fixed launch pads that were under construction, thirty missile chemical warheads, and other missile support equipment and materials. It also supervised the destruction of a variety of assembled and nonassembled "super-gun" components. The super-gun concept employs an extremely long barrel that could conceivably fire projectiles over hundreds, possibly thousands, of kilometers.

UNSCOM was instrumental in assisting the November 1995 interception by the nation of Jordan of a large shipment of high-grade missile components destined for Iraq. The Commission's experts also participated in negotiations with the Russian Federation regarding the sale of the nuclear fuel removed from Iraq and reprocessed in the Russian Federation. The disclosures of Iraq's nuclear program led to efforts to strengthen the IAEA safeguard agreements used to monitor and verify compliance among parties to the Nuclear Nonproliferation Treaty (NPT).

On December 17, 1999, the UN Security Council adopted Resolution 1284, replacing UNSCOM with the United Nations Monitoring, Verification, and Inspection Commission (UNMOVIC).

UNITED STATES: CHEMICAL AND BIOLOGICAL WEAPONS PROGRAMS

During the twentieth century, the United States developed one of the largest arsenals of chemical and biological weapons in the world, second only to that of the former Soviet Union. Since the ratification of the 1975 Biological and Toxin Weapons Convention (BTWC) and the 1993 Chemical Weapons Convention (CWC), the United States has demilitarized its biological and chemical weapons programs. As of 2004, no offensive biological weapons exist in the United States, but thousands of tons of chemical weapons remaining on U.S. soil await their final destruction in keeping with the terms of the CWC.

Chemical Warfare

The potential use of chemical agents, in the form of poisonous gases or substances to contaminate water wells, was considered early in U.S. history. In 1862, during the Civil War, an American engineer by the name of John W. Doughty wrote to the U.S. Secretary of War, suggesting that chlorine be used in artillery shells. He believed that the introduction of chemical weapons on the battlefield would lead to more decisive results. It is not certain whether this plan inspired U.S. Army General Order No. 100, issued in 1863, which admonished: "The use of poison in any manner, be it to poison wells, or food, or arms, is wholly excluded from modern warfare" (Smart, p. 13).

Little development in the area of chemical warfare (CW) in the United States occurred after that until 1915, when chemicals were used on a large scale for the first time. Because the United States had yet to become involved in the European hostilities of the time, efforts in "gas warfare" were mostly limited to the manufacture of protective equipment, especially gas masks. Six years prior to the conflagration in Europe, in 1908, Van H. Manning, director of the U.S. Bureau of Mines, had organized a department of scientists and engineers to develop equipment to protect coal miners from toxic gases in the mines. Research included the use of self-contained breathing apparatuses and medical treatment for personnel exposed to poisonous gases. In February 1917, Director Manning suggested that the Bureau could assist in testing gas masks for the U.S. Army. This was the only significant CW work that had been conducted by the time the United States declared war on Germany on April 6, 1917.

When U.S. troops entered the combat of World War I in 1917, however, it became clear that the American Expeditionary Forces were woefully unprepared for the chemical battlefield. The U.S. Chemical Warfare Service (CWS), led by Major General William L. Siebert, was founded on June 29, 1918. But by early September 1917, a "Gas Service" had already been established as a separate branch of the American Expeditionary Force (AEF) in France.

In May 1917, the CWS Research Division—in coordination with American industrial entities that included Goodyear Rubber, American Can Company, and the General Chemical Company—undertook a crash development program to supply the first 20,000 gas masks to U.S. forces. The issue of quality control—paramount in the case of chemical defense equipment—was dealt with in an interesting way. Those employees who had relatives serving in the AEF were chosen first to participate in the gas mask project. Workers who had a personal interest, it was reasoned, would be expected to make a higher-quality mask. When full-scale production was achieved, more than 40,000 masks could be produced in a single day, and eventually 5.7 million gas masks were manufactured by the end of World War I.

The U.S. military began filling chemical shells under the auspices of the Trench Warfare Section of the Ordnance Department. The Offense Research Section of the CWS selected certain substances for their possible use in combat. Approximately 250 chemicals were researched and evaluated for their suitability as chemical weapons for the western front. Although chemical weapons used by U.S. forces in the European theater were initially provided by the European allies of the United States, phosgene, mustard, and lewisite production facilities were built in the United States from 1917–1918. (Lewisite was a late entry into the U.S. chemical arsenal, and it was never used in World War I.) Because of its isolated location and ready access to shipping via Chesapeake Bay, "Gunpowder Reservation," 20 miles east of Baltimore, Maryland, was chosen in December 1917 to be the site for producing toxic agents and filling chemical shells and bombs. On May 4, 1918, the 3,400-acre district was officially renamed Edgewood Arsenal.

Except for the highly toxic nature of the chemicals being put into shells, the methods employed at the Arsenal were in many ways similar to those used by the bottling industry to handle carbonated water. The dangerous nature of the chemicals demanded special measures, however, including sealed-off rooms and automated equipment. But these protective measures were quite basic, and working conditions were still extremely hazardous.

By war's end, Edgewood Arsenal had filled and shipped more than 150,000 mustard shells of 75-millimeter caliber to the western front. Despite these efforts, none of the gas projectors or chemical artillery shells arrived in Europe before the fighting ended.

Following the end of World War I, the CWS had to struggle to remain intact as a formal organization in the U.S. military, surviving due almost solely to the efforts of Major General Amos A. Fries. In the late 1920s, the U.S. chemical arsenal consisted mostly of mustard, chloroacetophenone

Table U-1: Chemical Products, Intermediates, and CW Agents Produced at Edgewood Arsenal, 1918

Material	*Amount in millions of lbs.*
Salt (NaCl)	17.4
Bleach (sodium hypochlorite)	42.4
Picric acid	3.7
Alcohol	3.7
Sulfur	24.9
Sulfur chloride	6.6
Bromine	0.24
Material	*Amount, millions of lbs.*
Chlorine (liquid)	5.4
Chlorine (gas)	2.2
Chloropicrin	5.5
Phosgene	3.2
Mustard	1.4

(CN), phosgene, lewisite, chloropicrin, and chlorine. In 1928, the M1 4.2-inch chemical mortar became the standard chemical delivery system in the U.S. arsenal. It was also used to deliver obscurant smokes and high explosive shells. But with defense spending cut by the Great Depression, preparations for CW took a low priority for the United States War Department. In the late 1930s, the U.S. military had only 5 percent of the chemical munitions and only 3 percent of the number of gas masks thought necessary for 6 months of war. The U.S. armed forces were also not prepared for chemical contingencies.

In 1937, as war loomed once again on the European continent, the United States revamped its offensive chemical weapons program, adding production capacity at Edgewood Arsenal. But the agents produced, mustard and phosgene, were of World War I vintage. In comparison to the groundbreaking work in military chemistry going on in Germany and elsewhere, the United States had only a limited chemical warfare capability when it declared war on Germany and Japan. Especially in light of the Japanese military's use of CW against China in the 1930s, a sense of urgency prevailed to increase the U.S. offensive chemical stockpile. From 1940 to 1945, the United States ramped up its chemical production capacity, producing nearly 150,000 tons of CW agents. In addition to the already venerable 4.2-inch chemical mortar, other delivery ordnance included 75-millimeter, 105-millimeter, and 155-millimeter artillery rounds. (The 155-millimeter has since found wide acceptance for use with chemical rounds in other countries.) In addition to artillery, the U.S. Army Air Corps standardized aerial munitions, including 1,000-pound bombs containing phosgene, cyanogen chloride, and hydrogen cyanide. Substantial chemical weapons were deployed to European staging grounds, including Bari, Italy. Bari became the scene of a chemical disaster when German aircraft attacked Allied shipping vessels, including the SS *John Harvey,* which was laden with 2,000-pound mustard bombs.

In June 1943—reflecting the general disapproval of chemical warfare by the American public—Franklin D. Roosevelt categorically stated, "we shall under no circumstances resort to the use of such weapons unless they are first used by our enemies" (Smart, p. 44). By 1945, however, public mood had shifted: 40 percent of the people responding to one survey were in favor of using chemicals against the Japanese, versus 23 percent just a year before. Pitched battles in the Pacific island campaign had resulted in horrendous U.S. casualties, not to mention the massive loss of civilian life during the Okinawa campaign. This no doubt added to the public's acceptance of offensive CW. Defending from heavily fortified redoubts, Japanese troops rarely surrendered and fought ferociously to the very end. It was at this point that the U.S. Assistant Secretary of War, John J. McCloy, reconsidered the use of chemical weapons.

As plans were being drawn to invade the Japanese mainland, General "Vinegar Joe" Stilwell and General George C. Marshall suggested the use of gas. But the logistics and preparation for such CW would have conflicted with the shipment of sorely needed conventional materiel. Other influential decision makers within the military, notably Admiral William D. Leahy, thought it appalling that the employment of chemical weapons was being considered. In 1945, the United States could have mustered enough chemical weapons from existing stocks, and with its industrial capacity manufactured many thousands of tons more, to have conducted a debilitating attack against the Japanese military deployed in defense of the home islands. But without gas masks and other equipment being forward deployed—not to mention the lack of CW training among U.S. troops—practical considerations and moral qualms recommended against the use of CW against the Japanese. (Nonetheless, the ferocious nature of the battle for Okinawa did contribute to the decision to drop the atomic bomb on Japan.)

The discovery of Germany's nerve agent stocks, including 750 tabun artillery shells that were captured in Germany and shipped to the United States, was a shock to Allied CW experts. By the 1950s, sarin nerve agent and VX were produced in large quantity by the United States at Mussel Shoals, Alabama, and Newport, Indiana, respectively. By 1954, the M34 and M34A1 chemical cluster munitions were designed to drop sarin on targets. Little progress was made in delivering VX nerve agent, however, until the 1960s. During this time, incapacitants were researched and tested, often on human volunteers, leading to the weaponization of BZ (3-quinuclidinyl benzilate). Mortars, artillery rockets (M55), and land mines containing sarin or VX were produced. Longer-range systems, including the Honest John (16-mile range) rocket and the Sergeant rocket, were fitted with chemical warheads. During the 1960s, unmanned aerial vehicles (UAVs)—more accurately described as drone aircraft—were developed to deliver both chemical and biological agents. An accident on Okinawa, Japan, involving sarin nerve agent, however, led to a halt to both biological and chemical weapons production by the United States in 1969.

The aftermath of the 1973 Yom Kippur War in the Middle East served as yet another "wake-up call" for the U.S. Chemical Corps. Israeli forces, which barely prevailed after Egypt and Syria launched a surprise attack, discovered Soviet armored vehicles that were equipped to survive in contaminated chemical environments. This spurred the United States to rethink its approach to defensive and offensive CW. More advanced designs for chemical munitions, including the M-687 binary shell, were integrated into U.S. chemical weaponry in 1976.

Not without controversy, in the 1980s President Ronald Reagan revitalized U.S. offensive chemical weapons production. Defending his decision, Reagan stated, "the United States must maintain a limited [chemical] retaliatory capability until we achieve an effective ban" (Smart, p. 70). Not only the M-687, but also the VX binary bomb (Bigeye), went into full production by the late 1980s. Although these and other chemical weapons were available by the 1990–1991 Gulf War, they played no role in planning for retaliation in the event that Iraq introduced chemical weapons on the battlefield.

Having signed a memorandum of understanding with the former Soviet Union in 1989, the United States was set on a course to fully demilitarize its chemical arsenal, culminating in the ratification of the Chemical Weapons Convention in 1997. As of 2004, about 28,000 tons of chemical agent in bulk and weaponized form awaited their final destruction in the United States.

Biological Warfare

Before the renunciation of biological warfare by President Richard M. Nixon in 1969, the United States developed a series of weaponized BW agents. These included the causative agents of anthrax, brucellosis, tularemia, Venezuelan equine encephalitis, and Q-fever, as well as the toxin staphylococcal enterotoxin B. Anticrop agents were also produced in significant quantity to target the wheat and rice crops of communist Russia and China during the Cold War. A number of other BW agents, including smallpox, rift valley fever virus, and Rocky Mountain spotted fever bacteria were investigated as well. All offensive biological weapon stores were destroyed by 1972, and some toxins (such as saxitoxin) were redirected toward peaceful medical research.

Referring to a League of Nations committee formed on the subject, the U.S. Chemical Warfare Service wrote in its 1926 annual report that BW "would have little effect on the actual issue of a contest in view of the protective methods which are available for circumscribing its effects" (U.S. CWS, pp. 8–9). Later in the 1930s, however, prewar intelligence reports indicated that Japan and Germany had undertaken research into offensive BW. In February 1939, the U.S. State Department reported that a Japanese army physician in New York had tried to obtain yellow fever virus, possibly an attenuated strain, from the Rockefeller Institute for Medical Research. This and other intelligence reports contributed to a newfound sense of urgency, and in September 1939, American military scientists decided to reexamine the problem of BW.

The Chemical Warfare Service reported that nine diseases could be potential BW agents: yellow fever, the dysenteries, cholera, typhus, bubonic plague, smallpox, influenza, sleeping sickness (*Trypanosoma brucei,* via the tsetse fly), and tetanus. These agents were of great interest because they could be spread by insects, or because they required neither existing skin lesions nor did they need another agent to enter the human body. Although doubts still persisted in the United States about the real threat posed by BW, information in late 1939 indicated that Japan and Germany were interested in the subject. A consensus was reached to allocate funds for defensive research against biological weapons.

In 1941, the U.S. Chemical Warfare Service began BW-related research. In February 1942, the National Academy of Sciences (NAS) submitted a report to Secretary of War Henry L. Stimson describing the threat posed by BW agents against crops, livestock, and humans. The NAS concluded that both defensive and offensive BW research be conducted. In mid-1942, George W. Merck, President of Merck & Company, a large pharmaceutical company, became the chairman of the War Research Service (WRS), which was established to oversee U.S. BW-related activities. The CWS was given the responsibility of building and operating laboratories and production facilities. In March 1942, the CWS had suggested that, in addition to work conducted by civilian research scientists in biological weapons defense, the following BW agents be studied in an offensive context:

Antipersonnel:

- Coccidioidomycosis
- Psittacosis
- Plague
- Typhoid and paratyphoid
- Cholera
- Typhus
- Yellow fever
- Anthrax

Antianimal:

- Rinderpest
- Foot-and-mouth disease
- Fowl plague

Anticrop:

- Late blight of potato
- Rice fungi
- Wheat rusts
- South American rubber leaf blight

By 1944, this list had grown by adding the following agents:

Antipersonnel:

- Tularemia
- Brucellosis
- Glanders
- Melioidosis

Anticrop:

- Sclerotium rot

By 1942, the CWS began construction of a BW facility at Camp Detrick, Maryland (later renamed Fort Detrick) at a cost of $13 million. Operational in 1943, the facility at Camp Detrick employed approximately 4,000 people. Other BW-related facilities included a 250-acre site near Dugway Proving Grounds, Utah, and a 2,000-acre facility at Horn Island in Pascalouga, Mississippi, both of which were used for open-air testing.

Meanwhile, cooperation among the United States, Canada, and England continued in BW research. It was learned from tests conducted by the British at Gruinard Island (off the coast of Scotland) and Penclawdd (on the coast of Wales) during 1942 and 1943 that loading anthrax into bomblets arranged into cluster munitions was the most feasible method of agent delivery. In one experiment, sheep were placed at various distances from a bomb loaded with anthrax fill. The reach of the deadly spores was such that animals placed 250 yards downwind received a lethal dose of anthrax. Despite these results, effective cluster-type munitions using anthrax were never supplied to Allied forces in World War II.

In the period following World War II, U.S. BW production capacity was gradually reduced to laboratory-scale research and development. Between 1947 and 1949, small-scale, open-air testing of BW simulants *Bacillus globigii* (BG) and *Serratia marcescens* (SM) was carried out at Camp Detrick. Pathogen tests began at Camp Detrick in 1949 in an enclosed, one-million-liter steel sphere called the "eight ball." During the Korean War, the United States expanded its BW program. The government established the Pine Bluff Arsenal BW agent production facility in Arkansas, and it also expanded major research facilities at Camp Detrick. By 1951, the program developed, tested, and produced a variety of BW anticrop agents for military purposes and the bombs capable of delivering such agents. Spending on BW-related research and development amounted to more than $345 million during fiscal years 1951–1953. By September 1952, however, the ability to deliver biological agents effectively was still an open question, and it had become apparent, at least to the U.S. Air Force, that the United States still had no lethal, stable, viable, easily disseminated, low-cost, epidemic-producing BW agent.

During the 1950s, the U.S. military conducted a number of secret tests to assess the vulnerability of the American mainland to BW attack, or to test the effectiveness of BW agent delivery methods. Exercise Brown Derby was carried out November 7–20, 1953, by the Chemical Corps and U.S. Air Force to assess the ability of the United States to produce and transport BW weapons overseas. The exercise showed that an attack using BW could be launched within several days of the initial order. Operation Big Itch consisted of a series of field tests of E-23 and E-14 munitions loaded with *Xenopsylla cheopis* fleas, which in this case did not carry pathogens. The fleas were dropped from a height of 300 to 600 meters over guinea pigs on the Dugway Proving Grounds in 1954. Technical difficulties with the E-23 munition, however, caused fleas to escape into the plane, resulting in the bombadier, observer, and pilot all being bitten by the insects.

A series of at least three or four "Bellwether" tests, conducted beginning in the late 1950s, studied the biting behavior of mosquitoes. Bellwether 1, for example, was a study conducted in September–October 1959, during which uninfected, female *Aedes aegeypti* mosquitoes were released in fifty-two field trials and the number of mosquito bites on laboratory animals and on humans were counted.

Scientists from Fort Detrick also secretly performed animal studies at remote desert sites and on barges near Johnston Atoll in the Pacific Ocean. Between 1949 and 1968, the U.S. government also surreptitiously dropped BW simulants (such as *Serratia marcescens*) over a number of American cities, including San Francisco and New York City, to assess urban vulnerability to biological attack and to experiment with potential weapons and delivery systems. Simulants such as *Serratia marcescens* (SM) could be cultured at various points distant from release to determine length of travel. In 1955, American scientists and military experts began using human volunteers to test the effect of various BW simulants, including the anthrax simulant *Bacillus globigii* (BG). These tests were intended to help scientists learn how to strengthen American BW defenses, as well as to assist in developing the means to carry out a biological attack.

In 1956, further attention was brought to chemical and biological warfare, particularly as a result of the looming threat from the Soviet Union. In 1956, Soviet Defense Minister Marshal Georgi Zhukov's speech to the Twentieth Congress of the Soviet Communist Party in Moscow contained references to "weapons of mass destruction," including chemical weapons in future wars. The wording of the speech was used as support for the argument that a Soviet chemical threat existed, and by extension a threat from biological weaponry as well. A December 1958 meeting of the Defense Science Board recommended developing new unconventional weapons, expanding research, and placing greater resources into public relations. These recommendations, in turn, were supported by the Joint Chiefs of Staff in 1959. The Chiefs emphasized the need for stockpile modernization and increased research and development funding.

Despite increasing public interest in chemical and biological weapons disarmament during the 1960s, the American BW program continued to grow. The development of large-scale freeze-drying and spray-drying systems was undertaken to improve the ability of biological weapons agents to survive and remain potent during an offensive attack. Research using arthropods was conducted to deliver certain BW agents. By 1966, government facilities at Pine Bluff Arsenal and Fort Detrick had already mass-produced several BW agents, filling several types of biological munitions. The so-called Flettner rotor was designed to deliver BW agents in cluster-type munitions, but it was never mass-produced. The E120 bomblet was also developed to deliver biological weapons.

By the time the U.S. BW program was terminated in 1969, American BW scientists had seven standardized biological weapons. In the lethal category, the U.S. Army had weaponized the bacterial agents that cause anthrax and tularemia. For incapacitating agents, the causative agents of brucellosis, Q-fever, and Venezuelan equine encephalitis (VEE) were weaponized. Toxins that were developed into

CHRONOLOGICAL SKETCH OF THE U.S. BIOLOGICAL WEAPONS PROGRAM

1939	Possible threat from BW agents is reexamined in a study by the Chemical Warfare Service (CWS)
1941	Secretary of War Henry L. Stimson charges a committee from the National Academy of Sciences (NAS) to evaluate viability of biological weaponry
1941	NAS committee concludes BW is indeed a threat and recommends that vulnerability testing be performed for United States security in 1942
1943	Camp Detrick, Maryland, begins operations with a staff of approximately 4,000
1944	Dugway Proving Grounds, Utah, built as test site for pathogen/BW research
1945–1949	Some testing facilities are shut down, but small-scale outdoor testing using biological simulant (*Bacillus globigii*, or BG) is performed at Camp Detrick
1950	Expansion plans developed for BW research in response to threat from the Soviets
1953	Further construction of facilities at Camp Detrick, along with an increase in defensive and retaliatory BW research
1955	Pine Bluff Arsenal, Arkansas, produces large quantities of *Francisella tularensis* (the causative bacteria for tularemia)
1956	Marshal Georgi Zhukov of the U.S.S.R. delivers speech, stating that chemical/biological weapons were part of Soviet military doctrine; U.S. CBW policy reviewed, Camp Detrick changes name to Fort Detrick on February 3, 1956
1961	President John F. Kennedy reassesses BW, recommending expansion of BW programs
1964–1965	Production facilities for viruses and rickettsiae built at Pine Bluff Arsenal
1965	*Bacillus globigii* (BG) simulant used in (covert) vulnerability experiment on New York City subway system; tests conclude that many persons could be exposed to infectious doses of BW agents
1959–1968	Stable dry and liquid BW agents are developed, large-scale fermentation processes are improved, and effective dissemination munitions for microbes are manufactured
1969	President Richard Nixon renounces use of "lethal biological agents and weapons"
1970	President Nixon adds, "The United States will confine its military programs for toxins . . .to research for defensive purposes only"
1970–1972	Destruction of antipersonnel BW agents completed
1975	United States ratifies the Biological and Toxin Weapons Convention (BTWC)

validated weapons systems were the lethal toxin botulinum and the "incapacitant" staphylococcal enterotoxin B (SEB).

In 1969 and 1970, President Richard Nixon renounced all offensive development and production of microbial and toxin agents in National Security Directives 35 and 44, respectively. By 1972, all U.S. antipersonnel BW agent stocks and munitions were destroyed. The United States also terminated all offensive research, closed or cleaned up all offensive facilities, and turned these facilities over to other government agencies for other research. The American BW defense program was subsequently moved to Fort Detrick, Maryland. The unilateral disarmament initiated by President Nixon's directives set the stage for the 1972 Biological and Toxins Weapons Convention (BTWC). On January 22, 1975, the United States ratified the BTWC, which prohibited the development, production, and stockpiling of bacteriological and toxin weapons.

UNMANNED AERIAL VEHICLE (UAV)

An unmanned aerial vehicle is "a powered, aerial vehicle that does not carry a human operator, uses aerodynamic forces to provide vehicle lift, can fly autonomously or be piloted remotely, can be expendable or recoverable, and can carry a lethal or nonlethal payload. Ballistic or semiballistic vehicles, cruise missiles, and artillery projectiles are not considered unmanned aerial vehicles" (U.S. Department of Defense [DoD], online). Although some may consider cruise missiles and similar platforms as UAVs, most commentary reflects the U.S. definition of the term.

With applications ranging from battlefield reconnaissance to live target engagement, UAVs are a versatile and highly effective weapon. The United States, Germany, and the Soviet Union (now Russia) have been actively developing UAV technology—with varying degrees of success—since World War II. Recent use of UAVs in Operations Desert Storm, Allied Force, Enduring Freedom, and Iraqi Freedom has garnered significant public attention and convinced many senior leaders in the United States and elsewhere of their utility. In fact, some Pentagon officials now estimate that by 2015, UAVs will account for 10 percent of all U.S. aircraft. However, many of the characteristics that make UAVs attractive platforms for the United States and its allies also make them attractive to rogue states and terrorist organizations. Indeed, UAVs are potentially an effective delivery vehicle for chemical or biological weapons.

Although the United States has been experimenting with UAVs since the 1940s, it has only been within the past decade that U.S. policymakers and war planners have begun to realize the potential of UAVs. In the past, technology has been the most significant limiting factor. Advances in computer science and aerospace engineering, however, have transformed UAVs into a reliable platform for military operations. Indeed, U.S. Secretary of Defense Donald Rumsfeld was so impressed with the performance of U.S. UAVs during Operation Enduring Freedom (2001–2002) that he added approximately $1 billion to the DoD's UAV programs for fiscal year 2003.

UAVs enjoy many significant advantages over manned aircraft. UAVs are less expensive; the Air Force's Predator, for example, has a base cost of approximately $5 million, compared to manned fighter aircraft with price tags of two to four times as much. Such cost discrepancies will only increase as the systems needed by manned aircraft to defeat sophisticated enemy radar and ground defense systems become more complex. The UAV's biggest advantage, however, is that it can be employed for a variety of missions that are too dangerous for a manned aircraft. These include identifying enemy surface-to-air missile (SAM) batteries, triggering or locating enemy radar systems, or "parking" over the battlefield to transmit real-time video footage to the command center.

Background

U.S. attempts to develop UAVs began during World War II. For example, Operation Aphrodite involved the use of a pilot flying a specially modified airplane to a predetermined altitude. Once at the proper altitude, radio control of the first plane would be established by a pilot in another plane. At this point, the original pilot would parachute from the cockpit, allowing his plane to be flown via remote control to the target. It was during one of these Operation Aphrodite missions that President John F. Kennedy's older brother, Navy Lieutenant Joseph P. Kennedy, was killed. Germany had experimented with various unmanned aerial platforms as well during World War II.

Approximately 20 years later, UAV technology was employed in the jungles of Vietnam. The Air Force's AQM-34 Lightning Bug was the first U.S. photo reconnaissance UAV. It was used for photography, real-time video, electronic intelligence, communications intelligence, detection of SAM positions, and dropping leaflets in psychological operations. Despite the Lightning Bug's demonstrated utility, interest in UAV technology waned as

UAVs are the reconnaissance and combat platform of the future. Terrorists could also use them to deliver CBW agents. (Corbis/Sygma)

the Vietnam War came to an end. Significant interest in UAVs didn't emerge again until the 1980s.

Prompted by Israeli successes with UAV technology, the U.S. Navy began development of its Pioneer UAV in 1985. The Pioneer was a direct derivative of an existing Israeli UAV system and became the primary U.S. UAV during Operation Desert Storm (1991). In total, forty-three Pioneers were deployed during Operation Desert Storm, flying 330 sorties and completing more than 1,000 flight hours. The U.S. Army, Navy, and Marine Corps used the Pioneer for a variety of functions: destroying enemy artillery, providing imagery, and monitoring Iraqi troop movements.

The Navy also found that the Pioneer was highly useful for spotting targets for firing 16-inch guns from battleships that maintained station well out to sea. The U.S.S. *Missouri* used a Pioneer to spot for its guns as it bombarded Iraqi positions on Falakya Island, which was located off the coast near Kuwait City. As the U.S.S. *Wisconsin* arrived to relieve the U.S.S. *Missouri* and resume shelling the island, it sent its Pioneer to hover low over the Iraqi emplacements. At one point, some Iraqi forces even surrendered to a Pioneer. Hearing the Pioneer's motor and realizing that a new round of shelling was about to begin, the Iraqis frantically signaled their surrender. The DoD also used the Pioneer in military operations in Bosnia, Haiti, and Somalia. It was retired from service in 2000, however, due to production problems and cost overruns.

UAVs once again proved their worth in Operations Enduring Freedom and Iraqi Freedom, in which both the Predator and Global Hawk provided U.S. forces with valuable support. Although the Global Hawk gave U.S. forces the capability to receive timely and accurate reconnaissance, the Predator received more headlines, as it became the first UAV to engage and destroy enemy targets (when an armed Predator flying over Yemen engaged a vehicle carrying senior al-Qaeda members). The Predator had begun development in January 1994 as an advanced concept technology demonstration designed for reconnaissance, surveillance, and target acquisition. In October 2001, an undisclosed number of Predators, under the direction of the Central Intelligence Agency (CIA), were deployed to Afghanistan. Although initially used for reconnaissance, they were eventually modified to accommodate Hellfire rockets. These modified Predators were used extensively to destroy enemy targets. Following the successes of UAVs in Operation Enduring Freedom, the

DoD announced that it planned to spend $5 billion for research, development, and acquisition of UAVs.

UAVs and the Future

Although UAVs represent a potentially significant addition to the U.S. arsenal, there is mounting evidence that rogue states and international terrorist organizations are also interested in acquiring and using UAVs. With their ability to release an agent at the appropriate height for maximum effect, a UAV is an ideal delivery vehicle for chemical or biological weapons. In 1998 during Operation Desert Fox, the British military reported a missile attack on an Iraqi hangar and uncovered approximately twelve Iraqi UAVs modified with spray attachments and wing-mounted tanks capable of carrying 80 gallons of liquid anthrax. A British defense official dubbed these UAVs drones of death and speculated that under the right conditions, one would be capable of covering several city blocks with a deadly chemical cloud.

After the terrorist attacks on September 11, 2001, the U.S. government revealed that some al-Qaeda members had explored the possibility of learning to fly UAVs. Additionally, during Operation Enduring Freedom, U.S. forces discovered operation manuals for unmanned remote-controlled helicopters in an al-Qaeda safe house. There is a tendency to underestimate the potential threat that UAVs represent, as they fly relatively slowly and are vulnerable to air defense systems once such systems are alerted to the threat. But, it remains unclear how effective air defense systems are against UAVs, which constitute a relatively small and potentially stealthy target.

V

VACCINES

Vaccines, toxoids, and immunoglobulins (antibodies from blood preparations) can be used to protect or treat individuals exposed to biological warfare (BW) agents. Currently, few vaccines are approved for use in humans against potential BW agents.

As of this writing in 2004, the U.S. military continues a somewhat controversial anthrax vaccination program for active military personnel, and smallpox vaccine is also being administered to military servicepeople. The smallpox vaccine program also includes civilian first responders in the United States, but only a small percentage of civilian emergency workers participated in the program during 2003. Apart from these two vaccines, no other vaccines are routinely administered to protect military personnel against other BW agents, although it is possible that more will be added to the list of routine inoculations in the near future. Also available are botulinum toxoids (detoxified proteins used to generate an immune response) and an investigational new drug (IND) immunoglobulin for treatment of botulism, but these would only be used when an attack has already occurred or is nearly certain. As for the ten or so other potential BW threats (see Table V-1), vaccines are being researched and developed but will probably not see efficacy trials in humans for several years to come.

A preliminary list of the standard pathogens and toxins is rather daunting when one considers the possible BW agents that could pose a threat to civilian or military personnel (see Table V-1).

By the end of 2003, the United States had stockpiled sufficient smallpox vaccine for nearly all of its population. In the event of an attack using smallpox virus, the vaccine used to counter the disease can be effective if administered within two or three days of exposure. Among treatment modalities for the high-threat BW agents, however, smallpox vaccine is the exception. For other diseases, vaccines must be administered well before exposure to the pathogen or toxin (about 2 weeks in advance). When symptoms appear in a population, therefore, it will be too late to utilize most vaccines. The anthrax vaccine currently used in the United States for military personnel is effective against aerosolized

Table V-1: Vaccines Available in the United States against Major BW Threats

BW Agent Threat	*Disease Incubation Period*	*Vaccine Status (United States, as of 2002)*
Anthrax (*Bacillus anthracis*)	1–5 days	FDA-approved vaccine (U.S.)
Tularemia (*Francisella tularensis*)	2–10 days	Investigational New Drug (IND)
Plague (*Yersinia pestis*)	2–3 days	Not available in United States
Brucellosis (*Brucella* sp.)	5–60 days	None for human use
Q-fever (*Coxiella burnetii*)	10–40 days	Investigational New Drug (IND)
Smallpox	7–17 days	Wyeth (approved); other is IND
Hemorrhagic fevers (viral)	4–21 days	Investigational New Drug (IND)
Venezuelan equine encephalitis (VEE)	2–4 days	Available for certain serotypes
Botulinum toxin	1–5 days	Toxoid (pentavalent)
Staphylococcal enterotoxin B	1–6 hours	None available
Ricin (toxin)	3–24 hours	None available

Bacillus anthracis bacteria. Because anthrax tops the list of BW agent threats, the U.S. government decided to make it mandatory for active duty members of the U.S. military.

History of Vaccines and Warfare

The development of vaccines throughout modern history has often coincided with military operations. Although the recent threat of bioterrorism has triggered enormous research and development efforts in the United States to produce vaccines, immunization programs have for the most part emerged to counter naturally occurring disease threats in various parts of the globe.

Perhaps the first recorded use of preventative medicine in a military context occurred in the beginning of the Qing dynasty in China (ca. 1700 C.E.), when the emperor's armies faced smallpox from northern invaders. To accomplish this, variolation—the use of the smallpox virus—was introduced into military conscription. The practice of variolation that was later routinized in the Qing dynasty was basically a form of vaccination against smallpox. Variolation is said to have been used in Africa in ancient times, and it may have been practiced by Buddhist monks at the Mount E' Mei Temple in the Sichuan province of China sometime during the Renzong dynasty (1022–1063). These monks were said to have originally learned the procedure from the Tibetans, who in turn had been taught by Indians. By the 1500s, variolation was often mentioned in Chinese medical texts.

The Chinese method consisted of scraping the dried smallpox pustules from those who had become ill with the disease, pulverizing the crusts into a powder, and blowing the infectious material into the nasal passages of the noninfected. In Europe (as in Turkey), the process was one of scarification, that is, scratching the skin on the arm and applying the pulverized smallpox tissue. As one might expect, either route of inoculation was dangerous, for there was little guarantee that full-blown smallpox would not result. But in most cases, variolation caused a mild form of the disease but nothing more, affording protection from future exposures to the smallpox virus. Widespread use of variolation in China was not popular, by all accounts, and until the seventeenth century, the emperor's family did not see much need for it.

Seventeen years after the Manchurians conquered China, however, the Emperor Fulin (also referred to as Shizu) died from smallpox in 1661. In that same year, breaking tradition with previous Chinese defense policy, his brother, now the Kangxi emperor, decreed that his military carry out variolation for all troops. If true, this predates by more than 100 years General George Washington's order that Continental army soldiers undergo a similar procedure.

The British army had also adopted the practice of variolation in the early 1700s. Because many American colonists had themselves previously served in the British army, knowledge of the technique was widespread by the time of the American Revolution. A former British soldier himself, George Washington had more than a passing knowledge of smallpox, having survived the disease as a young man during a brief stay in Barbados. Around the time of the Revolution, smallpox was quite common in America, and smallpox was a constant problem for Continental army troops. General Washington had spent considerable time and effort emphasizing the importance of hygiene for his own army. In April 1775, he received intelligence that the British were making an attempt to use smallpox against the rebellion, and he concluded: "[T]he information that I received that the enemy intended Spreading the Small pox amongst us, I could not Suppose them Capable of—I now must give Some Credit to it, as it has made its appearance on Severall of those who Last Came out of Boston" [sic] (Bayne-Jones, p. 52).

In April 1776, Dr. John Morgan, who was physician in chief to the Continental army, urged that widespread variolation be conducted for the troops, and in 1777, Washington made it official:

> I have directed the Doctr. [Nathaniel] Bond, to prepare immediately for the inoculating this Quarter, keeping the matter as secret as possible, and request, that you will without delay inoculate all the Continental Troops that are in Philadelphia and those that shall come in, as fast as they arrive. . . . I would fain hope that they will soon be fit for duty, and that in a short space of time we shall have an Army not subject to this, the greatest of all calamities that can befall it, when taken in the natural way. (Bayne-Jones, p. 52)

Records from the routine variolation of Continental army soldiers showed that mortality due to the in-

Table V-2: Chronology of Selected Immunization Initiatives for Military Personnel

Country/Region	*Vaccine*	*Threat Mode(s)*
1661, China, Qing Dynasty	Variolation (smallpox)	Naturally occurring
1777, United States, American Revolutionary War	Variolation (smallpox)	Naturally occurring/possible BW sabotage
1899, Great Britain, Boer War in South Africa	Typhoid (Almroth Wright)	Naturally occurring
1938, Great Britain, World War II	Tetanus toxoid	Naturally occurring (war injuries)
Germany, World War II, Afrika Korps	Cholera, typhus	Naturally occurring
1942 (January), United States, World War II	Yellow fever	Biological warfare
1942–1943, Germany, Stalingrad front	Plague	Biological warfare (?)
1942, Soviet Union, Stalingrad front	Tularemia	Naturally occurring/biological warfare (?)
1943, United States, World War II	Influenza (type B)	Naturally occurring
1944, United States and Canada, World War II	Botulinum toxoid	Biological warfare
1945, United States, World War II (Army Air Force Technical School, experimental)	Pneumococcal (quadrivalent)	Naturally occurring
1945, United States, World War II (Okinawa)	Japanese B encephalitis vaccine	Naturally occurring
c. 1965–1975, United States, Vietnam War	Plague	Naturally occurring
1971–1999, United States, military recruits (to be resumed c. 2008)	Adenovirus (live type 4 and 7 vaccine)	Naturally occurring
1984, Soviet Union, resumption of vaccinating troops against smallpox following 5-year hiatus	Smallpox	Biological warfare
Until 1989, United States, part of routine military vaccinations; resumed 2002	Smallpox (*Vaccinia*)	Biological warfare
1991, United States, Gulf War	Anthrax	Biological warfare
1991, United Kingdom, Gulf War	Anthrax (U.K. version)	Biological warfare
1991, United States, Gulf War	Botulinum toxoid	Biological warfare
1997–present, United States	Anthrax	Biological warfare
1991–present, Israel	Smallpox (*Vaccinia*)	
2002–present, United States	Smallpox (*Vaccinia*)	Biological warfare

oculation procedure itself was approximately one in 300, compared to at least 16 percent for naturally acquired smallpox. Losses due to this disease dropped dramatically for the Continental army thereafter, no doubt influencing the outcome of the Revolutionary War.

Botulinum and D-Day

By World War II, incomplete but compelling intelligence indicated that the Axis powers were developing biological weapons. It turned out much later that the Allies underestimated Japanese biological weapons programs and that their threat perception of German BW was overblown. Still, by 1943, the United States, Great Britain, and Canada had instituted both defensive and offensive BW programs, starting with the development of vaccines.

By the time of the massive invasion of Normandy (D-Day) in 1944, the United States, Great Britain, and Canada had already considered the possible threat from German biological weapons. A year before D-Day, the American and Canadian intelligence services had reason to believe that Germany would use botulinum toxin against the Allies, possibly loaded on V-2 rockets to strike disembarking positions or used in some other fashion against the beach landing forces. Relying primarily upon the information provided by a German refugee scientist, Helmuth Simons, both Canada and the United States prepared large amounts of botulinum toxoid as a vaccine for the landing troops. Canada produced at least 25,000 doses of the toxoid, and the United States made enough (more than 1 million units) to inoculate at least 300,000 American troops if necessary. The latter was a formalin-denatured, alum-precipitated (the toxin was made non-toxic with formaldehyde solution, then brought out into extractable form) toxoid for type A botulism. (Botulinum type B toxoids were also under production, but these never made it to Europe.)

During the Normandy landing, however, none of these vaccines were used. Historical research by John Bryden and others showed that the higher echelon of Allied commanders was by that time reasonably secure in the knowledge that the German military had no immediate plans to use chemical or biological weapons. Because the British Ultra code decrypts were so strictly classified, however, security demanded that only the most highly ranked of the Allied leaders had a "need to know" this information. The scientists and their managers who were responsible for production of botulinum toxoid, therefore, were left unaware of this intelligence and continued their work until nearly war's end.

During Operations Desert Shield and Desert Storm during the Gulf War (1990–1991), 150,000 U.S. military personnel were given the anthrax vaccine. Due to limited quantities on hand, however, fewer of these (about 8,000) were able to receive a botulinum toxoid preparation. This pentavalent (protecting against five types of botulinum toxin) vaccine was prepared from *Clostridium botulinum* cultures (serotypes A through E) and had been previously used for hundreds of U.S. Army researchers since the 1950s. Although it was not entirely certain whether this would be effective against exposure to aerosolized botulinum toxin, a week into the air campaign against Iraq, the U.S. Food and Drug Administration (FDA) finally approved the safety of the botulinum toxoid for American troops.

During the Gulf War, the insufficient number of doses to inoculate everyone against anthrax and botulinum presented a moral dilemma for U.S. and Coalition military commanders: With a limited supply of both botulinum toxoid and anthrax vaccines, who should receive them? Some commanders clearly regretted that only partial vaccinations were performed and would rather have had the risk equally parceled out among all (i.e., they would rather have vaccinated no one than only some). It was finally decided, however, that some was better than none, and those troops and personnel stationed in areas more likely to be under a BW threat were given priority for inoculation. There is no evidence, however, that Saddam Hussein's military used biological weapons against Coalition forces.

At present, the U.S. military only vaccinates its personnel against two possible BW agents: *Bacillus anthracis* (anthrax) and smallpox. The justification for this ongoing immunization program is that foreign militaries and terrorist organizations such as al-Qaeda could weaponize these agents. Smallpox, although much less likely of a threat, would present such horrible consequences as a contagion that the U.S. government has decided to vaccinate active duty military personnel and civilian first responders.

It is difficult enough for militaries to conduct vaccination programs for soldiers against biological weapons. Governments face even greater challenges when it comes to vaccinating civilians against BW threat agents. Before measures are undertaken to immunize a population against a particular BW threat, one must balance the risks versus the benefits. In making a decision to vaccinate the general public against possible BW threats, one must know the relative safety of the vaccine and compare that to the projected risk from bioterrorism. Scientific studies can afford details as to the likely number of people who will suffer bad side effects from vaccines. However, we cannot predict with any accuracy the actual threat from BW agents. As a consequence, there is no current plan to vaccinate U.S. citizens in general against smallpox, anthrax, or any other BW threat.

V-AGENTS

The name *V-agents* is a shortened form of "venomous" agents. The category includes those organophosphate (OP) compounds that share similar structural and toxic properties to those of the G-nerve agents but possess even higher toxicity. Included in this category are VX, the former Soviet "V-gas," and other relatively obscure analogs VG (Amiton), VM, VE, and VS. Only VX and the Soviet version of VX, however, have been weaponized.

