To so many fine memories of my brother, Mohsen, for his
uncompromising belief in the power of education.

About the Editor-in-Chief

Hossein Bidgoli, Ph.D., is Professor of Management Information Systems at California State University. Dr. Bidgoli helped set up the first PC lab in the United States. He is the author of 43 textbooks, 27 manuals, and over four dozen technical articles and papers on various aspects of computer applications, e-commerce, and information systems, which have been published and presented throughout the world. Dr. Bidgoli also serves as the editor-in-chief of *Encyclopedia of Information Systems*.

Dr. Bidgoli was selected as the California State University, Bakersfield's 2001–2002 Professor of the Year.

Usability Testing: An Evaluation Process for Internet Communications

Preface

The Internet Encyclopedia is the first comprehensive examination of the core topics in the Internet field. *The Internet Encyclopedia*, a three-volume reference work with 205 chapters and more than 2,600 pages, provides comprehensive coverage of the Internet as a business tool, IT platform, and communications and commerce medium. The audience includes the libraries of two-year and four-year colleges and universities with MIS, IT, IS, data processing, computer science, and business departments; public and private libraries; and corporate libraries throughout the world. It is the only comprehensive source for reference material for educators and practitioners in the Internet field.

Education, libraries, health, medical, biotechnology, military, law enforcement, accounting, law, justice, manufacturing, financial services, insurance, communications, transportation, aerospace, energy, and utilities are among the fields and industries expected to become increasingly dependent upon the Internet and Web technologies. Companies in these areas are actively researching the many issues surrounding the design, utilization, and implementation of these technologies.

This definitive three-volume encyclopedia offers coverage of both established and cutting-edge theories and developments of the Internet as a technical tool and business/communications medium. The encyclopedia contains chapters from global experts in academia and industry. It offers the following unique features:

1) Each chapter follows a format which includes title and author, chapter outline, introduction, body, conclusion, glossary, cross references, and references. This unique format enables the readers to pick and choose among various sections of a chapter. It also creates consistency throughout the entire series.
2) The encyclopedia has been written by more than 240 experts and reviewed by more than 840 academics and practitioners chosen from around the world. This diverse collection of expertise has created the most definitive coverage of established and cutting edge theories and applications in this fast-growing field.
3) Each chapter has been rigorously peer reviewed. This review process assures the accuracy and completeness of each topic.
4) Each chapter provides extensive online and offline references for additional readings. This will enable readers to further enrich their understanding of a given topic.
5) More than 1,000 illustrations and tables throughout the series highlight complex topics and assist further understanding.
6) Each chapter provides extensive cross references. This helps the readers identify other chapters within the encyclopedia related to a particular topic, which provides a one-stop knowledge base for a given topic.
7) More than 2,500 glossary items define new terms and buzzwords throughout the series, which assists readers in understanding concepts and applications.
8) The encyclopedia includes a complete table of contents and index sections for easy access to various parts of the series.
9) The series emphasizes both technical and managerial issues. This approach provides researchers, educators, students, and practitioners with a balanced understanding of the topics and the necessary background to deal with problems related to Internet-based systems design, implementation, utilization, and management.
10) The series has been designed based on the current core course materials in several leading universities around the world and current practices in leading computer- and Internet-related corporations. This format should appeal to a diverse group of educators, practitioners, and researchers in the Internet field.

We chose to concentrate on fields and supporting technologies that have widespread applications in the academic and business worlds. To develop this encyclopedia, we carefully reviewed current academic research in the Internet field at leading universities and research institutions around the world. Management information systems, decision support systems (DSS), supply chain management, electronic commence, network design and management, and computer information systems (CIS) curricula recommended by the Association of Information Technology Professionals (AITP) and the Association for Computing Management (ACM) were carefully investigated. We also researched the current practices in the Internet field used by leading IT corporations. Our work enabled us to define the boundaries and contents of this project.

TOPIC CATEGORIES

Based on our research we identified 11 major topic areas for the encyclopedia:

- Foundation;
- Infrastructure;
- Legal, social, organizational, international, and taxation issues;
- Security issues and measures;
- Web design and programming;
- Design, implementation, and management;
- Electronic commerce;
- Marketing and advertising on the Web;

- Supply chain management;
- Wireless Internet and e-commerce; and
- Applications.

Although these 11 categories of topics are interrelated, each addresses one major dimension of the Internet-related fields. The chapters in each category are also interrelated and complementary, enabling readers to compare, contrast, and draw conclusions that might not otherwise be possible.

Although the entries have been arranged alphabetically, the light they shed knows no bounds. The encyclopedia provides unmatched coverage of fundamental topics and issues for successful design, implementation, and utilization of Internet-based systems. Its chapters can serve as material for a wide spectrum of courses, such as the following:

- Web technology fundamentals;
- E-commerce;
- Security issues and measures for computers, networks, and online transactions;
- Legal, social, organizational, and taxation issues raised by the Internet and Web technology;
- Wireless Internet and e-commerce;
- Supply chain management;
- Web design and programming;
- Marketing and advertising on the Web; and
- The Internet and electronic commerce applications.

Successful design, implementation, and utilization of Internet-based systems require a thorough knowledge of several technologies, theories, and supporting disciplines. Internet and Web technologies researchers and practitioners have had to consult many resources to find answers. Some of these sources concentrate on technologies and infrastructures, some on social and legal issues, and some on applications of Internet-based systems. This encyclopedia provides all of this relevant information in a comprehensive three-volume set with a lively format.

Each volume incorporates core Internet topics, practical applications, and coverage of the emerging issues in the Internet and Web technologies field. Written by scholars and practitioners from around the world, the chapters fall into the 11 major subject areas mentioned previously.

Foundation

Chapters in this group examine a broad range of topics. Theories and concepts that have a direct or indirect effect on the understanding, role, and the impact of the Internet in public and private organizations are presented. They also highlight some of the current issues in the Internet field. These articles explore historical issues and basic concepts as well as economic and value chain concepts. They address fundamentals of Web-based systems as well as Web search issues and technologies. As a group they provide a solid foundation for the study of the Internet and Web-based systems.

Infrastructure

Chapters in this group explore the hardware, software, operating systems, standards, protocols, network systems, and technologies used for design and implementation of the Internet and Web-based systems. Thorough discussions of TCP/IP, compression technologies, and various types of networks systems including LANs, MANS, and WANs are presented.

Legal, Social, Organizational, International, and Taxation Issues

These chapters look at important issues (positive and negative) in the Internet field. The coverage includes copyright, patent and trademark laws, privacy and ethical issues, and various types of cyberthreats from hackers and computer criminals. They also investigate international and taxation issues, organizational issues, and social issues of the Internet and Web-based systems.

Security Issues and Measures

Chapters in this group provide a comprehensive discussion of security issues, threats, and measures for computers, network systems, and online transactions. These chapters collectively identify major vulnerabilities and then provide suggestions and solutions that could significantly enhance the security of computer networks and online transactions.

Web Design and Programming

The chapters in this group review major programming languages, concepts, and techniques used for designing programs, Web sites, and virtual storefronts in the e-commerce environment. They also discuss tools and techniques for Web content management.

Design, Implementation, and Management

The chapters in this group address a host of issues, concepts, theories and techniques that are used for design, implementation, and management of the Internet and Web-based systems. These chapters address conceptual issues, fundamentals, and cost benefits and returns on investment for Internet and e-business projects. They also present project management and control tools and techniques for the management of Internet and Web-based systems.

Electronic Commerce

These chapters present a thorough discussion of electronic commerce fundamentals, taxonomies, and applications. They also discuss supporting technologies and applications of e-commerce inclining intranets, extranets, online auctions, and Web services. These chapters clearly demonstrate the successful applications of the Internet and Web technologies in private and public sectors.

Marketing and Advertising on the Web

The chapters in this group explore concepts, theories, and technologies used for effective marketing and advertising on the Web. These chapters examine both qualitative and quantitative techniques. They also investigate the emerging technologies for mass personalization and customization in the Web environment.

Supply Chain Management

The chapters in this group discuss the fundamentals concepts and theories of value chain and supply chain management. The chapters examine the major role that the Internet and Web technologies play in an efficient and effective supply chain management program.

Wireless Internet and E-commerce

These chapters look at the fundamental concepts and technologies of wireless networks and wireless computing as they relate to the Internet and e-commerce operations. They also discuss mobile commerce and wireless marketing as two of the growing fields within the e-commerce environment.

Applications

The Internet and Web-based systems are everywhere. In most cases they have improved the efficiency and effectiveness of managers and decision makers. Chapters in this group highlight applications of the Internet in several fields, such as accounting, manufacturing, education, and human resources management, and their unique applications in a broad section of the service industries including law, law enforcement, medical delivery, health insurance and managed care, library management, nonprofit organizations, banking, online communities, dispute resolution, news services, public relations, publishing, religion, politics, and real estate. Although these disciplines are different in scope, they all utilize the Internet to improve productivity and in many cases to increase customer service in a dynamic business environment.

Specialists have written the collection for experienced and not-so-experienced readers. It is to these contributors that I am especially grateful. This remarkable collection of scholars and practitioners has distilled their knowledge into a fascinating and enlightening one-stop knowledge base in Internet-based systems that “talk” to readers. This has been a massive effort but one of the most rewarding experiences I have ever undertaken. So many people have played a role that it is difficult to know where to begin.

I should like to thank the members of the editorial board for participating in the project and for their expert advice on the selection of topics, recommendations for authors, and review of the materials. Many thanks to the more than 840 reviewers who devoted their times by proving advice to me and the authors on improving the coverage, accuracy, and comprehensiveness of these materials.

I thank my senior editor at John Wiley & Sons, Matthew Holt, who initiated the idea of the encyclopedia back in spring of 2001. Through a dozen drafts and many reviews, the project got off the ground and then was managed flawlessly by Matthew and his professional team. Matthew and his team made many recommendations for keeping the project focused and maintaining its lively coverage. Tamara Hummel, our superb editorial coordinator, exchanged several hundred e-mail messages with me and many of our authors to keep the project on schedule. I am grateful to all her support. When it came to the production phase, the superb Wiley production team took over. Particularly I want to thank Deborah DeBlasi, our senior production editor at John Wiley & Sons, and Nancy J. Hulan, our project manager at TechBooks. I am grateful to all their hard work.

Last, but not least, I want to thank my wonderful wife Nooshin and my two lovely children Mohsen and Morvareed for being so patient during this venture. They provided a pleasant environment that expedited the completion of this project. Nooshin was also a great help in designing and maintaining the author and reviewer databases. Her efforts are greatly appreciated. Also, my two sisters Azam and Akram provided moral support throughout my life. To this family, any expression of thanks is insufficient.

Hossein Bidgoli
California State University, Bakersfield

Guide to the Internet Encyclopedia

The Internet Encyclopedia is a comprehensive summary of the relatively new and very important field of the Internet. This reference work consists of three separate volumes and 205 chapters on various aspects of this field. Each chapter in the encyclopedia provides a comprehensive overview of the selected topic intended to inform a board spectrum of readers ranging from computer professionals and academicians to students to the general business community.

In order that you, the reader, will derive the greatest possible benefit from *The Internet Encyclopedia,* we have provided this Guide. It explains how the information within the encyclopedia can be located.

ORGANIZATION

The Internet Encyclopedia is organized to provide maximum ease of use for its readers. All of the chapters are arranged in alphabetical sequence by title. Chapters titles that begin with the letters A to F are in Volume 1, chapter titles from G to O are in Volume 2, and chapter titles from P to Z are in Volume 3. So that they can be easily located, chapter titles generally begin with the key word or phrase indicating the topic, with any descriptive terms following. For example, "Virtual Reality on the Internet: Collaborative Virtual Reality" is the chapter title rather than "Collaborative Virtual Reality."

Table of Contents

A complete table of contents for the entire encyclopedia appears in the front of each volume. This list of titles represents topics that have been carefully selected by the editor-in-chief, Dr. Hossein Bidgoli, and his colleagues on the Editorial Board.

Following this list of chapters by title is a second complete list, in which the chapters are grouped according to subject area. The encyclopedia provides coverage of 11 specific subject areas, such as E-commerce and Supply Chain Management. Please see the Preface for a more detailed description of these subject areas.

Index

The Subject Index is located at the end of Volume 3. This index is the most convenient way to locate a desired topic within the encyclopedia. The subjects in the index are listed alphabetically and indicate the volume and page number where information on this topic can be found.

Chapters

Each chapter in *The Internet Encyclopedia* begins on a new page, so that the reader may quickly locate it. The author's name and affiliation are displayed at the beginning of the article.

All chapters in the encyclopedia are organized according to a standard format, as follows:

- Title and author,
- Outline,
- Introduction,
- Body,
- Conclusion,
- Glossary,
- Cross References, and
- References.

Outline

Each chapter begins with an outline indicating the content to come. This outline provides a brief overview of the chapter so that the reader can get a sense of the information contained there without having to leaf through the pages. It also serves to highlight important subtopics that will be discussed within the chapter. For example, the chapter "Computer Literacy" includes sections entitled Defining a Computer, Categories of Computers According to Their Power, and Classes of Data Processing Systems. The outline is intended as an overview and thus lists only the major headings of the chapter. In addition, lower-level headings will be found within the chapter.

Introduction

The text of each chapter begins with an introductory section that defines the topic under discussion and summarizes the content. By reading this section the readers get a general idea about the content of a specific chapter.

Body

The body of each chapter discusses the items that were listed in the outline section.

Conclusion

The conclusion section provides a summary of the materials discussed in each chapter. This section imparts to the readers the most important issues and concepts discussed within each chapter.

Glossary

The glossary contains terms that are important to an understanding of the chapter and that may be unfamiliar to the reader. Each term is defined in the context of the particular chapter in which it is used. Thus the same term may be defined in two or more chapters with the detail of the definition varying slightly from one to another. The encyclopedia includes approximately 2,500 glossary terms.

For example, the article “Computer Literacy” includes the following glossary entries:

Computer A machine that accepts data as input, processes the data without human interference using a set of stored instructions, and outputs information. Instructions are step-by-step directions given to a computer for performing specific tasks.

Computer generations Different classes of computer technology identified by a distinct architecture and technology; the first generation was vacuum tubes, the second transistors, the third integrated circuits, the fourth very-large-scale integration, and the fifth gallium arsenide and parallel processing.

Cross References

All the chapters in the encyclopedia have cross references to other chapters. These appear at the end of the chapter, following the text and preceding the references. The cross references indicate related chapters which can be consulted for further information on the same topic. The encyclopedia contains more than 2,000 cross references in all. For example, the chapter “Java” has the following cross references:

JavaBeans and Software Architecture; Software Design and Implementation in the Web Environment.

References

The reference section appears as the last element in a chapter. It lists recent secondary sources to aid the reader in locating more detailed or technical information. Review articles and research papers that are important to an understanding of the topic are also listed. The references in this encyclopedia are for the benefit of the reader, to provide direction for further research on the given topic. Thus they typically consist of one to two dozen entries. They are not intended to represent a complete listing of all materials consulted by the author in preparing the chapter. In addition, some chapters contain a Further Reading section, which includes additional sources readers may wish to consult.

A

Active Server Pages

J. Christopher Sandvig, *Western Washington University*

INTRODUCTION

Active server pages (ASP) and ASP.NET are server-side programming technologies developed by Microsoft Corporation. Server-side programs run on Web servers and are used for dynamically generating Web pages. Many data-intensive Web applications, such as Web-based e-mail, online banking, news, weather, and search engines, require the use of server-side programs. Server-side programming is also useful for many other applications, such as collecting data, processing online payments, and controlling access to information. Server-side programs are executed each time a Web user requests a dynamically generated Web page. ASP and ASP.NET Web pages are identified by the file extensions .asp and .aspx, respectively.

The primary advantage of server-side programming technologies is their ability to utilize databases. Databases are very efficient and powerful tools used for storing and retrieving data. Most sophisticated Web applications utilize databases for storing their data. Server-side programming is also very reliable. Servers provide a more stable, secure, and controllable programming environment then the client's browser.

In addition to ASP and ASP.NET other popular server-side Web technologies include Perl, PHP, J2EE, Java server pages, Python, and ColdFusion. All of these technologies run on the Web server and generate their output in HTML (hypertext markup language). The Web server sends the HTML to the client's browser, which interprets it and displays it as formatted text. Most server-side technologies have similar capabilities; the primary functional differences between them are scalability and programming complexity. These issues are discussed later in the chapter.

Server-side technologies may work in conjunction with client-side technologies. Client-side technologies are executed by the user's browser and include JavaScript, Java applets, and ActiveX controls. Client-side technologies are typically used for controlling browser display features, such as mouse rollovers, dynamic images, and opening new browser windows.

The advantage of client-side technologies is that the processing is done on the client's machine, thus reducing the load on the Web server. Client-side technologies can execute more quickly because they do not require the back-and-forth transmission of data between the client and the server. However, the functionality of client-side technologies is limited due to their inability to access databases. They also require sending more data to the client, which can increase the time required to load a Web page.

Server-side technologies are more reliable than client-side technologies. Because client-side technologies run on the user's browser, they are dependent on the capabilities of the browser. Because browsers vary in their capabilities, client-side code that works well on one browser may not work on another. Server-side technologies, on the other hand, are always executed on the server. Because developers know the capabilities of their server, the results are very predictable. They send only HTML to the client's browser, which all browsers support fairly consistently.

Introduction of ASP and ASP.NET

Microsoft introduced ASP in December 1997 as a feature of its Internet Information Server (IIS) 3.0. Most of the other popular server-side technologies were introduced prior to 1995, making ASP a relatively late entrant into the world of server-side technologies. One year later, in

December 1998, Microsoft released ASP 2.0 as part of the Windows NT4 option pack (a free download). Two years later, IIS 3.0 was introduced as part of Windows 2000. Each release introduced modest improvements in both functionality and performance.

Despite its late introduction, ASP quickly became a popular server-side technology. Its popularity was driven by both its ease of programming and the widespread availability of the IIS server, which is bundled free with several versions of Microsoft's Windows operating system. Major Web sites that use ASP include Barnes and Noble (http://www.bn.com), Dell Computer (http://www.dell.com), JC Penney (http://www.jcpenney.com), MSNBC (http://www.msnbc.com), Ask.com (http://www.ask.com), and Radio Shack (http://www.radioshack.com).

ASP.NET 1.0 was introduced by Microsoft in February 2002. ASP.NET differs significantly from ASP in its syntax, performance, and functionality. In many ways ASP.NET is a new product rather than simply an upgrade of ASP. ASP.NET was designed to support Microsoft's .NET strategy and has extensive support for two technologies that are at the core of the strategy: XML (extensible markup language) and SOAP (simple object access protocol). It was also designed to overcome some of the weakness of ASP in the area of scalability and reliability. The differences between ASP and ASP.NET are discussed in greater detail later in this chapter.

At the time of this writing, ASP.NET had been just recently introduced and had not yet been adopted by any major Webs sites. However, it has received many positive reviews from developers and is expected to capture 30% of the enterprise development market by 2004 (Sholler, 2002).

ASP and ASP.NET are both supported by Microsoft's IIS server. ASP is supported by all versions of IIS from 3.0 up and later. ASP engines are also available from third-party developers that support ASP on a number of non-Microsoft operating systems and Web servers. Vendors include ChilliSoft and Stryon.

The ASP.NET framework is a free download from Microsoft and runs with IIS under Windows 2000 and later. It is designed for portability between operating systems, and it is expected that third-party vendors will provide ASP.NET compilers for non-Microsoft servers and operating systems.

Framework

Both ASP and ASP.NET are programming frameworks rather than programming languages. A framework is a bundle of technologies that work together to provide the tools needed for creating dynamic Web pages.

The ASP framework provides support for two scripting languages, seven server objects, and Microsoft's ActiveX data objects (ADO). The two scripting languages supported by Microsoft's IIS server are VBScript and Jscript, of which VBScript is the most popular because of its similarity to the widely used Visual Basic programming language. Third-party vendors offer ASP scripting engines that support other scripting languages, such as Perl and Python.

Much of ASP's functionality is derived from a collection of seven server objects. These intrinsic objects provide the tools for sending output to the user's browser, receiving input from the client, accessing server resources, storing data, writing files, and many other useful capabilities. The seven objects are application, ASPerror, objectcontext, request, response, session, and server. Each object has a set of properties, methods, and events that are employed by the ASP programmer to access the object's functionality. A detailed description of ASP's server objects is beyond the scope of this chapter, but an excellent reference is available from Microsoft's developer library: http: // msdn.microsoft.com / library / default.asp ? URL=/ library/psdk/iisref/vbob74bw.htm.

The ASP framework provides database access through the recordset object, which is a member of Microsoft's ActiveX data objects (ADO). The recordset allows ASP scripts to utilize most commercial database products, including Microsoft Access, Microsoft SQL Server, Informix, and Oracle (Mitchell and Atkinson, 2000).

The ASP.NET framework supports a large number of programming languages and operating systems. Microsoft's .NET framework provides native support for VB.NET, C# (pronounced C sharp), and Jscript.NET. Third-party vendors have announced plans to produce ".NET-compliant" compilers for over a dozen other languages, including Eiffel, Pascal, Python, C++, COBOL, Perl, and Java (Kiely, 2002; Ullman, Ollie, Libre, & Go, 2001).

The ASP.NET framework replaces ASP's seven server objects with an extensive "base class library." The class library contains hundreds of classes and offers considerably more functionality than do ASP's seven server objects. ASP.NET programmers access this code by initiating objects from the class library. All ASP.NET programs utilize the same base class library regardless of the programming language used.

Scripting Versus Object-Oriented Programming Languages

An important difference between ASP and ASP.NET is that ASP uses scripting languages whereas ASP.NET supports object-oriented programming languages. Scripting languages are generally easier to write and understand, but their simple structure does not lend itself well to complex programs. Scripting languages are usually interpreted languages, meaning that the server compiles them each time a page is served.

ASP.NET supports object-oriented event-driven programming languages. Object-oriented languages organize computer code into small units of functionality, called objects. The advantage of these languages is that they encapsulate functionality into small reusable objects. Writing and understanding object-oriented programs can be more difficult than understanding scripts, but the encapsulation of program functionality into discrete, reusable objects offers considerable advantages in complex programs.

CODE EXAMPLES

ASP

The following two code samples illustrate how ASP and ASP.NET work. The ASP code in Listing 1 displays a time-of-day message. The scripting language used is

Time of Day Greeting

The current time is 8:29:22 AM

The current hour is 8

Good Morning

Figure 1: ASP example: code Listing 1 viewed through a Web browser.

VBScript and the file is saved on the Web server as TimeGreeting.asp. The code enclosed by the <% and%> tags is executed on the server and is a mixture of VBScript and ASP server objects. The code inside the < > tags is HTML, which describes how the output should be formatted on the user's browser.

A close look at Listing 1 illustrates how ASP works. The first tag, `<% @LANGUAGE=VBScript %>`, tells the server which scripting language is used. Because VBScript is ASP's default language, this tag is not required, but it is considered good programming practice to include it.

The second set of server tags, `<% response.write Time()%>`, instructs the server to insert the current time into the output. Time() is a VBScript function that returns the current time of day from the server's internal clock. The response object's write method is used to direct the output to the user's browser.

The third set of tags, `<% response.write hour (time())%>`, is similar to the previous line but the time function is nested inside the VBScript hour() function. The hour() function strips the minutes and seconds from the time and returns only the hour portion of the time as an integer value between 0 and 23.

The fourth set of tags uses an "If then . . . End If" statement to send an appropriate time-of-day message. The If then . . . End If statement evaluates expressions as either true or false. If an expression is true, then the statements that immediately follow it are executed, otherwise execution jumps to the next conditional statement (ElseIf). Each successive statement is evaluated until the first true one is found. If none of the conditions is true, then the statements following the "Else" statement are executed. If more than one expression is true, then only the first is evaluated and its associated statements are executed. Figure 1 shows the output of this script displayed on a Web browser.

Listing 1: Source code for TimeGreeting.asp.

         Good Morning
   </center>
</body>
</html>
```

ASP.NET

ASP.NET code differs from ASP code in many important ways. The most visible difference is the separation of the server-side code and the HTML. This is illustrated in Listing 3. The server-side code is located at the top of the page within <script> tags and the HTML is located below it. ASP.NET uses "Web controls" to insert the output of the server-side code into the HTML. The Web controls are themselves objects with properties, methods, and events.

The first line of code in Listing 3 contains a <script> tag. This tag instructs the compiler that the programming language is VB.NET and that the code enclosed within the <script> tags should be executed on the server.

The second line of Listing 3 defines a subroutine named Page_Load(). The Page_Load subroutine runs automatically each time the page is loaded. The first line within the Page_Load subroutine,

```
lbTime.text = DateTime.Now.ToString("T")
```

obtains the current time from the system clock and formats it as a string. The DateTime object is a member of ASP.NET's base class library. The current time obtained from the DateTime object is assigned to the text property of a label named lbTime. The label object is instantiated and named in the HTML portion of the page with the statement

```
<asp:label id=lbTime runat="server"/>
```

The current hour and time greeting are assigned to the label controls named lbHour and lbGreeting, respectively. This output is inserted into the HTML as before. The output produced by TimeGreeting.aspx is shown in Figure 2. Note that despite the differences in the code, the output is same as that produced by the ASP code shown in Listing 1. Underscore (_) indicates continuation of a line.

Listing 3: ASP.NET source code for TimeGreeting.aspx.