The toxicity of VX via inhalation is three times that of sarin, and VX is 100–400 times as toxic as sarin when absorbed through the skin. Pure VX has no color, is odorless, and at room temperature is a free-flowing oily liquid. It has a boiling point of 298° C and a freezing point of minus 39° C. In cases of skin exposure, symptoms can appear 5–7 minutes following skin absorption.

As with other nerve agents, the toxic principle of the V-agents is the inhibition of the enzyme acetylcholinesterase (AChE), the key to normal nerve impulse transmission at the molecular level. The resulting increased levels of the neurotransmitter acetylcholine produce exaggerated levels of bodily secretions and muscular twitching, as well as pronounced effects on the cardiovascular and central nervous systems. Death from respiratory paralysis can occur as a consequence. Victims also are prone to asphyxiation due to excess mucous and salivary excretions from the upper respiratory tree. Without timely medical intervention and follow-up treatment, those who do survive exposure to large doses of nerve agents can suffer permanent neurological damage. This may be even more true in the case of the V-agents, as these are fat-soluble compounds and quite capable of passing through the fatty membrane that composes the blood-brain barrier.

Background

The German chemist Gerhard Schräder and his team first discovered the highly toxic OP compounds tabun and sarin in the late 1930s. Other formulas that had commercial applications as insecticides (particularly those that were safe to use near mammals) were patented at the end of World War II. Some of these were also developed for large-scale insecticide use, marketed under the names Dimefox (1940) and Parathion (1944).

Like the G-series nerve agents, the V-series of compounds was also discovered during insecticide research involving OP compounds. In a roundabout way, the discovery of VX—the most potent military nerve agent ever developed—had its start in the Korean War. In early 1951, U.S. Army hygienists noted strong resistance in lice to DDT when delousing North Korean prisoners and refugees. When DDT and other organochlorine-based insecticides began to lose their effectiveness, chemical firms such as Bayer and Imperial Chemical Industries sensed that the market was especially ripe for new and better replacements, including OP-based chemicals.

In 1952, Dr. Ranajit Ghosh of the British company Imperial Chemical Industries patented some novel OP compounds that would later form the basic structure for VX. (Reportedly, in his independent work, Lars-Erik Tammelin of the Swedish Institute of Defense Research also discovered this type of compound in 1952). Although Ghosh's goal was to develop safe and effective insecticides, one of his new inventions was found to be quite toxic to mammals as well. These toxic chemicals had no apparent commercial value, but it was thought that they possibly could be of interest to the military.

Noting its military significance for development as a nerve agent, the formula and sample of Ghosh's toxic OP compound were handed over to the defense laboratories of Porton Down in the United Kingdom. But during the 1950s, the British military had already decided to adopt one of the G-series nerve agents for use and was in the process of building a chemical arsenal consisting of either tabun (GA) or sarin (GB). The British government gave Ghosh's basic formula to the United States in 1953, and in 1955, Ghosh's chemicals were coded V agents due to their "venomous" nature.

After some structural changes to Ghosh's molecule were made at the U.S. Edgewood Arsenal laboratories, one analog was coded VX and standardized in the U.S. military in December 1957. In a U.S. Chemical Corps annual report, it was subsequently noted that "the reign of mustard gas, which has been called the King of Battle gases since it was first used in July 1917, will probably come to an end" (Smart, p. 49). This opinion was based on the fact that VX is a highly potent nerve agent that can act through the skin as well as by inhalation.

In 1960, a facility formerly known as the Dana Heavy Water Plant in Newport, Indiana, was converted to produce VX for the U.S. chemical weapons arsenal. Production of VX in the United States continued through the 1960s. In 1968, while training with a VX aerial munition near Dugway Proving Grounds, Utah, a U.S. military aircraft accidentally released about 20 pounds of VX in an open field. There were no human casualties, but at least 3,000 sheep died in this incident. After another accident in Okinawa involving nerve agent (sarin), on July 22, 1969, the U.S. Department of Defense formerly announced the accelerated removal of these agents from the Pacific theater.

Finally, in November 1969, President Nixon ended production of chemical warfare (CW) agents, following an earlier decision to renounce offensive biological warfare. In 2003, more than 1,200 tons of VX nerve agent remained stored at the Newport Chemical Activity in canisters. After numerous delays, destruction of VX nerve agent was scheduled to begin in late 2003 using a neutralization process involving sodium hydroxide. Political, environmental, and technical issues have delayed the destruction timetable into 2004.

VG (also known by its trade name, Amiton) is an odorless, oily liquid with a similar viscosity to that of motor oil. It is relatively persistent. Like other oils, VG is soluble in fat, and skin absorption of the liquid presents a significant hazard. VG is not as toxic as VX, but its high toxicological profile—and suitability for weaponization—forced its inclusion as a Schedule 2 toxic chemical in the Chemical Weapons Convention (CWC). It is described in the chemical literature as either being colorless or having a yellowish color (perhaps due to impurities), as well as being a low-viscosity liquid with moderate volatility, evaporating only in small amounts at room temperature.

VECTOR

In the context of infectious disease, a vector is an arthropodic agent that transmits bacterial, viral, parasitic, and, in some cases, fungal diseases to humans, animals, or plants. Lice, fleas, and mosquitoes have been the vectors most responsible for the spread of diseases such as typhus (*Rickettsia prowazekii*), bubonic plague (*Yersinia pestis*), and malaria (*Plasmodium falciparum*), respectively. In modern times, the controlling of vectors—chiefly through the efficient use of insecticides, draining of standing water, and other hygienic practices—has led to dramatic improvements in public health.

The spread of bubonic plague, a disease that reduced European populations by as much as one-third in the fourteenth century, begins with a reservoir of infectious bacteria carried in rodents. When a flea consumes a blood meal from a plague-infected rat, it has a good chance of consuming *Y. pestis* bacteria. This can lead to the formation of a fibrinous (solidified material that forms in response to inflammation) plug in the upper region of the flea's stomach (proventriculus), preventing the flea from being able to digest additional blood meals. Now starving, the flea may bite a number of different mammals in an effort to feed, including humans. When the fleas bite humans or any other mammals, they disgorge the infectious material into the wound, which can lead to the development of bubonic plague. The flea in this cycle typifies the role of the vector, and the rat is the epizootic pool of a pathogen (*Y. pestis* bacteria).

Such vectors were utilized in the Japanese biological weapons program conducted in China (1937–1943). The notorious Unit 731, led by Ishii Shiro, grew fleas in the laboratory and allowed them to feed upon plague-infected rats. Later, the fleas were collected and placed into specially designed porcelain bombs (the porcelain shell was broken when the bomb was thrown, releasing plague-infested fleas into the area). Some reports indicated that plague spread quickly following Japanese attacks using these bombs and following other attacks using plague bacteria. Plague, however, had already been endemic in China since 1894, so it is difficult to assess the effectiveness of these Japanese biological warfare operations. During wartime, it is also typical to expect large natural outbreaks of disease, making it more difficult to estimate with certainty the effectiveness of this flea-based biological weapon.

Conceivably, other diseases such as viral encephalitis (e.g., Venezuelan equine encephalitis and West Nile virus) could be spread by infecting animal hosts, harvesting mosquitoes that carry the virus, and releasing these insects upon densely populated areas. From the bioweaponeer's perspective, however, it is unclear how many infections among targeted populations would result, to what degree infections could be sustained, and whether or not the whole exercise would be worth the expenditure of time and resources. Furthermore, there is an arsenal of weapons that can be deployed against arthropods to quickly neutralize the threat of spreading the infection. Although environmental regulations generally restrict the wider use of insecticides, in event of an emergency—such as a large spike of West Nile infections in New York City—there is little doubt that local authorities would be able to saturate suspect areas with insecticides such as malathion. With such a response, the major threat from the disease would be largely mitigated. In a military setting, the use of insect repellents (particularly diethyl toluamide or DEET) and insect control with insecticides can likewise prevent the spread of vector-borne disease, whether these are natural or deliberately caused.

VECTOR: STATE RESEARCH CENTER OF VIROLOGY AND BIOTECHNOLOGY

During the Soviet era, the State Research Center of Virology and Biotechnology (VECTOR) played a crucial role in the research and development of biological weapons. Although precise details are not known, it is likely that VECTOR participated in the experimental study of most, if not all, antihuman viral BW agents researched and developed for biological weapons, including highly infectious and virulent pathogens such as Marburg hemorrhagic fever. VECTOR also tested antiagricultural agents under the program code-named Ekologiya ("Ecology").

At its height of activity in the late 1980s, VECTOR had a staff of more than 4,500. Following the fall of the Soviet Union (and with it, the end of the Soviet offensive biological warfare program), the total number of workers at VECTOR in January 2003 stood at 1,147, most of these being researchers. Today, the State Research Center of Virology and Biotechnology is one of Russia's largest research and production facilities. It carries out basic and applied research in the natural sciences, and it develops and produces therapeutic, preventive, and diagnostic products.

Background

VECTOR had its origins in the 1974 establishment of the All-Union Research Institute of Molecular Biology (Order No. 1683 of the Central Administrative Board of the Microbiological Industry with the Council of Ministers, August 2, 1974). The main purpose of VECTOR was to provide scientific base technology and infrastructure to study pathogenic viruses, while exploiting advanced gene-based techniques to produce vaccines and clinical diagnostics. Officially, VECTOR was created following a decree by the Soviet BW organization Glavmikrobioprom in March 1985, but its essential elements as a research facility for studying dangerous pathogens had been built by 1980.

VECTOR still houses a number of smaller institutes in its unique facility. VECTOR can undertake advanced research on extremely dangerous pathogens and has one of the few biosafety level 4 laboratories in the world. Another important aspect of the facilities at VECTOR is the ability to breed and care for experimental animals, including primates, for laboratory research.

*VECTOR's Smallpox Virus (*Variola Major*) Collection*

Located in Koltsovo (outside Novosibirsk, Siberia), VECTOR is a massive complex consisting of some

100 buildings, occupying more than 200,000 square meters of working space. In addition to a large pathogenic microbe strain library housing more than 15,000 viruses (including Ebola and Marburg hemorrhagic fevers), VECTOR is one of two facilities that possesses smallpox virus (the other is in the United States at the Centers for Disease Control and Prevention, Atlanta, Georgia). Smallpox (*Variola major*) viruses had been collected in the former Soviet Union and stored since the 1950s at the Mechnikov Research Institute of Vaccines and Sera in Moscow. Later, about 120 strains were moved to VECTOR, where they are currently stored. Most are frozen, but twenty-four strains are kept in freeze-dried (lyophilized) storage. Today, VECTOR consists of the following research organizations:

- Scientific Research Institute of Molecular Biology
- Scientific Research Institute of Aerobiology
- Scientific Research Institute of Bio-Engineering
- Scientific Research Institute of Cell Cultures
- Scientific Research Institute of Microorganism Culture Collections
- Scientific Research, Design, and Technological Institute of Biologically Active Substances
- Vector-Farm Production and Marketing Firm
- Experimental Production Agricultural Enterprise

Among the many research projects that have been conducted at VECTOR is the complete genetic sequencing of *Variola major* (India strain) smallpox virus. Due to concerns about the security of one of the world's only two official repositories of the smallpox virus, the United States government conducted cooperative programs during the late 1990s to help secure VECTOR's collection from potential theft by terrorists, rogue states, or even insiders. Much of the funding for those efforts, including financing of peaceful research to keep former Soviet BW scientists gainfully employed, has come from the U.S. Cooperative Threat Reduction BioSafety Program.

After the fall of the Soviet Union, the full extent of the Soviet BW program became better known to the West, especially following the revelations of defectors Vladimir Pasechnik and Ken Alibek (Kanatjan Alibekov). With no more funds from the Soviet military to maintain buildings or pay scientists their living wages, the proliferation threat from former Soviet BW scientists selling their knowledge to foreign governments became an acute concern for security planners in the United States and other Western governments. Stemming a so-called brain drain became a new priority among nonproliferation activities. A number of funding programs, including those from the U.S. Congressional Defense Against Weapons of Mass Destruction Act of 1996 (PL 104-201, September 23, 1996; also known as the Nunn-Lugar-Domenici Act), also addressed the BW problem in former Soviet BW institutes.

With funding provided from the International Scientific Technical Center (ISTC) in Moscow, as well as from a number of other technical partnerships with U.S. and other foreign-based governments and biotech firms, VECTOR continues to engage in a variety of research projects in infectious disease and molecular biology. VECTOR has sequenced the complete genomes of, among other viruses, the causative agent of Venezuelan equine encephalitis, tick-borne encephalitis, and Marburg and Ebola viruses. Since 1995, VECTOR has engaged many other important studies, including the following:

- Organization of production of inactivated vaccine against hepatitis A
- Development of the live cultural influenza vaccine
- Development of the production technology for immunoenzyme diagnostic kit (using enzymes for clinical tests) for the parasite toxoplasmosis using purified proteins of *Toxoplasma gondii*
- Solving the problem of Y2K to provide reliable control of the main biosafety engineering system in the VECTOR building
- Study of the genomic structure of Crimean-Congo hemorrhagic fever virus isolates (specific types found) circulating in the southern regions of NIS (Newly Independent States) countries
- Study of the genetic and antigenic (genetic makeup and immunology) diversity of

hantaviruses (caused by Bunyaviridae type viruses) in the Asian part of Russia
- Study of monkey pox virus genome
- Development of the microencapsulated form of the live measles vaccine

Additionally, VECTOR has partnered with the U.S. Defense Advanced Research Project Agency to conduct the following research projects:

- Experimental evaluation of the efficiency of inactivating and protective preparations against viruses pathogenic for humans
- Study of the possibility of intranasal immunization against tick-borne encephalitis by recombinant (the use of genetic engineering) viral gene vaccines
- Development of new therapeutic preparation based on the orthopoxviral (smallpox type) protein binding human tumor necrosis factor (TNF, disease protein marker)
- Elaboration of the methods of predicting humans' susceptibility to and efficacy of protective preparations under the conditions of viral aerogenic (caused by inhalation) infection

VECTOR has also participated in studying other pathogens, including the parasite *Toxoplasma gondii* (the causative agent of toxoplasmosis), which can cause devastating infections in humans, especially in the prenatal stages and in those individuals with compromised immune systems.

VESICANTS

Vesicants (or blister agents) are chemicals that attack the skin. True vesicants such as mustard and lewisite cause extreme irritation of the skin, eyes, and, most critically, the upper respiratory tract. The cell-killing ability of these compounds results in the formation of blisters that start as small vesicles (thus the name) on the skin. Vesicants used as CW agents generally take the form of an oily liquid, with varying degrees of volatility (propensity to evaporate).

Mustard has true cell-killing ability, and damages genetic material in cells by cross-linking DNA. Thus, long-term exposure will increase the chance for cancerous growths, although single exposures (even large doses) are not expected to significantly increase the risk of cancer. The greatest danger from extensive mustard exposure is inhalation of vapors. Due to mustard's ability to kill tissue, dead layers of cells lining the airways flake off, forming a false membrane. These cells can fall into the smaller airway tubes, blocking the egress and ingress of air, causing collapse of the lungs.

Sulfur mustard has been used in conflicts since its entry on the battlefield in World War I and was used extensively by Iraq against Iranian forces during the 1980–1988 Gulf War. In contrast, nitrogen mustards and lewisite have rarely been used in combat. Sulfur mustard (and probably nitrogen mustard) affect tissues in a typical delayed fashion, creating painful irritation to exposed surfaces (especially the eyes) after some delay (one to two hours or more). Lewisite is immediately irritating to the ear, nose, and throat, with painful irritation of the skin also occurring much faster (about 15 minutes following contact).

The chemical warfare (CW) agent phosgene oxime (not to be confused with the World War I-era gas phosgene) is usually included in discussions concerning vesicants. Phosgene oxime, however, acts in a different manner on the skin and is immediately painful. In contrast to other vesicants, phosgene oxime is a solid in its pure state and could be delivered as a pulverized dust or in an aerosol. Phosgene oxime could also be delivered as a liquid in its impure state or in a solvent. The action of phosgene oxime has been compared to the type of stinging injury caused by the nettle, thus it is sometimes called nettle gas. There are actually a number of different oximes that could be utilized as CW agents; all are extremely irritating not only to the skin, but also to the respiratory tract.

During the first 2 years of World War I, the arsenal of CW agents available to the belligerents primarily consisted of volatile substances, that is, true "gas warfare." The use of toxic compounds that evaporated quickly—chlorine, phosgene, and diphosgene, for example—helped to create effective concentrations of toxic chemicals. Because these were vapors and gases, the only route for intoxication was via inhalation. In the latter stages of the war, however, both sides developed effective means to protect troops' respiratory systems from chemical injury by using protective masks. In response, the German military put great effort into the production of diphenylcyanoarsine (DC), a so-called arsenical that was irritating in very small concentrations. One of the strategies for using this substance was to render gas masks ineffective by delivering DC in a fine aerosol, producing very small particles that would penetrate the filters used in protective masks at the time. This would force the removal of the mask, thereby making the enemy vulnerable to further assault with other toxic agents. It proved difficult, however, to deliver these sternutators, or "sneeze" gases, in particles small enough to achieve this effect.

Mustards

Because enemy defensive masks could not be defeated with arsenical compounds in World War I, the German military command investigated other alternatives. Mustard proved to be the answer. Sulfur mustard had been known since the 1880s as a very toxic compound to exposed skin surfaces.

Although often described as a gas, sulfur mustard (code-named H, or HD for distilled mustard, in the North Atlantic Treaty Organization terminology) is in fact an oily liquid. Sulfur mustard can cause injury through vapors, inhalation of aerosols, contact with contaminated surfaces, or a combination of all of these. Mustard is fat soluble and able to penetrate clothing (including some forms of rubber), making full-body protection necessary. The toxicological effects of mustard are insidious, causing blisters on the skin, temporary blindness (sometimes with permanent loss of vision), and life-threatening damage to the upper airways. Such symptoms occur within hours of exposure. Not only the liquid itself, but also the vapors from the liquid present a hazard. For example, after 1 hour, redness and inflammation of the skin would follow exposure to as little as 0.001 milligram of mustard per liter of air.

Mustard is particularly insidious because the effects are delayed by at least 1–2 hours. Thus, victims of mustard exposure could receive lethal doses of mustard and not realize it until it was too late to seek treatment. Vesicants, including mustard, have a particular affinity for thin layers of skin, including those under the arms and in the groin. Following such injury, mobility of soldiers is significantly reduced, and function is further degraded by severe pain from eye irritation. Although most victims fully recover from such injuries, blindness can occur in cases of large doses, and infections can set in following blister formation. At present, there is no effective treatment for mustard exposure. Decontamination of affected areas and supportive care are the only options at present.

Mustard freezes at a relatively high temperature. Therefore, at temperatures near its freezing point, it requires some solvent to keep it liquid. During World War II, Allied researchers investigated the mixture of mustard with diisopropyl fluorophosphate (DFP). This concoction not only lowered the freezing temperature of mustard, but also added a nerve agent component to the mix.

Since it was first used in World War I, and particularly during the Iran-Iraq War (1980–1988), mustard has proven mostly to be a defensive weapon. In both conflicts mentioned above, mustard was intended to help prevent military units from being overrun by enemy forces. For example, in 1917, Germany's main concern was to protect against a final offensive push by Allied forces, and Iraqi forces were being harried by sheer numbers of fanatical Iranian volunteers who feared neither bullets nor land mines. Before the invention of the nerve agents, mustard was considered king of the CW agents due to its ability to cause many casualties, especially via secondary contamination of ground, equipment, off-gassing from clothes and shoes, etc.

Even today, mustard remains one of the top CW threat agents, not just because of its versatility as a weapon, but because it is relatively inexpensive and easy to make. It is therefore not surprising that Iraq made extensive use of mustard against both Iranian forces and Kurdish elements during the Iran-Iraq War. Although Western countries (led by the United States) cut off exports of mustard precursors to Iraq and Iran in 1984, Iraq was able, by adapting its own petroleum distillation capabilities, to produce sulfur mustard indigenously.

Nitrogen mustards were under development by about 1935. The different series of nitrogen mustards were code-named in the U.S. military as HN-1, HN-2, HN-3, and HN-4, but these did not find favor in the United States as a weapon. Germany, however, stockpiled significant quantities (2,000 tons) during World War II. Nitrogen mustards affect the skin and membranes of the eyes, nose, and respiratory tree in similar ways to sulfur mustard. Traditionally, nitrogen mustards have been described as having a fishy odor. Although nitrogen mustard has been little used in warfare, it was previously one of the most effective chemotherapeutic agents discovered for treating cancer. Now, however, nitrogen mustard (Mustargen) has been largely replaced by less toxic and more effective alternatives.

Lewisite

Another vesicant that has not seen much use in battle, aside from some unconfirmed use by the Japanese against China during World War II, is lewisite (L). An arsenical, lewisite was invented in 1917 by the American chemist Winford Lee Lewis, from whom it received its name. At the same time, a German chemist (Heinrich Wieland) also researched this chemical, but for reasons still uncertain rejected it for further development as a weapon. Lewisite was stockpiled by Germany, the Soviet Union, and the United States during World War II. Some of the larger stocks of mustard-lewisite mixtures include those in the former Soviet chemical stockpile. (Abandoned chemical weapons in China left over from invading Japanese forces in World War II also contained mustard-lewisite mixtures.)

Lewisite offered advantages over other vesicants: it could be used in much colder temperatures than mustard and still remain liquid. Unlike mustard, the effects from lewisite are not as delayed; lewisite forms highly irritating vapors almost immediately. Redness and blistering of the skin follow, similar to the effects of mustard. Lewisite reportedly has an odor resembling that of geraniums. Lewisite has traditionally had an antidote in the form of British Anti-Lewisite (BAL), a mercaptan (sulfur containing chemical that can attach to heavy metals) compound used to scavenge for arsenic. Still, it is unclear whether this or other treatments are very effective.

Vesicants could be delivered in the standard artillery shells designed for chemical ordnance, or from cannons, artillery rockets, and larger rocket warheads. Although vesicants can be effective in any form of assault, their primary advantages (as described in Soviet military doctrine) have been in terms of denying enemy access to particular areas and contaminating logistical targets, causing the enemy to have to move around contaminated areas or suffer casualties. Contamination would also require time-consuming decontaminating efforts to remediate airfields, railway centers, and port facilities.

Technical Details

The production of sulfur mustard (and, to a lesser degree, nitrogen mustards), lewisite, and phosgene oxime is rather simple, but overall their toxicities are much less than those of the nerve agents. Today, militaries—if they desired to obtain an offensive CW capability—might choose mustard and lewisite because they are persistent (remain hazardous in the environment for a long time) and highly effective casualty agents. Terrorists, on the other hand, would probably find these agents less appealing because they are hardly the most toxic, and because they pose significant challenges to produce in large quantities. Some countries that have great difficulty in producing even basic chemicals, such as North Korea, may look to vesicants to maintain a nominal CW capability. Developing countries such as China and India, on the other hand, have the ability to produce most, if not all, known CW agents, including the much more toxic nerve agents such as sarin and VX.

The vesicants are prohibited by the 1993 Chemical Weapons Convention (CWC). Their precursors, such as thiodiglycol (for mustard) and arsenic trichloride (for lewisite), are also controlled under the CWC schedules.

VIETNAM WAR

The term *Vietnam War* is often used to refer to U.S. military and diplomatic involvement in a series of wars fought in French Indochina from 1946–1975. Chemical agents were used in these conflicts, and the use of nuclear weapons always loomed on the horizon.

Historical Background

Starting in 1847, the land that is modern-day Vietnam was colonized by France. From 1940 to 1945, Japan added Indochina to its so-called coprosperity sphere. After Japan's surrender from World War II in August 1945, Vietnamese nationalists, led by Ho Chi Minh, launched the "August Revolution," proclaiming an independent state. France reasserted its claim to Indochina and by the end of 1945 had defeated Ho's Viet Minh forces in the southern provinces. In November 1946, the French governor general proclaimed an independent Republic of Cochin China in the south, leading to the First Indochina War, which lasted until French forces pulled out of the region in July 1954 following their defeat at Dien Bien Phu. The resulting Geneva Accords divided Vietnam at the seventeenth parallel, with national elections slated for 1956 to determine the government of a unified state including the north and south. This was not to be, as many fled the north to the south, and the latter part of the country proved resistant to the idea of Ho Chi Minh controlling all of Vietnam.

Fearing the likely rise of a communist government in the area, U.S. president Dwight Eisenhower began open support for the newly created government (1955) of the Republic of Vietnam in the south, led by Ngo Dinh Diem, a staunch anticommunist. A guerrilla-style war between the American-supported South Vietnam gradually became more intense as it could not reconcile with the northern communist regime. U.S. involvement in the conflict was gradual at first, with soldiers relegated to advisory roles until August 4, 1964, when the Gulf of Tonkin incident expedited heightened U.S. military involvement. In this instance, the United States claimed North Vietnamese torpedo boats attacked the U.S. Destroyer *Maddox*. President Lyndon Johnson ordered air strikes on North Vietnamese targets the same evening, and Congress supported this action with the Gulf of Tonkin Resolution. The wording if not the spirit of the resolution gave President Johnson more latitude to conduct offensive military operations in Vietnam, which then led to a dramatic escalation of U.S. military involvement in the war—including a massive bombing campaign against North Vietnam and the introduction of American combat forces on the ground. Despite a successful U.S. counterattack, the strong showing of the opposition in the 1968 Têt Offensive started the process of slow U.S. disengagement from the conflict.

A third phase of the war, this time involving just the Vietnamese, continued until Communist forces achieved victory in April 1975. In 1976, North and South Vietnam were officially reunited and became the Socialist Republic of Vietnam.

Chemical Weapons Use in Vietnam

The U.S. military used a chemical incendiary weapon called napalm during the war. U.S. forces also made extensive use of herbicides, most (in)famously Agent Orange, during Operation Ranch Hand from 1961 through 1970 to deny cover and concealment to the enemy and to damage food crops that were sustaining insurgent forces.

Napalm-B, used by the United States during this campaign, consisted of 50 percent polystyrene thickener, 25 percent benzene, and 25 percent gasoline. It was dropped from the air. Napalm was used on roughly 10 percent of all U.S. bomber missions during the conflict. This jellied gasoline mixture is virtually impossible to remove, and it kills those caught in the open by a combination of carbon monoxide asphyxiation and burning. After being ignited with phosphorus, napalmt burns at 850° centigrade for up to 15 minutes.

Nearly 19 million gallons of herbicide were used by the U.S. military in Vietnam between 1961 and 1970. Almost all of this herbicide was delivered using modified C-123 cargo aircraft. More localized application was accomplished using helicopters, towed vehicles, and backpacks. The optimal applica-

The U.S. Air Force used large quantities of Agent Orange and other herbicides during the Vietnam War. (Bettmann/Corbis)

tion rate was 3 gallons per acre. More than thirty herbicides were tested or used in Vietnam, six of which were given code names based on the colored bands on their 55-gallon storage drums. All were mixed with petroleum products to add stickiness for application. Agents Purple, Pink, and Green were used from 1962 to 1964 as defoliants. They contained significant levels of dioxin, which was later found to be highly toxic to humans.

Agent Orange was used extensively from 1965 through 1970. Although less potent than Purple, Pink, and Green, Agent Orange's widespread use made it the most notorious herbicide used in the conflict. A series of lawsuits by veterans of the war culminated in an out-of-court settlement in 1984 with the manufacturer of Agent Orange, Dow Chemical Company, which established a $180 million trust fund for individuals who claimed to have been sickened by exposure to the chemical. In 1992, the U.S. Centers for Disease Control and Department of Defense officially acknowledged Agent Orange's linkage to a wide variety of diseases, including Hodgkin's disease, Non-Hodgkin's lymphoma, and birth defects. However, the levels of dioxin required to cause disease in humans have not been well established.

Biological Programs during the War

The United States maintained a large biological weapons stockpile during the war but did not employ any of the weapons in combat. The U.S. stockpile included two lethal microbial agents (anthrax and tularemia bacteria); three incapacitating microbial agents (brucellosis bacteria, Q-fever rickettsiae, and Venezuelan equine encephalitis virus); one lethal toxin (botulinum); and one incapacitating toxin (staphylococcus enterotoxin B). Large volumes of these agents were manufactured and poured into cluster bomblets, spray tanks, and assorted other munitions, which were stored at Pine Bluff Arsenal in refrigerated bunkers and vans. President Nixon renounced the use of biological agents in a speech on November 25, 1969, and the U.S. stockpile was destroyed over the next 3 years, although research and development on defenses against biological attack continued.

Nuclear Considerations

Nuclear weapons were never used in the war, but the United States had a substantial nuclear arsenal. Although the use of these weapons was never imminent, there was support for limited nuclear strikes by some in the United States. Admiral Arthur Radford, chairman of the U.S. Joint Chiefs of Staff, and Air Force Chief of Staff Nathan Twining proposed using nuclear weapons to prevent the fall of Dien Bien Phu in 1954. The Eisenhower administration rejected this idea.

Later, during the U.S. phase of the war, retired General Curtis LeMay, who had commanded the U.S. Strategic Air Command, suggested that North Vietnam be bombed "back into the stone age." Senator Barry Goldwater, the Republican nominee for president in 1964, appeared on ABC's *Issues and Answers* program in May 1963 and stated, "defoliation of the forests by low-yield atomic weapons could well be done." Members of the Johnson administration were also concerned that Chinese intervention in the Vietnam War could prompt a large nuclear exchange in southeast Asia. At one point, the Nixon administration also escalated the nuclear alert levels of U.S. forces in a series of moves designed to make the Viet Cong and the Soviets believe that the United States was considering the nuclear option, hoping that this would give added leverage in negotiations to end the war.

VINCENNITE (HYDROGEN CYANIDE)

Vincennite is a French term for a cyanide-based weapon that was devised during World War I. It contained about 50 percent hydrogen cyanide (HCN), 30 percent arsenic (III) chloride, 15 percent tin (IV) chloride, and 5 percent trichloromethane, with HCN forming the "active ingredient" in this mixture. Throughout World War I, the other militaries had found HCN too difficult in terms of delivery as a weapon. Undaunted by the challenge, French military chemists devised a scheme using concoctions like vincennite and manguinite to work around the technically challenging issues posed by HCN when used alone—chiefly its high volatility and instability. Throughout World War I, the British military experimented with its own version of vincennite, but Germany did not pursue it beyond laboratory experiments. Despite the efforts by the French to weaponize HCN with various combinations of other chemicals, vincennite was ineffective as a war gas.

Background

By the end of 1915, the French military had filled significant numbers of "Special Shell 4" with HCN, but held back from using these due to the Hague Convention proscribing the offensive use of chemical artillery rounds. Under attack from German chemical shells in 1916, however, this consideration was made moot, and the French fired the first vincennite projectiles against German troops at Somme on July 1 that year. It is not known what, if any, casualties resulted from this chemical assault. The French might have used this as a means to break Germany's gas masks, which were thought to be effective only against chemicals such as phosgene. Having learned of French intentions to employ HCN a week prior to its introduction at Somme, however, Germany had prepared its troops with gas mask canisters augmented with silver oxide as a chemical barrier.

In addition to the extremely high volatility of HCN, the major technical hurdle involved in its use is its propensity to decompose in a violent polymerization (in a chain) reaction. Stannic chloride was used as a means to prevent HCN from evaporating too quickly. To stabilize HCN, chloroform was used to prevent it from polymerizing. Later, arsenic trichloride and other compounds were used in another concoction called manguinite, which was no more effective as a war gas than vincennite.

The failure of vincennite and other schemes to deliver this form of cyanide led most militaries to abandon HCN-based munitions, pursuing instead the development of cyanogen chloride. Intelligence gathered by Germany following World War II, however, indicated that the Soviet Union did not give up on HCN. According to Walter Hirsch, formerly with the German military intelligence apparatus, the Soviet Union began research into HCN weapons design in 1931, considering the chemical as "one of the most effective war gases for a surprise attack and destruction of living targets." The Soviets also employed stabilizers such as strong acids and metallic chlorides to create an effective HCN weapon. The disposition of these mixtures is not known, but it is presumed that they have long been discarded.

VX NERVE AGENT

See V-Agents

W

WETEYE BOMB

The Weteye chemical munition was a unitary nerve agent bomb used for sarin, formerly held in the U.S. chemical weapons stockpile. Coded the MK-116, the Weteye aerial bomb weighed approximately 240 kilograms and held about 160 kg of sarin nerve agent. Developed for the U.S. Navy in the 1960s, the Weteye was so named because the munition had a liquid nerve agent fill—hence the "wet"—and a camera-based guidance system—hence the eye.

Separated by perforated baffles, the inside was divided into three sections. The bomb itself was made of a thin aluminum alloy, with spring-loaded fins that would extend after the bomb's release from bomber aircraft. After the bomb was dropped, the fuse was armed. An explosive charge (composition B) would then break open the bomb's fuselage and spread sarin as an aerosol over the intended target.

In 1969, Weteye munitions were filled and stored at Rocky Mountain Arsenal, Colorado. The Weteye bombs were stored and shipped in MK 398 containers. All sarin bombs were neutralized at Rocky Mountain Arsenal in 1977, except for 900 Weteyes. These were then moved to the Deseret Chemical Depot in Utah, where they were destroyed pursuant to the U.S. ratification of the 1993 Chemical Weapons Convention. During the destruction process, some munitions were found to leak, and high levels of mercury were also discovered. Other factors—such as the potential for the aluminum casing to explode while inside the decontamination furnace—required special handling for this bomb's demilitarization. These factors made the final disposition of the Weteye bombs especially complicated for both political and technical reasons.

WORLD TRADE CENTER ATTACK (1993)

On February 26, 1993, a small group of men from the Middle East parked a rental van packed with 1,500 pounds of urea-nitrate explosive in the basement of the World Trade Center (WTC) in New York. There they detonated a bomb that killed 6 people and wounded 1,042. The destruction was not as great as the terrorists had hoped, or as others would later achieve against the same structure in September 2001, yet some reports suggested the involvement of chemical weapons in this attack. These accounts suggesting that chemical weapons were involved in the 1993 WTC attack are, however, most likely apocryphal.

Most members of the ad hoc group of perpetrators were inexperienced terrorists, at least in comparison to their mysterious and charismatic leader, Ramzi Yousef, who was linked with Islamic extremists (including Osama bin Laden) and the Iraqi government, though he likely belonged to neither group. Nonetheless, within 6 months, this small group succeeded in planning the attack, acquiring the necessary chemicals for the conventional explosive, and assembling a large, sophisticated explosive in a small apartment in Jersey City, NJ. Several of the conspirators were arrested shortly after the attack, but Yousef escaped to continue his terrorist career. He remained at large until he was captured on February 8, 1995.

Allegations that the WTC attack involved chemical weapons stem from comments made on May 24, 1994 by Judge Kevin Duffy during the sentencing of four of the perpetrators. Judge Duffy stated that the bombers had incorporated sodium cyanide into the bomb, intent on generating lethal levels of hydrogen cyanide gas to kill everyone in one of the towers. According to Duffy, the cyanide fortunately burned instead of vaporizing. Moreover, he asserted that many of the victims "had their lungs permanently scarred" by the burning cyanide. The judge's comments seem to be the source of subsequent reports of CW agents being used in the attack.

Although Yousef was an innovative and skilful bomb maker—he had a degree in electrical engineering and had received training in Afghan terrorist camps—it is unclear whether he had the technical capability to cause a large-scale release of hydrogen cyanide. However, his primary assistant in making the WTC bomb, Nidal Ayyad, was a chemical engineer, and together, they may have possessed the requisite skills to liberate hydrogen cyanide in an explosion.

Yousef, motivated by an intense hatred of the United States and Israel and driven by a need for self-aggrandizement, tried to kill as many people as possible by bringing down the WTC. He would have had no qualms about using CW to cause mass casualties. He certainly considered using chemical weapons in other attacks. In 1994 and 1995, Yousef had drafted letters threatening to use "chemicals and poison gas" unless authorities in the Philippines released a captured accomplice. He also reportedly contemplated attacking the Central Intelligence Agency with a chemical weapon-laden plane. Yousef admitted after his capture that he would have included sodium cyanide in the bomb, but claimed that he did not have enough money to do so.

The only physical evidence of chemical weapon use in the attack was a single, sealed bottle of aqueous sodium cyanide found with Yousef's fingerprints in a storage locker where the group stored its chemicals.

The heavily contaminated bomb site yielded no forensic traces indicating that the device had contained cyanide. A technical analysis of the amount of chemicals needed and conditions required to create hydrogen cyanide does not support Judge Duffy's conclusion, especially as the purchase of large quantities of sodium cyanide would likely have attracted attention, and as no significant cyanide repository connected to the group was ever found. The possibility of producing cyanide gas was, however, discussed during the 1994 trial, and this may have been the source of the judge's assertions about chemical weapons.

Although Yousef clearly had the motivation, and perhaps the technical capability, to cause the release of poison gas, his own admissions of financial limitations and a lack of forensic evidence make the presence of chemical weapons in the 1993 WTC bombing extremely unlikely.

WORLD WAR I

More than 8.5 million people were killed and more than 21 million were injured during World War I, which lasted for 4 years (1914–1918). World War I erupted at a time when advances in modern technology and logistics (such as railroads) created a synergistic effect, leading to mass human carnage. The use of a relatively new invention, the machine gun, and the ability to transport thousands of soldiers to the front contributed heavily to the deaths of millions in World War I. Although World War I is remembered for the advent of modern "gas warfare," bullets, bombs, and shells were responsible for most of the deaths during the war.

Before Germany resorted to using chlorine gas to break the Allied trenches in April 1915, fatalities on all sides had been averaging 150,000 dead every month. In only one day at the Somme (July 1, 1916), British casualties alone amounted to 57,470, and about 20,000 of these individuals died. Nearly all of these casualties were the result of conventional weapons. Although it is true that the use of gas in the Great War made an indelible mark upon postwar remembrances, the actual impact of chemical warfare (CW) was not very numerically significant. Throughout all of World War I, chemical weapons were the cause of less than 4 percent of the total casualties. Furthermore, the death rate from chemical injuries in World War I ran about 3 percent.

Much less is known about the role of biological warfare (BW) in World War I. The German agent

Most of these WWI British soldiers who were blinded by mustard eventually returned to active duty. (Bettmann/Corbis)

Anton Dilger might have managed to infect a number of pack animals that were to be used by the Allies by using cultured pathogens, but these unconventional attacks had no appreciable effect on the course of the war.

Gas Warfare

The first use of chemical weapons in World War I—Germany's chlorine cylinder attack on April 22, 1915 at Ypres, Belgium—caused at least 800 Allied deaths that day. It also required a massive effort for the Germans to haul (in the last stages of preparation by hand) some 6,000 chlorine gas cylinders to the front, all the while under observation by Allied forces. Contemporary observers (almost always French or British) claimed that the first major chemical attack at Ypres resulted in 5,000 deaths, but this is not supported by the evidence. A month later, however, Germany used chlorine gas (12,000 steel cylinders) against Russian troops along the Bzura-Ravka River to even greater effect, killing some 6,000 and injuring 3,100. In neither of these instances, however, did the use of chemical weapons change the outcome of the campaign. In the case of the April 1915 chlorine attack at Ypres, for example, Germany was not prepared to capitalize on the temporary break in the Allied lines.

Still, because gas warfare represented the dark side of modernity—and along with it, a cruel application for warfare—memories of World War I usually conjure up images of chemical weapons. The literature and subsequent images of gas warfare are indeed haunting. The Reverend O. S. Watkins wrote the following after the first major chlorine attack at Ypres, Belgium, on April 22, 1915:

> 'The French have broken,' we exclaimed. We hardly believed our words . . . . The story they told we could not believe; we put it down to their terror-stricken imaginings—a greenish-grey cloud had swept down upon them, turning yellow as it traveled over the country, blasting everything it touched, shriveling up the vegetation. No human courage could face such a peril. Then

> there staggered into our midst French soldiers, blinded, coughing, chests heaving, faces an ugly purple color—lips speechless with agony, and behind them, in the gas-choked trenches, we learned that they had left hundreds of dead and dying compadres. The impossible was only too true. It was the most fiendish, wicked thing I have ever seen. (Fries, p. 11)

The introduction of CW in World War I was actually more the result of desperation than evil genius. The father of modern CW, the German chemist Fritz Haber, himself admitted that he did not anticipate that the war would last much more than a year, and he certainly could not have foreseen the stalemated trench fortifications that would soon delineate the front. In northern France, Germany built up trenches near the Aisne River in September 1914. By year's end, the earthen fortifications stretched from Switzerland to the North Sea (about 475 miles). The extensive use of machine guns, as well as the improved accuracy in rifles, made offensive frontal assaults against these defended positions suicidal.

To turn the momentum in Germany's favor and to bring the war to an early conclusion, Haber directed the first use of chemicals (chlorine gas) for an attack at Ypres. This was the same site of the *Kindermord bei Ypren*—the massacre of the innocents at the battlefield in Ypres, Belgium—that occurred in November 1914. This horrendous skirmish made it clear early in the war that this world conflict would be one of "attrition, mass death and of receding hope of victory" (Keegan, p. 133). The April 1915 gas attack was (on a tactical level at least) a success, in that German troops were able to advance to where the chlorine cut a swath through Allied defenses, in this case comprised mostly of Algerian and Canadian troops. But Germany was not prepared with adequate numbers and materiel in reserve to exploit the temporary break in the Allied lines.

Momentarily shocked and staggered by Germany's use of chlorine at Ypres, the Allies created their own chemical munitions to respond in kind. The chemical attacks used in the early stages of the war, including those by Germany, France, and Great Britain, employed gas cylinders and relied upon wind to move clouds of poisonous vapor toward enemy lines. This tactic required a fair amount of luck to succeed. Later, both sides introduced delivery systems, including artillery shells and the Livens projector, that increased the probability that gas would actually reach its intended target.