```
<script language="vb" runat="server">
   Sub Page_Load()
      lbTime.text = _
         DateTime.Now.ToString("T")
      lbHour.text = _
         hour(DateTime.Now.ToString("T"))
      If hour(DateTime.Now. _
        ToString("T"))<12 then
        lbGreet.text = "Good Morning"
      ElseIf hour(DateTime.Now. _
        ToString("T"))<18 then
        lbGreet.text = "Good Afternoon"
      ElseIf hour(DateTime.Now. _
        ToString("T"))<22 then
        lbGreet.text = "Good Evening"
      ELSE
        lbGreet.text = "Good Night"
      End If
  End Sub
</script>
<html>
<head>
  <title>Time of Day Greeting</title>
</head>
<body>
<center>
  <h1>Time of Day Greeting</h1>
  <h3>The current time is
    <asp:label id=lbTime runat="server"/>
  </h3><br>
  <p>The current hour is
    <asp:label id=lbHour runat="server"/>
  <br>
  <p><asp:label id=lbGreet runat="server"/>
</center>
</body></html>
```

This example illustrates how ASP.NET separates the code from the presentation by placing all the code inside <script> tags and assigning the code output to Web controls. In this example, only one Web control is used, the label control, but ASP.NET's base class library contains dozens of Web controls. Many of them are quite sophisticated and offer a wide variety of options for displaying data.

The example also illustrates how ASP.NET encapsulates code within subroutines. The subroutines are called by events, such as the page being requested by a client or a client clicking a button on the page. Encapsulating code into discrete objects and then calling them when needed is advantageous for complex programs. Contrast this method to ASP, which executes code in a linear fashion starting at the top of the script.

ASP.NET is a central feature of Microsoft's .NET strategy and is expected to play a large role in the future of both Microsoft and the Internet. The following sections of this chapter overview the major features of ASP.NET.

MICROSOFT'S .NET STRATEGY

Microsoft's .NET strategy evolved from a series of e-mail messages sent from Microsoft President Bill Gates to Microsoft employees during the mid-1990s. The central point of the e-mail messages was that the world of computing was expanding from the desktop to the Internet and that Microsoft's new products were going to lead the way. By 2001, this strategic direction had evolved into Microsoft's .NET strategy.

The .NET strategy is articulated in an open letter, dated June 18, 2001, from Bill Gates to all information technology professionals (Gates, 2001). In this letter, Gates observes that the Internet is similar to the old mainframe world in which information is stored in large centralized databases. There is little communication between applications, creating "islands of functionality and data." This "server-centric computing model" results in huge inefficiencies because programs and data are replicated many times on different servers and because the functionality of many applications is diminished by their limited access to information.

A primary objective of the .NET strategy is to create the tools that allow applications to talk to each other. Gates' vision is that programs using the .NET model "will run across multiple Web sites, drawing on information and services from each of them and combining and delivering them in customized form to any device" (Gates, 2001).

The ASP.NET framework is a central feature of Microsoft's .NET strategy. The following sections of this chapter discuss the distinctive features of the ASP.NET framework.

Web Services

Web Services is a name given to a bundle of technologies that allows applications to communicate with each other. Web services create connections between the "islands of functionality and data."

An address validation service illustrates the benefits of Web services. Currently, a merchant wishing to validate customer-supplied shipping addresses needs to maintain a large database of valid addresses. Many merchants incur the high cost of maintaining such databases. Each merchant's database is accessible only to its owner and represents an "island of data."

Web services eliminate the need for merchants to incur the cost of maintaining such databases. Instead they can subscribe to a Web-based "address validation service." When a customer enters a shipping address on the merchant's Web site, the merchant's Web server sends the information to the Web service. The Web service immediately validates the address and returns the results. Invalid addresses are flagged, and the user is asked to correct it before his or her order is accepted. The service can even send a list of valid alternatives.

The entire transaction can be completed between the merchant's computer and the service provider's computer in a fraction of a second. The Web service can be shared by thousands of merchants, eliminating the cost of maintaining multiple databases.

Web services are already becoming available. United Parcel Service (UPS) offers several Web services, including address validation, shipping rate calculations, and package tracking. UPS provides these services as a free service to its customers. Providing Web services to its customers saves UPS money because fewer packages are shipped to incorrect address. They are also very convenient for UPS customers, provide them with an incentive to ship via UPS. More information on the Web services offered by UPS is available at http://www.ec.ups.com/ecommerce/solutions/c1.html.

ASP.NET's base class library provides many classes for supporting Web services. Microsoft hopes that ASP.NET's powerful tools for deploying and consuming Web services will provide it with an entrée into the profitable high-end corporate software market (Buckman & Bulkeley, 2002).

XML and SOAP

ASP.NET provides extensive support for the two key technologies underlying Web services: XML (extensible markup language) and SOAP (simple object access protocol). XML is similar to HTML in the sense that both are used to describe text. The difference is that HTML formats text for human consumption whereas XML formats text for machine consumption. HTML defines how data is displayed on a page, specifying, for instance, the fonts, font sizes, font color, and layout of the text used to display the data. XML describes the content of the data. For example, if the data consists of a book title and author, XML will label the data <title> and <author>, respectively. SOAP defines the protocols used for passing XML documents between computers. Both XML and SOAP are open industry standards managed by the World Wide Web Consortium (http://www. W3C.org). More information about XML and SOAP is available from the Organization for the Advancement of Structured Information Systems (http://www.xml.org).

Compiled Code

An important difference between ASP and ASP.NET is that ASP uses interpreted languages whereas ASP.NET uses compiled languages. Interpreted languages are translated from human-readable source code to machine-readable compiled code each time a program is called. This has the advantage of simplicity, because only one copy of the program needs to be stored on the computer. A major disadvantage of interpreted languages is that frequent compiling can cause performance problems on high-volume sites.

Compiled languages, such as those used by ASP.NET, are compiled once and stored in a compiled form. This eliminates the need to recompile the code each time the page is served. ASP.NET stores the compiled code as Microsoft intermediate language (MSIL), which is portable between operating systems. Each time an ASP.NET page is called, the MSIL code undergoes a final stage of compilation, called JIT (just in time) compilation. ASP.NET's compiled code is considerably more efficient than ASP's interpreted code, resulting in a significant increase in performance.

Another advantage of compiled code is that it can protect code from being plagiarized. Software companies make large investments in developing computer applications and usually do not want others to view their source code. Applications are typically distributed in a compiled format so that they will execute on computers but are unreadable to potential thieves. ASP scripts can be compiled, but the resulting components must go through an installation process on the server before they may be executed.

Common Language Run Time

The common language run time (CLR) manages the execution of ASP.NET code. The CLR checks to make sure that the MSIL reflects the most recent version of the source code. If the source code has been updated, the CLR recompiles the source code to MSIL before serving the page to the client. The CLR also provides such services as error handling, security features, and cross-language integration (Sussman, 2001; Payne, 2002). Code that is managed by the CLR is called managed code. The automated management features provided by the CLR saves ASP.NET developers the time and effort needed to manage their code manually.

Language and Platform Independence

An important feature of MSIL is that it provides both language and platform independence. An ASP.NET page can be written in any one of several CLR-supported programming languages. MSIL is independent of the programming language in which the source code is written.

MSIL can be compiled to run on any operating system for which a .NET-compliant JIT compiler is available. Microsoft's ASP.NET framework supports only Windows operating systems (9x, NT, 2000, and XP), but it is widely expected that third-party vendors and open development initiatives will produce JIT compilers for a variety of operating systems, including the popular UNIX and Linux operating systems. An open development initiative named the Mono Project has developed an open source, Unix version of the Microsoft .NET development platform (Mono Project).

Separation of Code and Content

Listing 3 illustrates how server-side code is separated from the HTML. The advantage of this structure is that the code is cleaner and easier to read. This division of code and output eliminates the infamous "spaghetti code" that can occur when program logic and formatting logic are intermingled.

Support for Multiple Client Types

The delivery of Web content is expanding to a broad range of digital devices, including personal digital assistants (PDAs), cell phones, and Internet appliances. The proliferation of Web-capable output devices makes it increas ingly important that server-side technologies be able to recognize the output device and format their output appropriately. ASP.NET automatically checks the client's output device and modifies the format of its output to match the device. This eliminates the need for developers to customize each application to handle different output devices, thereby reducing the cost of application development.

Modularity

ASP.NET uses event-driven object-oriented programming languages. One of the primary advantages of object-oriented languages is that they encapsulate program functionality into discrete reusable modules. Such modules can be written once, thoroughly tested, and reused many times. Because modules are self-contained and have well-defined inputs and outputs, they have the effect of reducing overall program complexity. Well-planned and programmed modules are easier to debug and more robust than non-object-oriented programs. The benefits of modularity are especially pronounced in large, complex applications.

Base Class Library

ASP.NET derives much of its functionality from an enormous library of prewritten code called the base class library. The library is organized into a hierarchal structure of *namespaces* and classes. Namespaces contain groupings of related classes. For instance, the Namespace System.Web.UI.WebControls contains over 90 classes that provide Web user interface controls. The label control used in Listing 3 is a member of the WebControl namespace, as are controls for creating text boxes, check boxes, radio buttons, and many other user interface controls. The .NET framework contains nearly 100 namespaces and provides a tremendous amount of functionality. Microsoft's base class library documentation may be viewed at the Microsoft developer's library (http://msdn.microsoft.com/library/default.asp?url = /library/en-us/cpref/html/cpref-start.asp).

Session-State Management

One limitation faced by Internet applications is that the client and the server communicate only intermittently. Communication occurs only when the client is sending a request to the server or when the server is responding. Between these short bursts of activity there is no communication between the client and the server (Bidgoli, 1999). This model of communication was quite satisfactory in the early days of the Internet, when most Web content was static, much like the page in a book. However, as the uses for the Web have expanded into transaction-oriented activities, such as online banking, e-mail, and stock trading, it has become increasingly important that the server be able to keep track of the status of each client. Keeping track of the status of each client's session is known as session-state management.

Online shopping carts are a good example of session-state management. Most online e-commerce sites offer shopping carts that allow customers to keep a list of items that they wish to purchase. This list is known as a *virtual shopping cart*. From the perspective of the server, each client is a session and all the information specific to the clients, such as what they have in their carts, is their session state. To manage the clients' shopping carts, the server must be able to keep track of which clients have added which items to their carts. Session state may also include client-specific information, such as credit card information, passwords, and account numbers. A single Web server may be managing hundreds of clients at one time.

There are several tools that can be used for managing session state including cookies, session objects, and the ASP.NET view state. Cookies are one of the most popular tools used for managing session state. Cookies are small text files that the server writes to the client's hard drive. The information contained within the cookies is sent to the server each time a client sends a request. The server can check the cookie information to identify which client sent the request and to retrieve session state that it has stored in the cookie. Cookies are supported by most server-side programming technologies.

Session objects allow developers to store client-specific information in the server's memory. This is useful when the developer does not want the client to be able to view or change the data. ASP also supports session objects, but it requires that they be used in conjunction with cookies. ASP.NET supports session objects without the use of cookies by embedding a unique session ID into the page URL.

View state is a powerful new tool available to ASP.NET developers and is the subject of the next section of this chapter.

View State

ASP.NET also introduced a new method of maintaining page state, called view state. All the information contained within a Web page's Web controls, such as text boxes, radio buttons, labels, and data grids, is saved in the page view state. ASP.NET automatically stores each page's view state in a hidden field, named _VIEWSTATE.

Figure 3 illustrates how view state works. In this example, the user has typed the name "Bill Adams" into the text box and clicked the submit button. He then typed the name "John Smith" into the text box and clicked the submit button again. The ASP.NET program is able to compare the name saved in the view state to the name in the text box and to determine that the user has changed the name in the text box.

Listing 4 shows the server-side source code that produced Figure 3. This page contains four Web controls: a text box, a button, and two labels. The Web controls are created in the HTML portion of the page. The text box and the button are both HTML-form elements and are enclosed within <form> tags. The contents of the Web controls are accessed programmatically within the <script> tabs at the top of the page.

When the user clicks the submit button, the page is submitted to the server. The server automatically executes the code within the Page_Load subroutine. The IF THEN statement then checks to see whether the text in the text box has changed by comparing its current value to its previous value, stored in tbCustomerName.text and ViewState("Name"), respectively. If the text has changed, a message is sent to the user that lists the original text stored in the view state.

The view state saves the data within all the Web controls, such as text boxes, check boxes, radio buttons, and text areas. That is why the name "John Smith" still appears in the text box in Figure 3 even after the user has clicked the submit button and the page has reloaded. Without the ASP.NET's view state feature, the text box would be empty.

Listing 5 show the source code that the ASP.NET has sent to the browser to produce Figure 3. This code shows how ASP.NET has stored the view state in a hidden form field, named "_VIEWSTATE." The view state contains an encrypted version of the information contained in the Web controls when the page was last submitted to the server. View state is useful to developers because it automatically helps maintain many types of session-state information.

            was: Bill Adams</span>
   </center>
</body>
</html>
```

Scalability and Reliability

ASP.NET is designed to meet the needs of high-volume, mission-critical applications. Such applications require software that is both scalable and reliable. A scalable application is one that can handle high transaction volumes. ASP.NET provides scalability through its use of compiled code, which reduces its demands on the server's central processing unit (CPU). Another important scalability feature is its ability to maintain session states across both Web farms (multiple servers) and Web gardens (single servers with multiple CPUs).

ASP.NET's scalability is also enhanced through its support for page caching. Caching is the ability to save the output from running a program and then reusing the saved output on subsequent requests without the need to rerun the underlying code. Caching can dramatically increase the efficiency of serving pages that are frequently viewed but whose content changes infrequently. For instance, a news Web site that is viewed thousands of times per day but is only updated once a day would be a good candidate for caching. ASP.NET allows caching of entire pages or portions of pages.

Reliability is an important performance criteria for Web applications. ASP.NET includes several features designed to minimize both the number of failures and the impact of failures when they do occur. Frequent garbage collection (removal of unused code from memory) prevents performance degradation caused by insufficient memory. System management tools monitor performance and can automatically restart failing processes. ASP.NET minimizes the impact of failures with centralized session-state management that can hand off failing processes without loss of data or disruption to the user.

Debugging and Error Handling

Even the best programmers occasionally write programs with errors. Errors can also be caused by incorrect user inputs, hardware failures, network failures, and myriad other causes. A good programmer anticipates such problems and writes programs that respond gracefully when they occur. ASP.NET provides programmers with a number of powerful tools for debugging and error handling. ASP.NETs Try-Catch blocks allow programmers to write custom error-handling routines for problematic code, such as database accesses. When errors occur Try-Catch automatically redirects program execution to specific error-handling code blocks. The feature can be used to provide a graceful response to the user and to report the problem to the system administrator.

ASP.NET's trace object provides developers with a useful tool for debugging and fine-tuning code during development. The trace object provides detailed analysis of code execution, including order of execution, CPU time, and memory usage (Homer, 2000).

FUTURE OF ASP AND ASP.NET

ASP.NET is the cornerstone of Microsoft's .NET strategy and the company has committed tens of millions of dollars to promoting it. It is a full-featured enterprise-scale development framework that provides Web developers with a rich array of powerful tools for creating Web sites and Web services. It is still in its infancy but there is little doubt that it will play an important role in the future of Web development.

The introduction of ASP.NET makes the long-term outlook for ASP uncertain. The large base of existing applications virtually assures that Microsoft will continue to support ASP for many years. Although ASP does not support many of ASP.NET's advanced capabilities, it is an easy-to-use technology and an excellent developmental tool for Web sites that do not require ASP.NET's advanced features. Both technologies have made a significant contribution to the advancement of server-side programming technologies.

GLOSSARY

Browser Software programs that run on the user's computer that are used to view Web pages.

Caching (pronounced CASH-ing) A technique computers use to save frequently accessed files.

Client An application that runs on a computer that relies on a server to perform some operations.

CLR Common language run time; responsible for managing code within Microsoft's ASP.NET framework. It also manages security and other tasks.

IIS Internet information server by Microsoft Corporation, one of the most widely used Web server applications on the market. It incorporates all the tools required by high-traffic commercial Web sites, such as security, extensions, logging, and database interfaces. It is included with several versions of Microsoft's Windows operating system.

MSIL Microsoft intermediate language is an intermediate level of code compilation between source code and machine code. It facilitates ASP.NET's ability to support a wide number of programming languages and operating systems.

.NET A flexible platform introduced by Microsoft that allows programs written in different languages to be compiled to run under .NET environments. The .NET platform can be used to develop programs for the Web, for desktops, for PDAs, or for any other Web-enabled device. ASP.NET is part of .NET and runs on Web servers.

Script An executable list of commands created by a scripting language, such as VBScript, JavaScript, PHP, Perl, or JScript.

Server A computer that serves Web pages and other files to a client via the Internet.

Tag Intermixed with text to describe the document's structure or its visual formatting. They are used with markup languages such as HTML and XML.

View State A hidden control used by ASP.NET to store form data in an encrypted format between page loads.

Web Services Technologies that allow computer applications to communicate via the Internet. Web services are built upon XML and SOAP technologies.

XML Etensible markup language; allows users to create their own tags to describe data content.

ActiveX

Roman Erenshteyn, *Goldey-Beacom College*

INTRODUCTION

ActiveX is a well-established technology that Microsoft developed in the early 1990s, and the ActiveX technologies have become an essential part of Microsoft applications and tools. Briefly, ActiveX is a term used to refer to a wide range of client/server technologies and components. ActiveX controls, formerly known as OLE (Object Linking and Embedding) objects, are components that one can insert into a Web page or other application. ActiveX controls enhance Web design with sophisticated features, such as advanced formatting or animation.

ActiveX components are incorporated in Microsoft's Component Object Model, which allows objects to interact with each other. ActiveX controls are an integral part of all current Windows operating systems. The technology is popular, and, because ActiveX is language independent, many traditional development tools (but not all of them) can build and deploy ActiveX controls. One of the most important and attractive features of ActiveX is its reusability. ActiveX controls extend the concept of classes, which was introduced in object-oriented programming languages to enable a programmer to reuse code easily in later projects. ActiveX takes this concept further, allowing programmers to package a control, reuse it in later applications, distribute it as a solution to other developers, or even develop a composite control—a control over other controls.

Thousands of ActiveX controls can be found on the Internet; some of them are freeware and some shareware, so a developer can easily download and include them into an application or Web design. ActiveX controls run in the same memory space as a browser. They must be downloaded and registered on the user's computer before the controls can be used. A number of ActiveX controls come as built-in objects with Windows. Other sets of ActiveX controls come with Internet Explorer, Microsoft FrontPage, ActiveX Control Pad, Microsoft Visual Studio 6.0, Microsoft Visual Studio.NET, and so on.

WHAT IS AN ACTIVEX CONTROL?

Historical Notes

Chappell and Linthicum (1997) reviewed processes and reasons that led to the development of ActiveX. It started with the introduction to OLE. The first release of Object Linking and Embedding (OLE 1) was developed as a technology that enabled users to create and to work with compound documents. A compound document contains elements created by two or more applications. For example, a user can combine pictures created using Adobe PhotoShop, text created using Microsoft Word, and a spreadsheet created using Microsoft Excel under a single document created using Microsoft PowerPoint. It enables users to focus more on the information they have to work on and less on the applications they use. The idea behind this was to link several documents together or to embed one document in another. The second version, OLE 2, provided users with the solution to a more general problem: how to connect different software components, that is, how software of different types should interact. This generalization produced what was called Component Object Model (COM). COM "establishes a common paradigm for interaction among all sorts of software—libraries, applications, system software, and more" (Chappell, 1996). Then Microsoft revised the definition of OLE, and this term was applied to anything that has been built using COM.

In the beginning of 1996, the definitions were changed again. Microsoft chose a new name—ActiveX. Primarily, this new term was associated with technologies related to the Internet and its applications. ActiveX was directly connected to OLE. Microsoft redefined the term OLE to mean only the technology used for creating the compound documents. As a result, new COM-based technologies labeled by OLE are now tagged with ActiveX.

An introduction to ActiveX controls can be found at http://msdn.microsoft.com/library/default.asp?url=/workshop/components/activex/intro.asp. ActiveX is defined as simply another term for "OLE object," or, more specifically, "COM object." A control is a COM object that at least supports the IUnknown interface and allows any control to be as lightweight as possible. Controls should actually support an interface, as well as methods, properties, and events.

OLE Control

ActiveX controls are often defined as OLE controls that support additional features. Chappell (1996) specified that OLE refers only to the technologies for creating compound documents: for embedding documents created by one application within a document created by a different application. For example, an Excel spreadsheet can be embedded within a Word document. In this case, the word processor doesn't need to build in the functions of a spreadsheet. The standard interfaces defined by OLE enable this interaction among all sorts of applications. Applications act as containers or servers, so one application always serves as the container (Word, for example) and another (Excel) acts as a server, which can place its documents within the container's document. Using OLE, a server's document can be linked to or embedded in the container's document.

The minimal requirement for an OLE control is a support of IUnknown and IClassFactory interfaces; however, an OLE control also supports a number of other interfaces that provide additional features, such as automation (methods, events, and properties) or user interface for the control. Every interface inherits from IUnknown that contains only three methods, the most important of which is QueryInterface. The IClassFactory interface allows programmers to create instances of a particular class. The following list is a sample OLE interfaces:

- IOleObject—supports communication between container and the control
- IOleInPlaceObject—supports in-place activation
- IDataObject—supports data transfer
- IDispatch—supports a control's methods and properties
- IPersist—includes six interfaces that support functions that enable a control to read or write its persistent data to storage, stream, or file
- IExternalConnections—supports functions that a control uses to track external connections
- IPerPropertyBrowsing—supports functions that allow container to retrieve individual control properties
- The complete description of these and other OLE interfaces can be found in MSDN on-line library (see references)

Additional features supported for ActiveX controls are initialization security, scripting security, run-time licensing, reduced footprint (for quick downloading), and digital certification.

COM Control

There are many sources of technical information, resources, and training on COM and COM-based technologies available on the Web. The Microsoft Developer Network (MSDN) is the first place to look for information on all Microsoft developer resources and Internet technologies (MSDN Library, n.d.). Some conceptual presentations from the 1998 Microsoft Professional Developers Conference in Denver are available (Microsoft, 1998). The Component Object Model defines how objects interact with each other. Charlie Kindel from Microsoft (1998) defined ActiveX simply as "A marketing name for a set of technologies and services, all based on the Component Object Model." ActiveX controls are using COM technologies to provide interaction with other types of COM components and technologies. Microsoft COM is the most widely used component software model. It provides a variety of integrated services, easy-to-use tools, and a lot of applications. Maloney (1998) defined COM as "a framework for creating and using components with a wide choice of tools, languages and applications." COM provides choice in the area of security because it provides common interface (SSPI, security support provider interface) where security providers can be plugged in. COM also provides the major elements necessary for technology to succeed: a solid specification and a single reference implementation that has been ported to multiple platforms (Maloney, 1998).

ACTIVEX FAMILY

ActiveX Controls

One of the most attractive features of ActiveX technology is the variety of ways that is components can be created. Figure 1 illustrates the ActiveX family, including tools that can be used to develop controls:

Chappell (1996) defined an ActiveX control as "a software component that performs common tasks in standard ways." The ActiveX controls specification specifies a standard set of interfaces that COM objects can support to carry out particular actions. Components need to interact with the code that uses them, and the ActiveX

Figure 2: ActiveX control's functionality.

controls specification and also determines rules for creating so-called control containers. A control container is client software that knows how to use an ActiveX control (Chappell, 1996). Applications developed using different computer languages, such as Visual Basic and C++, Java, can serve as control containers. Web browsers, such as Microsoft Internet Explorer, also are examples of containers. Netscape Navigator is not originally an ActiveX container; therefore, Web pages containing ActiveX controls may not function properly in Netscape browsers.

ActiveX controls for the Web are simple objects on a Web page that provide a user interface and support these interfaces. They add an interactive component to the page and allow users to communicate with the page. The code for a control can also be stored on a Web server and downloaded and executed when the browser or Web page requests them. An ActiveX control is compiled code with file extension.ocx.

Chappell (1996) also described the functionality of ActiveX control's specification as consisting of four main tasks:

1. Providing a user interface
2. Allowing the container to invoke control's methods
3. Exposing specific properties of the control and supporting modification of these properties
4. Examining the control's properties and modifying them

Each task is implemented by its own group of interfaces. This functionality is shown in Figure 2 (Chappell, 1996).

A variety of interfaces are implemented by an ActiveX control. This set of interfaces is available to ActiveX control developers so they can choose what they need. For example, Chappell (1996) described standard interfaces for an ActiveX control, and they support the control's functionality, which includes user's interface, methods, events, and properties. There are also a set of standard interfaces that ActiveX control containers support.

When the control is developed, it can be added to the Web page using the hypertext markup language (HTML) object tag `<OBJECT> </OBJECT>` and its attributes. (HTML is a simple language used to display information.) The following six attributes are important parts of control (Gilmore, 1999): CLASSID, CODEBASE, ID, WIDTH, HEIGHT, and BORDER. The CLASSID attribute contains the control's class ID, a unique identification tag generated when the control is compiled, and this allows recognizing and referencing the control. On a user's computer the control is then registered in the system registry with the class ID. The CLASSID attribute is the only one that is required; all others are optional. The following is an example of the `<OBJECT>` tag with its attributes for the Microsoft Animation Button Control. This button is an alternative to the common Command Button, and the Animated Button has a moving picture on it. In addition, the user can specify various start and end frames for conditions such as "mouse move," "mouse click," or "got focus" (the user presses the tab key until the button becomes the object on the document with the "focus"). This permits the user to display various visuals based on what the user is doing in relation to the button.

```
<OBJECT ID = "anbtn1" WIDTH = 127 HEIGHT = 71
       CLASSID = "CLSID:0482B100-739C-11CF-
         A3A9-00A0C9034920">
       <PARAM NAME = "_ExtentX" VALUE =
         "3360">
       <PARAM NAME = "_ExtentY" VALUE =
         "1879">
       <PARAM NAME = "defaultfrstart"
         VALUE = "0">
```

```
      <PARAM NAME = "defaultfrend" VALUE =
        "-1">
      <PARAM NAME = "mouseoverfrstart"
        VALUE = "0">
      <PARAM NAME = "mouseoverfrend"
        VALUE = "-1">
      <PARAM NAME = "focusfrstart" VALUE =
        "0">
      <PARAM NAME = "focusfrend" VALUE =
        "-1">
      <PARAM NAME = "downfrstart" VALUE =
        "0">
      <PARAM NAME = "downfrend" VALUE =
        "-1">
</OBJECT>
```

DefaultFrStart, DefaultFrEnd, DownFrStart, DownFrEnd, FocusFrStart, FocusFrEnd, MouseoverFrStart, and MouseoverFrEnd are the control's properties. The events for this control are Click, DblClick, Enter, Focus, Leave. Events are triggered when the user moves the mouse into the button (Enter) or off the button (Leave). Almost all editing tools today will automatically generate the correct HTML <OBJECT> tag code, including CLASSID information when ActiveX control is added to the Web page. The Class ID of a control can also be found by manually searching for the control in a system registry using the registry editor, REGEDIT.EXE. The CODEBASE attribute is used to specify a relative or absolute URL from where the control should be downloaded. An ID attribute works with the <OBJECT> tag the same as it works with other HTML tags, allowing the user to reference the element from scripting languages. The WIDTH, HEIGHT, and BORDER attributes specify the control's size and border. The <PARAM> tags, together with its NAME and VALUE attributes, are placed within <OBJECT> and </OBJECT> tags to assign initial values to a control's properties.

Gilmore (1999) also discussed the protection of controls from being used without permission. So-called run-time licenses allow controls to be executed, but not used for the development; design-time licenses allow controls to be used in the development stage. Different developers use different approaches to control licensing. Some developers require only design-time license, and some require both licenses. All the required licenses need to reside in the computer where the control is used. The License Manager ensures that run-time licenses (for controls that require them) are included in a license package file. The License Manager is included with Internet Explorer, and a reference to it should be included within the <OBJECT> tag. Another technology used for security is digital signature and code marking (Gilmore, 1999).

ActiveX Documents

ActiveX technology allows a user to work with embedded documents within a Web page as if the user were working in the original application. For example, a person using Web can activate an Excel spreadsheet, for example (see Figure 2), and use all Excel commands. ActiveX documents technology is based on OLE documents. The Web browser can serve as an ActiveX document container, whereas applications like Word, Excel and others are ActiveX document servers. Supporting ActiveX documents requires a number of additional user interfaces for an embedded document. For example, an interface is required to allow users to print the document in the same way it would be printed from the server application. Internet Explorer relies completely on ActiveX documents. For example, an HTML page is downloaded, the browser interprets it and displays the page, and, if a user downloads an Adobe Acrobat file, the browser also displays that information. A user may view the browser as one application, but the browser is actually built from several components that are linked together. Web browser objects can host any ActiveX document server, and it treats different servers (HTML viewer, Word, Excel, PowerPoint, Adobe Acrobat, etc.) identically.

ActiveX Scripting

Web browsers support HTML. Advanced user interface controls are not implemented. As the standard for creating a complete interface, Microsoft has provided ActiveX Scripting. Hillier (1996) defined ActiveX scripting as a language-independent standard that defines the relationship between a scripting host and a scripting engine. A scripting engine is an ActiveX component that conforms to the ActiveX specification (for example, Java Virtual Machine). A scripting host is an application that uses the scripting engine (an example of scripting host: Internet Explorer). The script is placed inside the actual HTML code between two tags <SCRIPT> and </SCRIPT>. After script is loaded into the engine, the host runs it.

Producing interactive Web pages is a primary goal for Web developers. Scripting languages is just one method of providing interactivity, but the use of scripting languages offers a number of advantages for developers. Scripts can be defined as a set of program instructions that a developer can embed in the HTML code, which is then executed by the browser. The most popular scripting languages are JavaScript and VBScript, but ActiveX Scripting is an open standard that allows other scripting languages to be used.

Server-Side ActiveX Controls

Dietel, Dietel, and Nieto (2001) described how server-side script or Active Server Pages (ASP) functionality can be extended with server-side ActiveX components. These types of ActiveX controls reside on the Web servers and lack a graphical user interface. Some of these controls included with Internet Information Server and Personal Web Server are the following:

- MSWC.BrowserType—ActiveX control for gathering information about the client's browser
- MSWC.AdRotator—ActiveX control for rotating advertisements on a Web page
- MSWC.NextLink—ActiveX control for linking Web pages together
- MSWC.ContentRotator—ActiveX control for rotating HTML content on a Web page

- MSWC.PageCounter—ActiveX control for storing the number of times a Web page has been requested
- MSWC.Counters—ActiveX control that provide general-purpose persistent counters
- MSWC.MyInfo—ActiveX control that provides information about a Web site Scripting.FileSystemObject—ActiveX control that provides an object library for accessing files on the server
- ActiveX Data Objects (ADO) Data Access Components—ActiveX controls that provide an object library for accessing databases

Java Virtual Machine

Java is a programming language that is similar to C++ but also provides exciting capabilities for the Internet and component technologies. Java Virtual Machine (Java VM) is implemented as an ActiveX control included with Internet Explorer and is used to execute Java programs and applets. Chappell (1996) specified that with Java VM these applets are treated as ActiveX controls, and because controls can be driven by scripts, Java applets can also be scripted. Then, using the ActiveX scripting interfaces, scripting languages can be used to access the methods exposed by an applet. In reality, when Internet Explorer encounters the `<APPLET>` tag, it internally converts it to an `<OBJECT>` tag with the CLSID of the Java VM's ActiveX control.

Security Features of ActiveX

As mentioned earlier, there are several security concerns related to ActiveX technology: initialization security, scripting security, run-time licensing, and digital certification.

After a control is initialized, it can receive data from a local or remote URL for initializing its state. Data can come from an untrusted source, and this is a security hazard. Several methods can be applied to ensure the control's security for initialization. Component Categories Manager creates the appropriate entries in the system registry. Microsoft Internet Explorer examines the registry before loading a control to determine whether these entries appear. Another method implements an interface IObjectSafety. If Internet Explorer determines that control supports this interface, it calls IObjectSafety::SetInterfaceSafetyOptions method before loading control to determine whether it is safe for initialization.

ActiveX controls can be accessed from scripts. Code signing can guarantee that the code is trusted. But even if a control is known to be safe, is not necessarily safe when automated by an untrusted script. The methods to ensure scripting security are identical to ones described earlier for initialization security.

Some ActiveX controls are distributed free of charge, but most of these should support design-time and run-time licensing. Design-time licensing ensures that a developer is building an application or Web page with a legally purchased control. In contrast, the run-time licensing ensures that a user is running an application or displaying a Web page that contains a legally purchased control. Design-time licensing is verified by control containers. Before these containers allow a control to be placed on Web page, they first verify that the control is licensed. This is achieved by calling certain functions in the control that validate the license. For run-time licensing the process is similar.

At the default security settings in Internet Explorer any object on an HTML page must be digitally signed. Digital signatures are created using Signing Code with Microsoft Authenicode Technology. It is a set of tools that can be downloaded from MSDN. A digital signature associates a software vendor's name and a unique public key with a file that contains an ActiveX object.

WHAT ARE THE ALTERNATIVES TO ACTIVEX?

Client-Side Scripting and Component Technologies

Component technologies are used in the Internet world to extend the functionality of Web pages. ActiveX is not the only way to accomplish this. Gilmore (1999) emphasized the role of component technologies in building e-business and other Web sites. Component technologies allow developers to create a flexible and user-friendly interface for Web pages. This interface can contain a large number of input fields, graphics, animations, event controls, and so on. As mentioned earlier, the component functionality is defined through the set of its properties, methods, and events. Components also make it possible to add a complex logic to a Web page in the same way it can be done for applications written in C++ or Visual Basic. The component technologies other than ActiveX control are Java applets and DHTML scriplets. Alternatives to component technology are client-side scripting and DHTML (Gilmore, 1999). Java applets can be created using Java language and they can run on any browser that has Java Virtual Machine, which serves as an interpreter for Java applet's code. DHTML scriplets (Gilmore, 1999) are Web pages with DHTML functionality. Similar to ActiveX controls, they can be used in COM applications, other then Web. DHTML scriplets are supported by Windows, Mac, and UNIX platforms.