Table W-1: Major Chemical Warfare (CW) Agents Developed and Produced during World War I

Chemical Agent	*First Use*
Chlorine	April 1915
Phosgene	1915–1916
Hydrogen cyanide	1916
Diphosgene	1916
Chloropicrin	1916
Mustard	July 1917
Lewisite	(Not used)

For chemical defenses, militaries frantically sought makeshift protective gear such as improvised masks. Chemical gas filters and protective eyepieces were invented, reducing the effectiveness of the potent CW agents. According to German army records, through the end of 1916, the mortality rate from CW agents was 50–60 percent, but then it dropped to 10–20 percent by the end of the war. As protective masks were being produced to outfit every soldier deployed in battle (as well as their horses, in some cases), Germany developed chemical compounds that could defeat Allied protective measures. One of these CW agents, diphenylcyanoarsine (DC), was an arsenical compound that was meant to be delivered in fine particles. The intent in this was to break through the masks, but such *Buntkreuz* or *Buntschiessen* techniques (both named for the color pattern painted on the shells) were ultimately unsuccessful.

Supported by Germany's advanced dye industry, which supplied the necessary chemical precursors, and with Haber's technical acumen, Germany developed processes for mass production of mustard agent. This highly effective casualty agent was also introduced on the Ypres battlefield in 1917. The most important feature of mustard is that it can penetrate clothing (including rubber), making life miserable for the Allied soldiers. But France and Britain were soon able to respond with sulfur mustard ("yperite"), and Corporal Adolf Hitler would himself be injured by this blister agent in 1918. Although its mortality was low in comparison to gases such as phosgene, mustard was responsible for the most injuries caused by CW agents throughout the entire war. For example, one month after Germany first began using mustard on the battlefield, British casualties from mustard approached the number of all those that had been caused by chemical weapons during the previous 2 years. Until the advent of highly toxic agents such as VX nerve agent in the 1950s, mustard was known as the king of CW agents.

The United States engaged its chemical manufacturing capacity to prepare for CW in World War I, although its late entry in the war (1917) meant that few of its chemical weapons would be used in battle. Lewisite, for example, was developed as a weapon, and large quantities were manufactured in 1917. By the time lewisite reached Europe, however, the war was already over.

Table W-2: World War I Casualties from Chemical Weapons

Country	*Wounded*	*Fatalities*
Austro-Hungary	97,000	3,000
Britain	180,597	8,109
France	182,000	8,000
Germany	191,000	9,000
Italy	55,373	4,627
Russia	419,340	56,000
United States	71,345	1,426
Others	9,000	1,000

Approximately 125,000 tons of chemical munitions were expended in World War I, delivered primarily by 65 million artillery shells. Perhaps as many as 13 million rounds were unexploded and today still litter the landscape of former European battlefields.

The belligerents of World War I later took pains to justify their use of chemical weapons, noting the right to retaliate against Germany's precedent at Ypres in 1915. Germany used a similar justification for what it claimed was French use of chemical weapons the year before. Other politicians and scholars of that era also noted that, when compared to the horrors of conventional warfare—bullets, shrapnel, and the like—in the end, CW was not that much worse. In 1920, the surgeon general of the United States summarized this feeling in the following way: "Gas is twelve times as humane as bullets and high explosives. That is to say, if a man gets gassed on the battlefield he has twelve times as many chances to get well as if he is struck by bullets or high explosives" (Ewing, p. 59). Still, there was enough visceral and vocal reaction among the general public in the United States and Europe to chemical warfare to set the stage for the Geneva Gas Protocol of 1925.

Biological Warfare (BW) during World War I

By 1914, the microbiological sciences had reached a level of development at which they were able to produce pathogens as a means of warfare. Reportedly, some German scientists considered the use of biological agents against the Allies, but their government would not allow it. One account is that of a German military doctor, who suggested to his superiors that plague bacteria (*Yersinia pestis*) could be dropped upon England from zeppelins. In reply, he was told, "My dear *Stabsarzt* (medical officer), all respects to your courage and patriotism, but if we undertake this step we will no longer be worthy to exist as a nation" (Wheelis, p. 38).

Nonetheless, a German-American physician by the name of Dr. Anton Dilger did conduct covert BW against American pack animals, culturing causative agents of anthrax and glanders at his home in Washington, D.C. He and other German agents paid Baltimore stevedores to assist them by inoculating some 3,000 mules, horses, and cattle bound for the Allies in Europe. (It is still unknown how these operatives managed to use highly infectious bacteria such as *Burkholderia mallei,* the causative agent of glanders, without becoming infected themselves. It is possible that they were also infected.) In World War II, a German expert in biological weapons recorded that these "agents took the cultures with them . . . cultivated the glanders bacilli with Ragitagar-gylcerine, which they had brought along, suspended the cultures and painted the nostrils of horses with the material" (Wheelis, p. 42). In a retrospective lecture delivered at Fort Detrick in 1944, it was posited that foot-and-mouth disease might also have been used against Allied horses and cattle that were being sent to the front in World War I. There is as of yet no conclusive evidence, however, that large numbers of animals or military personnel were affected by these acts of biological sabotage.

—Eric A. Croddy

THE BATTLE OF MESSINES, 1917

Under the leadership of British General Herbert Plumer, twenty-one underground explosive charges (these were referred to as mines, but this understates their actual mass) were placed by sappers beneath German lines. General Plumer made the now-famous remark to his staff before the mines were to be exploded: "Gentlemen, we may not make history tomorrow, but we shall certainly change the geography." Each of these charges had an estimated 40,000 pounds of explosives, and of these, nineteen detonated at almost exactly the same time on June 7, 1917. It is impossible to prove, but it is said that Prime Minister Lloyd George heard the blast in Downing Street, London.

Nor are there reliable records available as to how many Germans died. Most say, however, that Germany lost 10,000 men in the blast.

WORLD WAR II: BIOLOGICAL WEAPONS

During World War II, most major combatants conducted research on biological weapons. The Japanese undoubtedly used BW against the Chinese, but Japanese preparations for a BW attack against U.S. forces miscarried. The Russian front probably saw improvised biological attacks against German troops by Soviet and Polish partisans. Allegations that the Soviet national BW program mounted a BW attack are controversial. Other than these incidents, national military BW programs were limited to defensive actions and to offensive research programs of varying extent.

After World War I, popular outrage at the horrors of gas warfare led to several arms limitation treaties. The 1925 Geneva Protocol outlawed use of bacteriological agents in war, though it did not address the development of such weapons or the possession of biological weapons held for possible retaliation in kind.

There was a scientific consensus, however, that technical barriers made effective, reliable biological weapons impractical, if not impossible, to develop. Because military budgets were small, most countries did not investigate the development of biological weapons until the late 1930s when another war seemed likely.

The U.S.S.R. and Japan were exceptions to this general disinterest in biological warfare. Information on the Soviet biological weapons program is scant, but the program appears to have begun as early as the 1920s and remained active through the 1930s and 1940s, although it was disrupted by the Stalinist purges of the late 1930s. The Japanese biological weapons program began in 1932, spawned by a suspicion that the 1925 Geneva Protocol ban and the U.S. refusal to ratify it indicated that BW agents might be a valuable weapon.

The Canadian, French, British, and, possibly, the Polish governments began biological weapons programs in the 1930s as the rise of Fascism threatened another European war and as erroneous reports indicated German interest in BW. The French and Polish programs ended with the German occupation in 1939–1940. Italy briefly investigated BW in the 1930s but determined that the technical difficulties were too substantial to warrant further research. Germany showed little interest in BW until the fall of France revealed the French BW program. The Germans then belatedly began a small, ineffectual biological weapons program. The U.S. government began a biological weapons program in 1942 in response to threats perceived from Germany and Japan.

European Theater

As mentioned above, Great Britain and Canada started biological weapons programs in the late 1930s in response to reports of biological weapons development in Germany. Their efforts were limited in scale, and they concentrated on developing improvised offensive weapons, such as contaminated baits to infect enemy livestock and crude anthrax antipersonnel bombs. These were to be used for retaliation in kind should Germany use biological weapons.

Intelligence reports that both Germany and Japan were developing biological weapons resulted in the creation of the U.S. BW program. The U.S., British, and Canadian programs were coordinated and expanded to develop defensive measures as well as alternate, more sophisticated offensive systems.

The most important defensive program in the European theater was the development of an immunization against botulism toxin. Intelligence reports (which later proved to be inaccurate) indicated that Germany was preparing to use botulism toxin as a weapon to repel the Allied invasion of Europe. A crash program therefore developed a vaccine that protected humans against the botulism toxin. Sufficient material was manufactured to immunize the entire Allied force invading France on D-Day, but the immunization program was cancelled because more reliable intelligence became available that discounted the risk of such a German BW attack and because of the mistrust of new immunizations after a contaminated yellow fever vaccine had caused thousands of cases of hepatitis in 1942. At the end of the war, the German BW threat was found to have been inconsequential.

Little definitive information is available regarding BW in the Russian theater during the war. The Germans reported several instances of improvised biological sabotage of food by Russian and Polish partisans and resistance fighters. An allegation that the Russian military BW program may have deliberately caused an outbreak of tularemia is unproven. Many alleged incidents of biological warfare are probably due to naturally occurring disease outbreaks induced by the dislocation and disruption of sanitary and health services, caused by the war itself.

World War II storage of mustard agent shells, United States. (Bettmann/Corbis).

Pacific Theater

The earliest indications that the United States might face a biological attack from an opponent were the multiple attempts, beginning in 1939, by Japanese agents to obtain virulent and vaccine strains of the yellow fever virus. Japan had no legitimate use for yellow fever virus because yellow fever does not occur naturally in Asia or the Pacific region. Moreover, transport of even laboratory samples of the virus to Asia was forbidden by international agreement. Strategic U.S. bases in the Hawaiian Islands and Panama were highly vulnerable to introduction of yellow fever, as were wide areas of the mainland United States. This threat resulted in the decision immediately after Pearl Harbor to immunize all U.S. military personnel against yellow fever. Unfortunately, some lots of the vaccine had been contaminated with hepatitis

B virus, resulting in 350,000 cases of hepatitis requiring 50,000 hospitalizations.

In late 1941, reports reached Allied intelligence services that epidemics of plague in Chinese cities had been caused by the deliberate dropping of plague-infected fleas from Japanese aircraft. These reports were found to be persuasive by the leading U.S. expert in plague, and a crash program was instituted to produce plague vaccine. Because of the concern that plague would be used against U.S. forces, many U.S. military personnel were immunized against plague even though plague had never occurred in the areas of the Pacific where fighting occurred. When DDT became available near the end of World War II, it was used liberally to kill fleas, a traditional plague vector.

Concern that Japanese agents or sympathizers might use bacteria to contaminate food or drug supplies resulted in an extensive monitoring program in the Hawaiian Islands. All pharmacists, bacteriologists, and food handlers with a Japanese heritage were investigated for loyalty. A Caucasian soldier was stationed, full-time, in every food preparation facility in the Hawaiian Islands where a person of Japanese decent worked, in order to monitor the activity for possible tampering. Later in the war, similar monitoring was established in the Panama Canal zone.

In 1944, Japan began to release special high-altitude balloons carrying warheads that could reach the jet stream and cross the Pacific Ocean to fall on North America. Nearly 10,000 such balloons were released, and more than 250 reached the United States or Canada. They carried explosive and incendiary warheads intended to cause forest fires, but the small payload and the random nature of the targeting immediately gave rise to fears that they might carry biological agents. An intensive program of surveillance for balloons, analysis of the balloons' payloads, and monitoring of both human and livestock health throughout the United States and Canada was undertaken, all under intense secrecy. Although no evidence was found that biological agents were part of the payloads, a joint U.S.-Canadian program to produce veterinary vaccines against maliciously introduced exotic livestock diseases was reactivated. Postwar investigations revealed that a biological weapon warhead had been in development for balloon delivery, but it reportedly was not used.

In 1944, the United States was poised to invade the Mariana Islands, the proximity of which would allow U.S. planes to bomb the home islands of Japan. To strengthen the Pacific island defenses against the expected U.S. invasion, Japan sent a special contingent of biological warfare troops from China, but a U.S. submarine torpedoed the ship they were traveling on, and all of their equipment and biological agents were lost.

In late 1945, the Japanese devised a plan to close the Panama Canal by delivering a BW attack from submarine-launched aircraft. Although Japan possessed the necessary submarines, planes, and BW material, the war ended before the mission could depart.

The United States was near production of anticrop biological agents and antiplant chemical growth regulators (defoliants) in late 1945. These agents were developed as part of the U.S. BW program. Plans to starve the Japanese by attacking their crops were discarded, however, as the U.S. military had to consider its responsibilities for postwar reconstruction and feeding the Japanese population.

WORLD WAR II: CHEMICAL WEAPONS

Despite the widespread use of chemical weapons in World War I and the fact that all major belligerents possessed substantial chemical arsenals, combat use of toxic weapons in World War II was limited to the Sino-Japanese War. World War II saw the use of incendiary weapons on a scale that produced several urban firestorms, qualifying them as a weapon of mass destruction. Toxic gases were also used by the German military to murder millions of civilians in the death camps of the Holocaust.

Despite the fact that the 1925 Geneva Protocol banned the first use of chemical weapons, there was popular suspicion in the late 1930s that chemical weapons would be used in the event of war, against both military and urban targets. All major armies continued to supply antigas equipment and training to their troops during World War II. Officials were also concerned about the use of chemical weapons in terror bombing campaigns against cities.

European Theater

All European belligerents had ratified the 1925 Geneva Protocol banning first use of chemical weapons. Both the Allies and the Axis issued repeated pledges to refrain from first use of chemical weapons, and none were used in combat. Although Great Britain considered the option of first use of chemical weapons on British beaches to repel a German invasion, and although Great Britain evaluated the desirability of first use of CW to shorten the war, the decision was never made to employ chemical warfare against the Nazis. Throughout the war, however, both the Allies and the Axis did maintain large stockpiles of chemical munitions to allow retaliation in kind. A tragic accident in late 1943 in Bari, Italy, turned out to be the largest CW use of the war: When a U.S. merchant ship carrying mustard bombs was hit in a German air raid, it filled the harbor and adjacent city with mustard fumes, causing hundreds of chemical casualties.

Great Britain took the threat of CW against urban areas seriously, and it supplied its urban civilians with gas masks. The British also attempted to create a national CW detection system by painting postal deposit boxes with a paint that changed color if exposed to CW agents. Within a few days of the onset of the war, most children in the cities were evacuated to the countryside, which protected them against air bombardment and the possibility of chemical attacks against cities. Germany did not mount a comparable effort to protect its civilian population, and this may have contributed (along with Hitler's personal experience of being gassed in WWI) to the Nazis' reluctance to initiate chemical warfare and thereby risk retaliation in kind.

Nazi reluctance to engage in chemical warfare was not a forgone conclusion, however, because German development of nerve agents during the war gave the Nazis an edge in chemical warfare. Not only were these agents' orders of magnitude more deadly than the stockpiles of chemical agents maintained by the Allies, but the existing antigas equipment the Allies possessed would have been ineffective against them. Use of these nerve agents might have had profound military and political consequences. Although the Allies had air superiority, the Germans' V-1 and V-2 rockets would have been ideal nerve agent delivery systems. Indeed, despite the devastation they caused, Allied intelligence officials breathed a sigh of relief when the first V-1s and V-2s released by the Germans exploded conventionally on impact, giving conclusive proof that the Nazis had decided not to maximize their limited payloads by using them to deliver chemical weapons against urban targets.

Although primitive incendiary weapons had been developed in World War I, some believed that the large-scale incendiary bombardment of urban areas during World War II was the first modern example of a weapon of mass destruction. Incendiary attacks could result in "firestorms" destroying large urban areas in a single night. In three attacks in July–August 1943, 55 to 60 percent of Hamburg was destroyed, producing 60,000 to 100,000 fatalities. Between February 13 and 14, 1945, Dresden experienced a firestorm that killed more than 100,000 people.

Pacific Theater

Although Japan chose to use chemical weapons against Chinese troops and civilians in the Sino-Japanese War, it was careful to avoid such use against U.S. or British troops. The Japanese realized that the U.S. chemical arsenal was vastly superior to its own, and neither the United States nor Japan had ratified the 1925 Geneva Protocol. In other words, neither side was legally constrained against using chemical weapons first in combat.

Nevertheless, in 1942 and 1943, President Franklin Roosevelt stated a policy of no first use, but warned Japan that continued use of chemical weapons against China (now a member of the Allies) would be met with retaliation in kind by the United States. After these warnings, Japanese use of chemical weapons was greatly curtailed in China.

Japan became so concerned that an accident or an unauthorized chemical attack might provoke U.S. retaliation in kind, that all Japanese chemical munitions were withdrawn from forward areas in the Pacific theater in mid-1944.

Considerable planning by the United States for possible first use of chemical weapons occurred late in the war. Tests determined that CW would be effective against Japanese cave fortifications. Plans for a full-scale saturation of Iwo Jima with mustard gas prior to an invasion were prepared, but these plans were cancelled by President Roosevelt. The use of CW during the invasion of the Japanese home islands was considered, but it was made moot by the Japanese surrender.

The U.S. Army Air Corps employed incendiary weapons widely against highly flammable Japanese cities. On several occasions, these attacks produced firestorms or conflagrations that devastated entire cities. The most deadly incendiary attack occurred between March 9 and 10, 1945, when 25 percent of Tokyo was destroyed by fire, leaving more than 1,000,000 people homeless and killing nearly 84,000 Tokyo residents.

WUSHE INCIDENT

The Wushe Incident was probably the first time that chemical weapons were used in Asia. In 1930, Japanese forces occupying the island of Taiwan (then called Formosa) used poison gas against a rebellious group of Taiwanese citizens. This rebellion had begun with a local misunderstanding—exacerbated by years of harsh Japanese rule—between a Japanese policeman and the leader of an indigenous tribe. This led to the massacre of about 134 Japanese people at a sports event in the Wushe region. In order to punish the rebels and restore imperial rule, Japanese military units, including aircraft, were deployed to the area. What happened next is under some dispute. According to one report, the local Taiwanese, with only ancient firearms and bows and arrows to protect themselves, retreated to a large cave where they held out against attack. The Japanese resorted to the use of poison gas to flush them out. The gas was air-delivered in canisters, which broke on impact to release a "white smoke." As one local poet (who was not present during the event) described it years later:

> *We couldn't breathe, choking smoke filled the air*
> *Tearfully, some fell; others were killed in the forest; still others jumped to their*
> *Deaths from the cliff; no way to breathe in the white smoke.* (Quoted in Balcom, p. 65)

This description backs up the assertion that the weapon used was most probably a form of tear gas known as chloracetophenon (CN). Other accounts, however, tell of villagers being found dead in their huts, leading to the conclusion that a more deadly form of gas was employed. Overall, Japanese reprisals for the insurrection resulted in the deaths of 644 Taiwanese people—more than half of the local population of Wushe.

In 1930, the use of chemical agents was proscribed under international law by the Geneva Protocol of 1925. Japan, although a signatory of the treaty, never ratified it. In light of the World War I experience when they were used to good effect, chemical weapons were perceived by the Japanese military as useful, especially against poorly armed opponents. The Japanese had begun experimental production of mustard gas in 1928, and they expanded both production and training for the use of chemical weapons throughout the 1930s. Indeed, a large chemical weapons facility was established in northern Taiwan. Chemical weapons, including tear gas, mustard gas, and hydrogen cyanide, were used widely, although with limited success, in Japan's war with China in the late 1930s and early 1940s. The use of chemical agents in that war led U.S. officials to fear that Japanese forces would employ them against American troops. Japan never employed chemical weapons against U.S. forces, however, and it apparently never again employed them after 1942.

X

XYLYL BROMIDE

Xylyl bromide falls into the general category of the so-called halogenated compounds. These chemicals contain a halogen, that is, chlorine, bromine, iodine, or fluorine, in their chemical structures. During World War I, Germany investigated a number of different chemical structures for development of irritating CW agents, but mostly owing to cost and availability, they settled upon bromine. Xylyl bromide was originally chosen for use, but due to xylyl bromide's low volatility, it was replaced by a closely related candidate, benzyl bromide, which was first used at Verdun by the German army in March 1915.

The use of chlorine (Cl_2) by Germany in April 1915 (at Ypres, Belgium) ushered in modern chemical warfare. Months earlier, however, the German military had tried to use xylyl bromide on the battlefield. This chemical attack took place on January 31, 1915 at Bolimow, Poland. Although a dianisidine chemical munition had been tried on October 27, 1914 by the German military, this use of xylyl bromide was probably the first recorded use of a chemical artillery shell in modern history. Xylyl bromide is an extremely irritating compound, but it had little demonstrable effect upon the Russian and British troops at Bolimow—despite Germany's having fired some 500 tons of this "T-Stoff."

Germany discovered that xylyl bromide corroded most metals and required lead canisters to hold the liquid for artillery shells. Xylyl bromide is a potent lacrimator (tear gas), detectable in concentrations as low as 0.0018 milligrams (about 2 micrograms) per liter. Though the effectiveness of xylyl bromide was questionable, especially during the winter when the cold lowered its volatility, its use in artillery shells opened the door for more advanced chemical weaponry to follow.

YELLOW RAIN

Yellow rain refers to a family of chemically related toxins produced by fungi, purportedly making up the active ingredient in a toxic weapon. These fungal toxins (mycotoxins) were allegedly weaponized by the Soviet Union and used in Cold War conflicts such as those in Afghanistan, Laos, Kampuchea (Cambodia), and possibly Vietnam. The material was likely dispersed in droplet or aerosol form from aircraft, hence the term *yellow rain.* Rumors of the use of mycotoxins by the Soviets had circulated in the international community since the early 1970s, and Alexander Haig, the U.S. Secretary of State, made an emphatic allegation of the Soviets' use of yellow rain at a press conference in Berlin in September 1981. In March of the following year, Secretary Haig issued a written report formally accusing the Soviet Union and its client states of using mycotoxins against human targets in southeast Asia and in Afghanistan.

A large number of fungal metabolites (by-products of metabolism) have been implicated in adverse health effects in humans and domestic animals. Fungal growth on hay, rice, wheat and other cereal grains, cotton, and other agricultural products has been demonstrated to produce significant concentrations of mycotoxins. Of the many mycotoxins known to cause tissue damage in animals, the trichothecene family contains several toxic compounds, among which the T-2 mycotoxin is particularly harmful to humans and domestic livestock.

Controversial claims that the Soviets or Soviet clients used yellow rain have been based on the probable, but never proven, use of trichothecenes in southeast Asia and Afghanistan during the period from 1974 to 1981. Evidence compiled by U.S. intelligence analysts under the direction of the Working Group on Chemical/Biological Warfare Use, summarized in the State Department's 1982 monograph, cited epidemiological support for intelligence estimates of the biological warfare use of trichothecenes. Specific among these allegations were a series of attacks against Hmong villagers in the Laotian highlands in 1975–1981 and against Khmer Rouge troops in North Vietnam and Laos in 1979–1981. Scientific investigations, however, failed to provide unequivocal proof that trichothecenes were employed as biological warfare agents by the Soviets or the Laotian military.

Despite the apparent lack of a "smoking gun," considerable circumstantial and empirical findings strongly supported the allegations of use. The United States and its allies, for example, recovered and identified trichothecenes from both human and environmental specimens. Interviews with Hmong villagers who had survived or witnessed the aerial dispersion of yellow rain in Laos offered consistent and relevant testimony that supported the use of yellow rain. Defectors, including Laotian and North Vietnamese military personnel, also recounted in separate interviews the use of yellow rain, giving detailed information consistent with the testimony of local villagers. Repeated admissions of unconventional weapons use in southeast Asia and Afghanistan were recorded by intelligence officers from interrogated prisoners of war, with specific mention of yellow rain. Chemical warfare agents and Soviet technicians were also discovered in Laos.

Although the U.S. government's investigation provided considerable circumstantial evidence of Soviet-sponsored trichothecene use against human targets, the controversy was fueled by a lack of convincing scientific proof. Attempts by the United Nations to investigate the yellow rain allegations were derailed by the refusal of the Laotian and Vietnamese governments to cooperate with investigators and by their adamant denial of requests for access to alleged yellow rain sites. The Soviet and Russian governments have never admitted to the use of biological agents, and they have categorically refuted all such allegations.

Since the allegations were made, the passage of time, questionable investigation practices, disingenuous political influence, and a general disintegration of public concern over the military threat once posed by the Soviet Union have largely deflated the yellow rain controversy. Russian government officials have thus far declined to discuss related issues in recent years. Finally, the preponderance of evidence cited in Haig's 1982 report is constrained by security classifications that render it immune to public retrieval under the Freedom of Information Act. Thus, the putative use of yellow rain as a biological warfare agent remains a mystery and is likely to remain so for the foreseeable future.

Technical Details

Trichothecene mycotoxins are low molecular weight compounds that exhibit remarkable stability in the environment. The trichothecene family of toxins is characterized by a common tetracyclic (four carbon ring) trichothecene molecular structure with various side chain groups (molecular attachments) conferring specific chemical and toxic properties. Trichothecenes are nonvolatile (do not evaporate under normal conditions) and do not readily dissolve in water; large-scale production typically requires extraction from organic solvents. The toxins are not degraded by exposure to air, sunlight, or autoclaving; the compounds require high temperatures for extended time periods to be inactivated.

Filamentous fungi ("molds") are ubiquitous in nature, and dangerous levels of mycotoxins have been reported in grains, hay, and livestock feeds where these molds grow. Domestic animals are the most frequent victims of naturally occurring mycotoxicoses (poisoning events caused by mold), usually following ingestion of moldy feed or hay. Human intoxication is most often associated with fungal contaminants of rice, corn, barley, wheat, and other cereal grains that are unknowingly consumed in sufficient quantities for the victim to manifest symptoms. Natural production of the toxins often exhibits a distinct seasonality, generally coinciding with climatic conditions conducive to sustained fungal growth.

Trichothecenes effectively inhibit protein synthesis in a large number of cell types and are particularly toxogenic (poisonous) in rapidly proliferating host tissues. Some evidence suggests that the T-2 mycotoxin also causes damage to RNA and inhibits DNA synthesis, although these specific toxic effects are probably indirect effects of the inhibition of protein synthesis.

Trichothecenes, in particular T-2, are biologically active following skin absorption, oral ingestion, or inhalation. This is unique among known biological agents. Following absorption, systemic toxicity (poisoning throughout the body) occurs rapidly, then T-2 passes across the intestinal or pulmonary mucosa (layer of tissue in lung), with lethal effects recorded within 1 hour after experimental infection in laboratory animals. Transdermal uptake is considerably slower, although the use of a dermal penetrant increases the movement of T-2 through the skin. In fact, the presence of a dermal penetrant helps distinguish manufactured and purified trichothecenes from naturally occurring mycotoxins, which lack these chemical additives. Regardless of how they may be weaponized, the effective movement of the trichothecenes into systemic circulation, and their ability to achieve biologically effective concentrations after relatively short exposure periods, makes this class of compounds effective when formulated as powders, aerosols, or droplet sprays.

Considering their resistance to environmental degradation, their rapid uptake across biological membranes, the ability to achieve toxic levels within a short exposure interval, and the absence of sophisticated protocols for production, T-2 and related trichothecenes are serious candidates for weaponization and employment in an unconventional setting. The ability to harvest selected trichothecenes from liquid culture in substantive quantities and the ready availability of fermentation equipment make mycotoxins attractive biological agents for small- to medium-scale production with a minimal investment in technology or scientific prowess.

YEMEN

Concerns exist about contacts the Republic of Yemen has had with "rogue states," such as North Korea (Democratic People's Republic of Korea, or DPRK), and about Yemen as a possible training ground for international terrorists. Yemen's role as a possible base for international terrorists was highlighted by the attack on the USS *Cole* by a small boat loaded with high explosives on October 12, 2000, killing 17 U.S. Navy personnel, and the October 6, 2002, attack on the French supertanker *Limburg.* The French oil tanker was also hit off the coast of Yemen. During counterterrorist operations and in cooperation with Yemen, this latest attack was followed by a U.S. Hellfire rocket strike launched by a Predator aircraft (UAV) against suspected al-Qaeda operatives in November 2002.

Yemen, situated on the southeastern coast of the Arabian peninsula, was the site of a chemical weapons attack in the 1960s when Egyptian forces used mustard in attacks on Saudi Arabian-backed Royalist Yemeni forces. The civil war began with two competing entities, each hoping to rule Yemen after the death of the Imam (leader) in 1962. Egypt and the Soviet Union supported the military officers who formed the republican opposition, while the Imam royalists were supported by Saudi, Jordan, and Iran. At least by 1967, Egypt was using chemical warfare agents, including mustard, in the Yemeni conflict. Some reports claim that Egypt also used an organophosphate nerve agent against Royalist Yemeni forces. This was the first use of chemical weapons in the Middle East, and was of great concern to Israel as Egypt and other Arab countries prepared to invade in what would later be called the Six Day War (June 1967).

Today, Yemen has several aircraft capable of carrying weapons of mass destruction, including MiG-29s purchased from Russia. Yemen has no nuclear capability, however, and there is no evidence that it has undertaken any research in this field for either energy or weaponry purposes. It acceded to the Nuclear Nonproliferation Treaty on October 31, 1973, and signed the Comprehensive Test Ban Treaty on September 30, 1996.

Yemen has a number of Scud B ballistic missiles that have a range of 300 kilometers when carrying a 985-kilogram payload. A number of shorter-range Scuds were used during the 1994 civil war. It has purchased No Dong missiles from North Korea. A shipment of fifteen missiles was delivered in December 2002 after having been intercepted at sea (and subsequently released) by U.S. and Spanish maritime forces. Yemeni officials have pledged to purchase no additional missiles from North Korea and have stated that the missiles delivered at the end of 2002 were for only defensive purposes and would not be sold or transferred to third parties. Yemen does not, however, subscribe to the main international missile nonproliferation agreement, the Missile Technology Control Regime.

There is no evidence that Yemen has a chemical or biological weapons program. It signed the Chemical Weapons Convention (CWC) on February 8, 1993. The CWC entered into force for Yemen on November 1, 2000.

YPRES

Ypres, a small Flemish market town near the border of France, was the scene of some of the worst fighting in the First World War. Even more infamously, it is where poison gas was first used effectively in combat.

In the spring of 1915, British, Canadian, and French forces maintained a 10-mile military salient near Ypres that bulged into German occupied territory for 5 miles. During the morning of April 22, German troops mounted a heavy bombardment on the enemy line. When shelling resumed in the evening, French sentries noticed a curious yellow-green cloud drifting slowly toward their positions. They suspected that the cloud masked a German infantry attack, but no enemy troops advanced. What the Germans had done was open the valves of several thousand cylinders of chlorine gas, using a favorable wind to carry more than 160 tons of the deadly agent across the mostly French and Algerian lines. Those least affected experienced intense irritation of the eyes and difficulty breathing, causing damage to the tissue of the lungs. The lungs of those who were more exposed became flooded with fluid, resulting in slow and painful drowning. In this attack alone, it was reported that 5,000 Allied soldiers were killed, and another 10,000 were seriously injured. However, subsequent historians note that this was likely an exaggeration on the part of Allied propaganda. To be certain, at least 800 soldiers were killed in this gas attack.

Ironically, the Germans failed to fully exploit this attack. Panic-stricken French troops fled in disorder, creating a 4-mile gap in the Allied line. Had the Germans anticipated this outcome, they could have mounted a decisive breakthrough. The results of their experiment, however, caused as much surprise to the German high command as confusion within the opposing ranks.

Although the German infantry did seize control of a significant portion of the salient, the Allies nevertheless managed to re-form a continuous line, though in areas it remained dangerously weak. Germany used chlorine gas several more times on the Ypres salient during the spring of 1915. In their last chemical attack on May 24, they released chlorine gas over a front of 4.5 miles and took the Bellewaarde Ridge, thus gaining almost all the high ground around Ypres. This was to shape the salient over the next two "Quiet Years."

Germany's introduction of chemical warfare at Ypres provoked widespread international condemnation and certainly damaged German relations with the neutral powers, including the United States. The Ypres attack, however, brought an end to Germany's internal debate and hesitancy over the use of chemical weapons on the battlefield.

Once the Allies had recovered from the initial shock of the Germans' practical application of poison gas warfare, a determination existed to exact retaliation at the earliest opportunity. The British were the first to respond, using chlorine gas at the Battle of Loos in September 1915. After this incident, chemical warfare escalated both quantitatively and qualitatively for the remainder of the war.

Hague Declaration Documents

DECLARATION PROHIBITING THE USE OF ASPHYXIATING GASES

The undersigned, Plenipotentiaries of the Powers represented at the International Peace Conference at The Hague, duly authorized to that effect by their Governments, inspired by the sentiments which found expression in the Declaration of St Petersburg of 29 November (11 December) 1868.

DECLARE as follows:

The Contracting Powers agree to abstain from the use of projectiles the object of which is the diffusion of asphyxiating or deleterious gases.

The present Declaration is only binding on the Contracting Powers in the case of a war between two or more of them.

It shall cease to be binding from the time when, in a war between the Contracting Powers, one of the belligerents shall be joined by a non-Contracting Power.

The present Declaration shall be ratified as soon as possible.

The ratifications shall be deposited at The Hague.

A *procès-verbal* shall be drawn up on the receipt of each ratification, a copy of which, duly certified, shall be sent through the diplomatic channel to the Contracting Powers.

The non-Signatory Powers can adhere to the present Declaration. For this purpose they must make their adhesion known to the Contracting Powers by means of a written notification addressed to the Netherland Government, and by it communicated to all the other Contracting Powers.

In the event of one of the High Contracting Parties denouncing the present Declaration, such denunciation shall not take effect until a year after the notification made in writing to the Government of the Netherland, and forthwith communicated by it to all the other Contracting Powers.

This denunciation shall only affect the notifying Power.

IN FAITH OF WHICH the Plenipotentiaries have signed the present Declaration, and affixed their seals thereto.

DONE at The Hague the 29th July, 1899, in a single copy, which shall be kept in the archives of the Netherland Government, and copies of which, duly certified, shall be sent by the diplomatic channel to the Contracting Powers.

HAGUE DECLARATIONS:

Peace Conference at the Hague 1899:

General Report of the United States Commission
THE HAGUE, July 31, 1899.
THE HONORABLE JOHN HAY, Secretary of State,

Sir: On May 17, 1899, the American Commission to the Peace Conference of The Hague met for the first time at the house of the American Minister, The Honorable Stanford Newel, the members in the order named in the instructions from the State Department being Andrew D. White, Seth Low, Stanford Newel, Captain Alfred T. Mahan of the United States Navy, Captain William Crozier of the United States Army, and Frederick W. Holls, Secretary. Mr. White was elected President and the instructions from the Department of State were read.

On the following day the Conference was opened at the Palace known as "The House in the Wood," and delegates from the following countries, twenty-six in number, were found to be present: Germany, The United States of America, Austria-Hungary, Belgium, China, Denmark, Spain, France, Great Britain and Ireland, Greece, Italy, Japan, Luxemburg, Mexico, Montenegro, The Netherlands, Persia, Portugal, Roumania, Russia, Servia, Siam, Sweden and Norway, Switzerland, Turkey and Bulgaria.

The opening meeting was occupied mainly by proceedings of a ceremonial nature, including a telegram to the Emperor of Russia and a message of thanks to the Queen of the Netherlands, with speeches by M. de Beaufort, the Netherlands Minister of Foreign Affairs, and M. de Staal, representing Russia.

At the second meeting a permanent organization of the Conference was effected, M. de Staal being chosen President, M. de Beaufort honorary President, and M. van Karnebeek, a former Netherlands Minister of Foreign Affairs, Vice-President. A sufficient number of Secretaries was also named.

The work of the Conference was next laid out with reference to the points stated in the Mouravieff circular of December 30, 1898, and divided between three great committees as follows:

The first of these committees was upon the limitation of armaments and war budgets, the interdiction or discouragement of sundry arms and explosives which had been or might be hereafter invented, and the limitation of the use of sundry explosives, projectiles, and methods of destruction both on land and sea, as contained in Articles 1 to 4 of the Mouravieff circular.

The second great committee had reference to the extension of the Geneva Red Cross Rules of 1864 and 1868 to maritime warfare, and the revision of the Brussels Declaration of 1874 concerning the laws and customs of war and contained in Articles 5 to 7 of the same circular.

The third committee had as its subjects, mediation, arbitration, and other methods of preventing armed conflicts between nations, as referred to in Article 8 of the Mouravieff circular.

The American members of these three committees were as follows: of the first committee, Messrs. White, Mahan, Crozier; of the second committee, Messrs. White, Newel, Mahan, Crozier; of the third committee, Messrs. White, Low and Holls.

In aid of these three main committees sub-committees were appointed as follows:

The first committee referred questions of a military nature to the first sub-committee of which Captain Crozier was a member, and questions of a naval nature to the second sub-committee of which Captain Mahan was a member.

The second committee referred Articles 5 and 6, having reference to the extension of the Geneva Rules to maritime warfare to a sub-committee of which Captain Mahan was a member, and Article 7, concerning the revision of the laws and customs of war, to a sub-committee of which Captain Crozier was a member.

The third committee appointed a single sub-committee, of "examination," whose purpose was to scrutinize plans, projects, and suggestions of arbitration, and of this committee, Mr. Holls was a member.

The main steps in the progress of the work wrought by these agencies, and the part taken in it by our Commission are detailed in the accompanying reports made to the American Commission by the American members of the three committees of the Conference. It will be seen from these that some of the most important features finally adopted were the result of American proposals and suggestions.

As to that portion of the work of the First Committee of the Conference which concerned the non-augmentation of armies, navies, and war budgets for a fixed term and the study of the means for eventually diminishing armies and war budgets, namely Article 1, the circumstances of the United States being so different from those which obtain in other parts of the world and especially in Europe, we thought it best, under our instructions, to abstain from taking any active part. In this connection, the following declaration was made:

The Delegation of the United States of America has concurred in the conclusions upon the first clause of the Russian letter of December 30, 1898, presented to the Conference by the First Commission, namely: that the proposals of the Russian representatives, for fixing the amounts of effective forces and of budgets, military and naval, for periods of five and three years. cannot now be accepted, and that a more profound study upon the part of each State concerned is to be desired. But, while thus supporting what seemed to be the only practicable solution of a question submitted to the Conference by the Russian letter, the Delegation wishes to place upon the Record that the United States, in so doing, does not express any opinion as to the course to be taken by the States of Europe.

This declaration is not meant to indicate mere indifference to a difficult problem, because it does not affect the United States immediately, but expresses a determination to refrain from enunciating opinions upon matters into which, as concerning Europe alone, the United States has no claim to enter. The resolution offered by M. Bourgeois, and adopted by the First Commission, received also the hearty concurrence of this Delegation, because in so doing it expresses the cordial interest and sympathy with which the United States, while carefully abstaining from anything that might resemble interference, regards all movements that are thought to tend to the welfare of Europe. The military and naval armaments of the United States are at present so small, relatively, to the extent of territory and to the number of the population, as well as in comparison with those of other nations, that their size can entail no additional burden of expense upon the latter, nor can even form a subject for profitable mutual discussion.

As to that portion of the work of the first committee which concerned the limitations of invention and the interdiction of sundry arms, explosives, mechanical agencies, and methods heretofore in use or which might possibly be hereafter adopted both as regards warfare by land and sea, namely, Articles 2, 3, and 4, the whole matter having been divided between Captains Mahan and Crozier, so far as technical discussion was concerned, the reports made by them from time to time to the American Commission formed the basis of its final action on these subjects in the first committee and in the Conference at large.

The American Commission approached the subject of the limitation of invention with much doubt. They had been justly reminded in their instructions of the fact that by the progress of invention as applied to the agencies of war, the frequency, and indeed the exhausting character of war had been as a rule diminished rather than increased. As to details regarding missiles and methods, technical and other difficulties arose which obliged us eventually, as will be seen, to put ourselves on record in opposition to the large majority of our colleagues from other nations on sundry points. While agreeing with them most earnestly as to the end to be attained, the difference in regard to some details was irreconcilable. We feared falling into worse evils than those from which we sought to escape. The annexed Reports of Captains Mahan and Crozier will exhibit very fully these difficulties and the decisions thence arising.

As to the work of the Second great Committee of the Conference, the matters concerned in Articles 3 and 6 which related to the extension to maritime warfare of the Red Cross Rules regarding care for the wounded adopted in the Geneva Conventions of 1864 and 1868 were, as already stated, referred as regards the discussion of technical questions in the committee and sub-committee to Captain Mahan, and the matters concerned in Article 7, on the revision of the laws and customs of war were referred to Captain Crozier. On these technical questions Captains Mahan and Crozier reported from time to time to the American Commission, and these reports having been discussed both in regard to their general and special bearings, became the basis of the final action of the entire American Commission, both in the second committee and in the Conference at large.

As to the first of these subjects, the extension of the Geneva Red Cross Rules to maritime warfare, while the general purpose of the articles adopted elicited the especial sympathy of the American Commission, a neglect of what seemed to us a question of almost vital importance, namely: the determination of the status of men picked up by the hospital ships of neutral states or by other neutral vessels, has led us to refrain from signing the Convention prepared by the Conference touching this subject, and to submit the matter, with full explanation, to the Department of State for decision.

As to the second of these subjects, the revision of the laws and customs of war, though the code adopted and embodied in the third convention commends our approval, it is of such extent and importance as to appear to need detailed consideration in connection with similar laws and customs already in force in the army of the United States, and it was thought best, therefore, to withhold our signature from this Convention, also, and to refer it to the State Department with a recommendation that it be there submitted to the proper authorities for special examination and signed, unless such examination shall disclose imperfections not apparent to the Commission.

In the Third great Committee of the Conference, which had in charge the matters concerned in Article 3 of the Russian circular, with reference to good offices, mediation, and arbitration, the proceedings of the sub-committee above referred to became especially important.

While much interest was shown in the discussions of the first of the great Committees of the Conference, and still more in those of the second, the main interest of the whole body centered more and more in the third. It was felt that a thorough provision for arbitration and its cognate subjects is the logical precursor of the limitation of standing armies and budgets, and that the true logical order is, first, arbitration and then disarmament.

As to subsidiary agencies, while our Commission contributed much to the general work regarding good offices and mediation, it contributed entirely, through Mr. Holls, the plan for " Special Mediation," which was adopted unanimously, first by the committee and finally by the Conference.

As to the plan for "International Commissions of Inquiry" which emanated from the Russian Delegation, our Commission acknowledged its probable value, and aided in elaborating it; but added to the safeguards against any possible abuse of it, as concerns the United States, by our Declaration of July 25, to be mentioned hereafter.

The functions of such commissions is strictly limited to the ascertainment of facts, and it is hoped that, both by giving time for passions to subside and by substituting truth for rumor, they may prove useful at times in settling international disputes. The Commissions of Inquiry may also form a useful auxiliary both in the exercise of Good Offices and to Arbitration.

As to the next main subject, the most important of all under consideration by the third committee-the plan of a Permanent Court or Tribunal-we were able, in accordance with our instructions, to make contributions which we believe will aid in giving such a court dignity and efficiency.

On the assembling of the Conference, the feeling regarding the establishment of an actual, permanent tribunal was evidently chaotic, with little or no apparent tendency to crystallize into any satisfactory institution. The very elaborate and, in the main, excellent proposals relating to procedure before special and temporary tribunals, which were presented by the Russian Delegation, did not at first contemplate the establishment of any such permanent institution. The American plan contained a carefully devised project for such a tribunal, which differed from that adopted mainly in contemplating a tribunal capable of meeting in full bench and permanently in the exercise of its functions, like the Supreme Court of the United States, instead of a Court like the Supreme Court of the State of New York, which never sits as a whole, but whose members sit from time to time singly or in groups, as occasion may demand. The Court of Arbitration provided for, resembles in many features the Supreme Court of the State of New York, and courts of unlimited original jurisdiction in various other States. In order to make this system effective a Council was established, composed of the diplomatic representatives of the various Powers at The Hague, and presided over by the Netherlands Minister of Foreign Affairs, which should have charge of the central office of the proposed Court, of all administrative details, and of the means and machinery for speedily calling a proper bench of judges together, and for setting the Court in action. The reasons why we acquiesced in this plan will be found in the accompanying report This compromise involving the creation of a Council and the selection of judges, not to be in session save when actually required for international litigation, was proposed by Great Britain, and the feature of it, which provided for the admission of the Netherlands with its Minister of Foreign Affairs as President of the Council, was proposed by the American Commission. The nations generally joined in perfecting the details. It may truthfully be called, therefore, the plan of the Conference.

As to the revision of the decisions by the tribunal in case of the discovery of new facts, a subject on which our instructions were explicit, we were able, in the face of determined and prolonged opposition, to secure recognition in the Code of Procedure for the American view.

As regards the procedure to be adopted in the International Court thus provided, the main features having been proposed by the Russian Delegation, various modifications were made by other Delegations, including our own. Our Commission was careful to see that in this Code there should be nothing which could put those conversant more especially with British and American Common Law and Equity at a disadvantage. To sundry important features proposed by other Powers our own Commission gave hearty support. This was the case more especially with Article 27 proposed by France. It provides a means, through the agency of the Powers generally, for calling the attention of any nations apparently drifting into war, to the fact that the tribunal is ready to hear their contention. In this provision, broadly interpreted, we acquiesced, but endeavored to secure a clause limiting to suitable circumstances the "duty" imposed by the article. Great opposition being shown to such an amendment as unduly weakening the article, we decided to present a declaration that nothing contained in the convention should make it the duty of the United States to intrude in or become entangled with European political questions or matters of internal administration, or to relinquish the traditional attitude of our nation toward purely American questions. This declaration was received without objection by the Conference in full and open session.

As to the results thus obtained as a whole regarding arbitration, in view of all the circumstances and considerations revealed during the sessions of the Conference, it is our opinion that the " Plan for the Peaceful Adjustment of International Differences," which was adopted by the Conference, is better than that presented by any one nation. We believe that, though it will doubtless be found imperfect and will require modification as time goes on, it will form a thoroughly practical beginning, that it will produce valuable results from the outset, and that it will be the germ out of which a better and better system will be gradually evolved.

As to the question between compulsory and voluntary arbitration, it was clearly seen, before we had been long in session, that general compulsory arbitration of questions, really likely to produce war, could not be obtained; in fact, that not one of the nations represented at the Conference was willing to embark in it so far as the more serious questions were concerned. Even as to questions of less moment it was found to be impossible to secure agreement except upon a voluntary basis. We ourselves felt obliged to insist upon the omission from the Russian list of proposed subjects for compulsory arbitration, international conventions relating to rivers, to inter-oceanic canals, and to monetary matters. Even as so amended, the plan was not acceptable to all. As a consequence, the Convention prepared by the Conference provides for voluntary arbitration only. It remains for public opinion to make this system effective. As questions arise threatening resort to arms, it may well be hoped that public opinion in the nations concerned, seeing in this great international court a means of escape from the increasing horrors of war, will insist more and more that the questions at issue be referred to it. As time goes on such reference will probably more and more seem, to the world at large, natural and normal, and we may hope that recourse to the tribunal will finally, in the great majority of serious differences between nations, become a popular means of avoiding the resort to arms. There will also be another effect worthy of consideration. This is the building up of a body of international law growing out of the decisions handed down by the judges. The procedure of the tribunal requires that reasons for such decisions shall be given, and these decisions and reasons can hardly fail to form additions of especial value to international jurisprudence.

It now remains to report the proceedings of the Conference, as well as our own action, regarding the question of the immunity of private property not contraband, from seizure on the seas in time of war. From the very beginning of our sessions it was constantly insisted by leading representatives from nearly all the great Powers that the action of the Conference should be strictly limited to the matters specified in the Russian circular of December 30, 1898, and referred to in the invitation emanating from the Netherlands Ministry of Foreign Affairs.

Many reasons for such a limitation were obvious. The members of the Conference were, from the beginning, deluged with books, pamphlets, circulars, newspapers, broadsides, and private letters on a multitude of burning questions in various parts of the world. Considerable numbers of men and women devoted to urging these questions came to The Hague or gave notice of their coming. It was very generally believed in the Conference that the admission of any question not strictly within the limits proposed by the two circulars above mentioned would open the door to all those proposals above referred to and that this might lead to endless confusion, to heated debate, perhaps even to the wreck of the Conference and consequently to a long postponement of the objects which both those who summoned it and those who entered it had directly in view.

It was at first held by very many members of the Conference that under the proper application of the above rule, the proposal made by the American Commission could not be received. It required much and earnest argument on our part to change this view, but finally the Memorial from our Commission, which stated fully the historical and actual relation of the United States to the whole subject, was received, referred to the appropriate committee, and finally brought by it before the Conference.

In that body it was listened to with close attention and the speech of the Chairman of the Committee, who is the eminent President of the Venezuelan Arbitration Tribunal, nowin session at Paris, paid a hearty tribute to the historical adhesion of the United States to the great principle concerned. He then moved that the subject be referred to a future Conference. This motion we accepted and seconded, taking occasion in doing so to restate the American doctrine on the subject, with its claims on all the nations represented at the Conference.

The Commission was thus, as we believe, faithful to one of the oldest of American traditions, and was able at least to keep the subject before the world. The way is paved also for a future careful consideration of the subject in all its bearings and under more propitious circumstances.

The conclusions of the Peace Conference at The Hague took complete and definite shape in the final act laid before the Delegates on July 29th, for their signature. This Act embodied three Conventions, three Declarations, and seven Resolutions as follows:

First, a Convention for the peaceful adjustment of international differences. This was signed by sixteen Delegations, including that of the United States of America, there being adjoined to our signatures a reference to our declaration above referred to, made in open Conference on July 25, and recorded in the proceedings of that day.

Second, a Convention concerning the laws and customs of war on land. This was signed by fifteen Delegations. The United States Delegation refer the matter to the Government at Washington with the recommendation that it be there signed.

Third, a Convention for the adaptation to maritime warfare of the principles of the Geneva Conference of 1864. This was signed by fifteen Delegations. The United States representatives refer it, without recommendation, to the Government at Washington.

The three Declarations were as follows:

First: a Declaration prohibiting the throwing of projectiles and explosives from balloons or by other new analogous means, such prohibition to be effective during five years. This was signed by seventeen Delegations as follows: Belgium, Denmark, Spain, The United States of America, Mexico, France, Greece, Montenegro, The Netherlands, Persia, Portugal, Roumania, Russia, Siam, Sweden and Norway, Turkey and Bulgaria.

Second, a Declaration prohibiting the use of projectiles having as their sole object the diffusion of asphyxiating or deleterious gases. This, for reasons given in the accompanying documents, the American Delegation did not sign. It was signed by sixteen Delegations as follows: Belgium, Denmark, Spain, Mexico, France, Greece, Montenegro, The Netherlands, Persia, Portugal, Roumania, Russia, Siam, Sweden and Norway, Turkey and Bulgaria.

Third, a Declaration prohibiting the use of bullets which expand or flatten easily in the human body, as illustrated by certain given details of construction. This for technical reasons, also fully stated in the report, the American Delegation did not sign. It was signed by fifteen Delegations as follows: Belgium, Denmark, Spain, Mexico, France, Greece, Montenegro, The Netherlands, Persia, Roumania, Russia, Siam, Sweden and Norway, Turkey and Bulgaria.

The seven Resolutions were as follows:

First, a Resolution that the limitation of the military charges which at present so oppress the world is greatly to be desired, for the increase of the material and moral welfare of mankind.

This ended the action of the Conference in relation to matters considered by it upon their merits. In addition the Conference passed the following resolutions, for all of which the United States Delegation voted, referring various matters to the consideration of the Powers or to future Conferences. Upon the last five resolutions a few Powers abstained from voting.

The Second Resolution was as follows: The Conference taking into consideration the preliminary steps taken by the federal government of Switzerland for the revision of the Convention of Geneva, expresses the wish that there should be in a short time a meeting of a special conference having for its object the revision of that Convention.

This Resolution was voted unanimously.

Third: The Conference expresses the wish that the question of rights and duties of neutrals should be considered at another Conference.

Fourth: The Conference expresses the wish that questions relative to muskets and marine artillery, such as have been examined by it, should be made the subject of study on the part of the governments with a view of arriving at an agreement concerning the adoption of new types and calibers.

Fifth: The Conference expresses the wish that the governments, taking into account all the propositions made at this Conference, should study the possibility of an agreement concerning the limitation of armed forces on land and sea and of war budgets.

Sixth: The Conference expresses the wish that a proposition having for its object the declaration of immunity of private property in war on the high seas, should be referred for examination to another Conference.

Seventh: The Conference expresses the wish that the proposition of regulating the question of bombardment of ports, cities, or villages by a naval force, should be referred for examination to another Conference.

It will be observed that the conditions upon which Powers not represented at the Conference can adhere to the Convention for the Peaceful Regulation of International Conflicts is to "form the subject of a later agreement between the Contracting Powers." This provision reflects the outcome of a three days' debate in the Drafting Committee as to whether this Convention should be absolutely open, or open only with the consent of the Contracting Powers. England and Italy strenuously supported the latter view. It soon became apparent that, under the guise of general propositions, the Committee was discussing political questions, of great importance at least to certain Powers. Under these circumstances the representatives of the United States took no part in the discussion, but supported by their vote the view that the Convention, in its nature, involved reciprocal obligations; and also the conclusion that political questions had no place in the Conference, and must be left to be decided by the competent authorities of the Powers represented there.

It is to be regretted that this action excludes from immediate adherence to this Convention our sister Republics of Central and South America, with whom the United States is already in similar relations by the Pan-American Treaty. It is hoped that an arrangement will soon be made which will enable these States, if they so desire, to enter into the same relations as ourselves with the Powers represented at the Conference.

This report should not be closed without an acknowledgment of the great and constant courtesy of the Government of the Netherlands and all its representatives to the American Commission as well as to all the members of the Conference. In every way they have sought to aid us in our work and to make our stay agreeable to us. The accommodations they have provided for the Conference have enhanced its dignity and increased its efficiency.

It may also be well to put on record that from the entire Conference, without exception, we have constantly received marks of kindness, and that although so many nations with different interests were represented, there has not been in any session, whether of the Conference or of any of the committees or subcommittees, anything other than calm and courteous debate.

The text of the Final Act of the various Conventions and Declarations referred to therein, is appended to this report.

All of which is most respectfully submitted:
ANDREW D. WHITE, President,
SETH LOW,
STANFORD NEWEL,
A. T. MAHAN,
WILLIAM CROZIER,
FREDERICK W. HOLLS, Secretary.

FINAL ACT OF THE INTERNATIONAL PEACE CONFERENCE; JULY 29, 1899

The International Peace Conference, convoked in the best interests of humanity by His Majesty the Emperor of All the Russias, assembled, on the invitation of the Government of Her Majesty the Queen of the Netherlands, in the Royal House in the Wood at The Hague on the 18th May, 1899.

The Powers enumerated in the following list took part in the Conference, to which they appointed the Delegates named below:

[List of Plenipotentiaries]

In a series of meetings, between the 18th May and the 29th July, 1899, in which the constant desire of the Delegates above mentioned has been to realize, in the fullest manner possible, the generous views of the August Initiator of the Conference and the intentions of their Governments, the Conference has agreed, for submission for signature by the Plenipotentiaries, on the text of the Conventions and Declarations enumerated below and annexed to the present Act:

I. Convention for the peaceful adjustment of international differences.

II. Convention regarding the laws and customs of war by land.

III. Convention for the adaptation to maritime warfare of the principles of the Geneva Convention of the 22d August, 1864.

IV. Three Declarations:

1. To prohibit the launching of projectiles and explosives from balloons or by other similar new methods.
2. To prohibit the use of projectiles the only object of which is the diffusion of asphyxiating or deleterious gases.
3. To prohibit the use of bullets which expand or flatten easily in the human body, such as bullets with a hard envelope, of which the envelope does not entirely cover the core, or is pierced with incisions.

These Conventions and Declarations shall form so many separate Acts. These Acts shall be dated this day, and may be signed up to the 31st December, 1899, by the Plenipotentiaries of the Powers represented at the International Peace Conference at The Hague.

Guided by the same sentiments, the Conference has adopted unanimously the following Resolution:

"The Conference is of opinion that the restriction of military charges, which are at present a heavy burden on the world, is extremely desirable for the increase of the material and moral welfare of mankind."

It has, besides, formulated the following wishes:

1. The Conference, taking into consideration the preliminary step taken by the Swiss Federal Government for the revision of the Geneva Convention, expresses the wish that steps may be shortly taken for the assembly of a Special Conference having for its object the revision of that convention.

This wish was voted unanimously.

2. The Conference expresses the wish that the questions of the rights and duties of neutrals may be inserted in the programme of a Conference in the near future.
3. The Conference expresses the wish that the questions with regard to rifles and naval guns, as considered by it, may be studied by the Governments with the object of coming to an agreement respecting the employment of new types and calibers.
4. The Conference expresses the wish that the Governments, taking into consideration the proposals made at the Conference, may examine the possibility of an agreement as to the limitation of armed forces by land and sea, and of war budgets.
5. The Conference expresses the wish that the proposal, which contemplates the declaration of the inviolability of private property in naval warfare, may be referred to a subsequent Conference for consideration.
6. The Conference expresses the wish that the proposal to settle the question of the bombardment of posts, towns, and villages by a naval force may be referred to a subsequent Conference for consideration.

The last five wishes were voted unanimously, saving some abstentions.

In faith of which, the Plenipotentiaries have signed the present Act, and have affixed their seals thereto.

Done at The Hague, 29th July, 1899, in one copy only, which shall be deposited in the Ministry for Foreign Affairs, and of which copies, duly certified, shall be delivered to all the Powers represented at the Conference.

[Signatures.]

Geneva Protocol (1925)

PROTOCOL FOR THE PROHIBITION OF THE USE IN WAR OF ASPHYXIATING, POISONOUS OR OTHER GASES, AND OF BACTERIOLOGICAL METHODS OF WARFARE

Opened for signature: 17 June 1925, entered into force: 8 February 1928.

The undersigned Plenipotentiaries, in the name of their respective governments:

Whereas the use in war of asphyxiating, poisonous or other gases, and of all analogous liquids, materials or devices, has been justly condemned by the general opinion of the civilised world; and

Whereas the prohibition of such use has been declared in Treaties to which the majority of Powers of the world are Parties; and

To the end that this prohibition shall be universally accepted as a part of International Law, binding alike the conscience and the practice of nations;

Declare:

That the High Contracting Parties, so far as they are not already Parties to Treaties prohibiting such use, accept this prohibition, agree to extend this prohibition to the use of bacteriological methods of warfare and agree to be bound as between themselves according to the terms of this declaration.

The High Contracting Parties will exert every effort to induce other States to accede to the present Protocol. Such accession will be notified to the Government of the French Republic, and by the latter to all signatories and acceding Powers, and will take effect on the date of the notification by the Government of the French Republic.

The present Protocol, of which the English and French texts are both authentic, shall be ratified as soon as possible. It shall bear to-day's date.

The ratifications of the present Protocol shall be addressed to the Government of the French Republic, which will at once notify the deposit of such ratification to each of the signatory and acceding Powers.

The instruments of ratification of and accession to the present Protocol will remain deposited in the archives of the Government of the French Republic.

The present Protocol will come into force for each signatory Power as from the date of deposit of its ratification, and, from that moment, each Power will be bound as regards other Powers which have already deposited their ratifications.

In witness whereof the Plenipotentiaries have signed the present Protocol.

Done at Geneva in a single copy, the seventeenth day of June, One Thousand Nine Hundred and Twenty-Five.

Biological and Toxin Weapons Convention (1972)

CONVENTION ON THE PROHIBITION OF THE DEVELOPMENT, PRODUCTION AND STOCKPILING OF BACTERIOLOGICAL (BIOLOGICAL) AND TOXIN WEAPONS AND ON THEIR DESTRUCTION

Signed at Washington, London, and Moscow April 10, 1972

Ratification advised by U.S. Senate December 16, 1974

Ratified by U.S. President January 22, 1975

U.S. ratification deposited at Washington, London, and Moscow March 26, 1975

Proclaimed by U.S. President March 26, 1975

Entered into force March 26, 1975

The States Parties to this Convention,

Determined to act with a view to achieving effective progress towards general and complete disarmament, including the prohibition and elimination of all types of weapons of mass destruction, and convinced that the prohibition of the development, production and stockpiling of chemical and bacteriological (biological) weapons and their elimination, through effective measures, will facilitate the achievement of general and complete disarmament under strict and effective international control,

Recognizing the important significance of the Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous or Other Gases, and of Bacteriological Methods of Warfare, signed at Geneva on June 17, 1925, and conscious also of the contribution which the said Protocol has already made, and continues to make, to mitigating the horrors of war,

Reaffirming their adherence to the principles and objectives of that Protocol and calling upon all States to comply strictly with them,

Recalling that the General Assembly of the United Nations has repeatedly condemned all actions contrary to the principles and objectives of the Geneva Protocol of June 17, 1925,

Desiring to contribute to the strengthening of confidence between peoples and the general improvement of the international atmosphere,

Desiring also to contribute to the realization of the purposes and principles of the Charter of the United Nations,

Convinced of the importance and urgency of eliminating from the arsenals of States, through effective measures, such dangerous weapons of mass destruction as those using chemical or bacteriological (biological) agents,

Recognizing that an agreement on the prohibition of bacteriological (biological) and toxin weapons represents a first possible step towards the achievement of agreement on effective measures also for the prohibition of the development, production and stockpiling of chemical weapons, and determined to continue negotiations to that end,

Determined, for the sake of all mankind, to exclude completely the possibility of bacteriological (biological) agents and toxins being used as weapons,

Convinced that such use would be repugnant to the conscience of mankind and that no effort should be spared to minimize this risk,

Have agreed as follows:

ARTICLE I

Each State Party to this Convention undertakes never in any circumstances to develop, produce, stockpile or otherwise acquire or retain:

1. Microbial or other biological agents, or toxins whatever their origin or method of production, of types and in quantities that have no justification for prophylactic, protective or other peaceful purposes;
2. Weapons, equipment or means of delivery designed to use such agents or toxins for hostile purposes or in armed conflict.

ARTICLE II

Each State Party to this Convention undertakes to destroy, or to divert to peaceful purposes, as soon as possible but not later than nine months after the entry into force of the Convention, all agents, toxins, weapons, equipment and means of delivery specified in article I of the Convention, which are in its possession or under its jurisdiction or control. In implementing the provisions of this article all necessary safety precautions shall be observed to protect populations and the environment.

ARTICLE III

Each State Party to this Convention undertakes not to transfer to any recipient whatsoever, directly or indirectly, and not in any way to assist, encourage, or induce any State, group of States or international organizations to manufacture or otherwise acquire any of the agents, toxins, weapons, equipment or means of delivery specified in article I of the Convention.

ARTICLE IV

Each State Party to this Convention shall, in accordance with its constitutional processes, take any necessary measures to prohibit and prevent the development, production, stockpiling, acquisition, or retention of the agents, toxins, weapons, equipment and means of delivery specified in article I of the Convention, within the territory of such State, under its jurisdiction or under its control anywhere.

ARTICLE V

The States Parties to this Convention undertake to consult one another and to cooperate in solving any problems which may arise in relation to the objective of, or in the application of the provisions of, the Convention. Consultation and cooperation pursuant to this article may also be undertaken through appropriate international procedures within the framework of the United Nations and in accordance with its Charter.

ARTICLE VI

1. Any State Party to this Convention which finds that any other State Party is acting in breach of obligations deriving from the provisions of the Convention may lodge a complaint with the Security Council of the United Nations. Such a complaint should include all possible evidence confirming its validity, as well as a request for its consideration by the Security Council.
2. Each State Party to this Convention undertakes to cooperate in carrying out any investigation which the Security Council may initiate, in accordance with the provisions of the Charter of the United Nations, on the basis of the complaint received by the Council. The Security Council shall inform the States Parties to the Convention of the results of the investigation.

ARTICLE VII

Each State Party to this Convention undertakes to provide or support assistance, in accordance with the United Nations Charter, to any Party to the Convention which so requests, if the Security Council decides that such Party has been exposed to danger as a result of violation of the Convention.

ARTICLE VIII

Nothing in this Convention shall be interpreted as in any way limiting or detracting from the obligations assumed by any State under the Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous or Other Gases, and of Bacteriological Methods of Warfare, signed at Geneva on June 17, 1925.

ARTICLE IX

Each State Party to this Convention affirms the recognized objective of effective prohibition of chemical weapons and, to this end, undertakes to continue negotiations in good faith with a view to reaching early agreement on effective measures for the prohibition of their development, production and stockpiling and for their destruction, and on appropriate measures concerning equipment and means of delivery specifically designed for the production or use of chemical agents for weapons purposes.

ARTICLE X

1. The States Parties to this Convention undertake to facilitate, and have the right to participate in, the fullest possible exchange of equipment, materials and scientific and technological information for the use of bacteriological (biological) agents and toxins for peaceful purposes. Parties to the Convention in a position to do so shall also cooperate in contributing individually or together with other States or international organizations to the further development and application of scientific discoveries in the field of bacteriology (biology) for prevention of disease, or for other peaceful purposes.
2. This Convention shall be implemented in a manner designed to avoid hampering the economic or technological development of States Parties to the Convention or international cooperation in the field of peaceful bacteriological (biological) activities, including the international exchange of bacteriological (biological) agents and toxins and equipment for the processing, use or production of bacteriological (biological) agents and toxins for peaceful purposes in accordance with the provisions of the Convention.

ARTICLE XI

Any State Party may propose amendments to this Convention. Amendments shall enter into force for each State Party accepting the amendments upon their acceptance by a majority of the States Parties to the Convention and thereafter for each remaining State Party on the date of acceptance by it.

ARTICLE XII

Five years after the entry into force of this Convention, or earlier if it is requested by a majority of Parties to the Convention by submitting a proposal to this effect to the Depositary Governments, a conference of States Parties to the Convention shall be held at Geneva, Switzerland, to review the operation of the Convention, with a view to assuring that the purposes of the preamble and the provisions of the Convention, including the provisions concerning negotiations on chemical weapons, are being realized. Such review shall take into account any new scientific and technological developments relevant to the Convention.

ARTICLE XIII

1. This Convention shall be of unlimited duration.
2. Each State Party to this Convention shall in exercising its national sovereignty have the right to withdraw from the Convention if it decides that extraordinary events, related to the subject matter of the Convention, have jeopardized the supreme interests of its country. It shall give notice of such withdrawal to all other States Parties to the Convention and to the United Nations Security Council three months in advance. Such notice shall include a statement of the extraordinary events it regards as having jeopardized its supreme interests.

ARTICLE XIV

1. This Convention shall be open to all States for signature. Any State which does not sign the Convention before its entry into force in accordance with paragraph (3) of this Article may accede to it at any time.
2. This Convention shall be subject to ratification by signatory States. Instruments of ratification and instruments of accession shall be deposited with the Governments of the United States of America, the United Kingdom of Great Britain and Northern Ireland and the Union of Soviet Socialist Republics, which are hereby designated the Depositary Governments.
3. This Convention shall enter into force after the deposit of instruments of ratification by twenty-two Governments, including the Governments designated as Depositaries of the Convention.
4. For States whose instruments of ratification or accession are deposited subsequent to the entry into force of this Convention, it shall enter into force on the date of the deposit of their instruments of ratification or accession.

5. The Depositary Governments shall promptly inform all signatory and acceding States of the date of each signature, the date of deposit of each instrument of ratification or of accession and the date of the entry into force of this Convention, and of the receipt of other notices.
6. This Convention shall be registered by the Depositary Governments pursuant to Article 102 of the Charter of the United Nations.

ARTICLE XV

This Convention, the English, Russian, French, Spanish and Chinese texts of which are equally authentic, shall be deposited in the archives of the Depositary Governments. Duly certified copies of the Convention shall be transmitted by the Depositary Governments to the Governments of the signatory and acceding states.

IN WITNESS WHEREOF the undersigned, duly authorized, have signed this Convention.

DONE in triplicate, at the cities of Washington, London and Moscow, this tenth day of April, one thousand nine hundred and seventy-two.

Chemical Weapons Convention[1] (1993)

PREAMBLE

The States Parties to this Convention,

Determined to act with a view to achieving effective progress towards general and complete disarmament under strict and effective international control, including the prohibition and elimination of all types of weapons of mass destruction,

Desiring to contribute to the realization of the purposes and principles of the Charter of the United Nations,

Recalling that the General Assembly of the United Nations has repeatedly condemned all actions contrary to the principles and objectives of the Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous or Other Gases, and of Bacteriological Methods of Warfare, signed at Geneva on 17 June 1925 (the Geneva Protocol of 1925),

Recognizing that this Convention reaffirms principles and objectives of and obligations assumed under the Geneva Protocol of 1925, and the Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on their Destruction signed at London, Moscow and Washington on 10 April 1972,

Bearing in mind the objective contained in Article IX of the Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on their Destruction,

Determined for the sake of all mankind, to exclude completely the possibility of the use of chemical weapons, through the implementation of the provisions of this Convention, thereby complementing the obligations assumed under the Geneva Protocol of 1925,

Recognizing the prohibition, embodied in the pertinent agreements and relevant principles of international law, of the use of herbicides as a method of warfare,

Considering that achievements in the field of chemistry should be used exclusively for the benefit of mankind,

Desiring to promote free trade in chemicals as well as international cooperation and exchange of scientific and technical information in the field of chemical activities for purposes not prohibited under this Convention in order to enhance the economic and technological development of all States Parties,

Convinced that the complete and effective prohibition of the development, production, acquisition, stockpiling, retention, transfer and use of chemical weapons, and their destruction, represent a necessary step towards the achievement of these common objectives,

Have agreed as follows:

ARTICLE I

GENERAL OBLIGATIONS

1. Each State Party to this Convention undertakes never under any circumstances:

(a) To develop, produce, otherwise acquire, stockpile or retain chemical weapons, or transfer, directly or indirectly, chemical weapons to anyone;
(b) To use chemical weapons;
(c) To engage in any military preparations to use chemical weapons;
(d) To assist, encourage or induce, in any way, anyone to engage in any activity prohibited to a State Party under this Convention.

2. Each State Party undertakes to destroy chemical weapons it owns or possesses, or that are located in any place under its jurisdiction or control, in accordance with the provisions of this Convention.

3. Each State Party undertakes to destroy all chemical weapons it abandoned on the territory of another State Party, in accordance with the provisions of this Convention.

4. Each State Party undertakes to destroy any chemical weapons production facilities it owns or possesses, or that are located in any place under its jurisdiction or control, in accordance with the provisions of this Convention.

5. Each State Party undertakes not to use riot control agents as a method of warfare.

ARTICLE II

DEFINITIONS AND CRITERIA

For the purposes of this Convention:

1. "Chemical Weapons" means the following, together or separately:

(a) Toxic chemicals and their precursors, except where intended for purposes not prohibited under this Convention, as long as the types and quantities are consistent with such purposes;
(b) Munitions and devices, specifically designed to cause death or other harm through the toxic properties of those toxic chemicals specified in subparagraph (a), which would be released as a result of the employment of such munitions and devices;
(c) Any equipment specifically designed for use directly in connection with the employment of munitions and devices specified in subparagraph (b).

2. "Toxic Chemical" means:

Any chemical which through its chemical action on life processes can cause death, temporary incapacitation or permanent harm to humans or animals. This includes all such chemicals, regardless of their origin or of their method of production, and regardless of whether they are produced in facilities, in munitions or elsewhere.

(For the purpose of implementing this Convention, toxic chemicals which have been identified for the application of verification measures are listed in Schedules contained in the Annex on Chemicals.)

3. "Precursor" means:

Any chemical reactant which takes part at any stage in the production by whatever method of a toxic chemical. This includes any key component of a binary or multicomponent chemical system.

(For the purpose of implementing this Convention, precursors which have been identified for the application of verification measures are listed in Schedules contained in the Annex on Chemicals.)

4. "Key Component of Binary or Multicomponent Chemical Systems" (hereinafter referred to as "key component") means:

The precursor which plays the most important role in determining the toxic properties of the final product and reacts rapidly with other chemicals in the binary or multicomponent system.

5. "Old Chemical Weapons" means:

(a) Chemical weapons which were produced before 1925; or
(b) Chemical weapons produced in the period between 1925 and 1946 that have deteriorated to such extent that they can no longer be used as chemical weapons.

6. "Abandoned Chemical Weapons" means:

Chemical weapons, including old chemical weapons, abandoned by a State after 1 January 1925 on the territory of another State without the consent of the latter.

7. "Riot Control Agent" means:

Any chemical not listed in a Schedule, which can produce rapidly in humans sensory irritation or disabling physical effects which disappear within a short time following termination of exposure.

8. "Chemical Weapons Production Facility":

(a) Means any equipment, as well as any building housing such equipment, that was designed, constructed or used at any time since 1 January 1946:

(i). As part of the stage in the production of chemicals ("final technological stage") where the material flows would contain, when the equipment is in operation:
(1) Any chemical listed in Schedule 1 in the Annex on Chemicals; or
(2) Any other chemical that has no use, above 1 tonne per year on the territory of a State Party or in any other place under the jurisdiction or control of a State Party, for purposes not prohibited under this Convention, but can be used for chemical weapons purposes; or

(ii). For filling chemical weapons, including, inter alia, the filling of chemicals listed in Schedule 1 into munitions, devices or bulk storage containers; the filling of chemicals into containers that form part of assembled binary munitions and devices or into chemical submunitions that form part of assembled unitary munitions and devices, and the loading of the containers and chemical submunitions into the respective munitions and devices;

(b) Does not mean:

(i). Any facility having a production capacity for synthesis of chemicals specified in subparagraph (a) (i) that is less than 1 tonne;

(ii). Any facility in which a chemical specified in subparagraph (a) (i) is or was produced as an unavoidable by-product of activities for purposes not prohibited under this Convention, provided that the chemical does not exceed 3 per cent of the total product and that the facility is subject to declaration and inspection under the Annex on Implementation and Verification (hereinafter referred to as "Verification Annex"); or

(iii). The single small-scale facility for production of chemicals listed in Schedule 1 for purposes not prohibited under this Convention as referred to in Part VI of the Verification Annex.

9. "Purposes Not Prohibited Under this Convention" means

(a) Industrial, agricultural, research, medical, pharmaceutical or other peaceful purposes;
(b) Protective purposes, namely those purposes directly related to protection against toxic chemicals and to protection against chemical weapons;
(c) Military purposes not connected with the use of chemical weapons and not dependent on the use of the toxic properties of chemicals as a method of warfare;
(d) Law enforcement including domestic riot control purposes.

10. "Production Capacity" means:

The annual quantitative potential for manufacturing a specific chemical based on the technological process actually used or, if the process is not yet operational, planned to be used at the relevant facility. It shall be deemed to be equal to the nameplate capacity or, if the nameplate capacity is not available, to the design capacity. The nameplate capacity is the product output under conditions optimized for maximum quantity for the production facility, as demonstrated by one or more test-runs. The design capacity is the corresponding theoretically calculated product output.

11. "Organization" means the Organization for the Prohibition of Chemical Weapons established pursuant to Article VIII of this Convention.

12. For the purposes of Article VI:

(a) "Production" of a chemical means its formation through chemical reaction;
(b) "Processing" of a chemical means a physical process, such as formulation, extraction and purification, in which a chemical is not converted into another chemical;
(c) "Consumption" of a chemical means its conversion into another chemical via a chemical reaction.

ARTICLE III

DECLARATIONS

1. Each State Party shall submit to the Organization, not later than 30 days after this Convention enters into force for it, the following declarations, in which it shall:

(a) With respect to chemical weapons:

(i) Declare whether it owns or possesses any chemical weapons, or whether there are any chemical weapons located in any place under its jurisdiction or control;
(ii) Specify the precise location, aggregate quantity and detailed inventory of chemical weapons it owns or possesses, or that are located in any place under its jurisdiction or control, in accordance with Part IV (A), paragraphs 1 to 3, of the Verification Annex, except for those chemical weapons referred to in sub-subparagraph (iii);
(iii) Report any chemical weapons on its territory that are owned and possessed by another State and located in any place under the jurisdiction or control of another State, in accordance with Part IV (A), paragraph 4, of the Verification Annex;
(iv) Declare whether it has transferred or received, directly or indirectly, any chemical weapons since 1 January 1946 and specify the transfer or receipt of such weapons, in accordance with Part IV (A), paragraph 5, of the Verification Annex;
(v) Provide its general plan for destruction of chemical weapons that it owns or possesses, or that are located in any place under its jurisdiction or control, in accordance with Part IV (A), paragraph 6, of the Verification Annex;

(b) With respect to old chemical weapons and abandoned chemical weapons:

(i) Declare whether it has on its territory old chemical weapons and provide all available information in accordance with Part IV (B), paragraph 3, of the Verification Annex;
(ii) Declare whether there are abandoned chemical weapons on its territory and provide all available information in accordance with Part IV (B), paragraph 8, of the Verification Annex;
(iii) Declare whether it has abandoned chemical weapons on the territory of other States and provide all available information in accordance with Part IV (B), paragraph 10, of the Verification Annex;

(c) With respect to chemical weapons production facilities:

(i) Declare whether it has or has had any chemical weapons production facility under its ownership or possession, or that is or has been located in any place under its jurisdiction or control at any time since 1 January 1946;
(ii) Specify any chemical weapons production facility it has or has had under its ownership or possession or that is or has been located in any place under its jurisdiction or control at any time since 1 January 1946, in accordance with Part V, paragraph 1, of the Verification Annex, except for those facilities referred to in sub-subparagraph (iii);
(iii) Report any chemical weapons production facility on its territory that another State has or has had under its ownership and possession and that is or has been located in any place

under the jurisdiction or control of another State at any time since 1 January 1946, in accordance with Part V, paragraph 2, of the Verification Annex;

(iv) Declare whether it has transferred or received, directly or indirectly, any equipment for the production of chemical weapons since 1 January 1946 and specify the transfer or receipt of such equipment, in accordance with Part V, paragraphs 3 to 5, of the Verification Annex;

(v) Provide its general plan for destruction of any chemical weapons production facility it owns or possesses, or that is located in any place under its jurisdiction or control, in accordance with Part V, paragraph 6, of the Verification Annex;

(vi) Specify actions to be taken for closure of any chemical weapons production facility it owns or possesses, or that is located in any place under its jurisdiction or control, in accordance with Part V, paragraph 1 (i), of the Verification Annex;

(vii) Provide its general plan for any temporary conversion of any chemical weapons production facility it owns or possesses, or that is located in any place under its jurisdiction or control, into a chemical weapons destruction facility, in accordance with Part V, paragraph 7, of the Verification Annex;

(d) With respect to other facilities: Specify the precise location, nature and general scope of activities of any facility or establishment under its ownership or possession, or located in any place under its jurisdiction or control, and that has been designed, constructed or used since 1 January 1946 primarily for development of chemical weapons. Such declaration shall include, inter alia, laboratories and test and evaluation sites;

(e) With respect to riot control agents: Specify the chemical name, structural formula and Chemical Abstracts Service (CAS) registry number, if assigned, of each chemical it holds for riot control purposes. This declaration shall be updated not later than 30 days after any change becomes effective.

2. The provisions of this Article and the relevant provisions of Part IV of the Verification Annex shall not, at the discretion of a State Party, apply to chemical weapons buried on its territory before 1 January 1977 and which remain buried, or which had been dumped at sea before 1 January 1985.

ARTICLE IV

CHEMICAL WEAPONS

1. The provisions of this Article and the detailed procedures for its implementation shall apply to all chemical weapons owned or possessed by a State Party, or that are located in any place under its jurisdiction or control, except old chemical weapons and abandoned chemical weapons to which Part IV (B) of the Verification Annex applies.

2. Detailed procedures for the implementation of this Article are set forth in the Verification Annex.

3. All locations at which chemical weapons specified in paragraph 1 are stored or destroyed shall be subject to systematic verification through on-site inspection and monitoring with on-site instruments, in accordance with Part IV (A) of the Verification Annex.

4. Each State Party shall, immediately after the declaration under Article III,

paragraph 1 (a), has been submitted, provide access to chemical weapons specified in paragraph 1 for the purpose of systematic verification of the declaration through on-site inspection. Thereafter, each State Party shall not remove any of these chemical weapons, except to a chemical weapons destruction facility. It shall provide access to such chemical weapons, for the purpose of systematic on-site verification.

5. Each State Party shall provide access to any chemical weapons destruction facilities and their storage areas, that it owns or possesses, or that are located in any place under its jurisdiction or control, for the purpose of systematic verification through on-site inspection and monitoring with on-site instruments.

6. Each State Party shall destroy all chemical weapons specified in paragraph 1 pursuant to the Verification Annex and in accordance with the agreed rate and sequence of destruction (hereinafter referred to as "order of destruction"). Such destruction shall begin not later than two years after this Convention enters into force for it and shall finish not later than 10 years after entry into force of this Convention. A State Party is not precluded from destroying such chemical weapons at a faster rate.

7. Each State Party shall:

(a) Submit detailed plans for the destruction of chemical weapons specified in paragraph 1 not later than 60 days before each annual destruction period begins, in accordance with Part IV (A), paragraph 29, of the Verification Annex; the detailed plans shall encompass all stocks to be destroyed during the next annual destruction period;

(b) Submit declarations annually regarding the implementation of its plans for destruction of chemical weapons specified in paragraph 1, not later

than 60 days after the end of each annual destruction period; and
(c) Certify, not later than 30 days after the destruction process has been completed, that all chemical weapons specified in paragraph 1 have been destroyed.

8. If a State ratifies or accedes to this Convention after the 10-year period for destruction set forth in paragraph 6, it shall destroy chemical weapons specified in paragraph 1 as soon as possible. The order of destruction and procedures for stringent verification for such a State Party shall be determined by the Executive Council.

9. Any chemical weapons discovered by a State Party after the initial declaration of chemical weapons shall be reported, secured and destroyed in accordance with Part IV (A) of the Verification Annex.

10. Each State Party, during transportation, sampling, storage and destruction of chemical weapons, shall assign the highest priority to ensuring the safety of people and to protecting the environment. Each State Party shall transport, sample, store and destroy chemical weapons in accordance with its national standards for safety and emissions.

11. Any State Party which has on its territory chemical weapons that are owned or possessed by another State, or that are located in any place under the jurisdiction or control of another State, shall make the fullest efforts to ensure that these chemical weapons are removed from its territory not later than one year after this Convention enters into force for it. If they are not removed within one year, the State Party may request the Organization and other States Parties to provide assistance in the destruction of these chemical weapons.

12. Each State Party undertakes to cooperate with other States Parties that request information or assistance on a bilateral basis or through the Technical Secretariat regarding methods and technologies for the safe and efficient destruction of chemical weapons.

13. In carrying out verification activities pursuant to this Article and Part IV (A) of the Verification Annex, the Organization shall consider measures to avoid unnecessary duplication of bilateral or multilateral agreements on verification of chemical weapons storage and their destruction among States Parties.

To this end, the Executive Council shall decide to limit verification to measures complementary to those undertaken pursuant to such a bilateral or multilateral agreement, if it considers that:

(a) Verification provisions of such an agreement are consistent with the verification provisions of this Article and Part IV (A) of the Verification Annex;
(b) Implementation of such an agreement provides for sufficient assurance of compliance with the relevant provisions of this Convention; and
(c) Parties to the bilateral or multilateral agreement keep the Organization fully informed about their verification activities.

14. If the Executive Council takes a decision pursuant to paragraph 13, the Organization shall have the right to monitor the implementation of the bilateral or multilateral agreement.

15. Nothing in paragraphs 13 and 14 shall affect the obligation of a State Party to provide declarations pursuant to Article III, this Article and Part IV (A) of the Verification Annex.

16. Each State Party shall meet the costs of destruction of chemical weapons it is obliged to destroy. It shall also meet the costs of verification of storage and destruction of these chemical weapons unless the Executive Council decides otherwise. If the Executive Council decides to limit verification measures of the Organization pursuant to paragraph 13, the costs of complementary verification and monitoring by the Organization shall be paid in accordance with the United Nations scale of assessment, as specified in Article VIII, paragraph 7.

17. The provisions of this Article and the relevant provisions of Part IV of the Verification Annex shall not, at the discretion of a State Party, apply to chemical weapons buried on its territory before 1 January 1977 and which remain buried, or which had been dumped at sea before 1 January 1985.

ARTICLE V

CHEMICAL WEAPONS PRODUCTION FACILITIES

1. The provisions of this Article and the detailed procedures for its implementation shall apply to any and all chemical weapons production facilities owned or possessed by a State Party, or that are located in any place under its jurisdiction or control.