ASP as a Server-side Alternative to ActiveX

There are several server-side alternatives to ActiveX, and most of these are covered in other chapters. Briefly, ASP (and its most recent version, ASP.NET; Kalata, 2002) is Microsoft's implementation of Web server programming technology. ASP makes it easier for Web developers to create dynamic Web applications. Active Server Pages are Web pages that contain server side scripting. When the client requests an ASP page, the Web server passes the request to the ASP application. The ASP application then detects if there are any global scripts that need to be processed. The ASP application inserts the code from any server-side include pages. ASP.NET is a language-independent technology that is used to develop Web applications. The two main types of Web resources created with ASP.NET applications are WebForms and Web Services. WebForms allow users to develop and process forms on Web pages, as well as to develop cross-browser Web applications. Web Services are ASP.NET pages that contain publicly exposed code so the other applications can interact with them. ASP applications run much faster than CGI scripts and can incorporate HTML pages and forms, scripts written in VBScript or JavaScript, as well as ActiveX components

ActiveX Strengths and Limitations

Gilmore (1999) provided a detailed analysis of the advantages and limitations of component technologies and client-side scripting, highlighting the main benefits of using components in the Web pages:

- **Robustness.** Traditionally used Web technologies cannot compete with what is possible using programming languages such as C++, Java, and Visual Basic. The code written in one of these languages can be included in a component and then into a Web page;
- **No duplicated scripts.** The same component can be used in different pages instead of duplicating scripts.
- **Maintenance and reusability.** In the case when several Web pages use the same component, its source code is stored only once. This modular approach makes maintenance simple. Code encapsulation in a single entity allows reusing the component in other applications.
- **Implementation hiding.** Developers need to know only what the component does, not how it does it. Because developers do not need to worry about the specifics of component's code, they only need to know how to interact with the component's interface.

The biggest limitation for ActiveX is that there many products on the market that lack of the tools necessary for designing ActiveX controls.

Chappell (1996) and Linthicum (1997) discussed the debate over ActiveX and Java applet component technologies. Gilmore (1999) offered a detailed comparison of ActiveX versus Java applets and versus DHTML scriplets and client-side scripting. ActiveX controls can be developed using different programming languages and are not limited to Web browsers; they can run on different platforms, including Macintosh and UNIX, as well. Java applets must be created using the Java language, but they can run on any platform that has a Java VM. This is possible because a Java VM shields the applets from the details of the host operating system. Today Java applets are used more frequently in Web applications than ActiveX controls. ActiveX controls have to register themselves with the Windows registry and execute as native Windows applications. This allows the controls access to all native features, such as file I/O (input/output) and devices and even memory.

ActiveX controls are fully supported by Internet Explorer and partially supported by Netscape Navigator. Users of Netscape Navigator need an ActiveX plug-in, and because most of them don't have it, they may prefer other alternatives. ActiveX controls run faster than alternative technologies because the controls are compiled into code. Client-side scripting and DHTML scriplets are the slowest options because they must be interpreted. The functionality of ActiveX is almost unlimited, while Java applets functionality is limited by Java language abilities. Client-side scripting and scriplets are also limited by scripting language features. Both ActiveX controls and Java applets provide similar levels of security. An important feature is the download speed. The download of ActiveX requires users to wait. ActiveX controls remain on the client, however, and therefore subsequent downloads are not required. The Java applet download is the slowest because class files have to be downloaded every time the Web page that contains an applet is opened. Client-side script download speed is the fastest. The set of skills required to create ActiveX controls includes C, C++, Visual Basic, Java, or other tools that can create them. The Java language is the only skill needed to develop a Java applet. All component technologies can be reused and maintained easily. ActiveX controls maintenance requires a development tool for the language used to create it. DHTML scriplets can be maintained with any text editor. An important feature is the security of business logic. The logic programmed using client-side script, DHTML, or DHTML scriplets can be seen using a Web browser. Source code developed for ActiveX control and Java applet is compiled and not accessible.

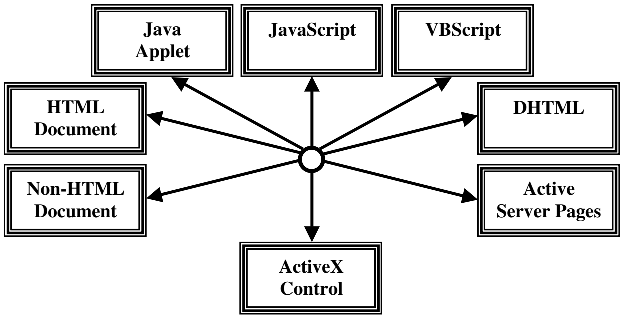

Figure 3: ActiveX integrates different Web technologies.

The answer to the question of which approach is better is simple. Developers must consider the strengths and weaknesses of ActiveX controls, Java applets, DHTML scriplets, and other technologies before making a choice. These technologies are not mutually exclusive; each is suited to particular situations. Nonetheless, one advantage ActiveX controls is obvious: They can be used in a wide variety of applications and are not limited to use in Web applications. This makes it easy to integrate and reuse a component from a variety of existing technologies used for Web design and development., a concept is illustrated in Figure 3.

ActiveX and Microsoft's .NET Framework

The next-generation platform introduced by Microsoft is called .NET, and it is closely related to COM and ActiveX. In general, .NET Framework "is a component of the Microsoft Windows operating system that provides the programming model for building, deploying, and running Web-based applications, smart client applications, and XML Web services" ("Top 10 Reasons," 2002). This technology has many features that improve existing component technologies, including COM and ActiveX. It promotes interaction with COM components and generates

a wrapper around existing components, so the programmer not needed to rewrite them. Applications built using the .NET Framework can connect with existing systems and packaged applications, regardless of their underlying platform, via XML Web services or via other system-specific connectors (“Top 10 Reasons,” 2002). The .NET Framework technology for interacting with data, Microsoft ADO.NET, is designed for today’s Web-based style of data access. ADO.NET is a new version of ActiveX Data Object Model that provides objects that allow programmer to interface with the database. With .NET Framework ADO.NET is installed, and XML is a standard that allows programmers to describe and store data within text files. ADO.NET also allows programmers to retrieve data from a variety of sources, including XML data. By using these technologies programmers can exchange data across products and platforms (Kalata, 2002). The future of .NET Framework is promising, but this is not directly related to the main subject of this chapter.

BASIC AND ADVANCED ACTIVEX TOOLS

Microsoft ActiveX Control Pad

Microsoft ActiveX Control Pad is a smart Web development tool that allows adding ActiveX controls and ActiveX scripting (VBScript or Jscript) to Web pages. It also includes the Microsoft HTML Layout Control. Using this tool, a developer can include advanced layout and multimedia features, such as exact object placement, layering, and other effects. At the time of this writing, setuppad.exe file can be downloaded from the MSDN library page (msdn.microsoft.com/library/default.asp). It looks similar to HTML editors, extended to insert ActiveX controls. Figure 4 illustrates the use of ActiveX Control Pad to insert calendar control (shows the object and properties).

Microsoft FrontPage 2002

Microsoft Front Page also allows adding ActiveX controls to existing or new Web pages. To insert ActiveX control to the Web page, a developer has to open this page and then follow the following sequence: Insert—Web Component—Advanced Controls—ActiveX Controls. It opens a list of available controls. Figure 5 shows an example of inserting a control. The figure shows the Multimedia Control itself and a properties window that includes several tabs, such as General, Parameters, Controls (it is open), Object Tag.

Text and Graphics Editors

Important components of ActiveX Control development tools are decent text and graphics editors. The simplest

text editor that can be used for this purpose is Notepad, which comes with Windows. HTML editors, such as CoffeeCup HTML Editor (www.cofeecup.com) or Web Edit, contain shortcuts for automatic insertion of a large number of HTML tags. There are also hundreds of graphics editors available on the market. The following list contains only a small sample of available graphics editors: Adobe PhotoShop, Microsoft Photo Editor, Microsoft Image Composer, ArcSoft Photo Studio, MGI Photo Suite, and Paint Shop Pro 6.2.

ActiveX Software Development Kit

The Microsoft Platform Software Development Kit (SDK) provides the documentation, samples, header files, libraries, and tools a user needs to develop Windows-based applications. The applications developed with this edition of the SDK can run on Windows .NET Server, Windows XP, Windows ME, Windows 2000, Windows 98, Windows 95, and Windows NT.

Microsoft Visual Basic Control Creation Edition

Visual Basic Control Creation Edition, a member of the Microsoft Visual Basic programming system family, is designed specifically to be the fastest and easiest way to create ActiveX controls. There are three general usage scenarios for creating ActiveX controls with the 1996 Control Creation Edition:

1. Creating ActiveX controls from scratch. Everything is included in the Control Creation Edition to allow the creation of complete, stand-alone ActiveX controls from scratch. It is expected that the following two usage scenarios will be more common, however.
2. Subclassing and customizing an existing ActiveX control. Developers can take advantage of the variety of commercially available and free ActiveX controls. An existing control can be subclassed, customized, and then compiled, creating a custom version of the same control.
3. Aggregating multiple ActiveX controls into a control "assembly." Developers can take advantage of the large market of commercially available ActiveX controls by aggregating multiple controls together into an ActiveX control project, customizing their look and behavior, and then compiling the group of controls together into a single control. The resultant control can then be inserted into a Web page or a client/server application to "wrap" or contain the entire user interface elements of that application.

Microsoft Visual Studio Visual Basic comes with a variety of ActiveX controls that can be easily included in different applications. The instructions and scenarios for almost all of them can be found in MSDN. The following is a list of several controls:

- Communications Control—provides an interface to a standard set of communication commands (establish a connection to a serial port, connect to another communication device, exchange data, monitor and respond to various events and errors)
- CoolBar Control—allows creation of user-configurable toolbars
- DayTimePicker Control—displays date and time information and acts as the interface through which users can modify this information (see Figure 4);
- DataRepeater Control—functions as a data-bound container of any other user control. It allows the user to create a catalog that includes images and descriptions of each product and to create bankbook applications to track personal finances (can be found in almost all banks' online services)
- ImageCombo Control—has the ability to include a picture with each item in the list portion of the combo
- Internet Transfer Control—implements hypertext transfer protocol (HTTP) and file transfer protocol (FTP), which allows a user to add an FTP browser to any application, to create an application that automatically downloads files from a public FTP site, to parse a Web site for graphics references and download graphics only, among other things
- MSChart Control—allows a user to plot data in charts according to specifications (e.g., dynamic data, such as current prices of selected stocks)
- Multimedia Controls—manages the recording and playback of MCI (Media Control Interface) devices (see Figure 5)
- PictureClip Control—creates an image resource bitmap that stores all the images needed for an animation

Microsoft Foundation Classes (MFC) and ActiveX Template Library (ATL)

ActiveX controls can be also developed using Visual C++. Microsoft offers some tools that help a C++ programmer to create an ActiveX control. MFC is a set of C++ classes that support COM, OLE, and ActiveX (among other things). An existing OLE control can be converted into ActiveX control adding additional features (typical for ActiveX), such as safety, run-time licensing, and digital certificates. This technology allows for creating small controls, but it requires the correct MFC dynamic link library to be installed.

An ActiveX Template Library (ATL) is a set of C++ template classes designed to create small and fast ActiveX controls (COM objects). If a control is developed using ATL, the end user needs to download only the object, because the control doesn't need a run-time dynamic link library to be resident. With ATL developers can create several control types. The use of ATLs minimizes the number of interfaces that a control needs; the control will draw itself. More detailed information about ATL and its downloads can be found at msdn.microsoft.com/visualc/prodinfo/.

Online ActiveX Services

Thousands of ActiveX Controls are available on the Web, including freeware that can be used for private purposes and is helpful for developers. The following are the links to the most attractive and useful sites at the time of this writing.

- **www.webdeveloper.com/activex** This site contains useful information and links for developers, including technical articles, downloads, development guides, and more.
- **download.cnet.com/downloads/0–10081.html** This site features ActiveX Controls grouped into the following clusters: application development, browser enhancements, control development, database connectivity, online applications, and tools and utilities.
- **browserwatch.internet.com/activex.html** This site is called BrowserWatch—ActiveX Arena. It is the place where users can find the links to all of the ActiveX Controls available on the Web. There are links to a variety of form design controls, multimedia controls, graphic controls, sound controls, document viewer controls, and productivity controls—to almost everything a user may need for Web design and development.
- **www.geocites.com/SiliconValley/Park/3545** This site features new and interesting ways to use ActiveX controls and contains directions to do-it-yourself, step-by-step guides on how to use these controls. The information and examples from this site are especially useful for beginners.
- **www.vision-factory.com/activex.htm** This site offers several ActiveX Controls downloads free of charge for private use, including rounded buttons control, text scrolling, Outlook-like user interface, a Windows Explorer–style tree, list view of files and directories, among others.
- **www.webexpressions.com/resource/registry/activex.cfm** This site contains helpful information about using ActiveX Controls on the Web as well as downloadable samples. Many of the samples are useful for almost any type of site; others of them are just for fun. Short explanations of how each one works and can be modified are included. There are also links to hundreds of sites that are using these to make their pages interactive. There are ActiveX Controls for simple and dual pop-up menus, cascading popup menus, text and button menus, marquees, stock and news tickers, info buttons and various text effects.
- **www.active-x.com** This is a large repository of ActiveX Controls developed by different companies. It includes a variety of useful controls (some are free). The following is the list of top downloads in mid-2002:
  1. TILISOFT—These Internet ActiveX Controls allow users to retrieve HTML pages from the Net, to post data to or retrieve data from an HTTP server, and to transfer files over the Net using Transmission Control Protocol and Internet Protocol.
  2. BetterButton—This replaces the standard Windows button to add many more effects, such as color, pictures, drop shadows, and various styles. It also creates

new styles that break from tradition, such as Visual Studio.NET and active (hover button) styles. It can create various picture styles, set alignment, wrap text, and more.

3. Active Image—These ActiveX Controls features include the ability to create or modify images on the fly, to perform text drawing with font styles and angles, and to use drawing tools such as rectangles, polygons, pie charts, arcs and circles, and linear image transformations.
4. Animation GIF ActiveX—This ActiveX Control allows users to display animation GIF files.
5. FreeLink ActiveX—This is a label control that is highlighted when the user moves the mouse over it. It will also start a URL in the user's default Web browser or e-mail client if it is clicked. It is freeware and includes complete source code.

- **www.vbfreeware.com/download.asp?type=ax66** This site offers ActiveX Controls for different tastes and purposes that can be downloaded for free. Controls are available for a variety of applications, including communication, multimedia, Web development, and more.
- **shop.store.yahoo.com/componentone-llc/comstudenful.html** ComponentOne Studio Enterprise is the most comprehensive collection of components for ActiveX, .NET, and ASP.NET. It is subscription service that provides more than 30 components, including grid components, reporting components, charting components, data components, user interface components, and e-commerce components.

ACTIVEX CONTROL EXAMPLES

The following examples have been taken from a Web site, Actives Controls examples (members.tripod.com/~activecontrol/index.htm, developed by Greg Jarol, University of British Columbia, Canada) and can be viewed there.

The structured graphics control comes as a default with Internet Explorer and allows the user to create powerful three-dimensional graphics using simple vector primitives that can then by animated using scripting (such as VBScript or JavaScript). This particular example (Figure 6) uses JavaScript.

Source code for structured graphics control:

```
<OBJECT ID = "piechart"
     CLASSID = "clsid:369303C2-D7AC-11d0-
       89D5-00A0C90833E6"
     STYLE = "position:relative; Width:125;
       height:100">
     <PARAM NAME = "Line0001" VALUE =
       "SetFillColor(0,0,255)">
     <PARAM NAME = "Line0002" VALUE =
       "SetFillStyle(1)">
     <PARAM NAME = "Line0003" VALUE =
       "SetFont('Verdana',40,650,0,0,0)">
     <PARAM NAME = "Line0004" VALUE =
       "Text'Arc',40,650,0,0,0)">
     <PARAM NAME = "Line0005" VALUE =
       "SetLineColor(0,0,0)">
     <PARAM NAME = "Line0006" VALUE =
       "SetLineStyle(1,3)">
     <PARAM NAME = "Line0007" VALUE =
       "SetFillColor(0,0,255)">
     <PARAM NAME = "Line0008" VALUE =
       "SetFillStyle(1)">
     <PARAM NAME = "Line0009" VALUE =
       "Pie(-150,-70, 200,200,15,22,0)">
</OBJECT>
<SCRIPT LANGUAGE = "JavaScript1.2">
     if (document.all)
            setInterval("piechart.
              Rotate(5,5,5)",100)
</SCRIPT>
```

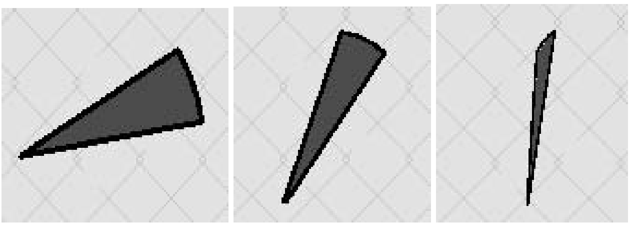

Figure 6: Example of the structured graphics control.

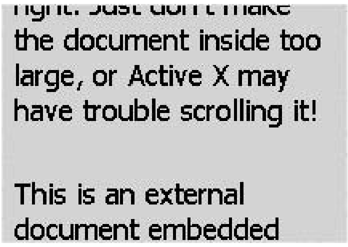

right. Just don't make the document inside too large, or Active X may have trouble scrolling it!

This is an external document embedded

Figure 7: Example of the document scroller.

The document scroller (Figure 7) control allows you not only to embed another HTML document inside the main document, but also to have the "internal" document scroll up-down or left-right all by itself. Note that there are no scroll bars.

Source code for document scroller:

```
<OBJECT ID = test2 CLASSID = "clsid:
  1A4DA620-6217-11CF-BE62-0080C72EDD2D"
     WIDTH = 220 HEIGHT = 150>
     <PARAM NAME = "szURL" VALUE =
       "page1.htm">
     <PARAM NAME = "ScrollDelay" VALUE = 7>
     <PARAM NAME = "ScrollPixelsY"
       VALUE = -2>
     <PARAM NAME = "ScrollPixelsX"
       VALUE = 0>
     <PARAM NAME = "LoopsY" VALUE = -1>
     <PARAM NAME = "DrawImmediately"
       VALUE = 1>
</OBJECT>
```

Figure 8: Screen capture example of the path control.

The path control (Figure 8) is an advanced control available in Internet Explorer that allows the user to animate visual objects (images, text, etc.). Objects can move around inside the document freely following complex, predetermined paths. The example in Figure 8 animated an HTML form button.

Source code for path control:

```
<INPUT TYPE = BUTTON NAME = btnSpline
  VALUE = "Flying button!"
      STYLE = "position:absolute;LEFT: 20;
        TOP: 200">
<OBJECT ID = "pthPolygon" CLASSID = "CLSID:
  D7A7D7C3-D47F-11D0-89D3-00A0C90833E6">
      <PARAM NAME = "AutoStart" VALUE = "-1">
      <PARAM NAME = "Repeat" VALUE = "-1">
      <PARAM NAME = "Bounce" VALUE = "0">
      <PARAM NAME = "Duration" VALUE = "10">
      <PARAM NAME = "Shape" VALUE =
        "Polygon(8,50,100,50,150,100,100,100,
        250,50,250,50,275,25,150,0,150)">
      <PARAM NAME = "Target" VALUE =
        "btnSpline">
</OBJECT>
```

The drop-down menu control (Figure 9) creates a contextual menu that can be further enhanced with extra functionality, such as going to the selected URL when clicked on. VB Script is used for this control.

Source code for the drop-down menu control:

```
<OBJECT ID = "IEMenu1" CLASSID = "clsid:
  7823A620-9DD9-11CF-A662-00AA00C066D2"
      WIDTH = 1 HEIGHT = 1 ALIGN =
        LEFT HSPACE = 0 VSPACE = 0>
      <PARAM NAME = "Menuitem[0]" VALUE =
        "This is the first item">
      <PARAM NAME = "Menuitem[1]" VALUE =
        "This is the second item">
      <PARAM NAME = "Menuitem[2]" VALUE =
        "This is the third item">
      <PARAM NAME = "Menuitem[3]" VALUE =
        "This is the fourth item">
```

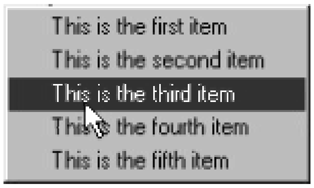

Figure 9: Screen capture example of the drop-down menu control.

```
      <PARAM NAME = "Menuitem[4]" VALUE =
        "This is the fifth item">
</OBJECT>
<SCRIPT LANGUAGE = "VBScript">
      sub IEMenu1_Click(ByVal x)
             Alert "You clicked on menu item:
               "& x
      end sub
      sub ShowMenu_onClick
              call IEMenu1.PopUp()
      end sub
</SCRIPT>
<DIV onClick = "IEMenu1.PopUp()">
  <B>Drop down menu!</B></DIV>
```

Gilmore (1999) offered another interesting and useful example of ActiveX Controls. Often Web page contains a number of ActiveX controls that interact with each other. In this example, a Web page contains two controls—a calendar control and a list box control, as well as an HTML button. The calendar and list box ActiveX controls are included into Microsoft Visual Studio. The Web page is shown in Figure 10.

When the date is checked on the calendar, it appears in the list box. This happens because the calendar's Value property is passed as a parameter to the list box's AdItem method, and this takes place in an event handler for the calendar's Click event. The VBscript for is as follows:

```
sub Calendar1_Click()
       ListBox1.AddItem Calendar1.Value
end sub
       The list box entries can be cleared
by clicking on an HTML button, the OnClick
event of the button invokes the ClearList
subroutine:
sub ClearList()
        ListBox1.Clear
end sub
        Finally, a list box item and its
value are displayed in a message box when
that item is clicked:
sub ListBox1_Click()
        msgbox "Item" & ListBox1.ListIndex
          + 1 & " in the list box has a
          value of " &
               ListBox1.Value
end sub
        The control for the ListBox1:
<OBJECT ID = "ListBox1" WIDTH = 160
  HEIGHT = 60
          CLASSID = "CLSID:8BD21D20-EC42-
            11CE-9E0D-00AA006002F3">
          <PARAM NAME = "ScrollBars" VALUE =
            "3">
          <PARAM NAME = "DisplayStyle"
            VALUE = "2">
          <PARAM NAME = "Size" VALUE =
            "4233;1588">
          <PARAM NAME = "MatchEntry" VALUE =
            "0">
```

Clear Listbox Dates
VBScript
OK

This Web page consists of two ActiveX controls and an HTML button element that interact with each other. The Web contains three subroutines to handle the following functionality:

- Move the date selected on the Calendar control directly into the Listbox control
- Display a Listbox item and its value when the item is clicked
- Clear the Listbox control by clicking an HTML button element

May 2002 May 2002

Sun	Mon	Tue	Wed	Thu	Fri	Sat
28	29	30	1	2	3	4
5	6	7	8	9	10	11
12	13	14	15	16	17	18
19	20	21	22	23	24	25
26	27	28	29	30	31	1
2	3	4	5	6	7	8

4/22/2002
5/2/2002
5/4/2002
5/6/2002

Item 5 in the listbox has a value of 5/4/2002

Figure 10: Web page with multiple ActiveX controls (Gilmore, 1999).

```
        <PARAM NAME = "FontName" VALUE =
          "Courier">
        <PARAM NAME = "FontHeight" VALUE =
          "200">
        <PARAM NAME = "FontCharSet" VALUE =
          "0">
        <PARAM NAME = "FontPitchAndFamily"
          VALUE = "2">
        <PARAM NAME = "FontWeight" VALUE =
          "0">
</OBJECT>
```

This example clearly shows how simple it is to develop multiple controls on a Web page and how they can communicate with each other.

CONCLUSION

ActiveX controls have grown from OLE technology and become very efficient for use in a number of different containers. A variety of software development tools, as well as user-productivity tools facilitate the coding of ActiveX controls. ActiveX controls make it easy for software developers to create, reuse, and integrate different software components. ActiveX allows Web developers to build multimedia rich and productive Web sites quickly. Web browsers serve as ActiveX containers, and therefore Web page developers are able to include ActiveX objects and documents. These objects establish a variety of useful interfaces that make a Web page interactive. This is especially important for e-commerce Web sites on which interaction with customers is a key feature. ActiveX technology is flexible; it can easily be combined with other Web design technologies such as HTML, Java applets, JavaScript, VBScript, and others. There are thousands of ActiveX controls available online as freeware or shareware. Web development software and tools, such as Microsoft FrontPage or Macromedia Dreamweaver, make it easy to include ActiveX controls in Web pages.

GLOSSARY

ActiveX A broad range of client/server technologies that are part of Microsoft's Component Object Model. ActiveX technology is frequently incorporated on Web pages but can also be used in a variety of applications in the Windows environment (and occasionally in the Mac environment but not in Unix or Linux environment).

ActiveX Control A component that can be easily inserted into a Web page to enhance design. Controls can also be used in other Microsoft's applications not related to Web.

ActiveX Documents The document contained in an ActiveX container (Internet Explorer). Whereas a traditional document (such as a Word document) is static, ActiveX documents need not be. Using Visual Basic, the user can create a complete application with the semantics of a traditional document. In other words, users have the functionality of the application but the flexibility of a document. Thus, the "document" is truly active. The concept can be found at http://msdn.microsoft.com/library/default.asp?url=/library/en-us/vbcon98/html/vbcondocumentobjectsthefutureofforms.asp

ActiveX Scripting Any use of VBScript and Jscript within Internet Explorer that controls the integrated behavior of active controls.

Class A data structure that specifies the properties and behavior of objects.

Component Object Model (COM) Microsoft's framework for developing and supporting program component objects.

Component A unit of compiled or scripted code that encapsulates a set of functionalities (e.g., a set of functions).

Container An application that defines the outermost document that embeds another document; an application that can run components.

Event A notification sent by one object to another that an action has occurred. The receiving object executes an associated method.

Java Virtual Machine A component that enables a Web page to run Java applets.

Method Code that is executed when an object receives an event message.

Object An instance of a class. The object consists of the data variables (properties) declared in the class definition along with any methods or procedures that act on this data.

Object Linking and Embedding (OLE) Microsoft's framework for a compound document technology. Briefly, a compound document is something like a display desktop that can contain visual and information objects of all kinds: text, calendars, animations, sound, motion video, continually updated news, controls, and so forth. Part of Microsoft's ActiveX technologies, OLE takes advantage and is part of a larger, more general concept, the Component Object Model.

OLE custom control (OLX) A special-purpose program that can be created for use by applications running on Microsoft Windows systems. The file extension for ActiveX controls is .olx.

Properties An attribute (or characteristic) of a control (size, fonts, color, etc.).

ActiveX Data Objects (ADO)

Bhushan Kapoor, *California State University, Fullerton*

INTRODUCTION

The field of Web applications development has seen significant changes over the past several years. Early Web applications consisted of simplistic static Web pages with text, graphics, and hyperlinks to other Web pages and had no database access. Over time, Web applications were developed that were dynamic in nature and could access traditional databases. Many organizations also developed e-commerce applications to do business on the Internet. These applications utilized databases to perform such tasks as storing and tracking customer information, purchases, and preferences, as well as monitoring company inventory and updating product catalogs and sales tax rates. Customers are now able to remotely access e-commerce applications and databases at negligible communication costs. Overall, these applications and databases have brought tremendous benefit and cost savings to the organizations that have installed them.

Having realized the gains from these new Web-based applications, organizations want to expand their Web applications base. They want to enrich and expand their information systems not only by converting or rewriting their existing traditional client/server applications to make them Web enabled, but also by creating new Web applications to take advantage of new opportunities created by intranets and the Internet. Organizations want to convert most, if not all, of their existing applications to Web-based applications because they are keenly aware that it will be very productive if their employees and business associates, including customers, suppliers, and salespeople, could access company applications and databases and do their work remotely as efficiently and cheaply as they could locally. In addition, they want to write additional Web-based applications that exploit the opportunities offered by their intranets and the Internet.

This is the information age, and the size and complexity of information continues to grow. Further, organizations have their important information distributed in various forms and locations. The information is more than likely stored not just in different types of traditional databases, such as Access, MS SQL Server, DB2, Oracle, and Sybase, but also in other data stores, including e-mail files, legacy flat files, spreadsheets, and Web-based text and graphics files. The latter set of data stores is likely to contain unstructured information, and new strategies and technologies are needed to access the information they contain. The easy and seamless exchange of information, irrespective of its form and data store, both within an individual organization and between various organizations, increases efficiency and effectiveness. This chapter intends to explain Microsoft's strategy for universal data access (UDA) and the technologies, including ActiveX data objects (ADO), used for implementing this strategy.

Over the past several years, Microsoft has developed or patronized several tools and technologies to access data from a wide range of data stores in order to comply with its UDA strategy. These technologies range from an early technology, namely open database connectivity (ODBC), to the Object Linking & Embedding Database (OLE DB), to the latest ActiveX data objects. Following a general description of these Microsoft technologies, this chapter will present a detailed discussion of ActiveX data objects. Microsoft UDA technologies can be effectively applied to both traditional client/server applications and Web-based applications. In this chapter, however, we concentrate primarily on ADO and its role in developing Web-based applications.