2. Detailed procedures for the implementation of this Article are set forth in the Verification Annex.

3. All chemical weapons production facilities specified in paragraph 1 shall be subject to systematic verification through on-site inspection and monitoring with on-site instruments in accordance with Part V of the Verification Annex.

4. Each State Party shall cease immediately all activity at chemical weapons production facilities specified in paragraph 1, except activity required for closure.

5. No State Party shall construct any new chemical weapons production facilities or modify any existing

facilities for the purpose of chemical weapons production or for any other activity prohibited under this Convention.

6. Each State Party shall, immediately after the declaration under Article III, paragraph 1 (c), has been submitted, provide access to chemical weapons production facilities specified in paragraph 1, for the purpose of systematic verification of the declaration through on-site inspection.

7. Each State Party shall:

(a) Close, not later than 90 days after this Convention enters into force for it, all chemical weapons production facilities specified in paragraph 1, in accordance with Part V of the Verification Annex, and give notice thereof; and
(b) Provide access to chemical weapons production facilities specified in paragraph 1, subsequent to closure, for the purpose of systematic verification through on-site inspection and monitoring with on-site instruments in order to ensure that the facility remains closed and is subsequently destroyed.

8. Each State Party shall destroy all chemical weapons production facilities specified in paragraph 1 and related facilities and equipment, pursuant to the Verification Annex and in accordance with an agreed rate and sequence of destruction (hereinafter referred to as "order of destruction"). Such destruction shall begin not later than one year after this Convention enters into force for it, and shall finish not later than 10 years after entry into force of this Convention. A State Party is not precluded from destroying such facilities at a faster rate.

9. Each State Party shall:

(a) Submit detailed plans for destruction of chemical weapons production facilities specified in paragraph 1, not later than 180 days before the destruction of each facility begins;
(b) Submit declarations annually regarding the implementation of its plans for the destruction of all chemical weapons production facilities specified in paragraph 1, not later than 90 days after the end of each annual destruction period; and
(c) Certify, not later than 30 days after the destruction process has been completed, that all chemical weapons production facilities specified in paragraph 1 have been destroyed.

10. If a State ratifies or accedes to this Convention after the 10-year period for destruction set forth in paragraph 8, it shall destroy chemical weapons production facilities specified in paragraph 1 as soon as possible. The order of destruction and procedures for stringent verification for such a State Party shall be determined by the Executive Council.

11. Each State Party, during the destruction of chemical weapons production facilities, shall assign the highest priority to ensuring the safety of people and to protecting the environment. Each State Party shall destroy chemical weapons production facilities in accordance with its national standards for safety and emissions.

12. Chemical weapons production facilities specified in paragraph 1 may be temporarily converted for destruction of chemical weapons in accordance with Part V, paragraphs 18 to 25, of the Verification Annex. Such a converted facility must be destroyed as soon as it is no longer in use for destruction of chemical weapons but, in any case, not later than 10 years after entry into force of this Convention.

13. A State Party may request, in exceptional cases of compelling need, permission to use a chemical weapons production facility specified in paragraph 1 for purposes not prohibited under this Convention. Upon the recommendation of the Executive Council, the Conference of the States Parties shall decide whether or not to approve the request and shall establish the conditions upon which approval is contingent in accordance with Part V, Section D, of the Verification Annex.

14. The chemical weapons production facility shall be converted in such a manner that the converted facility is not more capable of being reconverted into a chemical weapons production facility than any other facility used for industrial, agricultural, research, medical, pharmaceutical or other peaceful purposes not involving chemicals listed in Schedule 1.

15. All converted facilities shall be subject to systematic verification through on-site inspection and monitoring with on-site instruments in accordance with Part V, Section D, of the Verification Annex.

16. In carrying out verification activities pursuant to this Article and Part V of the Verification Annex, the Organization shall consider measures to avoid unnecessary duplication of bilateral or multilateral agreements on verification of chemical weapons production facilities and their destruction among States Parties.

To this end, the Executive Council shall decide to limit the verification to measures complementary to those undertaken pursuant to such a bilateral or multilateral agreement, if it considers that:

(a) Verification provisions of such an agreement are consistent with the verification provisions of this Article and Part V of the Verification Annex;
(b) Implementation of the agreement provides for sufficient assurance of compliance with the relevant provisions of this Convention; and

(c) Parties to the bilateral or multilateral agreement keep the Organization fully informed about their verification activities.

17. If the Executive Council takes a decision pursuant to paragraph 16, the Organization shall have the right to monitor the implementation of the bilateral or multilateral agreement.

18. Nothing in paragraphs 16 and 17 shall affect the obligation of a State Party to make declarations pursuant to Article III, this Article and Part V of the Verification Annex.

19. Each State Party shall meet the costs of destruction of chemical weapons production facilities it is obliged to destroy. It shall also meet the costs of verification under this Article unless the Executive Council decides otherwise. If the Executive Council decides to limit verification measures of the Organization pursuant to paragraph 16, the costs of complementary verification and monitoring by the Organization shall be paid in accordance with the United Nations scale of assessment, as specified in Article VIII, paragraph 7.

ARTICLE VI

ACTIVITIES NOT PROHIBITED UNDER THIS CONVENTION

1. Each State Party has the right, subject to the provisions of this Convention, to develop, produce, otherwise acquire, retain, transfer and use toxic chemicals and their precursors for purposes not prohibited under this Convention.

2. Each State Party shall adopt the necessary measures to ensure that toxic chemicals and their precursors are only developed, produced, otherwise acquired, retained, transferred, or used within its territory or in any other place under its jurisdiction or control for purposes not prohibited under this Convention. To this end, and in order to verify that activities are in accordance with obligations under this Convention, each State Party shall subject toxic chemicals and their precursors listed in Schedules 1, 2 and 3 of the Annex on Chemicals, facilities related to such chemicals, and other facilities as specified in the Verification Annex, that are located on its territory or in any other place under its jurisdiction or control, to verification measures as provided in the Verification Annex.

3. Each State Party shall subject chemicals listed in Schedule 1 (hereinafter referred to as "Schedule 1 chemicals") to the prohibitions on production, acquisition, retention, transfer and use as specified in Part VI of the Verification Annex. It shall subject Schedule 1 chemicals and facilities specified in Part VI of the Verification Annex to systematic verification through on-site inspection and monitoring with on-site instruments in accordance with that Part of the Verification Annex.

4. Each State Party shall subject chemicals listed in Schedule 2 (hereinafter referred to as "Schedule 2 chemicals") and facilities specified in Part VII of the Verification Annex to data monitoring and on-site verification in accordance with that Part of the Verification Annex.

5. Each State Party shall subject chemicals listed in Schedule 3 (hereinafter referred to as "Schedule 3 chemicals") and facilities specified in Part VIII of the Verification Annex to data monitoring and on-site verification in accordance with that Part of the Verification Annex.

6. Each State Party shall subject facilities specified in Part IX of the Verification Annex to data monitoring and eventual on-site verification in accordance with that Part of the Verification Annex unless decided otherwise by the Conference of the States Parties pursuant to Part IX, paragraph 22, of the Verification Annex.

7. Not later than 30 days after this Convention enters into force for it, each State Party shall make an initial declaration on relevant chemicals and facilities in accordance with the Verification Annex.

8. Each State Party shall make annual declarations regarding the relevant chemicals and facilities in accordance with the Verification Annex.

9. For the purpose of on-site verification, each State Party shall grant to the inspectors access to facilities as required in the Verification Annex.

10. In conducting verification activities, the Technical Secretariat shall avoid undue intrusion into the State Party's chemical activities for purposes not prohibited under this Convention and, in particular, abide by the provisions set forth in the Annex on the Protection of Confidential Information (hereinafter referred to as "Confidentiality Annex").

11. The provisions of this Article shall be implemented in a manner which avoids hampering the economic or technological development of States Parties, and international cooperation in the field of chemical activities for purposes not prohibited under this Convention including the international exchange of scientific and technical information and chemicals and equipment for the production, processing or use of chemicals for purposes not prohibited under this Convention.

ARTICLE VII

NATIONAL IMPLEMENTATION MEASURES

General undertakings

1. Each State Party shall, in accordance with its constitutional processes, adopt the necessary measures to implement its obligations under this Convention. In particular, it shall:

(a) Prohibit natural and legal persons anywhere on its territory or in any other place under its jurisdiction as recognized by international law from undertaking any activity prohibited to a State Party under this Convention, including enacting penal legislation with respect to such activity;
(b) Not permit in any place under its control any activity prohibited to a State Party under this Convention; and
(c) Extend its penal legislation enacted under subparagraph (a) to any activity prohibited to a State Party under this Convention undertaken anywhere by natural persons, possessing its nationality, in conformity with international law.

2. Each State Party shall cooperate with other States Parties and afford the appropriate form of legal assistance to facilitate the implementation of the obligations under paragraph 1.

3. Each State Party, during the implementation of its obligations under this Convention, shall assign the highest priority to ensuring the safety of people and to protecting the environment, and shall cooperate as appropriate with other States Parties in this regard.

Relations between the State Party and the Organization

4. In order to fulfil its obligations under this Convention, each State Party shall designate or establish a National Authority to serve as the national focal point for effective liaison with the Organization and other States Parties. Each State Party shall notify the Organization of its National Authority at the time that this Convention enters into force for it.

5. Each State Party shall inform the Organization of the legislative and administrative measures taken to implement this Convention.

6. Each State Party shall treat as confidential and afford special handling to information and data that it receives in confidence from the Organization in connection with the implementation of this Convention. It shall treat such information and data exclusively in connection with its rights and obligations under this Convention and in accordance with the provisions set forth in the Confidentiality Annex.

7. Each State Party undertakes to cooperate with the Organization in the exercise of all its functions and in particular to provide assistance to the Technical Secretariat.

ARTICLE VIII

THE ORGANIZATION

A. General Provisions

1. The States Parties to this Convention hereby establish the Organization for the Prohibition of Chemical Weapons to achieve the object and purpose of this Convention, to ensure the implementation of its provisions, including those for international verification of compliance with it, and to provide a forum for consultation and cooperation among States Parties.

2. All States Parties to this Convention shall be members of the Organization. A State Party shall not be deprived of its membership in the Organization.

3. The seat of the Headquarters of the Organization shall be The Hague, Kingdom of the Netherlands.

4. There are hereby established as the organs of the Organization: the Conference of the States Parties, the Executive Council, and the Technical Secretariat.

5. The Organization shall conduct its verification activities provided for under this Convention in the least intrusive manner possible consistent with the timely and efficient accomplishment of their objectives. It shall request only the information and data necessary to fulfil its responsibilities under this Convention. It shall take every precaution to protect the confidentiality of information on civil and military activities and facilities coming to its knowledge in the implementation of this Convention and, in particular, shall abide by the provisions set forth in the Confidentiality Annex.

6. In undertaking its verification activities the Organization shall consider measures to make use of advances in science and technology.

7. The costs of the Organization's activities shall be paid by States Parties in accordance with the United Nations scale of assessment adjusted to take into account differences in membership between the United Nations and this Organization, and subject to the provisions of Articles IV and V. Financial contributions of States Parties to the Preparatory Commission shall be deducted in an appropriate way from their contributions to the regular budget. The budget of the Organization shall comprise two separate chapters, one relating to administrative and other costs, and one relating to verification costs.

8. A member of the Organization which is in arrears in the payment of its financial contribution to the Organization shall have no vote in the Organization if the amount of its arrears equals or exceeds the amount of the contribution due from it for the preceding two full years. The Conference of the States Parties may, nevertheless, permit such a member to vote if it is satisfied that the failure to pay is due to conditions beyond the control of the member.

B. The Conference of the States Parties

Composition, procedures and decision-making

9. The Conference of the States Parties (hereinafter referred to as "the Conference") shall be composed of all members of this Organization. Each member shall have

one representative in the Conference, who may be accompanied by alternates and advisers.

10. The first session of the Conference shall be convened by the depositary not later than 30 days after the entry into force of this Convention.

11. The Conference shall meet in regular sessions which shall be held annually unless it decides otherwise.

12. Special sessions of the Conference shall be convened:

(a) When decided by the Conference;
(b) When requested by the Executive Council;
(c) When requested by any member and supported by one third of the members; or
(d) In accordance with paragraph 22 to undertake reviews of the operation of this Convention.

Except in the case of subparagraph (d), the special session shall be convened not later than 30 days after receipt of the request by the Director-General of the Technical Secretariat, unless specified otherwise in the request.

13. The Conference shall also be convened in the form of an Amendment Conference in accordance with Article XV, paragraph 2.

14. Sessions of the Conference shall take place at the seat of the Organization unless the Conference decides otherwise.

15. The Conference shall adopt its rules of procedure. At the beginning of each regular session, it shall elect its Chairman and such other officers as may be required. They shall hold office until a new Chairman and other officers are elected at the next regular session.

16. A majority of the members of the Organization shall constitute a quorum for the Conference.

17. Each member of the Organization shall have one vote in the Conference.

18. The Conference shall take decisions on questions of procedure by a simple majority of the members present and voting. Decisions on matters of substance should be taken as far as possible by consensus. If consensus is not attainable when an issue comes up for decision, the Chairman shall defer any vote for 24 hours and during this period of deferment shall make every effort to facilitate achievement of consensus, and shall report to the Conference before the end of this period. If consensus is not possible at the end of 24 hours, the Conference shall take the decision by a two-thirds majority of members present and voting unless specified otherwise in this Convention. When the issue arises as to whether the question is one of substance or not, that question shall be treated as a matter of substance unless otherwise decided by the Conference by the majority required for decisions on matters of substance.

Powers and functions

19. The Conference shall be the principal organ of the Organization. It shall consider any questions, matters or issues within the scope of this Convention, including those relating to the powers and functions of the Executive Council and the Technical Secretariat. It may make recommendations and take decisions on any questions, matters or issues related to this Convention raised by a State Party or brought to its attention by the Executive Council.

20. The Conference shall oversee the implementation of this Convention, and act in order to promote its object and purpose. The Conference shall review compliance with this Convention. It shall also oversee the activities of the Executive Council and the Technical Secretariat and may issue guidelines in accordance with this Convention to either of them in the exercise of their functions.

21. The Conference shall:

(a) Consider and adopt at its regular sessions the report, programme and budget of the Organization, submitted by the Executive Council, as well as consider other reports;
(b) Decide on the scale of financial contributions to be paid by States Parties in accordance with paragraph 7;
(c) Elect the members of the Executive Council;
(d) Appoint the Director-General of the Technical Secretariat (hereinafter referred to as "the Director-General");
(e) Approve the rules of procedure of the Executive Council submitted by the latter;
(f) Establish such subsidiary organs as it finds necessary for the exercise of its functions in accordance with this Convention;
(g) Foster international cooperation for peaceful purposes in the field of chemical activities;
(h) Review scientific and technological developments that could affect the operation of this Convention and, in this context, direct the Director-General to establish a Scientific Advisory Board to enable him, in the performance of his functions, to render specialized advice in areas of science and technology relevant to this Convention, to the Conference, the Executive Council or States Parties. The Scientific Advisory Board shall be composed of independent experts appointed in accordance with terms of reference adopted by the Conference;
(i) Consider and approve at its first session any draft agreements, provisions and guidelines developed by the Preparatory Commission;
(j) Establish at its first session the voluntary fund for assistance in accordance with Article X;

(k) Take the necessary measures to ensure compliance with this Convention and to redress and remedy any situation which contravenes the provisions of this Convention, in accordance with Article XII.

22. The Conference shall not later than one year after the expiry of the fifth and the tenth year after the entry into force of this Convention, and at such other times within that time period as may be decided upon, convene in special sessions to undertake reviews of the operation of this Convention. Such reviews shall take into account any relevant scientific and technological developments. At intervals of five years thereafter, unless otherwise decided upon, further sessions of the Conference shall be convened with the same objective.

C. The Executive Council

Composition, procedure and decision-making

23. The Executive Council shall consist of 41 members. Each State Party shall have the right, in accordance with the principle of rotation, to serve on the Executive Council. The members of the Executive Council shall be elected by the Conference for a term of two years. In order to ensure the effective functioning of this Convention, due regard being specially paid to equitable geographical distribution, to the importance of chemical industry, as well as to political and security interests, the Executive Council shall be composed as follows:

(a) Nine States Parties from Africa to be designated by States Parties located in this region. As a basis for this designation it is understood that, out of these nine States Parties, three members shall, as a rule, be the States Parties with the most significant national chemical industry in the region as determined by internationally reported and published data; in addition, the regional group shall agree also to take into account other regional factors in designating these three members;
(b) Nine States Parties from Asia to be designated by States Parties located in this region. As a basis for this designation it is understood that, out of these nine States Parties, four members shall, as a rule, be the States Parties with the most significant national chemical industry in the region as determined by internationally reported and published data; in addition, the regional group shall agree also to take into account other regional factors in designating these four members;
(c) Five States Parties from Eastern Europe to be designated by States Parties located in this region. As a basis for this designation it is understood that, out of these five States Parties, one member shall, as a rule, be the State Party with the most significant national chemical industry in the region as determined by internationally reported and published data; in addition, the regional group shall agree also to take into account other regional factors in designating this one member;
(d) Seven States Parties from Latin America and the Caribbean to be designated by States Parties located in this region. As a basis for this designation it is understood that, out of these seven States Parties, three members shall, as a rule, be the States Parties with the most significant national chemical industry in the region as determined by internationally reported and published data; in addition, the regional group shall agree also to take into account other regional factors in designating these three members;
(e) Ten States Parties from among Western European and other States to be designated by States Parties located in this region. As a basis for this designation it is understood that, out of these 10 States Parties, 5 members shall, as a rule, be the States Parties with the most significant national chemical industry in the region as determined by internationally reported and published data; in addition, the regional group shall agree also to take into account other regional factors in designating these five members;
(f) One further State Party to be designated consecutively by States Parties located in the regions of Asia and Latin America and the Caribbean. As a basis for this designation it is understood that this State Party shall be a rotating member from these regions.

24. For the first election of the Executive Council 20 members shall be elected for a term of one year, due regard being paid to the established numerical proportions as described in paragraph 23.

25. After the full implementation of Articles IV and V the Conference may, upon the request of a majority of the members of the Executive Council, review the composition of the Executive Council taking into account developments related to the principles specified in paragraph 23 that are governing its composition.

26. The Executive Council shall elaborate its rules of procedure and submit them to the Conference for approval.

27. The Executive Council shall elect its Chairman from among its members.

28. The Executive Council shall meet for regular sessions. Between regular sessions it shall meet as often as may be required for the fulfilment of its powers and functions.

29. Each member of the Executive Council shall have one vote. Unless otherwise specified in this Convention,

the Executive Council shall take decisions on matters of substance by a two-thirds majority of all its members. The Executive Council shall take decisions on questions of procedure by a simple majority of all its members. When the issue arises as to whether the question is one of substance or not, that question shall be treated as a matter of substance unless otherwise decided by the Executive Council by the majority required for decisions on matters of substance.

Powers and functions

30. The Executive Council shall be the executive organ of the Organization. It shall be responsible to the Conference. The Executive Council shall carry out the powers and functions entrusted to it under this Convention, as well as those functions delegated to it by the Conference. In so doing, it shall act in conformity with the recommendations, decisions and guidelines of the Conference and assure their proper and continuous implementation.

31. The Executive Council shall promote the effective implementation of, and compliance with, this Convention. It shall supervise the activities of the Technical Secretariat, cooperate with the National Authority of each State Party and facilitate consultations and cooperation among States Parties at their request.

32. The Executive Council shall:

(a) Consider and submit to the Conference the draft programme and budget of the Organization;
(b) Consider and submit to the Conference the draft report of the Organization on the implementation of this Convention, the report on the performance of its own activities and such special reports as it deems necessary or which the Conference may request;
(c) Make arrangements for the sessions of the Conference including the preparation of the draft agenda.

33. The Executive Council may request the convening of a special session of the Conference.

34. The Executive Council shall:

(a) Conclude agreements or arrangements with States and international organizations on behalf of the Organization, subject to prior approval by the Conference;
(b) Conclude agreements with States Parties on behalf of the Organization in connection with Article X and supervise the voluntary fund referred to in Article X;
(c) Approve agreements or arrangements relating to the implementation of verification activities, negotiated by the Technical Secretariat with States Parties.

35. The Executive Council shall consider any issue or matter within its competence affecting this Convention and its implementation, including concerns regarding compliance, and cases of non-compliance, and, as appropriate, inform States Parties and bring the issue or matter to the attention of the Conference.

36. In its consideration of doubts or concerns regarding compliance and cases of non-compliance, including, inter alia, abuse of the rights provided for under this Convention, the Executive Council shall consult with the States Parties involved and, as appropriate, request the State Party to take measures to redress the situation within a specified time. To the extent that the Executive Council considers further action to be necessary, it shall take, inter alia, one or more of the following measures:

(a) Inform all States Parties of the issue or matter;
(b) Bring the issue or matter to the attention of the Conference;
(c) Make recommendations to the Conference regarding measures to redress the situation and to ensure compliance.

The Executive Council shall, in cases of particular gravity and urgency, bring the issue or matter, including relevant information and conclusions, directly to the attention of the United Nations General Assembly and the United Nations Security Council. It shall at the same time inform all States Parties of this step.

D. The Technical Secretariat

37. The Technical Secretariat shall assist the Conference and the Executive Council in the performance of their functions. The Technical Secretariat shall carry out the verification measures provided for in this Convention. It shall carry out the other functions entrusted to it under this Convention as well as those functions delegated to it by the Conference and the Executive Council.

38. The Technical Secretariat shall:

(a) Prepare and submit to the Executive Council the draft programme and budget of the Organization;
(b) Prepare and submit to the Executive Council the draft report of the Organization on the implementation of this Convention and such other reports as the Conference or the Executive Council may request;
(c) Provide administrative and technical support to the Conference, the Executive Council and subsidiary organs;
(d) Address and receive communications on behalf of the Organization to and from States Parties on matters pertaining to the implementation of this Convention;

(e) Provide technical assistance and technical evaluation to States Parties in the implementation of the provisions of this Convention, including evaluation of scheduled and unscheduled chemicals.

39. The Technical Secretariat shall:

(a) Negotiate agreements or arrangements relating to the implementation of verification activities with States Parties, subject to approval by the Executive Council;
(b) Not later than 180 days after entry into force of this Convention, coordinate the establishment and maintenance of permanent stockpiles of emergency and humanitarian assistance by States Parties in accordance with Article X, paragraphs 7 (b) and (c). The Technical Secretariat may inspect the items maintained for serviceability. Lists of items to be stockpiled shall be considered and approved by the Conference pursuant to paragraph 21 (i) above;
(c) Administer the voluntary fund referred to in Article X, compile declarations made by the States Parties and register, when requested, bilateral agreements concluded between States Parties or between a State Party and the Organization for the purposes of Article X.

40. The Technical Secretariat shall inform the Executive Council of any problem that has arisen with regard to the discharge of its functions, including doubts, ambiguities or uncertainties about compliance with this Convention that have come to its notice in the performance of its verification activities and that it has been unable to resolve or clarify through its consultations with the State Party concerned.

41. The Technical Secretariat shall comprise a Director-General, who shall be its head and chief administrative officer, inspectors and such scientific, technical and other personnel as may be required.

42. The Inspectorate shall be a unit of the Technical Secretariat and shall act under the supervision of the Director-General.

43. The Director-General shall be appointed by the Conference upon the recommendation of the Executive Council for a term of four years, renewable for one further term, but not thereafter.

44. The Director-General shall be responsible to the Conference and the Executive Council for the appointment of the staff and the organization and functioning of the Technical Secretariat. The paramount consideration in the employment of the staff and in the determination of the conditions of service shall be the necessity of securing the highest standards of efficiency, competence and integrity. Only citizens of States Parties shall serve as the Director-General, as inspectors or as other members of the professional and clerical staff. Due regard shall be paid to the importance of recruiting the staff on as wide a geographical basis as possible. Recruitment shall be guided by the principle that the staff shall be kept to a minimum necessary for the proper discharge of the responsibilities of the Technical Secretariat.

45. The Director-General shall be responsible for the organization and functioning of the Scientific Advisory Board referred to in paragraph 21 (h). The Director-General shall, in consultation with States Parties, appoint members of the Scientific Advisory Board, who shall serve in their individual capacity. The members of the Board shall be appointed on the basis of their expertise in the particular scientific fields relevant to the implementation of this Convention. The Director-General may also, as appropriate, in consultation with members of the Board, establish temporary working groups of scientific experts to provide recommendations on specific issues. In regard to the above, States Parties may submit lists of experts to the Director-General.

46. In the performance of their duties, the Director-General, the inspectors and the other members of the staff shall not seek or receive instructions from any Government or from any other source external to the Organization. They shall refrain from any action that might reflect on their positions as international officers responsible only to the Conference and the Executive Council.

47. Each State Party shall respect the exclusively international character of the responsibilities of the Director-General, the inspectors and the other members of the staff and not seek to influence them in the discharge of their responsibilities.

E. Privileges and Immunities

48. The Organization shall enjoy on the territory and in any other place under the jurisdiction or control of a State Party such legal capacity and such privileges and immunities as are necessary for the exercise of its functions.

49. Delegates of States Parties, together with their alternates and advisers, representatives appointed to the Executive Council together with their alternates and advisers, the Director-General and the staff of the Organization shall enjoy such privileges and immunities as are necessary in the independent exercise of their functions in connection with the Organization.

50. The legal capacity, privileges, and immunities referred to in this Article shall be defined in agreements between the Organization and the States Parties as well as in an agreement between the Organization and the State in which the headquarters of the Organization is seated. These agreements shall be considered and approved by the Conference pursuant to paragraph 21 (i).

51. Notwithstanding paragraphs 48 and 49, the privileges and immunities enjoyed by the Director-General and the staff of the Technical Secretariat during the conduct of verification activities shall be those set forth in Part II, Section B, of the Verification Annex.

ARTICLE IX

CONSULTATIONS, COOPERATION AND FACT-FINDING

1. States Parties shall consult and cooperate, directly among themselves, or through the Organization or other appropriate international procedures, including procedures within the framework of the United Nations and in accordance with its Charter, on any matter which may be raised relating to the object and purpose, or the implementation of the provisions, of this Convention.

2. Without prejudice to the right of any State Party to request a challenge inspection, States Parties should, whenever possible, first make every effort to clarify and resolve, through exchange of information and consultations among themselves, any matter which may cause doubt about compliance with this Convention, or which gives rise to concerns about a related matter which may be considered ambiguous. A State Party which receives a request from another State Party for clarification of any matter which the requesting State Party believes causes such a doubt or concern shall provide the requesting State Party as soon as possible, but in any case not later than 10 days after the request, with information sufficient to answer the doubt or concern raised along with an explanation of how the information provided resolves the matter. Nothing in this Convention shall affect the right of any two or more States Parties to arrange by mutual consent for inspections or any other procedures among themselves to clarify and resolve any matter which may cause doubt about compliance or gives rise to a concern about a related matter which may be considered ambiguous. Such arrangements shall not affect the rights and obligations of any State Party under other provisions of this Convention.

Procedure for requesting clarification

3. A State Party shall have the right to request the Executive Council to assist in clarifying any situation which may be considered ambiguous or which gives rise to a concern about the possible non-compliance of another State Party with this Convention. The Executive Council shall provide appropriate information in its possession relevant to such a concern.

4. A State Party shall have the right to request the Executive Council to obtain clarification from another State Party on any situation which may be considered ambiguous or which gives rise to a concern about its possible non-compliance with this Convention. In such a case, the following shall apply:

(a) The Executive Council shall forward the request for clarification to the State Party concerned through the Director-General not later than 24 hours after its receipt;
(b) The requested State Party shall provide the clarification to the Executive Council as soon as possible, but in any case not later than 10 days after the receipt of the request;
(c) The Executive Council shall take note of the clarification and forward it to the requesting State Party not later than 24 hours after its receipt;
(d) If the requesting State Party deems the clarification to be inadequate, it shall have the right to request the Executive Council to obtain from the requested State Party further clarification;
(e) For the purpose of obtaining further clarification requested under subparagraph (d), the Executive Council may call on the Director-General to establish a group of experts from the Technical Secretariat, or if appropriate staff are not available in the Technical Secretariat, from elsewhere, to examine all available information and data relevant to the situation causing the concern. The group of experts shall submit a factual report to the Executive Council on its findings;
(f) If the requesting State Party considers the clarification obtained under subparagraphs (d) and (e) to be unsatisfactory, it shall have the right to request a special session of the Executive Council in which States Parties involved that are not members of the Executive Council shall be entitled to take part. In such a special session, the Executive Council shall consider the matter and may recommend any measure it deems appropriate to resolve the situation.

5. A State Party shall also have the right to request the Executive Council to clarify any situation which has been considered ambiguous or has given rise to a concern about its possible non-compliance with this Convention. The Executive Council shall respond by providing such assistance as appropriate.

6. The Executive Council shall inform the States Parties about any request for clarification provided in this Article.

7. If the doubt or concern of a State Party about a possible non-compliance has not been resolved within 60 days after the submission of the request for clarification to the Executive Council, or it believes its doubts warrant urgent consideration, notwithstanding its right to request

a challenge inspection, it may request a special session of the Conference in accordance with Article VIII, paragraph 12 (c). At such a special session, the Conference shall consider the matter and may recommend any measure it deems appropriate to resolve the situation.

Procedures for challenge inspections

8. Each State Party has the right to request an on-site challenge inspection of any facility or location in the territory or in any other place under the jurisdiction or control of any other State Party for the sole purpose of clarifying and resolving any questions concerning possible non-compliance with the provisions of this Convention, and to have this inspection conducted anywhere without delay by an inspection team designated by the Director-General and in accordance with the Verification Annex.

9. Each State Party is under the obligation to keep the inspection request within the scope of this Convention and to provide in the inspection request all appropriate information on the basis of which a concern has arisen regarding possible non-compliance with this Convention as specified in the Verification Annex. Each State Party shall refrain from unfounded inspection requests, care being taken to avoid abuse. The challenge inspection shall be carried out for the sole purpose of determining facts relating to the possible non-compliance.

10. For the purpose of verifying compliance with the provisions of this Convention, each State Party shall permit the Technical Secretariat to conduct the on-site challenge inspection pursuant to paragraph 8.

11. Pursuant to a request for a challenge inspection of a facility or location, and in accordance with the procedures provided for in the Verification Annex, the inspected State Party shall have:

(a) The right and the obligation to make every reasonable effort to demonstrate its compliance with this Convention and, to this end, to enable the inspection team to fulfil its mandate;
(b) The obligation to provide access within the requested site for the sole purpose of establishing facts relevant to the concern regarding possible non-compliance; and
(c) The right to take measures to protect sensitive installations, and to prevent disclosure of confidential information and data, not related to this Convention.

12. With regard to an observer, the following shall apply:

(a) The requesting State Party may, subject to the agreement of the inspected State Party, send a representative who may be a national either of the requesting State Party or of a third State Party, to observe the conduct of the challenge inspection.
(b) The inspected State Party shall then grant access to the observer in accordance with the Verification Annex.
(c) The inspected State Party shall, as a rule, accept the proposed observer, but if the inspected State Party exercises a refusal, that fact shall be recorded in the final report.

13. The requesting State Party shall present an inspection request for an on-site challenge inspection to the Executive Council and at the same time to the Director-General for immediate processing.

14. The Director-General shall immediately ascertain that the inspection request meets the requirements specified in Part X, paragraph 4, of the Verification Annex, and, if necessary, assist the requesting State Party in filing the inspection request accordingly. When the inspection request fulfils the requirements, preparations for the challenge inspection shall begin.

15. The Director-General shall transmit the inspection request to the inspected State Party not less than 12 hours before the planned arrival of the inspection team at the point of entry.

16. After having received the inspection request, the Executive Council shall take cognizance of the Director-General's actions on the request and shall keep the case under its consideration throughout the inspection procedure. However, its deliberations shall not delay the inspection process.

17. The Executive Council may, not later than 12 hours after having received the inspection request, decide by a three-quarter majority of all its members against carrying out the challenge inspection, if it considers the inspection request to be frivolous, abusive or clearly beyond the scope of this Convention as described in paragraph 8. Neither the requesting nor the inspected State Party shall participate in such a decision. If the Executive Council decides against the challenge inspection, preparations shall be stopped, no further action on the inspection request shall be taken, and the States Parties concerned shall be informed accordingly.

18. The Director-General shall issue an inspection mandate for the conduct of the challenge inspection. The inspection mandate shall be the inspection request referred to in paragraphs 8 and 9 put into operational terms, and shall conform with the inspection request.

19. The challenge inspection shall be conducted in accordance with Part X or, in the case of alleged use, in accordance with Part XI of the Verification Annex. The inspection team shall be guided by the principle of conducting the challenge inspection in the least intrusive

manner possible, consistent with the effective and timely accomplishment of its mission.

20. The inspected State Party shall assist the inspection team throughout the challenge inspection and facilitate its task. If the inspected State Party proposes, pursuant to Part X, Section C, of the Verification Annex, arrangements to demonstrate compliance with this Convention, alternative to full and comprehensive access, it shall make every reasonable effort, through consultations with the inspection team, to reach agreement on the modalities for establishing the facts with the aim of demonstrating its compliance.

21. The final report shall contain the factual findings as well as an assessment by the inspection team of the degree and nature of access and cooperation granted for the satisfactory implementation of the challenge inspection. The Director-General shall promptly transmit the final report of the inspection team to the requesting State Party, to the inspected State Party, to the Executive Council and to all other States Parties. The Director-General shall further transmit promptly to the Executive Council the assessments of the requesting and of the inspected States Parties, as well as the views of other States Parties which may be conveyed to the Director-General for that purpose, and then provide them to all States Parties.

22. The Executive Council shall, in accordance with its powers and functions, review the final report of the inspection team as soon as it is presented, and address any concerns as to:

(a) Whether any non-compliance has occurred;
(b) Whether the request had been within the scope of this Convention; and
(c) Whether the right to request a challenge inspection had been abused.

23. If the Executive Council reaches the conclusion, in keeping with its powers and functions, that further action may be necessary with regard to paragraph 22, it shall take the appropriate measures to redress the situation and to ensure compliance with this Convention, including specific recommendations to the Conference. In the case of abuse, the Executive Council shall examine whether the requesting State Party should bear any of the financial implications of the challenge inspection.

24. The requesting State Party and the inspected State Party shall have the right to participate in the review process. The Executive Council shall inform the States Parties and the next session of the Conference of the outcome of the process.

25. If the Executive Council has made specific recommendations to the Conference, the Conference shall consider action in accordance with Article XII.

ARTICLE X

ASSISTANCE AND PROTECTION AGAINST CHEMICAL WEAPONS

1. For the purposes of this Article, "Assistance" means the coordination and delivery to States Parties of protection against chemical weapons, including, inter alia, the following: detection equipment and alarm systems; protective equipment; decontamination equipment and decontaminants; medical antidotes and treatments; and advice on any of these protective measures.

2. Nothing in this Convention shall be interpreted as impeding the right of any State Party to conduct research into, develop, produce, acquire, transfer or use means of protection against chemical weapons, for purposes not prohibited under this Convention.

3. Each State Party undertakes to facilitate, and shall have the right to participate in, the fullest possible exchange of equipment, material and scientific and technological information concerning means of protection against chemical weapons.

4. For the purposes of increasing the transparency of national programmes related to protective purposes, each State Party shall provide annually to the Technical Secretariat information on its programme, in accordance with procedures to be considered and approved by the Conference pursuant to Article VIII, paragraph 21 (i).

5. The Technical Secretariat shall establish, not later than 180 days after entry into force of this Convention and maintain, for the use of any requesting State Party, a data bank containing freely available information concerning various means of protection against chemical weapons as well as such information as may be provided by States Parties.

The Technical Secretariat shall also, within the resources available to it, and at the request of a State Party, provide expert advice and assist the State Party in identifying how its programmes for the development and improvement of a protective capacity against chemical weapons could be implemented.

6. Nothing in this Convention shall be interpreted as impeding the right of States Parties to request and provide assistance bilaterally and to conclude individual agreements with other States Parties concerning the emergency procurement of assistance.

7. Each State Party undertakes to provide assistance through the Organization and to this end to elect to take one or more of the following measures:

(a) To contribute to the voluntary fund for assistance to be established by the Conference at its first session;
(b) To conclude, if possible not later than 180 days after this Convention enters into force for it,

agreements with the Organization concerning the procurement, upon demand, of assistance;
(c) To declare, not later than 180 days after this Convention enters into force for it, the kind of assistance it might provide in response to an appeal by the Organization. If, however, a State Party subsequently is unable to provide the assistance envisaged in its declaration, it is still under the obligation to provide assistance in accordance with this paragraph.

8. Each State Party has the right to request and, subject to the procedures set forth in paragraphs 9, 10 and 11, to receive assistance and protection against the use or threat of use of chemical weapons if it considers that:

(a) Chemical weapons have been used against it;
(b) Riot control agents have been used against it as a method of warfare; or
(c) It is threatened by actions or activities of any State that are prohibited for States Parties by Article I.

9. The request, substantiated by relevant information, shall be submitted to the Director-General, who shall transmit it immediately to the Executive Council and to all States Parties. The Director-General shall immediately forward the request to States Parties which have volunteered, in accordance with paragraphs 7 (b) and (c), to dispatch emergency assistance in case of use of chemical weapons or use of riot control agents as a method of warfare, or humanitarian assistance in case of serious threat of use of chemical weapons or serious threat of use of riot control agents as a method of warfare to the State Party concerned not later than 12 hours after receipt of the request. The Director-General shall initiate, not later than 24 hours after receipt of the request, an investigation in order to provide foundation for further action. He shall complete the investigation within 72 hours and forward a report to the Executive Council. If additional time is required for completion of the investigation, an interim report shall be submitted within the same time-frame. The additional time required for investigation shall not exceed 72 hours. It may, however, be further extended by similar periods. Reports at the end of each additional period shall be submitted to the Executive Council. The investigation shall, as appropriate and in conformity with the request and the information accompanying the request, establish relevant facts related to the request as well as the type and scope of supplementary assistance and protection needed.

10. The Executive Council shall meet not later than 24 hours after receiving an investigation report to consider the situation and shall take a decision by simple majority within the following 24 hours on whether to instruct the Technical Secretariat to provide supplementary assistance. The Technical Secretariat shall immediately transmit to all States Parties and relevant international organizations the investigation report and the decision taken by the Executive Council. When so decided by the Executive Council, the Director-General shall provide assistance immediately. For this purpose, the Director-General may cooperate with the requesting State Party, other States Parties and relevant international organizations. The States Parties shall make the fullest possible efforts to provide assistance.

11. If the information available from the ongoing investigation or other reliable sources would give sufficient proof that there are victims of use of chemical weapons and immediate action is indispensable, the Director-General shall notify all States Parties and shall take emergency measures of assistance, using the resources the Conference has placed at his disposal for such contingencies. The Director-General shall keep the Executive Council informed of actions undertaken pursuant to this paragraph.

ARTICLE XI

ECONOMIC AND TECHNOLOGICAL DEVELOPMENT

1. The provisions of this Convention shall be implemented in a manner which avoids hampering the economic or technological development of States Parties, and international cooperation in the field of chemical activities for purposes not prohibited under this Convention including the international exchange of scientific and technical information and chemicals and equipment for the production, processing or use of chemicals for purposes not prohibited under this Convention.

2. Subject to the provisions of this Convention and without prejudice to the principles and applicable rules of international law, the States Parties shall:

(a) Have the right, individually or collectively, to conduct research with, to develop, produce, acquire, retain, transfer, and use chemicals;
(b) Undertake to facilitate, and have the right to participate in, the fullest possible exchange of chemicals, equipment and scientific and technical information relating to the development and application of chemistry for purposes not prohibited under this Convention;
(c) Not maintain among themselves any restrictions, including those in any international agreements, incompatible with the obligations undertaken under this Convention, which would restrict or impede

trade and the development and promotion of scientific and technological knowledge in the field of chemistry for industrial, agricultural, research, medical, pharmaceutical or other peaceful purposes;
(d) Not use this Convention as grounds for applying any measures other than those provided for, or permitted, under this Convention nor use any other international agreement for pursuing an objective inconsistent with this Convention;
(e) Undertake to review their existing national regulations in the field of trade in chemicals in order to render them consistent with the object and purpose of this Convention.

ARTICLE XII

MEASURES TO REDRESS A SITUATION AND TO ENSURE COMPLIANCE, INCLUDING SANCTIONS

1. The Conference shall take the necessary measures, as set forth in paragraphs 2, 3 and 4, to ensure compliance with this Convention and to redress and remedy any situation which contravenes the provisions of this Convention. In considering action pursuant to this paragraph, the Conference shall take into account all information and recommendations on the issues submitted by the Executive Council.

2. In cases where a State Party has been requested by the Executive Council to take measures to redress a situation raising problems with regard to its compliance, and where the State Party fails to fulfil the request within the specified time, the Conference may, inter alia, upon the recommendation of the Executive Council, restrict or suspend the State Party's rights and privileges under this Convention until it undertakes the necessary action to conform with its obligations under this Convention.

3. In cases where serious damage to the object and purpose of this Convention may result from activities prohibited under this Convention, in particular by Article I, the Conference may recommend collective measures to States Parties in conformity with international law.

4. The Conference shall, in cases of particular gravity, bring the issue, including relevant information and conclusions, to the attention of the United Nations General Assembly and the United Nations Security Council.

ARTICLE XIII

RELATIONS TO OTHER INTERNATIONAL AGREEMENTS

Nothing in this Convention shall be interpreted as in any way limiting or detracting from the obligations assumed by any State under the Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous or Other Gases, and of Bacteriological Methods of Warfare, signed at Geneva on 17 June 1925, and under the Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on Their Destruction, signed at London, Moscow and Washington on 10 April 1972.

ARTICLE XIV

SETTLEMENT OF DISPUTES

1. Disputes that may arise concerning the application or the interpretation of this Convention shall be settled in accordance with the relevant provisions of this Convention and in conformity with the provisions of the Charter of the United Nations.

2. When a dispute arises between two or more States Parties, or between one or more States Parties and the Organization, relating to the interpretation or application of this Convention, the parties concerned shall consult together with a view to the expeditious settlement of the dispute by negotiation or by other peaceful means of the parties' choice, including recourse to appropriate organs of this Convention and, by mutual consent, referral to the International Court of Justice in conformity with the Statute of the Court. The States Parties involved shall keep the Executive Council informed of actions being taken.