This chapter is divided into several sections. Following the introduction, we introduce the three generations of UDA technologies. In the next section, we take up the first generation of UDA technologies, including ODBC. Next, we take up the second-generation UDA technology, namely OLE-DB. The next four sections are devoted to the third-generation UDA technology, namely ADO. We devote next section to a brief discussion of advantages of the ADO technology. Following that, we discuss the basic elements of the ADO object model. We also take up, in that section, built-in ADO objects and collections, and their significant properties and methods. Next, we discuss the role of ADO in developing Web-based applications written with active server pages (ASP). The following section focuses on combining HTML, VB Script, ASP, and ADO for developing interactive Web-based applications. This topic is explained with the help of several examples. The final section summarizes the topics covered in this chapter.

UNIVERSAL DATA ACCESS

UDA is a strategy employed by Microsoft that is designed to provide a comprehensive means of accessing data from a wide range of data stores across intranets or the Internet. The data stores may be traditional structured databases, such as relational databases, or nonstructured data stores, such as text documents, spreadsheets, images, or pictures, supplied by various vendors. These data stores may also reside on heterogeneous computing platforms, including Windows-based and non-Windows-based operating systems. In summary, UDA provides high-performance, easy-to-use, transparent, and seamless access from a variety of client devices, programming languages, and scripts to a wide range of data stores, irrespective of their type, location, or platform.

Unlike other approaches, this strategy is designed to access data directly from their sources. Alternate approaches to UDA, called datacentric database strategies, require that data be transformed or converted into a common format, location, and platform before can be accessed by applications. UDA applications do not require costly data transformations or conversions and, therefore, accelerate development.

Because UDA is based on open industry specifications, it enjoys broad industry support. The UDA technologies can be grouped into three generations. The first generation of UDA technologies include open database connectivity, remote data objects (RDO), and data access objects (DAO). The second generation UDA technology consists of the Object Linking & Embedding Database. The third, and latest, generation of UDA technologies is composed of ActiveX data objects.

Although the first-generation technologies were developed before Microsoft formally announced its UDA strategy, they contain several important features of the UDA approach and they continue to be widely used in the industry. The second-generation technology, OLE DB, significantly extends the functionality of the first-generation technologies. Similarly, the third, and most recent, generation of UDA technologies, ADO, significantly extends the functionality present in the first two generation of UDA technologies.

ADO is built upon and works in close conjunction with some first- and second-generation technologies, especially ODBC and OLE DB. Because ODBC, OLE DB, and ADO are the primary and interrelated UDA technologies, Microsoft has bundled them together to a unified software package called the Microsoft data access components (MDAC). The MDAC software package may be downloaded from http://www.microsoft.com/data/default.htm.

FIRST-GENERATION UDA TECHNOLOGIES—ODBC, RDO, AND DAO

The ODBC technology continues to be a very important and successful data access standard. It provides a common interface to data stored in almost any relational database management system (DBMS) or even some flat-file systems, including ISAM/VSAM file systems. ODBC uses structured query language (SQL) as a standard means of accessing data. This has enabled applications, through a common set of codes built into the SQL language, to access information stored in any database or file that has an ODBC driver. Such a data store is sometimes called a SQL database, an ODBC data source, or simply a data source. Use of the SQL language and ODBC drivers has enabled applications to be independent of the data sources. Thus, a developer can build and distribute a client/server or a Web-based application without targeting a specific data source.

The following are the key software components of ODBC.

ODBC API: A library of function calls, error codes, and SQL syntax for accessing data.

ODBC database drivers: A set of dynamic link library (DLL) programs that process ODBC API function calls for specific data sources.

ODBC driver manager (ODBC32.DLL): Loads ODBC driver(s) specific to the data source(s) and keeps track of which database drivers are connected to which data sources. When an application creates a connection to a data source, this component works in the background, completely transparent to the application.

ODBC cursor library (ODBCCR32.DLL): Resides between the ODBC driver manager and the ODBC database drivers and handles cursoring within recordsets. We discuss cursoring and recordsets in detail later.

ODBC administrator: Allows the configuring of a database management system or a flat-file system to make it available as a data source for an application. Microsoft has included this important tool within its Windows operating systems. We discuss it in further detail later.

An application achieves independence from data stores by working through an ODBC driver written specifically for the database management system or the file system rather than by working directly with the system. The driver translates the ODBC API function calls and SQL into commands its database or file system can execute, making it available for a wide range of data stores.

Despite such advantages, ODBC has shortcomings. Two significant examples are the fact that ODBC is limited to relational database management systems and some flat-file systems, and ODBC API function calls are complex and difficult to use.

In response to the complexity of ODBC API function calls, Microsoft has developed two high-level programming models: data access objects and remote data objects. These high-level models have simplified the ODBC model and enhanced programmers' productivity. DAO and RDO, like ODBC, are limited to working with relational database management systems and flat-file systems only. But unlike ODBC, DAO and RDO are simple and easy to use.

DAO is designed to work primarily with file-server-based systems, such as Microsoft access database and legacy file systems. In a file-server-based system, the client (or workstation) is responsible for executing all processing logic components, including the presentation, the business, and the data access logic. The file-server's role is simply to provide shared access of files to the client. When a client requests particular data in a file, the server responds by sending an entire copy of the file. File-server models work well where file transfers are infrequent and file sizes are small.

Although DAO is designed to work with the file-server-based systems, RDO is developed to work with modern (client/server) database-server systems, such as MS SQL Server, DB2, Sybase, and Oracle databases. In a database-server model, the data access logic is executed at the database server and the presentation logic is performed at a client's computer.

In two-tier client/server applications, both the client and the database server participate in the execution of business logic execution. A portion of the business logic is executed at the server, while the remaining part is completed at the client.

In multi-tier applications, the client, database, and application servers are responsible for the execution of the business logic.

For Web-based applications, the business logic processing is shared among the Web server, database server, and client. The client-side processing code is executed at the client and the server-side processing code is executed at the Web server. The database server executes business logic using stored procedures. A stored procedure is made up of precompiled SQL statements that carry out a series of tasks on the database server. These procedures are written, stored, and executed on the database server. Although the file-server systems are mostly suited to small-scale applications, the database-server systems are designed for mission critical applications, requiring scalability, flexibility, maintainability, and better performance.

Although DAO is optimized to work with file-server-based systems, later versions of DAO also support client/server database systems. However, the performance is not satisfactory. RDO, on the other hand, is tuned for database-server systems and is well suited for developing large-scale multi-tier applications.

SECOND-GENERATION UDA TECHNOLOGY—OLE DB

OLE DB is a low-level programming interface to diverse sources of data, ranging from flat files, to relational databases, to object-oriented databases. OLE DB is based on Microsoft's Object Linking & Embedding and on the component object model (COM), both of which provide applications with uniform access to diverse data sources. Another important advantage of the OLE DB model is its high-performance design and support for multi-tier client/server and Web-based applications.

There are three key software components of OLE DB: OLE DB data providers, OLE DB services, and OLE DB data consumers.

OLE DB data providers are software components that allow access to diverse data stores. These include structured data stores, such as relational databases, and unstructured data stores, such as e-mail files, legacy flat files, spreadsheets, and Web-based text and graphics files. They provide access to each data store within a standard level of uniformity and functionality.

The OLE DB programming interface interacts with OLE DB data providers similarly to the way the ODBC API interacts with ODBC drivers—both OLE DB data providers and ODBC drivers provide direct access to specific data stores. Although there are a large number of ODBC drivers available for most popular database management systems, OLE DB data providers are available for a limited set of popular data stores, such as Microsoft access, MS SQL server, Oracle, and Exchange server. However, Microsoft has written an OLE DB provider for ODBC drivers, effectively providing OLE DB programmers access to both ODBC and OLE DB data source. Thus, OLE DB applications can be written for data stores that have ODBC drivers but no OLE DB providers.

OLE DB services are components that extend the functionality of data providers. Some database systems, for example, may lack cursoring features in their native data provider software. An OLE DB service, called the Microsoft cursor service, will add cursor functionality, allowing OLE DB data consumer applications to use this feature, irrespective of whether the native data provider software supports this feature.

OLE DB data consumers are software components that consume OLE DB data. Important data consumers are high-level data access models, such as ActiveX data objects.

THIRD-GENERATION UDA TECHNOLOGY—ADO

OLE DB, like ODBC, is a low-level, complex interface for accessing data. Although ODBC provides access to any SQL data store, OLE DB provides universal data access to SQL and non-SQL data stores. Just as DAO and RDO were developed to simplify access to SQL data stores, ADO was developed to provide a simple and easy-to-use interface for SQL and non-SQL data stores. ADO was developed as an OLE DB data consumer and provides a consistent high-level interface between applications and data stores. A traditional client/server or a Web-based application interacts with ADO to provide data required by the application.

The are several key advantages to ADO.

Programming language independence: ADO can be used with a wide range of languages, including Visual Basic, C++, Delphi, Java, J++, Java Script, Jscript, and VB Script. It can be used with any language that supports OLE and COM.

Support for traditional and Web-based applications: For developing traditional client/server and Web-based applications, ADO is an excellent mechanism for accessing data. It is required for developing Web-based applications with scripting languages, such as Java Script, Jscript, and VB Script, whenever they need to access data.

Easy to use and learn: ADO is easy to use and learn because it is based on a COM object interface, and it provides the ability to perform data queries and data manipulation using familiar commands, such as select, insert, update, and delete.

Universal data: ADO applications can access data from any OLE DB and ODBC data source. Applications that use ADO can use the OLE DB interface without losing any of the underlying OLE DB functionality.

ADO OBJECT MODEL

The ADO object model is made up of five top-level built-in objects: Connection, Recordset, Command, Record, and Stream. In addition to these top-level objects, ADO also contains four subordinate collections: Parameters, Fields, Properties, and Errors. These ADO collections contain Field, Property, Parameter, and Error objects, respectively. A collection consists of one or more objects referred to collectively.

Each top-level ADO object can exist independent of the other top-level objects. These top-level objects may contain subordinate collections that, in turn, contain their associated objects. For example, the Connection object has two subordinate collections, Errors and Properties, which, in turn, contain Error and Property objects. Similarly, the Recordset object has two subordinate collections, Fields and Properties, which, in turn, contain Field and Property objects (see Figure 1).

Each ADO object has two types of properties: ADO-defined built-in properties and provider-defined dynamic properties. ADO-defined built-in properties are available to the ASP (active server pages) programmer regardless of the particular data provider in use. Properties that are specific to a particular data provider are contained in the Properties collection as Property objects. Each top-level object has its own Properties collection.

In the ADO model, the subordinate objects relative to their parent object cannot be created independently. The top-level object must be created before its subordinate objects are created. The only exception is the Parameter object. The Parameters collection may be created independently of the Command object; however, it must be associated with a Command object before it can be utilized. A brief description of each ADO top-level objects and some of its associated collections and objects follows below.

Connection Object

The main purpose of the Connection object is to establish a link between an application and a data source. Once a connection is established the Execute method of this object can also be used to execute SQL queries, commands, and stored procedures against the target data source. For each query, a Recordset object is created and the result of the query execution, called a recordset or a cursor, is stored in this object. Recordsets, or cursors, are further examined later in this section.

The Connection object is also responsible for retrieving errors. An Error object contains details about a single operation involving data access. The Error collection contains all the Error objects.

In establishing a link between an application and a data source, the Connection object uses one of the following two types connections: a DSN connection or a DSN-less connection.

DSN Connection

A DSN connection is established in two steps: (a) Create an ODBC data source name (DSN), (b) execute "Open" method of the connection object. The DSN connection is created outside the ADO application using the ODBC administrator program. The ODBC administrator program is referred to by different names in different Windows operating systems. The program is called ODBC Data Sources (32-bit) on a Windows 95 or 98 systems, ODBC on a Windows NT system, and Data Sources (ODBC) on a Windows 2000 system. The shortcut used to execute the ODBC administrator program is located in the control panel (or administrative tools folder within the control panel) of the Windows operating system. To set up an ODBC DSN, the ODBC administrator program requires the following information: a unique name that represents the DSN; the selection of an ODBC driver, such as the

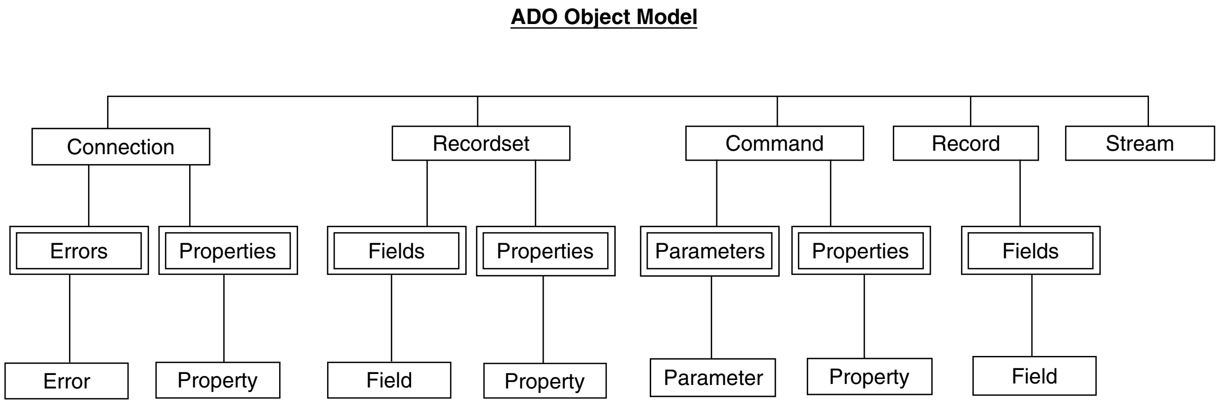

Figure 1: ADO object model.

Microsoft access driver (*.mdb), Microsoft ODBC for Oracle, SQL server, or Microsoft Excel driver (*.xls); he name of the data store (database or data file) to which the DSN will connect; and additional information, such as UserId and password, if required by the data provider to access the data store.

The Selection of a DSN Type. There are three types of DSNs: user DSN, system DSN, and file DSN. User DSN is limited to one user. The only user who will be able to connect to the data store with a user DSN is the user who creates it. A data store with a system DSN is available to all authorized users of the machine, including Windows NT and Windows 2000 services. A data store with a file DSN is available to each user who has the same driver installed. User and system DSN information is stored in the Window's registry. File DSN information is not part of the Window's registry but, instead, is held as a separate text file.

After creating an ODBC DSN, the ASP programmer may establish a DSN connection by passing the name of the ODBC DSN as a parameter to the "Open" method of the Connection object.

DSN-less Connection

In some cases the programmer may not be able or authorized to get physical or remote access to execute the ODBC administrator program needed to set up a DSN connection. This is especially true in the case of Web applications development. Developers of Web applications, generally, do not have physical or remote access for establishing a DSN connection on the Web server or the database server. In such cases, a DSN-less connection is suitable.