3. The Executive Council may contribute to the settlement of a dispute by whatever means it deems appropriate, including offering its good offices, calling upon the States Parties to a dispute to start the settlement process of their choice and recommending a time-limit for any agreed procedure.

4. The Conference shall consider questions related to disputes raised by States Parties or brought to its attention by the Executive Council. The Conference shall, as it finds necessary, establish or entrust organs with tasks related to the settlement of these disputes in conformity with Article VIII, paragraph 21 (f).

5. The Conference and the Executive Council are separately empowered, subject to authorization from the General Assembly of the United Nations, to request the International Court of Justice to give an advisory opinion on any legal question arising within the scope of the activities of the Organization. An agreement between the Organization and the United Nations shall be concluded for this purpose in accordance with Article VIII, paragraph 34 (a).

6. This Article is without prejudice to Article IX or to the provisions on measures to redress a situation and to ensure compliance, including sanctions.

ARTICLE XV

AMENDMENTS

1. Any State Party may propose amendments to this Convention. Any State Party may also propose changes, as specified in paragraph 4, to the Annexes of this Convention. Proposals for amendments shall be subject to the procedures in paragraphs 2 and 3. Proposals for changes, as specified in paragraph 4, shall be subject to the procedures in paragraph 5.

2. The text of a proposed amendment shall be submitted to the Director-General for circulation to all States Parties and to the Depositary. The proposed amendment shall be considered only by an Amendment Conference. Such an Amendment Conference shall be convened if one third or more of the States Parties notify the Director-General not later than 30 days after its circulation that they support further consideration of the proposal. The Amendment Conference shall be held immediately following a regular session of the Conference unless the requesting States Parties ask for an earlier meeting. In no case shall an Amendment Conference be held less than 60 days after the circulation of the proposed amendment.

3. Amendments shall enter into force for all States Parties 30 days after deposit of the instruments of ratification or acceptance by all the States Parties referred to under subparagraph (b) below:

(a) When adopted by the Amendment Conference by a positive vote of a majority of all States Parties with no State Party casting a negative vote; and
(b) Ratified or accepted by all those States Parties casting a positive vote at the Amendment Conference.

4. In order to ensure the viability and the effectiveness of this Convention, provisions in the Annexes shall be subject to changes in accordance with paragraph 5, if proposed changes are related only to matters of an administrative or technical nature. All changes to the Annex on Chemicals shall be made in accordance with paragraph 5. Sections A and C of the Confidentiality Annex, Part X of the Verification Annex, and those definitions in Part I of the Verification Annex which relate exclusively to challenge inspections, shall not be subject to changes in accordance with paragraph 5.

5. Proposed changes referred to in paragraph 4 shall be made in accordance with the following procedures:

(a) The text of the proposed changes shall be transmitted together with the necessary information to the Director-General. Additional information for the evaluation of the proposal may be provided by any State Party and the Director-General. The Director-General shall promptly communicate any such proposals and information to all States Parties, the Executive Council and the Depositary;
(b) Not later than 60 days after its receipt, the Director-General shall evaluate the proposal to determine all its possible consequences for the provisions of this Convention and its implementation and shall communicate any such information to all States Parties and the Executive Council;
(c) The Executive Council shall examine the proposal in the light of all information available to it, including whether the proposal fulfils the requirements of paragraph 4. Not later than 90 days after its receipt, the Executive Council shall notify its recommendation, with appropriate explanations, to all States Parties for consideration. States Parties shall acknowledge receipt within 10 days;
(d) If the Executive Council recommends to all States Parties that the proposal be adopted, it shall be considered approved if no State Party objects to it within 90 days after receipt of the recommendation. If the Executive Council recommends that the proposal be rejected, it shall be considered rejected if no State Party objects to the rejection within 90 days after receipt of the recommendation;
(e) If a recommendation of the Executive Council does not meet with the acceptance required under subparagraph (d), a decision on the proposal, including whether it fulfils the requirements of paragraph 4, shall be taken as a matter of substance by the Conference at its next session;
(f) The Director-General shall notify all States Parties and the Depositary of any decision under this paragraph;
(g) Changes approved under this procedure shall enter into force for all States Parties 180 days after the date of notification by the Director-General of their approval unless another time period is recommended by the Executive Council or decided by the Conference.

ARTICLE XVI

DURATION AND WITHDRAWAL

1. This Convention shall be of unlimited duration.

2. Each State Party shall, in exercising its national sovereignty, have the right to withdraw from this Convention if it decides that extraordinary events, related to the subject-matter of this Convention, have jeopardized the supreme interests of its country. It shall give notice of such withdrawal 90 days in advance to all other States

Parties, the Executive Council, the Depositary and the United Nations Security Council. Such notice shall include a statement of the extraordinary events it regards as having jeopardized its supreme interests.

3. The withdrawal of a State Party from this Convention shall not in any way affect the duty of States to continue fulfilling the obligations assumed under any relevant rules of international law, particularly the Geneva Protocol of 1925.

ARTICLE XVII

STATUS OF THE ANNEXES

The Annexes form an integral part of this Convention. Any reference to this Convention includes the Annexes.

ARTICLE XVIII

SIGNATURE

This Convention shall be open for signature for all States before its entry into force.

ARTICLE XIX

RATIFICATION

This Convention shall be subject to ratification by States Signatories according to their respective constitutional processes.

ARTICLE XX

ACCESSION

Any State which does not sign this Convention before its entry into force may accede to it at any time thereafter.

ARTICLE XXI

ENTRY INTO FORCE

1. This Convention shall enter into force 180 days after the date of the deposit of the 65th instrument of ratification, but in no case earlier than two years after its opening for signature.

2. For States whose instruments of ratification or accession are deposited subsequent to the entry into force of this Convention, it shall enter into force on the 30th day following the date of deposit of their instrument of ratification or accession.

ARTICLE XXII

RESERVATIONS

The Articles of this Convention shall not be subject to reservations. The Annexes of this Convention shall not be subject to reservations incompatible with its object and purpose.

ARTICLE XXIII

DEPOSITARY

The Secretary-General of the United Nations is hereby designated as the Depositary of this Convention and shall, inter alia:

(a) Promptly inform all signatory and acceding States of the date of each signature, the date of deposit of each instrument of ratification or accession and the date of the entry into force of this Convention, and of the receipt of other notices;
(b) Transmit duly certified copies of this Convention to the Governments of all signatory and acceding States; and
(c) Register this Convention pursuant to Article 102 of the Charter of the United Nations.

ARTICLE XXIV

AUTHENTIC TEXTS

This Convention, of which the Arabic, Chinese, English, French, Russian and Spanish texts are equally authentic, shall be deposited with the Secretary-General of the United Nations.

IN WITNESS WHEREOF the undersigned, being duly authorized to that effect, have signed this Convention.

Done at Paris on the thirteenth day of January, one thousand nine hundred and ninety-three.

ANNEX ON CHEMICALS

GUIDELINES FOR SCHEDULES OF CHEMICALS[1]

Guidelines for Schedule 1

1. The following criteria shall be taken into account in considering whether a toxic chemical or precursor should be included in Schedule 1:

(a) It has been developed, produced, stockpiled or used as a chemical weapon as defined in Article II;

(b) It poses otherwise a high risk to the object and purpose of this Convention by virtue of its high potential for use in activities prohibited under this Convention because one or more of the following conditions are met:

(i) It possesses a chemical structure closely related to that of other toxic chemicals listed in Schedule 1, and has, or can be expected to have, comparable properties;
(ii) It possesses such lethal or incapacitating toxicity as well as other properties that would enable it to be used as a chemical weapon;
(iii) It may be used as a precursor in the final single technological stage of production of a toxic chemical listed in Schedule 1, regardless of whether this stage takes place in facilities, in munitions or elsewhere;

(c) It has little or no use for purposes not prohibited under this Convention.

Guidelines for Schedule 2
1. The following criteria shall be taken into account in considering whether a toxic chemical not listed in Schedule 1 or a precursor to a Schedule 1 chemical or to a chemical listed in Schedule 2, part A, should be included in Schedule 2:

(a) It poses a significant risk to the object and purpose of this Convention because it possesses such lethal or incapacitating toxicity as well as other properties that could enable it to be used as a chemical weapon;
(b) It may be used as a precursor in one of the chemical reactions at the final stage of formation of a chemical listed in Schedule 1 or Schedule 2, part A;
(c) It poses a significant risk to the object and purpose of this Convention by virtue of its importance in the production of a chemical listed in Schedule 1 or Schedule 2, part A;
(d) It is not produced in large commercial quantities for purposes not prohibited under this Convention.

Guidelines for Schedule 3
3. The following criteria shall be taken into account in considering whether a toxic chemical or precursor, not listed in other Schedules, should be included in Schedule 3:

(a) It has been produced, stockpiled or used as a chemical weapon;
(b) It poses otherwise a risk to the object and purpose of this Convention because it possesses such lethal or incapacitating toxicity as well as other properties that might enable it to be used as a chemical weapon;
(c) It poses a risk to the object and purpose of this Convention by virtue of its importance in the production of one or more chemicals listed in Schedule 1 or Schedule 2, part B;
(d) It may be produced in large commercial quantities for purposes not prohibited under this Convention.

B. SCHEDULES OF CHEMICALS

The following Schedules list toxic chemicals and their precursors. For the purpose of implementing this Convention, these Schedules identify chemicals for the application of verification measures according to the provisions of the Verification Annex. Pursuant to Article II, subparagraph 1 (a), these Schedules do not constitute a definition of chemical weapons.

(Whenever reference is made to groups of dialkylated chemicals, followed by a list of alkyl groups in parentheses, all chemicals possible by all possible combinations of alkyl groups listed in the parentheses are considered as listed in the respective Schedule as long as they are not explicitly exempted. A chemical marked "*" on Schedule 2, part A, is subject to special thresholds for declaration and verification, as specified in Part VII of the Verification Annex.)

Schedule 1
(CAS registry number)

A. Toxic chemicals:
(1) O-Alkyl (<C10, incl. cycloalkyl) alkyl (Me, Et, n- Pr or i-Pr)-phosphonofluoridates, e.g.: Sarin: O- Isopropyl methylphosphonofluoridate (107-44-8); Soman: O-Pinacolyl methylphosphonofluoridate (96-64-0)

(2) O-Alkyl (<C10, incl. cycloalkyl) N,N-dialkyl (Me, Et, n- Pr or i- Pr) phosphoramidocyanidates

e.g. Tabun: O-Ethyl N,N-dimethyl phosphoramidocyanidate (77-81-6)

(3) O-Alkyl (H or <C10, incl. cycloalkyl) S-2-dialkyl (Me, Et, n- Pr or i- Pr)-aminoethyl alkyl (Me, Et, n- Pr or i- Pr) phosphonothiolates and corresponding alkylated or protonated salts, e.g. VX: O-Ethyl S-2-diisopropylaminoethyl methyl phosphonothiolate (50782- 69- 9)

(4) Sulfur mustards:

2-Chloroethylchloromethylsulfide (2625-76-5)
Mustard gas: Bis(2-chloroethyl)sulfide (505-60-2)
Bis(2-chloroethylthio)methane (63869-13-6)
Sesquimustard: 1,2-Bis(2-chloroethylthio)ethane (3563-36-8)

1,3- Bis(2-chloroethylthio)-n-propane (63905-10-2)
1,4- Bis(2-chloroethylthio)-n-butane (142868-93-7)
1,5- Bis(2-chloroethylthio)-n-pentane (142868-94-8)
Bis(2-chloroethylthiomethyl)ether (63918-90-1)
O-Mustard: Bis(2- chloroethylthioethyl)ether (63918-89-8)

(5) Lewisites:

Lewisite 1: 2-Chlorovinyldichloroarsine (541-25-3)
Lewisite 2: Bis(2-chlorovinyl)chloroarsine (40334-69-8)
Lewisite 3: Tris(2-chlorovinyl)arsine (40334-70-1)

(6) Nitrogen mustards:

HN-1: Bis(2-chloroethyl)ethylamine (538-07-8)
HN-2: Bis(2-chloroethyl)methylamine (51-75-2)
HN-3: Tris(2-chloroethyl)amine (555-77-1)

(7) Saxitoxin (35523-89-8) [note: also a biotoxin]
(8) Ricin (9009-86-3) [note: also a biotoxin]

B. Precursors:
(9) Alkyl (Me, Et, n- Pr or i- Pr) phosphonyldifluorides, e.g. DF: Methylphosphonyldifluoride (676-99-3)

(10) O-Alkyl (H or <C10, incl. cycloalkyl) O-2-dialkyl (Me, Et, n-Pr or i-Pr)-aminoethyl alkyl (Me, Et, n- Pr or i-Pr) phosphonites and corresponding alkylated or protonated salts, e.g. QL: O-Ethyl O-2 diisopropylaminoethyl methylphosphonite (57856-11-8)

(11) Chlorosarin: O-Isopropyl methylphosphonochloridate (1445-76-7)

(12) Chlorosoman: O-Pinacolyl methylphosphonochloridate (7040-57-5)

Schedule 2
A. Toxic chemicals:
(1) Amiton: O,O-Diethyl S-[2-(diethylamino)ethyl] phosphorothiolate (78-53-5) and corresponding alkylated or protonated salts

(2) PFIB: 1,1,3,3,3-Pentafluoro-2-(trifluoromethyl)-1-propene (382-21-8)

(3) BZ: 3-Quinuclidinyl benzilate (*) (6581-06-2)

B. Precursors:
(4) Chemicals, except for those listed in Schedule 1, containing a phosphorus atom to which is bonded one methyl, ethyl or propyl (normal or iso) group but not further carbon atoms, e.g. Methylphosphonyl dichloride (676-97-1), Dimethyl methylphosphonate (756-79-6)

[Exemption: Fonofos: O-Ethyl S-phenyl ethylphosphonothiolothionate (944-22-9)]

(5) N,N- Dialkyl (Me, Et, n-Pr or i-Pr) phosphoramidic dihalides

(6) Dialkyl (Me, Et, n- Pr or i-Pr) N,N-dialkyl (Me, Et, n- Pr or i-Pr)- phosphoramidates

(7) Arsenic trichloride (7784-34-1)

(8) 2,2- Diphenyl-2-hydroxyacetic acid (76-93-7)

(9) Quinuclidin-3-ol (1619-34-7)

(10) N,N- Dialkyl (Me, Et, n- Pr or i-Pr) aminoethyl-2-chlorides and corresponding protonated salts

(11) N,N- Dialkyl (Me, Et, n- Pr or i-Pr) aminoethane-2-ols and corresponding protonated salts

[Exemptions: N,N- Dimethylaminoethanol (108-01-0) and corresponding protonated salts, N,N- Diethylaminoethanol (100-37-8) and corresponding protonated salts

(12) N,N-Dialkyl (Me, Et, n- Pr or i-Pr) aminoethane-2-thiols and corresponding protonated salts

(13) Thiodiglycol: Bis(2-hydroxyethyl)sulfide (111-48-8)

(14) Pinacolyl alcohol: 3,3-Dimethylbutan-2-ol (464-07- 3)

Schedule 3
A. Toxic chemicals:
(1) Phosgene: Carbonyl dichloride (75-44-5)
(2) Cyanogen chloride (506-77-4)
(3) Hydrogen cyanide (74-90-8)
(4) Chloropicrin: Trichloronitromethane (76-06-2)

B. Precursors:
(5) Phosphorus oxychloride (10025-87-3)
(6) Phosphorus trichloride (7719-12-2)
(7) Phosphorus pentachloride (10026-13-8)
(8) Trimethyl phosphite (121-45-9)
(9) Triethyl phosphite (122-52-1)
(10) Dimethyl phosphite (868-85-9)
(11) Diethyl phosphite (762-04-9)
(12) Sulfur monochloride (10025-67-9)
(13) Sulfur dichloride (10545-99-0)
(14) Thionyl chloride (7719-09-7)
(15) Ethyldiethanolamine (139-87-7)
(16) Methyldiethanolamine (105-59-9)
(17) Triethanolamine (102-71-6)

STATES PARTIES TO THE CHEMICAL WEAPONS CONVENTION (CWC)[1]

(As of 5 February 2004)

1. Afghanistan
2. Albania

3. Algeria
4. Andorra
5. Argentina
6. Armenia
7. Australia
8. Austria
9. Azerbaijan
10. Bahrain
11. Bangladesh
12. Belarus
13. Belgium
14. Belize
15. Benin
16. Bolivia
17. Bosnia and Herzegovina
18. Botswana

Australia Group

Annex 7
Australia Group Doc
AG/Dec92/BW/Chair/8

LIST OF DUAL-USE BIOLOGICAL EQUIPMENT FOR EXPORT CONTROL

(FINAL VERSION)

The experts propose that the following items of equipment should be subject to export controls.

1. Complete containment facilities at P3, P4 contrainment level

Complete containment facilities that meet the criteria for P3 or P4 (BL3, BL4, L3, L4) containment as specified in the WHO Laboratory Biosafety manual (Geneva, 1983) should be subject to export control.

2. Fermenters*

Fermenters capable of cultivation of pathogenic micro-organisms, viruses or for toxin production, without the propagation of aerosols, and having all the following characteristics:

(a) capacity equal to or greater than 300 litres;
(b) double or multiple sealing joints within the steam containment area;
(c) capable of in-situ sterilisation in a closed state.

* Sub-groups of fermenters include bioreactors, chemostats and continuous-flow systems.

3. Centrifugal Separators*

Centrifugal separators capable of the continuous separation of pathogenic micro-organisms, without the propagation of aerosols, and having all the following characteristics:

(a) flow rate greater than 100 litres per hour;
(b) components of polished stainless steel or titanium;
(c) double or muliple sealing joints within the steam containment area;
(d) capable of in-situ steam sterilisation in a closed state.

* Centrifugal separators include decanters.

4. Cross-flow Filtration Equipment

Cross-flow filtration equipment designed for continuous separation of pathogenic microorganisms, viruses, toxins and cell cultures without the propagation of aerosols, having all the following characteristics:

(a) equal to or greater than 5 square metres;
(b) capable of in-situ sterilisation.

5. Freeze-drying Equipment

Steam sterilisable freeze-drying equipment with a condensor capacity greater than 50 kgs of ice in 24 hours and less than 1000 kgs of ice in 24 hours.

6. Equipment that incorporates or is contained in P3 or P4 (BL3, BL4, L3, L4) containment housing, as follows:

(a) Independently ventilated protective full or half suits;
(b) Class III biological safety cabinets or isolators with similar performance standards.

7. Aerosol inhalation chambers

Chambers designed for aerosol challenge testing with pathogenic microorganisms, viruses or toxins and having a capacity of 1 cubic metre or greater.

The experts propose that the following item be included in awareness raising guidelines to industry:

1. Equipment for the micro-encapsulation of live micro-organisms and toxins in the range of 1-10 um particle size, specifically:

(a) Interfacial polycondensors;
(b) Phase separators.

2. Fermenters of less than 300 litre capacity with special emphasis on aggregate orders or designs for use in combined systems.
3. Conventional or turbulent air-flow clean-air rooms and self-contained fan-HEPA filter units that may be used for P3 or P4 (BL3, BL4, L3, L4) containment facilities.

AUSTRALIA GROUP LISTS:[1]

AUSTRALIA GROUP CONTROL LIST OF DUAL-USE CHEMICALS

1. Thiodiglycol
2. Phosphorus oxychloride
3. Dimethyl methylphosphonate
4. Methyl phosphonyl difluoride
5. Methyl phosphonyl dichloride
6. Dimethyl phosphite
7. Phosphorus trichloride
8. Trimethyl phosphite
9. Thionyl chloride
10. 3-Hydroxy-l-methylpiperidine
11. N,N-Diisopropyl-(beta) aminoethyl chloride
12. N,N-Diisopropyl-(beta)-aminoethane thiol
13. 3-Quinuclidinol
14. Potassium fluoride
15. 2-Chloroethanol
16. Dimethylamine
17. Diethyl ethylphosphonate
18. Diethyl N,N-dimethylosphoramidate
19. Diethyl phosphite
20. Dimethylamine hydrochloride
21. Ethyl phosphinyl dichloride
22. Ethyl phosphonyl dichloride
23. Ethyl Phosphonyl difluoride
24. Hydrogen fluoride
25. Methyl benzilate
26. Methyl phosphinyl dichloride
27. N,N-Diisopropyl-(beta)-amino-ethanol
28. Pinacolyl alcohol
29. O-Ethyl 2-diisopropylamino-ethyl methylphosphonite
30. Triethyl phosphite
31. Arsenic yrichloride
32. Benzilic acid
33. Diethyl methylphosphonite
34. Dimethyl ethylphosphonate
35. Ethyl phosphinyl difluoride
36. Methyl phosphinyl difluoride
37. 3 -Quinuclidone
38. Phosphorus pentachloride
39. Pinacolone
40. Potassium cyanide
41. Potassium bifluoride
42. Ammonium bifluoride
43. Sodium bifluoride
44. Sodium fluoride
45. Sodium cyanide
46. Tri-ethanolamine
47. Phosphorus pentasulphide
48. Di-isopropylamine
49. Diethylaminoethanol
50. Sodium sulphide
51. Sulphur monochloride
52. Sulphur dichloride
53. Triethanolamine hydrochloride
54. N,N-Diisopropyl-2-Aminoethyl Chloride Hydrochloride

LIST OF BIOLOGICAL AGENTS FOR EXPORT CONTROL CORE LIST 1 (AUGUST 2003)

Viruses

V1. Chikungunya virus

V2. Congo-Crimean haemorrhagic fever virus
V3. Dengue fever virus
V4. Eastern equine encephalitis virus
V5. Ebola virus
V6. Hantaan virus
V7. Junin virus
V8. Lassa fever virus
V9. Lymphocytic choriomeningitis virus
V10. Machupo virus
V11. Marburg virus
V12. Monkey pox virus
V13. Rift Valley fever virus
V14. Tick-borne encephalitis virus (Russian Spring-Summer encephalitis virus)
V15. Variola virus
V16. Venezuelan equine encephalitis virus
V17. Western equine encephalitis virus
V18. White pox
V19. Yellow fever virus
V20. Japanese encephalitis virus
V21. Kyasanur Forest virus
V22. Louping ill virus
V23. Murray Valley encephalitis virus
V24. Omsk haemorrhagic fever virus
V25. Oropouche virus
V26. Powassan virus
V27. Rocio virus
V28. St Louis encephalitis virus
V29. Hendra virus (Equine morbillivirus)
V30. South American haemorrhagic fever (Sabia, Flexal, Guanarito)
V31. Pulmonary & renal syndrome-haemorrhagic fever viruses (Seoul, Dobrava, Puumala, Sin Nombre)
V32. Nipah virus

Rickettsiae

R1. *Coxiella burnetii*
R2. *Bartonella quintana* (*Rochalimea quintana, Rickettsia quintana*)
R3. *Rickettsia prowazeki*
R4. *Rickettsia rickettsii*

Bacteria

B1. *Bacillus anthracis*
B2. *Brucella abortus*
B3. *Brucella melitensis*
B4. *Brucella suis*
B5. *Chlamydia psittaci*
B6. *Clostridium botulinum*
B7. *Francisella tularensis*
B8. *Burkholderia mallei* (*Pseudomonas mallei*)
B9. *Burkholderia pseudomallei* (*Pseudomonas pseudomallei*)
B10. *Salmonella typhi*
B11. *Shigella dysenteriae*
B12. *Vibrio cholerae*
B13. *Yersinia pestis*
B14. *Clostridium perfringens,* epsilon toxin producing types2
B15. Enterohaemorrhagic *Escherichia coli,* serotype O157 and other verotoxin producing serotypes

Toxins

T1. Botulinum toxins4
T2. Clostridium perfringens toxins
T3. Conotoxin
T4. Ricin
T5. Saxitoxin
T6. Shiga toxin
T7. Staphylococcus aureus toxins
T8. Tetrodotoxin
T9. Verotoxin
T10. Microcystin (Cyanginosin)
T11. Aflatoxins
T12. Abrin
T13. Cholera toxin
T14. Diacetoxyscirpenol toxin
T15. T-2 toxin
T16. HT-2 toxin
T17. Modeccin toxin
T18. Volkensin toxin
T19. Viscum Album Lectin 1 (Viscumin)

1. Biological agents are controlled when they are an isolated live culture of a pathogen agent, or a preparation of a toxin agent which has been isolated or extracted from any source, or material including living material which has been deliberately inoculated or contaminated with the agent. Isolated live cultures of a pathogen agent include live cultures in dormant form or in dried preparations, whether the agent is natural, enhanced or modified.

An agent is covered by this list except when it is in the form of a vaccine. A vaccine is a medicinal product in a pharmaceutical formulation licensed by, or having marketing or clinical trial authorisation from, the regulatory authorities of either the country of manufacture or of use, which is intended to stimulate a protective immunological response in humans or animals in order to prevent disease in those to whom or to which it is administered.

2. It is understood that limiting this control to epsilon toxin-producing strains of *Clostridium perfringens* therefore exempts from control the transfer of other *Clostridium perfringens* strains to be used as positive control cultures for food testing and quality control.

3. Excluding immunotoxins.

4. Excluding botulinum toxins in product form meeting all of the following criteria: are pharmaceutical for-

mulations designed for human administration in the treatment of medical conditions; are pre-packaged for distribution as medical products;

are authorised by a state authority to be marketed as medical products.

Genetic Elements and Genetically-modified Organisms:

G1. Genetic elements that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the list.

G2. Genetic elements that contain nucleic acid sequences coding for any of the toxins in the list, or for their sub-units.

G3. Genetically-modified organisms that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the list.

G4. Genetically-modified organisms that contain nucleic acid sequences coding for any of the toxins in the list or for their sub-units.

Technical note:

Genetic elements include inter alia chromosomes, genomes, plasmids, transposons, and vectors whether genetically modified or unmodified. These controls do not apply to nucleic acid sequences associated with the pathogenicity of enterohaemorrhagic *Escherichia coli*, serotype O157 and other verotoxin producing strains, other than those coding for the verotoxin, or for its sub-units.

WARNING LIST1

Bacteria

WB1. *Clostridium tetani**

WB2. *Legionella pneumophila*

WB3. *Yersinia pseudotuberculosis*

* Australia Group recognises that this organism is ubiquitous, but, as it has been acquired in the past as part of biological warfare programs, it is worthy of special caution.

1. Biological agents are controlled when they are an isolated live culture of a pathogen agent, or a preparation of a toxin agent which has been isolated or extracted from any source, or material including living material which has been deliberately inoculated or contaminated with the agent. Isolated live cultures of a pathogen agent include live cultures in dormant form or in dried preparations, whether the agent is natural, enhanced or modified.

An agent is covered by this list except when it is in the form of a vaccine. A vaccine is a medicinal product in a pharmaceutical formulation licensed by, or having marketing or clinical trial authorisation from, the regulatory authorities of either the country of manufacture or of use, which is intended to stimulate a protective immunological response in humans or animals in order to prevent disease in those to whom or to which it is administered.

Genetic Elements and Genetically-modified Organisms:

WG1. Genetic elements that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the list.

WG2. Genetic elements that contain nucleic acid sequences coding for any of the toxins in the list, or for their sub-units.

WG3. Genetically-modified organisms that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the list.

WG4. Genetically-modified organisms that contain nucleic acid sequences coding for any of the toxins in the list or for their sub-units.

Technical note:

Genetic elements include inter alia chromosomes, genomes, plasmids, transposons, and vectors whether genetically modified or unmodified.

AUSTRALIA GROUP: LIST OF ANIMAL PATHOGENS FOR EXPORT CONTROL[2]

CORE LIST1

Viruses

AV1. African swine fever virus
AV2. Avian influenza virus2
AV3. Bluetongue virus
AV4. Foot and mouth disease virus
AV5. Goat pox virus
AV6. Herpes virus (Aujeszky's disease)
AV7. Hog cholera virus (synonym: swine fever virus)
AV8. Lyssa virus
AV9. Newcastle disease virus
AV10. Peste des petits ruminants virus
AV11. Porcine enterovirus type 9 (synonym: swine vesicular disease virus)
AV12. Rinderpest virus
AV13. Sheep pox virus
AV14. Teschen disease virus
AV15. Vesicular stomatitis virus
AV16. Lumpy skin disease virus
AV17. African horse sickness virus

1. Except where the agent is in the form of a vaccine.

2. This includes only those Avian influenza viruses of high pathogenicity as defined in EC Directive 92/40/EC:

"Type A viruses with an IVPI (intravenous pathogenicity index) in 6 week old chickens of greater than 1.2: or Type A viruses H5 or H7 subtype for which nucleotide sequencing has demonstrated multiple basic amino acids at the cleavage site of haemagglutinin"

Bacteria
AB3. *Mycoplasma mycoides*

Genetic Elements and Genetically-modified Organisms
AG1 Genetic elements that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the list.

AG2 Genetically-modified organisms that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the list.

Technical note: Genetic elements include inter alia chromosomes, genomes, plasmids, transposons, and vectors whether genetically modified or unmodified.

AUSTRALIA GROUP: LIST OF PLANT PATHOGENS FOR EXPORT CONTROLS3

Bacteria
PB1. *Xanthomonas albilineans*
PB2. *Xanthomonas campestris* pv. *citri*

Fungi
PF1. *Colletotrichum coffeanum* var. *virulans* (*Colletotrichum kahawae*)
PF2. *Cochliobolus miyabeanus* (*Helminthosporium oryzae*)
PF3. *Microcyclus ulei* (syn. *Dothidella ulei*)
PF4. *Puccinia graminis* (syn. *Puccinia graminis* f. sp. *tritici*)
PF5. *Puccinia striiformis* (syn. *Puccinia glumarum*)
PF6. *Pyricularia grisea* / *Pyricularia oryzae*

Genetic Elements and Genetically-modified Organisms:
PG1 Genetic elements that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the Core List.

PG2 Genetically-modified organisms that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the Core List.

Technical note: Genetic elements include *inter alia* chromosomes, genomes, plasmids, transposons, and vectors whether genetically modified or unmodified.

ITEMS FOR INCLUSION IN AWARENESS-RAISING GUIDELINES

Bacteria
PWB1. *Xanthomonas campestris* pv. *Oryzae*
PWB2. *Xylella fastidiosa*

Fungi
PWF1. *Deuterophoma tracheiphila* (syn. *Phoma tracheiphila*)
PWF2. *Monilia rorei* (syn. *Moniliophthora rorei*)

Viruses
PWV1 Banana bunchy top virus

Genetic Elements and Genetically-modified Organisms:
PWG1 Genetic elements that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the Awareness-raising Guidelines.

PWG2 Genetically-modified organisms that contain nucleic acid sequences associated with the pathogenicity of any of the microorganisms in the Awareness-raising Guidelines.

Technical note: Genetic elements include *inter alia* chromosomes, genomes, plasmids, transposons, and vectors whether genetically modified or unmodified.

AUSTRALIA GROUP: GUIDELINES FOR TRANSFERS OF SENSITIVE CHEMICAL OR BIOLOGICAL ITEMS

The Government of xxx has, after careful consideration and consistent with its obligations under the BTWC and the CWC, decided that, when considering the transfer of equipment, materials, and technology that could contribute to chemical and biological weapons activities, it will act in accordance with the following Guidelines.

1. The purpose of these Guidelines is to limit the risks of proliferation and terrorism involving chemical and biological weapons (CBW) by controlling transfers that could contribute to CBW activities by states or non-state actors, consistent with Article III of the Biological Weapons Convention, Article I of the Chemical Weapons Convention, and all relevant United Nations Security Council Resolutions. In accordance with Article X of the Biological Weapons Convention and Article XI of the Chemical Weapons Convention, these Guidelines are not intended to impede chemical or biological trade or international cooperation that could not contribute to CBW activities or terrorism. These Guidelines, including the attached Australia Group (AG) control lists and subsequent amendments thereto, form the basis for controlling transfers to any destination beyond the Government's national jurisdiction or control of materials, equipment, and technology that could contribute to CBW activities. The Government will implement these Guidelines in accordance with its national legislation.

2. These Guidelines will be applied to each transfer of any item in the AG control lists. However, it is a matter for the Government's discretion to determine whether and to what extent to apply expedited licensing measures in the case of transfers to destinations it judges possess consistently excellent non proliferation credentials. Vigilance will be exercised in the consideration of all transfers of items on the AG control lists. Transfers will be denied if the Government judges, on the basis of all available, persuasive information, evaluated according to factors including those in paragraph 3, that the controlled items are intended to be used in a chemical weapons or biological weapons program, or for CBW terrorism, or that a significant risk of diversion exists. It is understood that the decision to transfer remains the sole and sovereign judgment of the Government.

3. In fulfilling the purposes of these Guidelines, national export control legislation, including enforcement and sanctions for violations, plays an important role.

4. To fulfill the purposes of these Guidelines, the evaluation of export applications will take into account the following non-exhaustive list of factors:

a) Information about proliferation and terrorism involving CBW, including any proliferation or terrorism-related activity, or about involvement in clandestine or illegal procurement activities, of the parties to the transaction;
b) The capabilities and objectives of the chemical and biological activities of the recipient state;
c) The significance of the transfer in terms of (1) the appropriateness of the stated end-use, including any relevant assurances submitted by the recipient state or end-user, and (2) the potential development of CBW;
d) The assessment of the end-use of the transfer, including whether a transfer has been previously denied to the end-user, whether the end-user has diverted for unauthorized purposes any transfer previously authorized, and, to the extent possible, whether the end-user is capable of securely handling and storing the item transferred;
e) The applicability of relevant multilateral agreements, including the BTWC and CWC.

5. In a manner consistent with its national legislation and practices, the Government should, before authorizing a transfer of an AG-controlled item, either (a) satisfy itself that goods are not intended for reexport; (b) satisfy itself that, if reexported, the goods would be controlled by the recipient government pursuant to these guidelines; or (c) obtain satisfactory assurances that its consent will be secured prior to any retransfer to a third country.

6. The objective of these Guidelines should not be defeated by the transfer of any non-controlled item containing one or more controlled components where the controlled component(s) are the principal element of the item and can feasibly be removed or used for other purposes. (In judging whether the controlled component(s) are to be considered the principal element, the

Government will weigh the factors of quantity, value, and technological know-how involved and other special circumstances that might establish the controlled component or components as the principal element of the item being procured.) The objective of these Guidelines also should not be defeated by the transfer of a whole plant, on any scale, that has been designed to produce any CBW agent or AG-controlled precursor chemical.

7. The Government reserves the discretion to: (a) apply additional conditions for transfer that it may consider necessary; (b) apply these guidelines to items not on the AG control lists; and c) apply measure to restrict exports for other reasons of public policy consistent with its treaty obligations.

8. In furtherance of the effective operation of the Guidelines, the Government will, as necessary and appropriate, exchange relevant information with other governments applying the same Guidelines.

9. The Government encourages the adherence of all states to these Guidelines in the interest of international peace and security.

Further provisions applicable to Australia Group Participants

In addition, participants in the Australia Group, consistent with their obligations under the BTWC and CWC and in accordance with their national legislation have, after careful consideration, decided also to give equal respect to the following provisions.

Catch-All

1. Participant states will ensure that their regulations require the following:

(a) an authorisation for the transfer of non-listed items where the exporter is informed by the competent authorities of the Participant State in which it is established that the items in question may be intended, in their entirety or part, for use in connection with chemical or biological weapons activities;

(b) that if the exporter is aware that non-listed items are intended to contribute to such activities it must notify the authorities referred to above, which will decide whether or not it is expedient to make the export concerned subject to authorisation.

2. Participant states are encouraged to share information on these measures on a regular basis, and to exchange information on catch-all denials relevant for the purpose of the AG.

   No Undercut Policy

3. In accordance with the Group's agreed procedures, a license for an export that is essentially identical to one denied by another AG participant will only be granted after consultations with that participant, provided it has not expired or been rescinded. Essentially identical is defined as being the same biological agent or chemical or, in the case of dual-use equipment, equipment which has the same or similar specifications and performance being sold to the same consignee. The terms of the Group's 'no undercut policy' do not apply to denials of items under national catch-all provisions.

   Common Approaches

4. AG participants implement these Guidelines in accordance with the Group's agreed common approaches on end-user undertakings and chemical mixtures.

   Intra EU Trade. (This provision applies to members of the European Union)

5. So far as trade within the European Union is concerned, each member State of the European Union will implement the Guidelines in the light of its commitments as a member of the Union.

UNSCOM Final Report (1999)

STATUS OF THE VERIFICATION OF IRAQ'S CHEMICAL WEAPONS PROGRAMME (SELECTED TABLES)[1]

January 29, 1999

Table I. Declared Iraqi Chemical and Biological Munitions

1. Munitions declared by Iraq as remaining after the 1991 Gulf War

Iraq's Declarations[1]

*Munition Type (fill)**	*Quantity*	*Accounting Status*
250 gauge aerial bombs (mustard)	1,243	1,233 aerial bombs were accounted for by UNSCOM. They were destroyed by Iraq under UNSCOM supervision during 1992 and 1993.
250 gauge aerial bombs (unfilled)	8,122	1) 7,627 aerial bombs were accounted for by UNSCOM. They were destroyed by Iraq under UNSCOM supervision during 1991 and 1993. 2) About 500 aerial bombs have not been found. According to Iraq, 500 aerial bombs were delivered damaged by a foreign supplier.
500 gauge aerial bombs (mustard)	1,426	1) 980 aerial bombs were accounted for by UNSCOM. They were destroyed by Iraq under UNSCOM supervision in 1992-1993. 2) Remnants of several hundred destroyed aerial bombs from 438 bombs declared by Iraq as destroyed in a fire accident in 1988, were seen by UNSCOM.
500 gauge aerial bombs (unfilled)	422	1) 331 aerial bombs were accounted for by UNSCOM and destroyed by Iraq under UNSCOM supervision. 2) Some 100 aerial bombs have not been found. According to Iraq, 100 aerial bombs were delivered damaged by a supplier.
R-400 aerial bombs (binary components of sarin)	337	1) 337 aerial bombs were accounted for by UNSCOM. 336 bombs were destroyed by Iraq under UNSCOM supervision in 1992. 2) One bomb was removed for analysis outside Iraq by UNSCOM. 3) Evidence of a few R-400 bombs produced by Iraq for BW purposes has been found among 337 CW bombs declared by Iraq.
R-400 aerial bombs (unfilled)	58	58 aerial bombs were accounted for by UNSCOM and destroyed by Iraq under UNSCOM supervision.
DB-2 aerial bombs (unfilled)	1,203	1,203 aerial bombs were accounted for by UNSCOM. They were destroyed by Iraq under UNSCOM supervision during 1992 and 1993.
122-mm rockets (sarin)	6,610	6,454 rockets were accounted for by UNSCOM. They were destroyed by Iraq under UNSCOM supervision during 1992 and 1993.
122-mm rockets (unfilled)	6,880	7,305 rockets were accounted for by UNSCOM and destroyed by Iraq under UNSCOM supervision.
155-mm artillery shells (mustard)	13,000	12,792 shells were accounted for by UNSCOM. They were destroyed by Iraq under UNSCOM supervision in the period 1992-1994.

(continues)

Table I. *(continued)*

1. Munitions declared by Iraq as remaining after the 1991 Gulf War

Iraq's Declarations[1]

*Munition Type (fill)**	*Quantity*	*Accounting Status*
155-mm artillery shells (unfilled)	16,950	1) 1,700 shells were accounted for by UNSCOM and destroyed by Iraq under UNSCOM supervision. 2) In 1998, Iraq presented documents on the conversion of 15,616 shells to conventional munitions. Of these, 1,779 converted shells were accounted for by UNSCOM.
Special missile warheads (sarin/binary components of sarin)	30	1) All 30 warheads were accounted for by UNSCOM. 2) Of those, 29 warheads were destroyed by Iraq under UNSCOM supervision during 1992 and 1993, and 3) One warhead was removed for analysis outside Iraq by UNSCOM.
Sub total of munitions remaining after the 1991 Gulf war	56,281	

[1] Components of special munitions, including boosters and fuzes, are not included in the table. The majority of these components were not presented by Iraq for verification. According to Iraq, single-use components were destroyed unilaterally and dual-use components were used for conventional purposes. UNSCOM was able to verify their disposition partially.

2. Munitions declared by Iraq as destroyed during the 1991 Gulf war

Iraq's Declarations[1]

*Munition Type (fill)**	*Quantity*	*Accounting Status*
500 gauge aerial bombs (CS riot control agent)	116	1) No remnants of destroyed bombs have been found. 2) In 1995, documentary evidence was provided by Iraq that 116 bombs filled with CS had been stored at a facility destroyed during the Gulf war.
R-400 aerial bombs	160	1) In 1992, remnants of bombs consistent with the declared quantity of bombs were seen by UNSCOM. 2) The circumstances of destruction have not been fully clarified.
DB-2 aerial bomb (sarin)	12	1) In 1991, remnants of up to 50 bombs were seen by UNSCOM. 2) In 1996, documentary evidence was found by UNSCOM that DB-2 bombs had also been filled with mustard (which was not declared). In 1997, Iraq stated that only a few bombs were filled with mustard for trials.
122-mm rockets (sarin)	4,660	1) In 1991, two locations were seen by UNSCOM where rockets had been destroyed. Evidence of many destroyed rockets was found. 2) In the period 1991-1998, remnants of about 4,000 rockets were recovered and accounted for by UNSCOM.

Table I. *(continued)*

2. Munitions declared by Iraq as destroyed during the 1991 Gulf war

Iraq's Declarations[1] *Munition Type (fill)**	*Quantity*	*Accounting Status*
122-mm rockets (unfilled)	36,500	1) Completely destroyed hangers where rockets had been destroyed were seen by UNSCOM. Evidence of many destroyed rockets was found. Accounting for the remnants was not possible due to the extent of the destruction. 2) In 1995, documentary evidence was provided by Iraq that 36,500 rockets had been stored at a facility destroyed during the Gulf war.
155-mm artillery shells (mustard)	550	1) No evidence has been found of 550 shells declared by Iraq as having been lost shortly after the Gulf war. 2) In July 1998, Iraq provided a progress report on its ongoing internal investigation.
Sub total of munitions destroyed during the 1991 Gulf war[1]	41,998	

[1]20,000 motor bombs filled with the riot control agent CS, which were destroyed during the Gulf war at one of the storage facilities, are not included in the table.

3. Munitions declared by Iraq as destroyed unilaterally

Iraq's Declarations[1] *Munition Type (fill)**	*Quantity*	*Accounting Status*
250 gauge aerial bombs (CS riot control agent)	125	Remnants of bombs consistent with the declared quantity were seen by UNSCOM.
250 gauge aerial bombs (unfilled)	2,000	1) Remnants of 1,400 destroyed bombs were accounted for by UNSCOM. 2) UNSCOM was presented with ingots declared to be from the melting of 600 bombs. The material presented could not be assessed as adequate for proper verification.
R-400 aerial bombs (binary components of sarin)	527	1) Remnants of bombs consistent with the declared quantity were seen by UNSCOM. 2) Iraq presented supporting documents on the destruction of 527 bombs.
R-400 aerial bombs (biological warfare agents)	157	1) In the period 1992-1998, remnants of up to 60 bombs were accounted for by UNSCOM. 2) Supporting documents on the destruction were presented by Iraq (without reference to the type of agents filled into them).
R-400 aerial bombs (unfilled)	308	1) No evidence was presented of 117 bombs declared by Iraq as having been melted. 2) No evidence was presented of 191 melted bombs declared as defective.
122-mm rockets (unfilled)	26,500	1) Remnants of 11,500 rockets destroyed through demolition were seen by UNSCOM. Accounting was not possible due to the state of destruction. 2) UNSCOM was presented with ingots declared to be from the melting of 15,000 rockets. The material presented could not be assessed as adequate for proper verification.

Table I. *(continued)*

3. Munitions declared by Iraq as destroyed unilaterally

Iraq's Declarations[1]

*Munition Type (fill)**	*Quantity*	*Accounting Status*
Special missile warheads (binary components of sarin/biological warfare agents)	45	1) In the period from 1992 to 1998, remnants of 43-45 special warheads were recovered and accounted for by UNSCOM. 2) In the period from 1997 to 1998, remnants of 3 additional warheads declared as special training warheads were recovered. 3) In 1998, degradation products of CW agent VX were found on some of the remnants of special warheads. 4) Supporting documents were provided by Iraq on the overall accounting for special warheads and on the unilateral destruction of 45 warheads.
Sub total of munitions destroyed unilaterally	29,662	

Table II. Iraqi Declared Bulk Agents

1. Iraqi declared bulk chemical warfare (CW) agents (not weaponized)

Bulk agent type	*Quantity (tonnes)*	*Accounting Status*
Mustard ($20m^3/1m^3$ containers)	295	295 tonnes of mustard were destroyed by Iraq under UNSCOM supervision.
Tabun (GA) nerve agent ($2m^3$ containers)	76	76 tonnes of tabun were destroyed by Iraq under UNSCOM supervision.
Sarin (GB) nerve agent and its mixtures ($2m^3$ containers)	40	40 tonnes of tabun were destroyed by Iraq under UNSCOM supervision.
VX nerve agent ($1m^3$ containers)	1.5	1) According to Iraq, 1.5 tonnes of VX were discarded unilaterally by dumping on the ground. 2) Traces of one VX-degradation product and a chemical known as a VX-stabilizer were found in the samples taken from the VX dump sites. 3) A quantified assessment is not possible.
Total	412.5	

Material Balance of key CW Precursor Chemicals

1. Iraq declared that some 20,150 tonnes of key precursor chemicals had been produced by Iraq and procured from abroad for the production of CW agents during the entire period of the implementation of its CW programme.
2. According to Iraq, of the declared total quantity of over 20,000 tonnes of key precursors, 14,500 tonnes were used either for the production of CW agents or for the production of other key precursors for these CW agents. The rest, 5,650 tonnes, was not used in the production of CW agents, and therefore needs to be accounted for separately.
3. Iraq's declarations on its total holdings of key precursors over the period of 8 years could not be fully verified due to the absence of sufficient evidence provided by Iraq and its foreign suppliers for Iraq's procurement and the consumption of key precursors in the production of CW agents prior to 1988, as declared by Iraq.
4. Iraq declared that 3,915 tonnes of key precursors remained in Iraq as of January 1991. According to Iraq, the discrepancy between calculated quantities of precursors left over from the production of CW agents (5,650

tonnes) and quantities of precursors declared by Iraq as remaining in January 1991 (3,915 tonnes) could have occurred due to the lack of sufficient information and full records on the actual delivery by former suppliers, on the consumption of precursors in the production of CW agents, and on the losses of key precursors, including through unsuitable storage, spillage, leakage etc.

5. 3,915 tonnes of key precursors remaining in January 1991 have been accounted for as follows:

- 2,850 tonnes were accounted for by UNSCOM. Of these, 2,610 tonnes of key precursors were destroyed under UNSCOM supervision
- 823 tonnes were declared by Iraq as having been destroyed during the Gulf war. The Commission was able to confirm qualitatively the destruction of these precursors. It was not possible to make a quantitative verification
- 242 tonnes were declared by Iraq as having been destroyed unilaterally in the summer of 1991. These include all precursors for the production of VX. The declared destruction of these 242 tonnes of key precursors was only partly accounted for.

1. The material balance of 3,915 tonnes of key precursors declared by Iraq remaining as of January 1991 is provided in table III.

Table III. Iraqi declared CW agent precursors

1. Precursor declarations.

CW precursor (related CW agent)	*Quantity of key precursor left over from production of CW agents in tonnes (calculated quantity)*	*Quantity of key precursor destroyed during the Gulf War (1991)*	*Quantity of key precursor destroyed unilaterally by Iraq in summer 1991*	*Key precursors physically remaining in Iraq and destroyed under UNSCOM supervision, tonnes*
D4 (tabun)*	166	None	None	166
$POCl_3$ (tabun)**	477	None	None	576
Dimethylamine hydrochloride (tabun)	295	30 1) Evidence of destruction was seen by UNSCOM. 2) Accounting was not possible due to the state of destruction.	None	272 tonnes were destroyed under UNSCOM supervision.
Sodium cyanide (tabun) **	371	None	None	180 tonnes were destroyed under UNSCOM supervision.
Thiodiglycol (mustard)*	377	120 1) Evidence of destruction was seen by UNSCOM. 2) Accounting was not possible due to the state of destruction.	None	188 tonnes were destroyed under UNSCOM supervision.
Thionylchloride* (mustard, GB, GF and VX) **	None	100 1) Evidence of destruction was seen by UNSCOM 2) Accounting was not possible due to the state of destruction.	None	282 tonnes were destroyed under UNSCOM supervision.

(continues)

Table III. *(continued)*

1. Precursor declarations.

CW precursor (related CW agent)	*Quantity of key precursor left over from production of CW agents in tonnes (calculated quantity)*	*Quantity of key precursor destroyed during the Gulf War (1991)*	*Quantity of key precursor destroyed unilaterally by Iraq in summer 1991*	*Key precursors physically remaining in Iraq and destroyed under UNSCOM supervision, tonnes*
PCl_3 (mustard, GB, GF and VX) **	2,422	None	None	650 tonnes were destroyed under UNSCOM supervision.
MPF (GB, GF)*	67	9 1) Evidence of destruction was seen by UNSCOM. 2) Accounting was not possible due to the state of destruction.	30 1) Evidence of destruction was seen by UNSCOM. 2) Accounting was not possible due to the state of destruction.	20 tonnes were destroyed under UNSCOM supervision.
HF (GB, GF) **	181	None	None	1) 11 tonnes were destroyed under UNSCOM supervision. 2) About 200 tonnes were released by UNSCOM for civilian use. 60 tonnes thereof have already been consumed and 140 tonnes remain under UNSCOM monitoring.
Isopropanol (GB)**	465	None	None	445 tonnes were destroyed under UNSCOM supervision.
Cyclohexanol (GF)	120	105 1) Evidence of destruction was seen by UNSCOM 2) Accounting was not possible due to the state of destruction.	None	Tens of tonnes were consumed by Iraq in the 1990s for civilian purposes under UNSCOM supervision.
P_2S_5 (VX)	242	85 1) Evidence of destruction was seen by UNSCOM. 2) 168 empty barrels (200L) from P_2S_5 sufficient for 34 tonnes were accounted for by UNSCOM.	157 1) Evidence of destruction was seen by UNSCOM. 2) 153 tonnes were accounted for by UNSCOM.	None

(continues)

Table III. *(continued)*

1. Precursor declarations.

CW precursor (related CW agent)	*Quantity of key precursor left over from production of CW agents in tonnes (calculated quantity)*	*Quantity of key precursor destroyed during the Gulf War (1991)*	*Quantity of key precursor destroyed unilaterally by Iraq in summer 1991*	*Key precursors physically remaining in Iraq and destroyed under UNSCOM supervision, tonnes*
Diisopropylamine (VX)	210	174 1) Evidence of destruction was seen by UNSCOM. 2) Accounting was not possible due to the state of destruction.	22 tonnes were destroyed under UNSCOM supervision.	None
Chloroethanol (VX)	202	200 1) Evidence of destruction was seen by UNSCOM. 2) Accounting was not possible due to the state of destruction.	None	2 tonnes were destroyed under UNSCOM supervision.
Iraqi Choline (VX)*	55[113]]	None	55[13] 1) UNSCOM took samples from the dump site. 2) Degradation products of choline were found in the samples. 3) Accounting was not possible due to the state of destruction.	None
Sub total	5,650[2]	823	242	2,810

[1]Quantities of key precursors declared by Iraq in 1995 as having been destroyed unilaterally in 1991.
[2]Only key precursors that Iraq declared as remaining as of January 1991 are included in the column. The following key precursors, according to Iraq, were fully consumed prior to 1991: DMMP, MPC, TMP, MPS, and they are not included in the table.
* Key precursors, which Iraq was able to produce indigenously in varying quantities (including DMMP, MPC, MPS and TMP).
** According to Iraq, discrepancies in rows # 2, 4, 6, 7, 9, 10 between calculated quantities of precursors left over from the production of CW agents (column 3) and quantities of precursors presented by Iraq (column 6) could have occurred due to the lack of sufficient information and/or proper record keeping:

a) on the actual delivery of precursors by foreign suppliers,
b) on the actual consumption of precursors in the production of CW agents, and
c) on the losses of key precursors, including through unsuitable storage, spillage, leakage etc.

2. Iraqi declared CW agent production equipment

Production Plant/Unit (Location and past use)	*Iraqi declarations on quantities of key equipment in their original configuration*	*Accounting status*
Mustard plant, P8, Muthanna State Establishment (MSE) production of mustard, attempts to produce VX nerve agent	22	1) The majority of equipment was destroyed during the Gulf war. 2) 12 remaining pieces were destroyed under UNSCOM supervision.

(continues)

Table III. *(continued)*

2. Iraqi declared CW agent production equipment

Production Plant/Unit (Location and past use)	*Iraqi declarations on quantities of key equipment in their original configuration*	*Accounting status*
Tabun/sarin plant and hydrolysis plant, P7 (MSE), production of tabun (GA) and sarin (GB) nerve agents.	16+20	1) Equipment was partly destroyed during the Gulf war. 2) The hydrolysis plant was used for the destruction under UNSCOM supervision of tabun, sarin and their precursors. After the completion of the destruction of sarin, the remaining 17 pieces of equipment were destroyed under UNSCOM supervision.
Multipurpose plant, Dhia (MSE), production of precursors (MPS), production of VX.	42	1) A few pieces of equipment were destroyed during the Gulf war. 2) 39 remaining pieces of equipment were destroyed under UNSCOM supervision.
Multipurpose plant, Malek (MSE), production of precursors (DMMP, MPC, MPS, choline), production of tabun (GA) and VX nerve agents.	25	1) All equipment was damaged during the Gulf war. 2) 24 broken pieces of equipment were accounted for by UNSCOM.
Multipurpose plant, Mohammed (MSE), production of precursors (D4, MPC), production of tabun (GA) nerve agent.	32	1) All equipment was destroyed or damaged during the Gulf war. 2) 25 broken pieces of equipment were accounted for by UNSCOM.
Multipurpose plant, A1 (MSE), production of nerve agent precursors (MPC, MPF).	33	1) All equipment was destroyed or damaged during the Gulf war. 2) 7 remaining pieces of equipment were destroyed under UNSCOM supervision. 3) 26 broken pieces of equipment were accounted for by UNSCOM.
Multipurpose plant, A2 (MSE), production of nerve agent precursors (MPF), production of sarin (GB).	29	1) Equipment was partly destroyed during the Gulf war. 2) 14 remaining pieces of equipment were destroyed under UNSCOM supervision.
Nerve agent precursor plant, TMP (Fallujah 2), construction was not completed.	15	All equipment was completely destroyed during the Gulf war.
Inhalation chamber (MSE)	1	Destroyed under UNSCOM supervision.
Equipment stores	85	85 pieces of equipment were destroyed under UNSCOM supervision.
Aerial Bomb Workshop (MSE)	100	100 pieces of equipment were destroyed under UNSCOM supervision.
Filling station (MSE)	5	1) 4 pieces of equipment were completely destroyed during the Gulf war. 1) 1 unit was destroyed under UNSCOM supervision.

(continues)

Table III. *(continued)*

2. Iraqi declared CW agent production equipment *Production Plant/Unit (Location and past use)*	*Iraqi declarations on quantities of key equipment in their original configuration*	*Accounting status*
Total	553	1) 405 pieces of equipment were destroyed under UNSCOM supervision. 2) 75 pieces of broken equipment damaged during the 1991 Gulf war were accounted for by UNSCOM. 3) Several tens of pieces of equipment are buried under the debris of production buildings destroyed during the 1991 Gulf war.
Misc.		1) 197 pieces of glass production equipment procured by MSE for pilot plants were admitted by Iraq in 1997 and destroyed under UNSCOM supervision.

Foreword

David Kay

Senior Research Analyst, Potomac Institute, Washington, D.C., and former Director, Iraq Survey Group (2003–2004)

The importance of this encyclopedia was underscored by the fact that virtually the only area of agreement in the 2004 U.S. presidential campaign between the two major candidates, President George W. Bush and Senator John F. Kerry, was that the proliferation of weapons of mass destruction poses the most serious national security threat with which the next president would have to deal.

While the prospect of chemical, biological, radiological, or nuclear weapons falling into the hands of terrorists or regimes hostile to the United States and its friends is indeed a frightening prospect, how many of us understand exactly what this means? When were such weapons first developed? Which states and scientists are leading these developments? Have these weapons actually been used in the past? How often and with what consequence—not only for the populations they were used against, but for those that used them, as well? Do these weapons really give states a decisive edge over their adversaries? How easy are they to develop and use? Does the ease of development or use of such weapons by states, like North Korea, differ from the obstacles faced by terrorist groups, like al-Qaeda? What are the tools available to the United States to halt the spread of such weapons? Have we had any success in limiting the spread of these weapons? Are there any protective measures that individuals can take to lessen their vulnerability if such weapons are used?

These are but a few of the questions that the authors of this authoritative two-volume study attempt to answer. This encyclopedia will have enduring importance as states and societies attempt to come to terms with the consequence of the collision of scientific progress with the failure to develop a reliable global security structure. The initial development of chemical, biological, and nuclear weapons, as this study makes clear, often involved scientific and engineering breakthroughs of the highest order. The paths to enriching uranium and genetically modifying pathogens are but two examples of such successes, scientific breakthroughs that have made new classes of weapons possible. But scientific progress marches at a very fast rate, leaving behind old, but still dangerous, knowledge. For example, the secrets regarding methods for enriching uranium were simply bought by the Iraqis from the U.S. Government Printing Office. That office could not imagine that there was anything important in a 40-year-old project from the dawn of the U.S. nuclear program.

In another remarkable case, uranium enrichment technology was stolen from a commercial company in Holland by A. Q. Khan—a rather ordinary Pakistani who went to Germany to earn an engineering degree. Khan subsequently used this technology to develop Pakistan's nuclear weapons and then sold the same technology to North Korea, Iran, and Libya. The techniques of gene modification, which less than 20 years ago were the stuff of Nobel prizes, are now routinely taught in American high schools and community colleges and have opened up whole new classes of biological weapons. As this study also makes clear, even the safe disposal of weapons of mass destruction following a state's decision to abandon or limit their programs presents serious challenges of preventing the weapons and associated technology from falling into the hands of terrorists. The thousands of Soviet-era nuclear weapons and the engineering talent that created them represent a clear and present danger with which the world has not yet completely dealt. The readers of this work will find numerous examples of the lowering of the barriers to the acquisition by states and terrorists of these most terrible of weapons.

But this study does not simply present the horrors of a world filled with weapons of mass destruction. It also catalogs and illuminates the various methods of attempting to control and constrain these weapons—including treaties and agreements such as the Nuclear Non-Proliferation Treaty and the Chemical Weapons Convention, as well as intrusive inspections, such as the efforts of the United Nations to hunt such weapons in Iraq after the first Gulf War. As will be clear to the reader, such endeavors have had both successes and failures. Much remains to be done to ensure that their effectiveness matches the problems posed by the proliferation of such weapons. The largest gap in effective mechanisms of control and response to the acquisition of such weapons is with regard to the efforts of terrorists groups to acquire the means of mass murder. While these volumes identify the few efforts made in this regard, it is hard not to come away with a sense of dread for the future. Most control efforts have been aimed at states, not at terrorists operating outside of the control of states. Hopefully students and policy makers using this book a few years hence will be able to record more progress toward meeting this new challenge.

The authors and editors have done an important service by pulling together such an illuminating study at exactly the point when there is a broad political consensus of the importance of the problem. One can only hope that our citizens and our political leaders take the time to explore the depth of information presented here.

Preface: Weapons of Mass Destruction

Eric A. Croddy and James J. Wirtz

The term "weapon of mass destruction" (WMD) is a relatively modern expression. It was probably first used in print media following the international uproar over Germany's aerial bombardment of the Basque city of Guernica in April 1937. (The latter event was famously depicted in Picasso's painting *Guernica y Luno.*) Only a year before, another Axis power, Italy, had begun using mustard and other chemical warfare (CW) agents in Abyssinia (modern-day Ethiopia).[1] During the anxious years leading up World War II, WMD referred to the indiscriminate killing of civilians by modern weaponry, especially aircraft. It also echoed the fear of chemical weapons that was unleashed by World War I, which had come to a conclusion just a few years earlier.

Following the development of the atomic bomb in 1945, the term "WMD" came to include nuclear and eventually biological weapons. WMD was apparently first used to describe nuclear warfare by Soviet strategists. In 1956, during the 20th Communist Party Congress in Moscow, the Soviet Minister of Defense—and "Hero of Stalingrad"—Marshal Georgy Konstantinovich Zhukov prophesied that modern warfare "will be characterized by the massive use of air forces, various rocket weapons and various means of mass destruction such as atomic, thermonuclear, chemical and bacteriological weapons."[2] In that same year, the Hungarian Minister of Defense echoed Marshal Zhukov, stating that "Under modern conditions, the decisive aspect of operational planning is the use of nuclear and other weapons of mass destruction."[3]

When the West learned of Zhukov's speech, national security strategists in the United States and elsewhere became quite concerned. By inference, they concluded that WMD—nuclear, biological, and chemical weapons—were an integral part of Soviet military doctrine. Partly in response to Zhukov's ministrations on WMD, the United States reviewed its offensive chemical and biological weapons program in 1958. The U.S. military was never particularly enamored by chemical or biological weapons and treated them as a deterrent to be used in retaliation for the use of chemical or biological weapons used by the opponent. By the early 1990s, the U.S. military had abandoned offensive use of these weapons, although it maintained a research and development program designed to produce effective equipment, procedures, medications, and inoculations to defend against chemical and biological attack.

Over the last decade, much has been written about WMD. The meaning of the term itself is somewhat controversial, although there is a formal, legalistic definition. According to U.S. Code Title 50, "War and National Defense," per the U.S. Congress, the term "weapon of mass destruction" means "any weapon or device that is intended, or has the capability, to cause death or serious bodily injury to a significant number of people through the release, dissemination, or impact of toxic or poisonous chemicals or their precursors; a disease organism; radiation or radioactivity."[4] For its part, the U.S. Department of Defense has a similar characterization of WMD, although in addition it includes " . . .the means to deliver [WMD]."[5] So, what makes a weapon massively destructive? Is it the type of injurious agents involved, namely radioactive, chemical, or biological, or is it that the attack itself produces significant casualties or destruction? Also what would "significant" mean in this context: ten, a hundred, or a thousand casualties? What if very few people are actually killed or hurt by at attack? In the latter respect, the U.S. Federal Bureau of Investigation has a rather unique and somewhat satisfying interpretation of the term "WMD," invoked when the U.S. government indicted Timothy McVeigh with using a WMD in his 1995 terrorist attack in Oklahoma City. In this case, although the device used was a conventional bomb (employing ammonium nitrate-fuel oil explosive), "A weapon crosses the WMD threshold when the consequences of its release overwhelm local responders."[6]

Some analysts, however, have suggested that various technical hurdles prevent chemical and even biological weapons from causing casualties on a truly massive scale. Some point to the Aum Shinrikyo sarin attack on the Tokyo subway system on March 20, 1995, which resulted in eleven deaths, as an example of the *limits* of WMD. They note that high-explosives have been used with far greater lethal effects than sarin in the annals of modern terrorism. Others are increasingly concerned about the destructive potential of even rudimentary weapons. Analysts today are worried, for instance, that terrorists might try to employ radiological dispersal devices or "dirty bombs." These weapons do not detonate with a fission reaction, but rather utilize conventional explosives to distribute radiological materials and contaminate a given area. Few deaths are likely to result from the effects of a dirty bomb, but the consequences—in terms of anxiety, clean-up, and the recognized ability of a terrorist to conduct the very act itself—would likely be far reaching.

About the Encyclopedia

The very presence of chemical, biological and nuclear weapons in international arsenals and the potential that they might fall into the hands of terrorist organizations guarantees that weapons of mass destruction will be of great policy, public, and scholarly interest for years to come. We cannot resolve the debates prompted by WMD, but we hope that we and our contributors can provide facts to help the reader sort through the controversies that are likely to emerge in the years ahead. Much that is contained in these volumes is disturbing and even frightening; it is impossible to write a cheery encyclopedia about weapons whose primary purpose is to conduct postindustrial-scale mass murder. The sad truth of the matter is that chemical, biological, radiological, and nuclear weapons reflect the willingness of humans to go to great lengths to find increasingly lethal and destructive instruments of war and violence. We are pleased to note, however, that much of what is reported in these volumes is historical in nature and that civilized people everywhere reject the use of chemical and biological weapons. International law is replete with treaties, agreements, and regimes whose purpose is to proscribe the use of these weapons, or mitigate the consequences of any such use. In particular, the world has successfully kept nuclear weapons in reserve for almost sixty years as truly deterrent weapons of last resort.

Our encyclopedia covers a wide range of topics, some historical, some drawn from today's headlines. We describe many of the pathogens, diseases, substances, and machines that can serve as weapons of mass destruction, as well as their associated delivery systems. We also describe important events and individuals that have been influential in the development of weapons of mass destruction and doctrines for their use (or control). We have encouraged our contributors to highlight ongoing controversies and contemporary concerns about WMD and current international arms control and nonproliferation efforts intended to reduce the threat they pose to world peace and security. Even a work of this length, however, cannot completely cover the history, science, and personal stories associated with a topic of this magnitude, so we have included abundant references to help readers take those initial steps for further study of the topics we survey.

Acknowledgments

Our deepest debt is to the contributors who made this volume a reality. Many of them joined the project at its inauguration several years ago and have waited a long time to see their work in print. It is impossible for just three people to be experts on all of the subjects covered in this volume, and without the hard work of our contributors, this encyclopedia would never have been completed. Thanks to our research assistants, Abraham Denmark and Laura Fontaine, who uncovered most of the key documents in both volumes and wrote a few entries for us, as well. We also want to express our appreciation to a senior government official who reviewed Volume II for accuracy and sensitive material. We owe a special debt to Jeff Larsen, our managing editor, whose help was instrumental in the success of this project. Not only did he provide editorial support to both volumes, but he displayed a keen ability to deal with the publisher and our 95 contributors, keep track of timelines, requirements, and progress, and gently push the two of us when we needed encour-

agement during this multiyear project that involved over 500 separate parts. Finally, we also want to express our appreciation to Alicia Merritt, Martha Whitt, Giulia Rossi, and the behind-the-scenes copyeditors at ABC-CLIO who worked tirelessly to help get this manuscript into print. We discovered that nothing is a trivial matter when it comes to a manuscript of this size. The commitment of our publisher to this topic, and the dedication of the production staff at ABC-CLIO, greatly facilitated the completion of these volumes.

We hope that this encyclopedia will help inform the public debate about weapons of mass destruction and international security policy, with the goal of never again seeing such weapons used in anger.

Introduction: Nuclear Weapons

James J. Wirtz

On July 16, 1945, the world changed forever when British and American scientists and engineers tested an implosion-type atomic device in the desert near Alamogordo, New Mexico, producing the first nuclear explosion. Developed under the code name "Manhattan Project," this first-generation fission device was quickly weaponized, and when the U.S. Army Air Corps dropped atomic bombs on the Japanese cities of Hiroshima and Nagasaki in August 1945, World War II in the Pacific came to an end. The United States did not retain a nuclear monopoly for long. The Soviet Union detonated a nuclear device in 1949. By the early 1950s, a second generation of fusion weapons, with explosive power measuring in millions of tons of trinitrotoluene (TNT), was entering Soviet and U.S. nuclear arsenals. As the Cold War unfolded, the Soviet and U.S. militaries deployed tens of thousands of tactical, theater, and strategic nuclear weapons to deter both conventional and nuclear attacks. Soviet-American strategic relations reflected a situation of mutual assured destruction (MAD), which moderated superpower behavior but risked catastrophic destruction if some military or diplomatic insult upset the delicate "balance of terror." People everywhere breathed a collective sigh of relief as the risk of nuclear Armageddon became increasingly remote at the end of the Cold War. Since the early 1990s, Russia and the United States have cut the number of their deployed nuclear forces and ended nuclear force modernization and testing. At the turn of the century, it appeared that the threat posed by nuclear weapons was diminishing.

Just as the superpowers pulled back from the nuclear abyss, however, new nuclear threats appeared on the horizon. India and Pakistan tested nuclear weapons in the late 1990s, joining Great Britain, France, and China as overt nuclear powers. It also is widely believed that Israel and North Korea possess a nuclear arsenal. For a time, South Africa possessed a few nuclear weapons, but it renounced its nuclear ambitions and joined the Nuclear Nonproliferation Treaty (NPT) as a non–nuclear weapons state in 1991. Ukraine, Belarus, and Kazakhstan inherited large nuclear arsenals for a short period following the collapse of the Soviet Union in the early 1990s, but all three states were persuaded to give up those weapons and join the NPT by the mid-1990s. Other states have made modest efforts toward acquiring their own arsenals but for various reasons have not yet reached that objective. Nonetheless, some thirty states remain technologically capable of creating atomic weapons fairly quickly should they decide to do so.

The September 11, 2001, terrorist attacks on the World Trade Center and the Pentagon highlighted the fact that terrorists and nonstate actors were interested in creating mass casualty attacks, and many believe that terrorists might be attracted to nuclear or radiological devices as weapons of terror. The risk that any state would employ its nuclear arsenal in a massive nuclear attack is diminishing, but the threat of a small-scale use by some state or nonstate actor is on the rise, especially as nonproliferation efforts fail to prevent the "hard cases" from acquiring nuclear weapons. Officials also worry about the emergence of an international black market in nuclear weapons technology, radiological materials, and even complete weapons. As world history enters the so-called "second nuclear age," nuclear weapons remain a force to be reckoned with, both on the battlefield and in international politics.

Is There a Nuclear Revolution?

Debate about the importance and impact of nuclear weapons on world politics is as fierce now as it was at the dawn of the nuclear era sixty years ago. Nuclear weapons, the advent of long-range delivery systems, and the establishment of a new organization, the U.S. Air Force, produced a revolution in military affairs (RMA) that fundamentally transformed warfare. Bernard Brodie, writing in 1946, was quick to recognize the nature of this RMA when he observed that national objectives for military efforts had changed: Whereas militaries traditionally strove to win wars, with the advent of nuclear weapons their purpose became deterring wars. Nuclear weapons would make major war a calamity, demanding that all military and diplomatic efforts be directed at deterring, by threat of retaliation in kind, nuclear war. Decades later, Robert Jervis (1989) noted that this RMA had produced a nuclear revolution: Stability (the absence of great-power war) now characterized relations between great powers because none dare risk direct military confrontation given the dark shadow of nuclear escalation. There were warnings that this nuclear stability might actually increase the likelihood of smaller wars, however, especially along the "periphery." Glenn Snyder (1961), for instance, identified a "stability-instability" paradox: Stability at the nuclear level of conflict actually made great powers more tolerant of instability (war) in peripheral areas or among clients. But at the end of the Cold War, it did appear that peace, or at least the absence of great-power conflict, was the by-product of the threat of massive nuclear destruction.

Nuclear weapons introduced stability in great-power relations because they produced a modicum of restraint in both diplomatic and military adventures undertaken by Soviets and Americans during the Cold War. Nuclear weapons effects also are predictable, and nuclear powers tend to share a similar knowledge base about the destructiveness of nuclear weapons. Both U.S. and Soviet officials recognized the destructiveness of a full-scale nuclear exchange. Moreover, as Thomas Schelling (1966) noted, the absence of an effective defense against massive nuclear attack allowed nuclear-armed states to engage in the "diplomacy of violence." States armed with large nuclear arsenals could destroy each other's societies while virtually bypassing direct engagement of the opponent's military forces. To a lesser extent than conventional warfare, which is influenced by strategy, tactics, leadership, equipment, training, and morale, the outcome of nuclear combat is driven by the enormous explosive yield of nuclear weapons themselves, not by superior strategy. In other words, once nuclear arsenals became very large and deployed in relatively survivable ways, there was little either the United States or the Soviet Union might do to prevent their opponent from undertaking a nuclear retaliatory strike. MAD was defense dominant because both sides had the ability to deny victory in a nuclear war to the opponent. No nation with a leader in his right mind would start a nuclear war that it would be sure to lose—at least that was the argument advanced by those who championed the nuclear revolution.

Critics of the nuclear revolution have generally come in two varieties: those who believe that it is mistaken to treat deterrence as the dominant nuclear doctrine, and those who believe that nuclear revolutionaries underestimate the risks involved in nuclear deterrence. Those who champion nuclear warfighting strategies believe that others might think nuclear war is winnable or that deterrence itself is unreliable and can fail because of misunderstandings, irrationality, or simple human frailty. Under these circumstances, they believe that for deterrence to be effective, it is imperative to develop credible nuclear warfighting options. Missile defenses that deny opponents the ability to hold U.S. or allied targets at risk thus become an important way to strengthen U.S. deterrent threats. They also believe that nuclear weapons should be integrated into forces and war plans to give national authorities limited nuclear options that could influence battlefield events in positive ways. The 2002 U.S. Nuclear Posture Review, for example, called for the development of highly selective and limited nuclear options to increase the credibility of U.S. deterrent threats and to hold opponents' small nuclear, chemical, and biological weapons arsenals at risk while reducing the prospect of collateral damage.

Other critics worry, however, that the circumstances that make nuclear deterrence "stable" are rare and unlikely to be found in emerging weapons states and regional rivalries. New nuclear weapons states might adopt nuclear doctrines or forces that are shaped by domestic political turmoil, by political dreams of regional domination, or by a specific leader's megalomania. Maintaining negative control over nuclear arsenals (preventing weapons from being used without proper authorization) is daunting in states that face ethnic, fundamentalist, or political unrest. Countries in immediate proximity to each other—here India and Pakistan come to mind—can expect virtually no tactical warning of nuclear attack, increasing the likelihood that they might adopt preventive or preemptive nuclear warfighting strategies. These critics also suggest that building "safe" nuclear weapons is technically challenging and financially demanding and might be beyond the resources of new nuclear powers. No matter what rich or poor states do, "normal accidents," the tendency of complex systems to interact with humans in unanticipated ways, are likely to defeat safety systems.

Those who champion disarmament as the best way to deal with nuclear weapons believe that nuclear deterrence is fundamentally immoral and misguided. Disarmament advocates suggest that those who believe in deterrence or warfighting strategies simply perpetuate a war system that is destined to fail catastrophically. They dismiss ideas about a so-called nuclear revolution as window dressing to justify using a nuclear arms race and threats of nuclear warfare as a means of achieving political objectives. In their view, nuclear weapons are so destructive that they are irrational instruments of war that place at risk far more people and infrastructure than their users can hope to protect. They point out that a full-scale nuclear exchange during the Cold War could have eliminated human beings from planet Earth. Disarmament advocates believe that efforts to develop forces for deterrence create arms races, fear, and hostility and that the only way to break this negative trend is to eliminate nuclear weapons as quickly as possible. Other disarmament advocates believe that nuclear deterrence was epiphenomenal when it came to maintaining stability during the Cold War. They believe that fear of conventional hostilities generally deters war, that most leaders are risk adverse, and often that the spread of democracy throughout the world will soon render nuclear weapons and deterrent strategies obsolete. Others believe that a nuclear taboo—a tradition of nonuse of nuclear weapons—governs the behavior of nuclear weapons states, and that nothing should be done to increase the likelihood that nuclear weapons could or would be used in battle. In general, disarmament advocates see nuclear weapons as simply a highly destructive and dangerous development in humanity's tendency to moderate behavior using threats and violence. They offer diplomacy, mediation, or accommodation as an alternative to nuclear threats to maintain the peace.

Nuclear Weapons Effects: A Primer

Unlike the debate about the political and strategic impact of nuclear weapons, the topic of basic nuclear physics holds few unknowns. The effects that nuclear weapons produce once they are detonated are well documented. A nuclear weapon is the general name given to any device that creates an explosion from energy involving atomic nuclei, either through a fission or a fusion reaction. A gun-type fission weapon is relatively simple to construct; the greatest barrier to obtaining this type of nuclear weapon is the difficulty in manufacturing or obtaining weapons-grade fissile material. By contrast, high-yield, low-weight fusion weapons are some of the most complex machines ever developed by human beings. They combine exquisite mechanical and electrical engineering design and manufacturing with innovative applications of nuclear physics and engineering. The details of specific weapons designs and operating principles are considered top secret by governments around the world.

When a nuclear weapon is detonated, it produces a series of weapons effects that occur in a predictable sequence: electromagnetic pulse (EMP), direct nuclear radiation, thermal radiation (which mostly takes the form of light), blast, and fallout. Bomb designers can vary the way the energy of a nuclear explosion is distributed across these effects. The so-called "neutron bomb," for instance, shifts more energy toward EMP and direct radiation in an effort to reduce collateral damage when used against targets on the ground (such as enemy armored formations) or to maximize damage to the electronic systems of targets in space (such as an opponent's incoming nuclear warheads). Weapons effects vary depending on a variety of influences, including the height of burst (for example, air burst, ground burst, underwater detonation, or underground detonation), weather, and local geography.

EMP and direct radiation are produced immediately upon detonation of a nuclear weapon. EMP is produced by the interaction of gamma radiation and matter that destroys all electronic systems that are not deliberately hardened against its effects. Although EMP effects fall off relatively quickly and are not harmful to humans, high-altitude air bursts can produce a very strong EMP wave that can affect systems thousands of miles away. It is easy to imagine ways that EMP can create indirect casualties as electronic systems necessary to sustain human life or prevent lethal accidents are destroyed by this burst of electronic energy. Although small nuclear weapons are capable of producing direct radiation that is lethal at greater ranges than are reached by other weapons effects, the lethal range of direct radiation for more powerful nuclear weapons is well within the lethal range of blast or thermal radiation produced by the explosion.

About 35 percent of the energy generated by a nuclear explosion takes the form of thermal radiation (in the form of a light pulse). The thermal radiation produced by a relatively large, 1-megaton air burst (a weapon that would have to be detonated at an altitude of about 8,000 feet to prevent the nuclear fireball from touching the ground) can produce first-degree burns on exposed skin at about a distance of 7 miles from the point of detonation, second-degree burns at a distance of about 6 miles, and third-degree burns within a radius of about 5 miles. Third-degree burns over 30 percent of the body will produce shock, a condition that requires immediate medical treatment. This weapon would also produce temporary flash blindness in anyone caught out in the open within about 13 miles on a clear day and within 53 miles on a clear night. The thermal light pulse also can produce retinal burn, causing permanent blindness, but this injury is relatively rare, suggesting those who suffer it probably would be killed by other weapons effects.

Blast, which arrives a few seconds after the light pulse, takes the form of overpressure (a quick rise in atmospheric pressure) and dynamic overpressure (wind). At about 1 mile away from a 1-megaton air burst, overpressure increases to about 20 pounds per square inch (psi) and wind velocities reach a peak of about 470 miles per hour. This is enough to level steel-reinforced concrete structures. At about 5 miles away from the blast, overpressure reaches about 5 psi and wind velocities reach about 160 miles an hour, which is sufficient to destroy lightly constructed commercial buildings and most residences. This "5-psi ring" is an important dividing line in terms of nuclear weapons effects: Planners assume that 50 percent of the people within this ring would be killed promptly by the blast effects of a nuclear weapon. At about 12 miles away from a 1-megaton air burst, overpressure drops to less than 1 psi and wind velocities drop to less than 35 miles per hour, making flying glass and debris the greatest hazard. When planners calculate damage expectancies from nuclear weapons, they generally rely on blast effects, not thermal effects, to predict the damage and casualties that will occur.

Irradiated earth and debris that is carried aloft in a nuclear detonation and then returns to the ground is known as fallout. A nuclear ground-burst intended to destroy hardened targets such as missile silos or underground command facilities would produce the greatest amount of fallout; air bursts intended to destroy area targets such as cities or to barrage-attack the operating areas of land-based mobile missiles would produce the least. How fallout is deposited is highly variable and depends on wind speed and direction, the height to which the fallout is initially lofted by the fireball, weather (rain can wash fallout out of the sky, creating local "hot spots"), and geography (weapons effects can be shaped by local geographic features, such as hills). The amount of radiation produced by fallout will diminish over time as the irradiated materials "decay." Most radioactive materials have short half-lives; in other words, they decay relatively quickly. Highly radioactive materials will decay by a factor of 1,000 in about two weeks. Some radioactive materials, however, have extremely long half-lives: Strontium 90 and cesium 137 remain radioactive for years and can contaminate the food chain, for example.

Exposure to radiation kills at the cellular level. An exposure of 600 rem (Roentgen equivalent man) over about a week has a 90 percent chance of killing an individual; an exposure of 300 rem is probably the minimal dose necessary to create a lethal illness quickly. Individuals who suffer from preexisting medical conditions probably would succumb to radiation sickness or secondary infections at relatively low levels of radiation exposure. Exposure to between 50 and 200 rem interferes with the body's ability to heal itself, increasing the probability that people exposed to nonlethal levels of radiation will die from thermal or kinetic injuries produced by other weapons effects. Exposure to radiation also can have a long-term effect on a population. Exposure to 50 rem would probably increase the occurrence of fatal cancers at a rate of between 0.4 and 2.5 percent among an exposed population (*The Effects of Nuclear War*).

Living with the Bomb

Three methods of dealing with the presence of nuclear weapons have emerged in international relations: deterrence, arms control, and disarmament. Deterrence remains the dominant strategy of nations to prevent the use of nuclear weapons by other states. It creates a state of mind in an adversary that makes an act of aggression on the part of the opponent less likely. States using this strategy must have the capability to retaliate in kind if the opponent uses nuclear weapons and must make credible threats that nuclear retaliation will occur. There is much debate about the effectiveness of deterrence, when it has failed in the past, and under what circumstances it is likely to fail again in the future. During the Cold War, both the Soviet and U.S. militaries went to great lengths to construct secure second-strike forces and command and control facilities that could survive a nuclear attack and strike a retaliatory blow. But as political motivations for war have diminished among nuclear powers over the past couple of decades, many observers believe that a little nuclear deterrence goes a long way toward reducing the likelihood of war.

Negotiations among enemies to take actions of mutual interest—a process that came to be known as arms control—was a revolutionary idea when it reemerged in the 1950s as a way to moderate the nuclear arms race. With the goals of making war less likely, reducing death and destruction if war should break out, and reducing the resources devoted to armament, arms control negotiations achieved some successes during the Cold War. Arms control probably made its greatest contribution by allowing the superpowers to clarify their strategic intentions and expectations and by demonstrating to all concerned that negotiation offered an alternative to violent confrontation as a means of managing the nuclear standoff. Because the "Russian" or "American" threat no longer drives defense planning in Washington or Moscow, traditional approaches to arms control are starting to produce diminishing returns in Russian-American relations. But arms control, especially new types of confidence-building measures, might help to moderate other regional rivalries that have been exacerbated by nuclear proliferation and an accelerating race to develop more advanced nuclear delivery systems.

Disarmament efforts have made modest progress over the past half-century. The Nuclear Nonproliferation Treaty (NPT) serves as the basis of the international nonproliferation regime. The NPT is a means by which states not interested in developing nuclear weapons can register formally their nonnuclear status. It also pressures nuclear powers to take action to reduce not only the size of their nuclear arsenals but also their reliance on nuclear weapons in their military and foreign policies. The nonproliferation regime provides a method for regulating legitimate commerce in nuclear materials, and it provides an inspection and monitoring mechanism run by the International Atomic Energy Agency to guarantee that nuclear materials are not diverted into nuclear weapons production. Revelations of a black market in nuclear materials, technologies, and associated delivery systems, however, have cast doubts on current international efforts to prevent nuclear materials from falling into the wrong hands, especially nonstate actors and terrorist groups.

About Volume II: Nuclear Weapons

Nuclear weapons create a set of ethical, political, and military challenges that are difficult to understand. There are no easy solutions to the problems created by nuclear weapons. Indeed, the nuclear question has concentrated some of the best minds on the planet over the past sixty years. The output of this effort is enough to fill an average municipal library. It is impossible to capture this entire body of knowledge in a single volume, but our contributors have provided matter-of-fact explanations of key concepts and accessible descriptions of events to provide a ready reference for those interested in learning more about nuclear weapons. The more societies know about the true effects and dangers of nuclear weapons, the less likely it will be that nuclear weapons will ever be used in war again.

Chronology: Nuclear Weapons

The "nuclear age" began at five o'clock on the morning of 16 July 1945 with the detonation of the world's first atomic bomb—the Trinity test in the high desert of central New Mexico. This successful explosion marked the culmination of three years of frantic scientific and engineering research and development under the auspices of the U.S. Manhattan Project, which the United States had instituted in 1942 to ensure that the Allies achieved atomic weapons before Germany. There had been scientific discoveries and research in the field of radiology prior to World War II (primarily in the 1930s), but the threat of an adversary achieving the "ultimate weapon" before the Allies had one was a strong motivating factor in the efforts of the Manhattan scientists.

Following the war the world entered a long twilight period known as the Cold War. The United States and its allies faced off against a seemingly implacable foe, the Soviet Union. Both sides rapidly built up their nuclear arsenals until there were some 60,000 atomic warheads pointed at one another. After years of "standing toe to toe," threatening nuclear war and "looking into the abyss," reason slowly began to enter into the equation. Concepts like arms control and nuclear disarmament began to determine international relations. Stockpile levels were already coming down dramatically by the time the Soviet Union dissolved in 1991, following which the world shifted from a bilateral standoff to a less well-defined era. Despite the fact that there are fewer nuclear weapons today, whether the post–Cold War era will be one our children look back on as "safer" than the Cold War is a question still out for consideration.

The history of the Cold War is replete with events falling into two alternative categories: new developments in weapons design and capabilities as the arms race between the two superpowers accelerated, on the one hand, while on the other, we see attempts to improve relations between the two primary actors on the international scene, involving summit meetings, arms control negotiations and agreements, and force reductions.

In this short chronology we have listed merely some of the highlights of this two-pronged effort over the past seventy years.

1933	Hungarian physicist Leo Szilard theorizes atomic structure.
1938	Otto Hahan and Fritz Strassmann's discovery of fission steers Germany toward developing an atomic weapon.
July 1939	Szilard and Edward Teller meet with Albert Einstein in New York to describe Germany's efforts. Einstein writes letter to President Franklin Roosevelt warning him of the possibility of building an atomic weapon.
Fall 1939	United States grants small funding for research into nuclear fission. Key scientists involved include Szilard, Teller, and Enrico Fermi. Early work is carried out primarily at Columbia University and the Universities of California and Chicago.

1941	By 1941, Germany leads the race for the atomic bomb. They have a heavy-water plant (in Norway), high-grade uranium compounds, a nearly complete cyclotron, capable scientists and engineers, and the greatest chemical engineering industry in the world.
June 1942	The United States begins major research program to develop and build a usable atomic weapon. The effort is called the Manhattan Project, and is directed by Major General Leslie Groves and Robert Oppenheimer.
1942–1943	Three entirely new towns are created for the sole purpose of developing the components of an atomic bomb: Los Alamos, New Mexico (center of scientific and engineering efforts), Oak Ridge, Tennessee (where uranium enrichment is centered), and Hanford, Washington (where plutonium is reprocessed from spent reactor fuel). This is the beginning of what will become a massive American atomic infrastructure.
2 December 1942	At the University of Chicago Fermi oversees the first controlled energy release from the nucleus of the atom using a uranium graphite reactor.
16 July 1945	The United States tests the world's first atomic bomb at the Trinity Site in central New Mexico.
6 August 1945	A United States B-29 bomber drops atomic bomb on Hiroshima, Japan (another bomber drops a second bomb on Nagasaki, Japan three days later).
4 April 1946	United States passes Atomic Energy Act (also known as the McMahon Act), creating the U.S. Atomic Energy Commission (which was absorbed into the United Nations Disarmament Commission in 1952).
14 June 1946	Baruch Plan presented by the United States to the United Nations, an early disarmament effort to place all nuclear material and weapons under UN control. (Proposal is rejected by the USSR in December 1946.)
29 August 1949	Soviet Union tests its first atomic bomb.
1 November 1951	United States tests the world's first hydrogen bomb.
3 October 1952	Great Britain tests its first atomic bomb.
August 1953	Soviet Union tests its first hydrogen bomb.
8 December 1953	United States makes an "Atoms for Peace" proposal to the UN General Assembly.
January 1954	United States launches its first nuclear powered submarine.
23 October 1954	In a protocol to the Brussels Treaty (which created the

	West European Union) and in return for permission to rearm itself with conventional weapons, West Germany pledges not to produce, procure, or possess weapons of mass destruction.
December 1954	The North Atlantic Treaty Organization deploys atomic weapons in Europe.
26 October 1956	International Atomic Energy Agency created.
4 October 1957	USSR launches Sputnik, the world's first orbiting satellite.
15 October 1957	USSR and China sign a defense agreement whereby the Soviets agree to provide China with technical help in developing their own atomic bomb.
10 January 1958	United States tests the world's first intercontinental ballistic missile (ICBM).
31 October 1958	United States, United Kingdom, and USSR begin negotiations on a comprehensive test ban treaty (CTBT).
June 1959	United States launches the first nuclear powered submarine equipped with submarine-launched ballistic missiles (SLBM).
1 December 1959	Twelve nations sign the Antarctic Treaty, demilitarizing the continent, and leading the way to future geographic nuclear weapon free zones.
13 February 1960	France tests its first atomic bomb.
15–28 October 1962	The United States and the Soviet Union come close to nuclear war during the Cuban Missile Crisis.
20 June 1963	United States and Soviet Union establish a crisis communications link by signing the Hot Line Agreement.
5 August 1963	United States, United Kingdom, and USSR sign the Limited Test Ban Treaty, banning nuclear weapon tests in the atmosphere, outer space, and underwater.
1964	United States ceases production of highly enriched uranium.
16 October 1964	China tests its first atomic bomb.
27 January 1967	Outer Space Treaty signed by 67 nations; demilitarizes space and celestial bodies.
14 February 1967	Treaty of Tlatelcolco signed, creating the Latin American Nuclear Weapon Free Zone.
13 December 1967	United States announces that it has successfully tested ICBM warheads with multiple independently targetable reentry vehicles (MIRVs).
1 July 1968	Nuclear Non-Proliferation Treaty (NPT) signed by 73 countries (currently there are 187 states parties to the treaty).

3 September 1971	The Zangger Committee created by 33 nations to voluntarily restrict nuclear-related exports.
30 September 1971	Nuclear War Risk Reduction Agreement signed by the United States and Soviet Union (also called the Accidents Measures Agreement).
26 May 1972	Strategic Arms Limitation Treaty (SALT I) signed in Moscow by the United States and Soviet Union. The first major strategic arms control treaty, it consists of an Interim Agreement on Strategic Offensive Arms (freezing the number of missile launch sites) and an Anti-Ballistic Missile Treaty (ABM) (which restricts the development of missile defenses).
18 May 1974	India tests its first atomic "device."
3 July 1974	United States and Soviet Union sign the Threshold Test Ban Treaty, limiting the size of allowable underground nuclear weapons test explosions.
23 April 1975	The Nuclear Suppliers Group is created to restrict the export of sensitive technology.
1 August 1975	The Helsinki Accords are signed by 35 states, creating the Conference on Security and Cooperation in Europe and emphasizing the value of confidence- and security building measures.
28 May 1976	Peaceful Nuclear Explosions Treaty signed by the United States and USSR.
March 1979	Three Mile Island nuclear power reactor accident in Pennsylvania.
18 June 1979	SALT II Treaty signed by the United States and Soviet Union (limiting the number and types of strategic delivery vehicles allowed); treaty is never ratified.
June 1981	Israeli jets strike Iraqi nuclear reactor in preemptive attack.
23 March 1983	United States announces its strategic defense initiative.
6 August 1985	Treaty of Rarotonga signed, creating the South Pacific Nuclear Free Zone.
April 1986	Soviet nuclear reactors explode and melt down at Chernobyl, Ukraine.
7 April 1987	Missile Technology Control Regime established to reduce proliferation risks through controls on technology transfers.
8 December 1987	Intermediate-Range Nuclear Forces Treaty (INF) signed by the United States and Soviet Union, eliminating an entire category of missiles with a range of 500 to 5,500 kilometers.
1988	United States closes its plutonium production facilities.

9 November 1989	Berlin Wall falls in peaceful revolution; within two years NATO has declared the Cold War over (July 1990) and the Soviet Union disappears (December 1991).
3 April 1991	Following the victory by the U.S.-led international military coalition that defeated Iraq in the Gulf War, the United Nations creates a Special Commission on Iraq (UNSCOM) to find and destroy Iraqi capabilities to make weapons of mass destruction.
9 July 1991	Strategic Arms Reduction Treaty (START I) signed by United States and Soviet Union; limits strategic delivery vehicles on each side.
27 September 1991	United States initiates series of reciprocated Presidential Nuclear Initiatives that eliminate or remove most tactical nuclear weapons systems from deployment and lead to the de-alerting or de-targeting of strategic systems.
27 November 1991	U.S. Congress passes Nuclear Threat Reduction Act (also called the Nunn-Lugar Program) to help the Soviet Union transport, store, safeguard, and destroy its residual nuclear arsenal; leads to creation of the Cooperative Threat Reduction Program.
20 January 1992	North and South Korea sign the Joint Declaration on the Denuclearization of the Korean Peninsula.
24 March 1992	Treaty on Open Skies signed by 25 nations to allow intrusive aerial reconnaissance for arms control monitoring and compliance verification.
23 September 1992	Last U.S. underground nuclear test.
3 January 1993	START II Treaty signed by the United States and Russia; further limits number of strategic delivery systems and eliminates warheads with multiple independently targetable reentry vehicles (MIRV) and heavy ICBMs.
14 January 1994	United States, Russia, and Ukraine sign Trilateral Agreement, whereby Ukraine agrees to return to Russia nuclear weapons left on its territory upon the demise of the Soviet Union.
24 March 1994	South Africa admits it had a secret nuclear weapons program that since 1974 had produced six weapons, now destroyed.
30 May 1994	United States and Russia agree to detarget their ICBMs and SLBMs away from each other's territory. Russia concludes similar agreements with Great Britain and China.
23 June 1994	United States and Russia sign agreement on shutting down Russia's plutonium production facilities (also

	called the Gore-Chernomyrdin Agreement).
22 September 1994	United States releases its Nuclear Posture Review, calling for a smaller version of the Cold War nuclear triad.
23 October 1994	United States and North Korea sign Agreed Framework to stop North Korea's attempts to develop nuclear weapons in return for food and energy assistance.
23 March 1995	Fissile Material Cutoff Talks begin in the UN Conference on Disarmament.
12 May 1995	States parties to the NPT Extension Review conference agree to extend the treaty indefinitely
15 December 1995	Treaty of Bangkok signed, creating the Southeast Asian Nuclear Weapons Free Zone.
11 April 1996	Pelindaba Treaty signed, creating the African Nuclear Weapons Free Zone.
10 September 1996	UN adopts the Comprehensive Test Ban Treaty (the United States is the first country to sign it, but the U.S. Congress refuses to ratify it on 13 October 1999).
21 March 1997	United States and Russia agree on parameters for START III negotiations (which never occur).
11 May 1998	India tests atomic weapons.
28 May 1998	Pakistan tests its first atomic weapon.
22 September 1998	United States and Russia begin Nuclear Cities Initiative to provide nonmilitary work for Russian scientists and engineers formerly involved in the nuclear weapons complex
December 2001	United States releases Nuclear Posture Review, calling for a new triad consisting of strategic strike forces, missile defenses, and an enhanced infrastructure.
24 May 2002	United States and Russia sign Strategic Offensive Reductions Treaty (SORT, also known as the Moscow Treaty), calling for reductions in deployed strategic warheads to approximately 2,000 by 2012.
13 June 2002	United States withdraws from the ABM Treaty, citing a need to develop and deploy a working antiballistic missile system.
27 June 2002	G-8 countries agree to a Global Partnership against the Spread of Weapons and Materials of Mass Destruction.
5 October 2002	North Korea admits it has an ongoing nuclear weapons program in defiance of its responsibilities under the NPT.
September 2003	Proliferation Security Initiative signed by 11 countries.

A

ACCIDENTAL LAUNCH PROTECTION SYSTEM
See Strategic Defense Initiative

ACCIDENTAL NUCLEAR WAR

An accidental nuclear war would be one resulting from the use of nuclear weapons without the approval of legitimate political or military authorities in decision-making processes evaluating the need for a nuclear attack or retaliation in light of national security concerns. Several potential causes of accidental nuclear war have emerged in the literature.

An accidental war could be caused by the malfunction of some weapon system or from human error involved in the operation of a weapon. In terms of operator error or equipment malfunction, weapons literally would begin to launch or detonate "accidentally," a scenario that could lead to a nuclear exchange, especially in time of crisis. Although many procedures are followed to maintain negative control of nuclear weapons (that is, to guarantee that they will not be used without orders), highly complex systems can interact in unexpected ways, defying the best efforts of operators to maintain or regain control. During the Cold War, for example, observers worried that the Soviet and U.S. early warning networks and command and control systems actually formed a single and tightly linked mechanism that might produce a "ratcheting effect" in time of crisis, generating a feedback loop that would force both sides to take steps greatly increasing the prospect of war. Another concern was that early warning data could be mislabeled or misinterpreted, leading to a mistaken decision to retaliate.

"Inadvertent war" is sometimes used interchangeably with the term "accidental war," but it identifies a different phenomenon. Inadvertent war is caused by the close interaction of opposing military forces in peacetime or during a crisis. Fighting erupts as a result of locally rational decisions or mistakes made by local commanders, decisions that effectively disconnect the use of force from political control. Inadvertent war is not accidental in the sense that it is caused by mechanical failure or operator error; rather, it is caused by the tendency of military interactions to unfold according to their own logic.

Since the dawn of the nuclear era, substantial thought and effort have gone into preventing accidental and inadvertent nuclear war. Nuclear powers have attempted to construct the most reliable technology and procedures for command and control of nuclear weapons, including robust, fail-safe early warning systems for verifying attacks. The United States and the Soviet Union also maintained secure second-strike capabilities to reduce their own incentives to launch a preemptive strike against each other during crisis situations or out of fear of a surprise attack. The two nuclear superpowers worked bilaterally to foster strategic stability by means of arms control and confidence-building measures and agreements. Several confidence-building agreements were negotiated between the two superpowers to reduce the risk of an accidental nuclear war: the 1971 Agreement on Measures to Reduce the Risk of Outbreak of Nuclear War, the 1972 Agreement on the Prevention of Incidents on and over the High Seas, and the 1973 Agreement on the Prevention of Nuclear War. Following the end of the Cold War, the United States and the Russian Federation have continued to offer unilateral initiatives and to negotiate bilateral agreements on dealerting and detargeting some of their nuclear forces to further reduce the likelihood of a catastrophic nuclear accident. They have concluded agreements on providing each other with notifications in the event of ballistic missile launches or other types of military activities that could possibly be misunderstood or misconstrued by the other party.

The likelihood of accidental nuclear war has always been viewed as low, but the consequences of such a war or incident were, and remain, viewed as so potentially catastrophic as to require serious diplomatic and scholarly attention and analysis. Today, many analysts consider the risk of accidental nuclear war greater than the possibility of a premeditated nuclear exchange between nations. As additional nuclear powers have emerged, so have concerns about the technology and procedures for command and control of nuclear weapons. The proliferation of nuclear weapons has been thought to increase the probability of accidental or inadvertent nuclear war, especially since stability criteria are less obvious in a multiplayer game. In addition, the risks of dramatic political changes in states possessing nuclear weapons, highlighted by the breakup of the Soviet Union and the political fragility of a nuclear-armed Pakistan, leave many observers uneasy about the safety and security of nuclear arsenals amid politically or militarily chaotic situations.

ACCURACY

A weapon's accuracy is usually measured in terms of "circular error probable" (CEP), that is, the radius within which a warhead or bomb will land 50 percent of the time. The lower the CEP, the more accurate the weapon. As technology and delivery systems have improved, CEP for most weapons has shrunk. Early bombs had CEPs only as accurate as the bombardiers or pilots who dropped them. The "precision-bombing" of World War II had CEPs of hundreds or even thousands of feet. Similarly, early cruise missiles and intercontinental ballistic missiles (ICBMs) also had CEPs in the thousands of feet. Because of this, nuclear warhead yield was very large to ensure destruction of a target. Today, accuracy is in the hundreds of feet for modern nuclear weaponry. Precision-guided technology is allowing CEPs as small as a few feet, allowing the use of very low-yield nuclear or conventional warheads to destroy even hard or deeply buried targets.

ACHESON-LILIENTHAL REPORT

The Acheson-Lilienthal Report, formally entitled *Report on the International Control of Atomic Energy,* was the first major nuclear proliferation-control document of the post–World War II era. It proposed the establishment of a safeguarding regime for nuclear materials.

The report, released in 1946 by Assistant Secretary of State Dean Acheson and the chairman of the Tennessee Valley Authority, David Lilienthal, was a result of a major effort to understand the global strategic environment following the use of atomic weapons against Japan. The devastation at Hiroshima and Nagasaki sparked immediate fear in the United States about the spread of atomic weapons.

The Acheson-Lilienthal Report also recognized the inherent interrelationship between peaceful and military uses of atomic energy and foresaw that no ban on atomic activities could be enacted without adversely affecting the development of peaceful uses that could benefit humankind. This need to constrain the military use of nuclear technology, on the one hand, while sharing its commercial applications, on the other, is reflected in subsequent nuclear nonproliferation efforts, such as the Nuclear Nonproliferation Treaty of 1968.

The report outlined the critical components of a safeguards regime and distinguished between safe and dangerous nuclear activities in terms of their relationship to the development of nuclear weapons. It also proposed establishing an international authority to monitor the nuclear fuel cycle. This report is an important foundational document for understanding current nonproliferation strategies.

ACTINIDES

Actinides are a series of heavy elements that are chemically similar to actinium, including uranium and plutonium, the two major elements used in nuclear power and weapons. Actinides include fifteen different elements, ranging from actinium (atomic number 89) to lawrencium (atomic number 103) on the periodic table. Many of these elements are manmade and have half-lives of thousands of years. All of these elements are radioactive, generally emitting alpha and gamma radiation. Other actinides, referred to as minor actinides, include neptunium, americium, and curium. These are produced in nuclear power plants and are present in spent fuel.

Certain unique chemical properties of actinides facilitate the ability to reprocess spent fuel from nuclear power reactors. These chemical properties allow for the extraction of actinides, particularly uranium and plutonium, from spent fuel using a solvent-extraction method. A solvent-extraction method uses water or other solutions to extract elements based on their ability to dissolve in the solution.

The United States does not currently reprocess spent fuel to recover usable fissile material. However, reprocessing methods are being used in France and may be used in the United States in the future. Terrorist organizations and rogue nations may seek to acquire spent fuel with the purpose of extracting actinides.

AIRBORNE ALERT

The U.S. alert operation, code-named Chrome Dome, was a realistic training mission designed by the Strategic Air Command (SAC) to deter enemy forces from a surprise attack on the United States. Chrome Dome was established in 1960 following a series of planning and training flights in the late 1950s, and a portion of the U.S. strategic nuclear bombing fleet remained on continuous airborne alert until 1968. In later years, these missions operated under the code names Head Start, Round Robin, and Hard Head. The alert ensured that up to a dozen nuclear-armed bombers were airborne twenty-four hours a day. It also demonstrated SAC's nearly immediate retaliatory capability in case of a Soviet surprise attack, thus strengthening America's nuclear deterrent. Fully combat-configured B-52s carrying nuclear weapons flew routes to points along the Soviet border. The southern route crossed the Atlantic, the Mediterranean, and then returned to the United States; the northern route went up the eastern coast of Canada, across Canada west toward Alaska, then down the west coast of North America. Other mission routes were substituted as required. The Hard Head missions were intended to ensure continuous visual surveillance of Thule Air Base, Greenland, and its vital Ballistic Missile Early Warning System (BMEWS) radar, a critical element for the U.S. response to a Soviet surprise attack on North America. SAC wings launched two combat-ready B-52s every twenty to twenty-three hours for thirty- to sixty-day operations (the duty rotated among SAC's B-52 wings). To keep the B-52s airborne for long periods, KC-135 tankers were launched to keep bombers air-refueled.

Airborne alert flights ended following two serious accidents involving nuclear bombs and B-52s. On January 17, 1966, a B-52 collided with its KC-135 during aerial refueling and crashed off the coast of Palomares, Spain, and on January 22, 1968, a B-52 crashed near Thule, Greenland. SAC thereafter placed 30 percent of its bomber force on ground alert with crews ready to take off within minutes if a warning was received from a BMEWS site or other radar.

ANTI-BALLISTIC MISSILE (ABM) TREATY
Signed in 1972 between the United States and the Soviet Union, the Anti-Ballistic Missile (ABM) Treaty severely restricted their respective development and deployment of ballistic missile defenses and was considered a significant milestone in the history of arms control. It was the first formal treaty between the two nations limiting systems related to their central strategic deterrent capabilities. The U.S. government at the time portrayed it as a significant first step in a new era of mutual restraint and arms limitation between the Cold War superpowers that would provide for a more stable strategic balance and lead to a broader, more comprehensive series of arms control agreements. The treaty also set important precedents that were followed by later arms control treaties, including the legitimization of "national technical means" of verification and the establishment of a commission to oversee implementation and compliance. Over the course of its existence, from May 26, 1972, until June 13, 2002, the ABM Treaty was viewed by many as the basis of Soviet- and then Russian-American strategic relations. Promoted on the one hand as the cornerstone of strategic stability, and vilified on the other as a constraint on U.S. self-defense that shackled Washington to a strategic doctrine of perpetual vulnerability, the ABM Treaty represented both the best and the worst aspects of modern arms control (*see* Missile Defense).

Negotiation of the Treaty
Soviet leaders were at first opposed in principle to the very idea of negotiating limits on missile defenses—which, after all, were entirely defensive weapons. Within days of the U.S. Senate's June 24, 1968, approval of a major U.S. ABM deployment program (*see* Sentinel Anti-Ballistic Missile System) designed to match the Soviet Union's own ABM system then being deployed around Moscow, however, they did a complete about-face on the subject and agreed to accept the U.S. proposal to begin immediate discussions on limiting ballistic missile defenses. Although the United States was most interested in achieving a treaty on offensive force limitations, following two years of negotiations it accepted a treaty limiting ABM systems along with an interim agreement on offensive arms limitations, with the prospect of pursuing a more comprehensive formal treaty on offensive arms in the future (*see* Strategic Arms Limitation Talks [SALT I and SALT II]).

Terms of the Treaty
The ABM Treaty originally limited the United States and the Soviet Union to two sites of 100 antiballistic missile launchers each, separated by at least 1,300 kilometers. A protocol to the treaty, signed in 1974, reduced this limit to just one site for each side. The treaty banned the deployment of ABM systems for a defense of national territory and obligated the parties not to provide a base for such a defense or for the defense of an individual region, except as provided for in the treaty. ABM systems were defined, for the purposes of the treaty, as ABM interceptor missiles, ABM launchers, and ABM radars. ABM missiles and ABM radars were defined as those "constructed and deployed for an ABM role, or of a type tested in an ABM mode"—a formulation that later posed significant problems of interpretation. The application of the treaty terms to ABM systems that used mechanisms other than missiles to intercept strategic missiles, such as lasers or directed-energy weapons, also became the subject of an intense controversy in the years subsequent to the signing of the treaty.

The ABM Treaty further provided for a complete prohibition on developing, testing, or deploying ABM systems or components that were not fixed and land based, that is, sea-, air-, space-, or mobile land-based systems or components. To reduce the potential for circumventing the terms of the treaty, the treaty also prohibited upgrading theater-range antiballistic missiles (which were not otherwise limited by the treaty), testing them concurrently with strategic ABM systems or components, or transferring ABM systems or components to other nations. ABM radars were limited to those at ABM launcher bases or located on the periphery of the national territory and oriented outward (restrictions violated by the Soviet ABM radar at Krasnoyarsk).

Relationship of the Treaty to Other Treaties
Many ABM Treaty supporters considered it the basis of international arms control regimes, which were all predicated to one degree or another on the assumption that the ABM Treaty had forestalled a U.S.-Soviet arms race between offensive and defensive weapons.

Premier Leonid Brezhnev and President Richard Nixon shake hands in Moscow after signing the Anti-Ballistic Missile Treaty, May 1972. (National Archives)

The Soviets took steps to codify a linkage between their interest in further strategic offensive arms reductions and preservation of the ABM Treaty. For example, they insisted, prior to the conclusion of the Strategic Arms Reduction Treaty (START), that START would be "effective and viable only under conditions of compliance with" the ABM Treaty as signed on May 26, 1972. Soviet negotiators also made clear in a unilateral statement associated with START that "events related to withdrawal by one of the Parties" from the ABM Treaty could be grounds for exercising the right to withdraw from START. A similar condition was associated with the Russian Duma's consent to ratify START II. Russia eventually chose not to implement this threat with respect to START I, which continues in force, but did issue a statement, the day after the U.S. withdrawal from the ABM Treaty became effective, saying it considered itself free of the constraints of START II, which in any event had never entered into force (*see* Strategic Arms Reduction Treaty [START I]; Strategic Arms Reduction Treaty [START II]).

Problems Interpreting the ABM Treaty

Almost from the beginning, the necessarily vague diplomatic language of the ABM Treaty posed serious problems of interpretation. One controversy in particular arose in the mid-1980s, soon after President Ronald Reagan announced the intention of the United States to pursue robust missile defenses through a Strategic Defense Initiative (SDI). Some argued that although the treaty banned the deployment of sea-, air-, space-, and mobile land-based ABM systems, it did not prohibit research and development into ABM systems related to those areas. Advocates of this position, which came to be known as the "broad interpretation," further argued that the language of Agreed Statement D, referring to the potential creation in the future of ABM systems "based on other physical principles," allowed their development and testing but not their deployment. Others believed that the ABM Treaty prohibited the development and testing as well as the deployment of such exotic ABM systems. This position came to be known as the "narrow interpretation." The Reagan administration officially adopted the broad interpretation in 1985, and this eventually led to a confrontation with the U.S. Congress over which interpretation had been associated with the treaty during its ratification process and whether the executive branch had a right to reinterpret treaties once ratified. In 1992, President William Clinton's administration officially renounced the "broad interpretation" and reinstated the "narrow interpretation" as the official policy of the United States. Thereafter, it substantially reduced funding for research into missile defenses and dismantled existing missile defense research and development programs.

The U.S. Decision to Withdraw from the ABM Treaty

Upon assuming office in 2001, President George W. Bush announced that it was the policy of his administration to deploy effective missile defenses against the threat of limited attacks by a handful of missiles launched by rogue states, and to do so as soon as technically feasible. This set the United States on an inevitable collision course with the ABM Treaty. On December 13, 2001, President Bush gave formal notice to Russia that the United States was withdrawing from the ABM Treaty in accordance with the requirement contained in Article XV of the treaty to give six months advance notice. In making his announcement, the president noted that the world was vastly different from that which existed in 1972 when the treaty was signed, that one of the signatories, the Soviet Union, no longer existed, and neither did the hostilities that once characterized relations between the two countries. He cited the imperative of having the freedom and flexibility to develop effective defenses against ballistic missile attack by terrorists or hostile rogue states and the need to move beyond mutual assured destruction (MAD) as the basis of deterrence. This withdrawal became effective on June 13, 2002.

Although the Bush administration had held a series of intense discussions with Russia over the fate of the ABM Treaty, in which ideas for revising or modifying it were discussed as alternatives to withdrawing from the treaty, the Bush administration was increasingly convinced that a clean break with the past was in order. There were three principal reasons for this decision. First, the ABM Treaty was no longer an appropriate basis for the increasingly cooperative U.S.-Russian relationship. Second, deterrence based solely on mutual assured destruction, as institutionalized by the ABM Treaty, could no longer be considered necessary vis-à-vis Russia nor credible against likely adversaries. Deterrence needed to be reinforced by both offensive and defensive means. Third, the ABM Treaty presented an obstacle to those testing and development activities considered essential by the administration to finding the most effective and affordable means of defending against ballistic missiles of all ranges. Moreover, the ABM Treaty prohibited cooperation between the United States and its allies in developing missile defenses, an avenue the United States was determined to pursue through NATO as well as bilaterally with key friends and allies.

Russia reacted with moderation, given the dire warnings its leaders and diplomats had issued up to that time regarding the potentially negative effects that would surely accompany any U.S. effort to withdraw from or substantially modify the ABM Treaty. In a response given the same day as the U.S. withdrawal announcement, President Vladimir Putin said Russia believed the U.S. decision to be mistaken but asserted it would not pose a threat to the national security of Russia. He reaffirmed his commitment to improving U.S.-Russian relations and called on the United States to put into legally binding form the unilateral strategic offensive reductions that both he and President Bush had respectively announced a month earlier during a summit meeting in Washington and at President Bush's ranch in Crawford, Texas. In fact, the United States and Russia subsequently agreed to a legally binding treaty on further reductions in strategic offensive arms in May 2002, despite the U.S. announcement of its pending withdrawal from the ABM Treaty.

ANTINUCLEAR MOVEMENT

Since the dawn of the nuclear age, the antinuclear movement has raised logistic, safety, environmental, moral, and other concerns about the use of nuclear technology for peaceful or military purposes. The movement's main policy goals, its size, and its perceived influence have varied over time, and its history can be divided into four main periods of activity. From 1944 to 1948, the movement consisted of elites who pushed for civilian control of nuclear technology and considered establishing international control of nuclear knowledge under the United Nations. From 1957 to 1963, the movement included the broader public and pushed for arms control, specifically focusing on limits on nuclear testing. From the late 1960s through 1980, the antinuclear movement worked with the emerging environmental movement to oppose the widespread use of nuclear power plants. And from 1979 through 1984, the movement was at its largest and most influential and was focused on the proposal for a U.S. and Soviet "nuclear freeze."

Distinct issues emerged in each of these four periods, but they all reflected changing views on two key questions: First, is it possible to get benefits from nuclear energy without encountering dangerous side effects such as the diversion of nuclear technology for military purposes or environmental damage? Second, is it possible to have arms control even when a nation fears its opponent's military strength? Across the four periods, the movement accumulated strength, even though most of its membership changed, because leaders and organizations involved in one issue often reemerged to provide leadership in later periods.

History and Background

Even as the first research and testing of nuclear weapons went forward, some of the scientists involved began to question the long-term implications of their work. These questions moved to a broader setting with the use of nuclear weapons at Hiroshima and Nagasaki. Within elite academic, political, and scientific circles, many expressed a mix of fear of the new weapons' power and hope that peaceful uses of nuclear energy might aid future development. There also was a general view that decisive action to establish control of the new technology was necessary, but there was less agreement on what action should be taken. The majority of the public, however, more focused on recovering from the end of a long war and keeping the postwar economy growing, expressed few worries about these issues.

Several leading scientists formed the Federation of Atomic Scientists in hopes of influencing debate. Because of the technical nature of the issues involved, the scientists' views were accorded great weight, but some politicians and military officials believed that the scientists were naive in their political objectives. Many of the scientists were pleased, though, when the 1946 Atomic Energy Act gave the civilian-led Atomic Energy Commission a near monopoly on control of peaceful and military U.S. nuclear programs (*see* Federation of American Scientists).

Debate then shifted to the idea of international control. This idea brought other groups, such as existing peace groups and world federalist organizations, into the antinuclear movement. Their hopes for real action on the Baruch Plan, the U.S.-backed initiative to give control of all nuclear weapons to the United Nations, were dashed by mounting Cold War tensions (*see* Baruch Plan). As fear of an emerging Soviet threat spread, support for any type of arms control or international action declined rapidly. Soon, those who continued to question U.S. government policies faced scrutiny by the Federal Bureau of Investigation and supporters of Senator Joseph McCarthy.

Although Cold War tensions played a major role in ending the first phase of antinuclear activity, they also contributed to activists staying focused on the issue and to the emergence of a second major phase of activity in the mid-1950s. By then, nuclear weapons technology had moved forward with the development of the hydrogen bomb and missile delivery systems, the defense budgets of both superpowers were increasing rapidly, and there was mounting global tension. Several new groups, notably Pugwash and the Committee for a Sane Nuclear Policy (SANE), were established to inform policymakers and the public on the dangers of nuclear escalation and possible flaws in deterrence strategies.

These new groups generated significant media and policymaker attention, but the mass public became more focused on issues related to nuclear testing. In 1954, radioactive fallout from a U.S. test on Bikini Island covered a Japanese fishing boat. There also were mounting reports that radioactive fallout would cause genetic defects and cancer. Quickly, polls showed widespread public support for a test ban, and existing antinuclear organizations began to push it as an important first step in arms control. Support for the test ban also came from religious figures, including Pope Pius XII, leaders in the nonaligned movement, such as Jawaharlal Nehru, and political parties from Japan to England. A small number of activists also used direct action, such as sailing boats close to test sites. It is difficult to say precisely how much influence these polls and various groups had, but it certainly was clear to both U.S. and Soviet leaders that they could win public opinion points by adopting moratoriums on testing and negotiating a test ban. In 1963, the Limited Test Ban Treaty, which banned testing in the atmosphere, under water, or in outer space, was signed. The treaty was a victory for the antinuclear movement, but now lacking a main issue around which to rally support, the movement again receded.

During the 1960s and 1970s, smaller groups of people continued to criticize the overall development of nuclear strategy, specific weapons systems, and missile defense systems. Many peace groups and other foreign policy–oriented groups shifted their focus to the Vietnam War. Another branch of the antinuclear movement began to work with environmental and local citizens groups to protest nuclear power plants. At first, these protests were small, but in time, four factors emerged that strengthened the movement. First, rising oil prices made nuclear energy a more attractive alternative. Second, the U.S. government radically reorganized its energy bureaucracy. Plans for the reorganization gave the movement an issue to focus on and, later, it had new entry points for lobbying. Third, both government and private research showed that the dangers of nuclear power had been understated. Fourth, several small accidents and near-accidents highlighted potential problems.

In their attempts to limit the spread of nuclear power, movement strategists first used legal action and demands for full environmental impact reports. By 1976, they had moved to an electoral strategy, placing several antinuclear referenda on ballots and supporting the Democratic Party's platform, which called for developing nonnuclear sources of energy. They then added tactics of direct action. For example, members of the Clamshell Alliance occupied the construction site of the Seabrook nuclear power plant in New Hampshire. These actions revitalized the old debate over whether the benefits of nuclear energy would outweigh the dangers. The movement was gradually gaining public support, although it lost a key referendum battle in California in 1976. Then, the debate was radically changed, settling in favor of opponents of nuclear power because of accidents at Three Mile Island, Pennsylvania, and Chernobyl, Ukraine (*see* Chernogyl; Three Mile Island).

Nuclear Freeze

By the late-1970s, many people in both the public and policymaking circles saw Cold War tensions, the dangers of nuclear war, and arms races that were only partially limited by arms control agreements as unpleasant but unavoidable facts of modern life. Randall Forsberg, a researcher trained at the Massachusetts Institute of Technology, disagreed. Forsberg argued that, as the first step toward international security, the United States and the Soviet Union needed to end the arms race by freezing the testing, production, and deployment of nuclear weapons. Forsberg took the idea to existing peace, religious, and antinuclear groups. By early 1980, an Ad Hoc Task Force for a Nuclear Freeze had been created. The idea captured the attention of peace activist Randy Kehler, who then led efforts to put a freeze referendum on the ballot in three western Massachusetts districts. The freeze referendum passed in all three districts and did well even in areas that supported Ronald Reagan for president.

The freeze's early popularity was striking. Ironically, the movement's later success and expansion into a national movement were due to the actions of one of its greatest opponents. Reagan and many of his top advisers, fearing a rising Soviet threat, spoke repeatedly of increasing U.S. defense spending, purging arms control supporters from the bureaucracy, negotiating only from a position of strength, and fighting and winning a nuclear war. These statements led many to conclude that Reagan was determined to confront the Soviet Union at all costs and that he was not serious about arms control. These people supported the freeze both as a bold policy alternative and as a symbolic sign of disapproval of Reagan's ideas. As the movement gained strength, Reagan and his supporters speculated that it was inspired by Communist forces. They also argued that a freeze would lock any Soviet superiority in place, potentially worsen the U.S. position if the Soviets cheated on the agreement, and weaken the position of U.S. arms control negotiators. Ironically, these administration arguments only served to further convince many that Reagan was exaggerating the Soviet threat and was unwilling to negotiate seriously.

The spread of the freeze movement was dramatic and reflected a combination of opposition to Reagan's policies, a general antinuclear mood in the country following the accident at Three Mile Island, and a widespread desire to achieve arms control objectives without increasing the Soviet threat. Freeze proposals were passed by dozens of town and city governments, by legislatures from Massachusetts to Oregon, and in eight statewide referenda votes in 1982. Polls consistently showed that over 70 percent of the public supported a freeze, although the numbers declined significantly if the question was worded to suggest that the freeze could lead to Soviet military superiority. In November 1982, a march in New York drew 750,000 people and an initiative signed by more than 2 million people was delivered to the United Nations.

The freeze idea also developed support in Congress. Congressional activity was ultimately a mixed blessing for the movement. Although the movement's concerns got attention in the halls of power and drew increased press attention, the movement's original organizers lost some authority. More important, once the freeze entered the legislative process, it became subject to political negotiation and compromises that were not supported by everyone in the grassroots movement. In 1982, the House of Representatives considered a freeze resolution, but it lost 204–202 in the key vote. The resolution was defeated largely by Republicans and southern Democrats who supported the administration's view that a freeze should come only after significant arms reductions were achieved. In 1983, following an election that brought many freeze supporters to office, debate began anew. The House passed a freeze resolution 278–149 following a complicated debate that stretched some forty hours. Dozens of amendments were proposed, and the final resolution included one that would terminate the freeze if no mutual arms control agreements were reached. Both supporters and detractors of the freeze claimed the wording as a victory. The final vote likely overstated actual support for a freeze, since many saw the vote as a way of prodding the administration to support arms control. The Republican-controlled Senate never formally voted on the freeze.

Proponents of the freeze remained active through the 1984 election, but the movement had begun to wane. Disputes over whether to use legislative or grassroots tactics, what final language would be acceptable, and whether the freeze would really lead to peace or only distract attention from other initiatives began to split the movement. Voters in 1984 seemed more interested in Reagan's economic policies than Walter Mondale's support for the freeze. Reagan also greatly affected the movement by restarting arms control negotiations and calling for a missile defense system that would arguably remove the need for a freeze and bring new security. Supporters of the freeze argued that these Reagan initiatives were spurred by public support for the freeze, claiming that they won the war even if they lost the battle.

ANTI-SATELLITE (ASAT) WEAPONS

Anti-satellite (ASAT) weapons are designed to attack satellites in orbit. Potential destruction and disruption mechanisms for ASAT weapons include nuclear warheads, high explosives, directed energy, kinetic energy, and electronic warfare.

The United States became concerned about countering the potential for nuclear weapons delivery systems in orbit soon after the beginning of the space age. It first tested an air-launched ASAT weapon from a B-47 bomber under the U.S. Air Force's Bold Orion program in 1959, and in the early 1960s the U.S. Navy tested systems launched by F-4 fighters. All of these earliest ASAT systems would have used nuclear warheads as the kill mechanism, but none of them became operational. In the early 1960s, Secretary of Defense Robert S. McNamara authorized development and deployment of limited numbers of two ground-based, nuclear-tipped ASAT systems. The army's Program 505 system used a Nike-Zeus launcher to conduct seven tests from Kwajalein Island in the Pacific between 1964 and 1966. Program 437, the U.S. Air Force system, used a Thor booster from Johnson Island and was tested sixteen times from 1964 to 1970. The indiscriminate nuclear kill mechanism on these systems could have destroyed or disabled all satellites in low-Earth orbit by pumping up radiation belts.

Both the Soviet Union and the United States began work on more discriminating ASAT systems during the 1960s. The Soviets developed a radar and optical guided co-orbital system with a high-explosive warhead that was launched from a Tsyklon-2 (SL-11) booster and tested it at least twenty times between 1968 and 1982. U.S. efforts during this period culminated in the successful September 13, 1985, test of the Miniature Homing Vehicle (MHV), a direct-ascent kinetic kill ASAT launched from an F-15 fighter.

Some analysts argued that these systems undermined strategic stability, and they were quite controversial in the United States. Congressional restrictions on testing led the administration of President Ronald Reagan to cancel the MHV system in 1988. The superpowers also attempted to address ASAT issues through formal arms control efforts, holding three rounds of dedicated ASAT negotiations in 1978–1979 and discussing the issue in the Defense and Space Talks from 1985 to 1991. None of these negotiations produced an agreement, an illustration of the considerable challenges surrounding efforts to control ASAT capabilities.

There has been no testing of dedicated ASAT systems by any nation since the 1980s, and there are no operational systems deployed today. There is, however, a large amount of residual ASAT capability worldwide, including nuclear-tipped ballistic missiles and ballistic missile defense systems, ground- and air-based lasers, and a wide range of electronic capabilities to spoof, disrupt, degrade, or destroy satellites.

ARMS CONTROL

Arms control is any tacit or explicit agreement among states aimed at reducing the likelihood of war, the costs of preparing for war, or the damage should war occur. Arms control agreements seek to achieve these goals by restricting or reducing the numbers of military weapons or by placing limits on their operation. They may include a variety of verification and transparency measures such as on-site inspections, reciprocal exhibitions of military hardware, notifications, joint exercises, and data exchanges. Arms control encompasses both formal and informal means of agreement. As the focus of

Arms control in practice: negotiators from the United States, Japan, China, North Korea, South Korea, and Russia begin talks on the North Korean nuclear crisis in Beijing, February 2004. (Greg Baker/Pool/Corbis)

arms control efforts increasingly shifts to combating the proliferation of weapons of mass destruction and other types of weapons, recent arms control arrangements have come to include agreements among supplier states to limit the export of certain categories of weapons or materials that have military application, such as missiles, conventional arms, land mines, and chemical weapon precursor ingredients. For this reason, a recent textbook offered a very broad definition of arms control as "any agreement among states to regulate some aspect of their military capability or potential" (Larsen, p. 1). Unilateral measures, undertaken with a view to influencing the military force policies of another state, also may be considered a form of arms control.