A DSN-less connection can be established explicitly or implicitly. An explicit DSN-less connection is established by providing connection information through the ConnectionString property of the Connection object. This information would vary depending on the data store and whether the connection uses an ODBC driver or an OLE DB provider, but it is similar to the information provided when setting up DSN connections in the ODBC administrator program. An implicit DSN-less connection is established with the Recordset object or the Command object.

Some of the methods built into the Connection object include Open, Close, and Execute. The Open method establishes a connection to the target data source while the Close method terminates the link. The Execute method allows the ASP programmer to perform basic SQL database operations, such as select, insert, delete, and update, on the data source specified by the Connection object. The Connection object is also capable of executing simple stored procedures. For stored procedures with dynamic parameters, the Command object is more suitable.

Some of the built-in properties of the Connection object are CommandTimeout, ConnectionString, ConnectionTimeout, Provider, State, and Version. The CommandTimeout property stores a number representing the number of seconds the Connection object will wait for a response from the data source after using the Execute method. The default CommandTimeout value is 30 seconds. If the Connection object does not receive a response within the CommandTimeout interval, it terminates the command and generates an error. The ConnectionTimeout property is similar to the CommandTimeout property but contains the time interval, in seconds, that the Connection object will wait for a connection after using the Open method. The default ConnectionTimeout value is 15 s. If no connection is established during the ConnectionTimeout period, the Connection object terminates the command and generates an error. The Provider property holds the name of the OLE DB provider for the Connection object. The State property is a read-only property that indicates whether the connection is open and the Version property is a read-only property that represents the ADO version number.

Recordset Object

Recordsets or cursors allow one to navigate through records and change data. Forward and backward navigation through records is performed in relation to the current record in a recordset. By default, the first record in a recordset is its current record. A recordset can be created with the help of the Recordset, Connection, or Command object. A recordset is made available when the Open method of the Recordset object is executed, the Execute method for the Command object is executed, or the Execute method for the Connection object is executed.

In the first two methods, there may be either an implicit or an explicit connection to the data store. In the third method, an explicit connection to the data store must be set prior to creating the recordset. In general, when using multiple recordsets within the same program, greater efficiency is achieved by creating an explicit connection to the data store prior to creating recordsets. Unlike implicit connections, when a connection is explicitly created, you have a handle for closing the connection. The implicit connection continues to remain open until the connection times out.

The Recordset object also provides control over the type of cursor and locking mechanism used. There are four different types of cursors, or recordsets. The cursor type must be specified before creating a recordset. Each cursor type is assigned a unique number between 0 and 3, as described below:

Cursor Type	Description
0	Forward only or read only cursor
1	Keyset cursor
2	Dynamic cursor
3	Static cursor

Type 0 (the forward only or read only) cursor is the default cursor. You can step through the recordset sequentially one by one using the MoveNext method. This cursor type does not support scrolling or updating.

Type 1 (keyset) cursor is a set of keys only. The other information is not duplicated in the recordset. In this type, records updated or deleted by other users are reflected in the recordset. However, new additions are not reflected in the recordset.

Type 2 (dynamic) is a scrollable cursor. All changes such as additions, updates, and deletions made by other users are reflected in the recordset.

Type 3 (static) is also a scrollable cursor; however, changes made by other users are not reflected in the recordset.

There are also several different lock types that can be used on a recordset when making changes such as additions, updates, and deletions to its records. The lock type must be specified before creating a recordset. Each lock type is assigned a unique number between 1 and 4, as described below:

Lock Type	Description
1	Read only
2	Pessimistic
3	Optimistic
4	Batch optimistic

Type 1 (read only) is the default lock type. It returns a read-only recordset and its records are available to other users.

Type 2 (pessimistic) lock type returns an updateable recordset. Before a particular record is updated, it is locked to other users. Update consists of two operations: read and write. The record is locked before the read operation is performed and is released just after it is written back.

Type 3 (optimistic) lock type returns an updateable recordset. As stated earlier, update consists of two operations: read and write. The record is not locked until the read operation is completed and is released just after the write operation is completed.

Type 4 (batch optimistic) is similar to lock type 3 cursors but updates are made to a batch of records at a time.

Built-in methods of the Recordset object include AddNew, Clone, Close, Delete, Move, MoveFirst, MoveLast, MoveNext, MovePrevious, Open, and Update. AddNew creates a new record to be added to the recordset. Clone creates a new recordset identical to the current recordset. Close method closes the recordset. Delete method removes the current record. MoveFirst method moves the position of the current record to the first record. MoveLast method moves the position of the current record to the last record. MoveNext method moves the position of the current record to the next record. MovePrevious method moves the position of the current record to the previous record. Open method opens a recordset; this method populates a recordset with records. Update saves any changes made to the recordset.

Built-in properties of the Recordset object include BOF, CursorType, EOF, LockType, and MaxRecords. BOF returns a Boolean value of true if the location of the current record is moved in front of the first record of the recordset. Otherwise, BOF returns false. CursorType indicates the type of cursor used in the recordset, such as forward only or read only, keyset, dynamic, and static. EOF returns a Boolean value of true if the location of the current record is moved past the last record of the recordset. Otherwise, BOF returns false. LockType indicates the type of lock used in the recordset, such as read only, pessimistic, optimistic, and batch optimistic. MaxRecords control the maximum number of records to return to a recordset from a query.

The Fields collection is created when the Recordset object's Open method executes. Field objects contain the metadata regarding the columns in the Recordset or the Record object, such as the name, type, length, precision, and data values.

Command Object

The Execute method of the Command object, similar to the Execute method of the Connection object, allows one to issue SQL queries, commands, and stored procedures against the target data source. However, the Command object is most useful when there is need to use a parameterized command or a stored procedure in an application repeatedly, passing in different values for the parameters each time. A collection of Parameter objects exposes the parameters associated with a Command object, based on a parameterized command or a stored procedure.

Record Object

The Record object is essentially a one-row Recordset object. The Record object can be created by (a) the execution of a query, a command, or a stored procedure that returns one row of data, (b) a row obtained from a Recordset, or (c) a row returned directly from a provider. Record objects facilitate access to information stored in nontraditional data stores. The row returned from the nontraditional data store may contain unstructured data, such as e-mail files, Web-based text, and directories, subdirectories, and files in a file system or folder. The directories, subdirectories, and files represented by Record objects can be copied or moved to another location with its CopyRecord or MoveRecord methods. Similarly, the directories, subdirectories, and files represented by Record objects can be deleted with its DeleteRecord method.

Stream Object

The Stream object provides the means of reading, writing, and managing a stream of bytes or text. The Stream object can be created from (a) a URL pointing to a file containing a stream of bytes or text data, (b) the default Stream object associated with a Record object, or (c) the independently created Stream object. The independently created Stream object is opened in memory. Data stream of bytes and text can be written to it and later saved in another stream or data store.

A stream of bytes or text data can be written to a Stream object with the Write and WriteText methods. Similarly, a stream of bytes or text data can be read to a Stream object with the Read and ReadText methods. The directories, subdirectories, and files represented by Record objects can be copied or moved to another location by its CopyRecord or MoveRecord methods. Similarly, the directories subdirectories, and files represented by Record objects can be deleted by its DeleteRecord method.

ADO AND ACTIVE SERVER PAGES (ASP)

The ADO provides a data model for Web-based applications that use active server pages (ASP). ASP is an open, compile-free, scripting model based on Microsoft technology. It is incorporated into and run as a part of

Microsoft Internet information server (IIS), which in turn is built into and runs on Windows NT server, Windows 2000 professional, or Windows 2000 server. ASP 3.0 is the latest version compatible with IIS 5.0 under Windows 2000 operating systems. Some earlier versions of ASP also run on the personal Web server (PWS), which in turn runs on Windows NT Workstation 4.0 or Windows 95/98 operating systems.

ASP allows client-side and server-side scripting in the same ASP page. It also contains text, HTML tags, and Java applets. However, only server-side scripts are executed on the server. The client-side code consists of scripts, ActiveX controls, and Java applets. These are sent to the client for its execution there. Two commonly used scripting languages are VB script and Java script. The default language of a server-side script is VB script. ASP interacts with data stores through ADO commands coded in server-side scripts.

The ASP files are saved as ASCII or text-only files and have an .asp file name extension. When the Web server receives a request for a Web page, the server first examines the file extension of the requested document. If the file extension is .asp, the Web server directs this ASP document to the ASP script host (ASP.DLL). The ASP script host sends out any server-side script it finds in the ASP file to the appropriate script engine. For example, the ASP script host sends server-side VB scripts to the VB script engine and server-side Java scripts to the Java script engine.

Each script engine interprets scripts submitted to it. When a script includes ADO commands, the script engine executes the command. The script engine returns an output consisting of HTML tags to the script host. The script host places all these outputs together and returns it, along with the client-side processing code, to the browser as an HTML stream.

ADO AND WEB-BASED APPLICATIONS DEVELOPMENT

Use the following steps to access and manipulate a database from an ASP Web page.

Create and open an ADO connection to a data store.

Create and open an ADO recordset from the data store.

Create one or more recordsets and manipulate their records.

Close the connection and recordsets.

These steps will be explained with the help of some examples. In these examples, the following information is used.

Database:	C:\group4\SampleDb.mdb
DSN name:	dsnDb
Driver:	Microsoft Access Driver (*.mdb)
Provider:	Microsoft.Jet.OLEDB.4.0
Table:	Customers
Fields:	CustName, CustPhone
User Id:	bkapoor
Password:	SECRET

Throughout these examples, <% and %> tags are used to indicate server-side scripts. The scripts included in these examples are written in VB script.

Step 1: Create and Open an ADO Connection

This step contains three examples, using DSN connection to a database, DSN-less connection with an ODBC driver, and DSN-less connection with an OLE DB driver.

DSN Connection to a Database

Before finalizing code that creates and opens a data source name (DSN) connection to the database, create a system DSN. A system DSN is created by the execution of the ODBC administrator shortcut from the control panel of the Windows operating system. During execution of the ODBC administrator program, the programmer will be asked to assign a unique name that represents the DSN. This name is referred to when creating a DSN connection. The following snippet contains code to create and open a DSN connection:

```
<%
Dim conn
Set conn = server.CreateObject
  ("ADODB.connection")
Conn.open "dsn=dsnDb; uid=bkapoor;
  pwd=SECRET;"
%>
```

DSN-less Connection to a Database

In this method, the programmer creates a connection string that contains information needed to create a connection to the database. The information includes an ODBC driver or an OLE DB provider, the database name, and user ID and password. The DSN-less connection to a database can be created either by using an ODBC driver or an OLE DB provider.

The following snippet contains code to create and open a DSN-less connection that uses an ODBC driver:

```
<%
Dim Conn, ConnString
Set Conn = Server.CreateObject
  ("ADODB.Connection")
ConnString = "DRIVER={Microsoft Access
  Driver (*.mdb)}; DBQ=C:\group4\
  SampleDb.mdb; "
Conn.ConnectionString=ConnString
Conn.Open
%>
```

The following snippet contains code to create and open a DSN-less connection that uses an OLE DB provider:

```
<%
Dim Conn, ConnString
Set Conn = Server.CreateObject
  ("ADODB.Connection")
ConnString="Provider=Microsoft.Jet.
  OLEDB.4.0; Data Source=C:\group4\
  SampleDb.mdb;"
```

```
Conn.ConnectionString=ConnString
Conn.Open
%>
```

Step 2: Create and Open an ADO Recordset to a Database

The following snippet contains code to create and open a DSN-less connection with an OLE DB provider, and a recordset:

```
<%
Dim Conn, ConnString, rs
set Conn=Server.CreateObject
  ("ADODB.Connection")
ConnString="Provider=Microsoft.Jet.
  OLEDB.4.0; Data Source=C:\group4\
  SampleDb. mdb;"
Conn.ConnectionString=ConnString
Conn.Open
set rs = Server.CreateObject
  ("ADODB.recordset")
dim CursorType, LockType
CursorType = 0
LockType = 1
rs.Open "Select * from Customers",
  Conn, cursorType, lockType
%>
```

Step 3: Create One or More Recordsets and Manipulate Their Records

This step contains five examples: read and display records from a recordset, read records from a recordset and display them as an HTML table, insert a record into a database, update a database record, and delete a database record.

The following ASP program contains code to read and display records from a recordset:

```
<HTML>
<HEAD>
  <TITLE>ADO EXAMPLE</TITLE>
</HEAD>
<BODY>
```

Here are results from the processed ASP page!

```
<%
Dim Conn, ConnString, rs
set Conn=Server.CreateObject
  ("ADODB.Connection")
ConnString="Provider=Microsoft.Jet.
  OLEDB.4.0; Data Source=C:\group4\
  SampleDb.mdb;"
Conn.ConnectionString=ConnString
Conn.Open
set rs = Server.CreateObject
  ("ADODB.recordset")
rs.Open "Select * from Customers", Conn
rs.MoveFirst
do until rs.EOF
  Response.Write rs("CustName") & " "
  Response.Write rs("CustPhone") & "<br>"
  rs.MoveNext
loop
rs.close
Conn.close
set rs=nothing
set Conn=nothing
%>
</BODY>
</HTML>
```

The following ASP program reads records from a recordset and displays them as an HTML table:

```
<HTML>
<HEAD>
<TITLE>ADO EXAMPLE</TITLE>
</HEAD>
<BODY>
```

The following are results from the processed ASP script:

```
<%
Dim Conn, ConnString, rs
set conn=Server.CreateObject
  ("ADODB.Connection")
ConnString="Provider=Microsoft.Jet.
  OLEDB.4.0; Data Source=C:\group4\
  SampleDb.mdb;"
Conn.ConnectionString=ConnString
Conn.Open
set rs=Server.CreateObject
  ("ADODB.recordset")
rs.Open "Select * from Customers", conn
rs.MoveFirst
do until rs.EOF
  Response.Write "<TABLE BORDER = '1'
    WIDTH ='100%'>"
  Response.Write "<TR><TD>" & rs("CustName")
    & "</TD>"
  Response.Write "<TD>" & rs("CustPhone")&
    "</TD></TR>"
  rs.MoveNext
loop
rs.close
Conn.close
set rs=nothing
set Conn=nothing
%>
</table>
</BODY>
</HTML>
```

The following ASP program contains code to insert a record into a database. After insertion, this program will display all its records as an HTML table.

```
<HTML>
<HEAD>
  <TITLE>ADO EXAMPLE</TITLE>
</HEAD>
<BODY>
```

The following are results from the processed ASP script:

```
<%
Dim Conn, ConnString, rs, rs1
set conn=Server.CreateObject
  ("ADODB.Connection")
ConnString="Provider=Microsoft.Jet.
  OLEDB.4.0;
Data Source=C:\group4\SampleDb.mdb;"
Conn.ConnectionString=ConnString
Conn.Open
SQLcmd = "INSERT INTO Customers(CustName,
  CustPhone) VALUES ('Bhushan Kapoor',
  '(714)333—3333')"
Set rs = Server.CreateObject
  ("ADODB.Recordset")
Dim cursorType1, lockType1
CursorType1 = 3
LockType1 = 3
rs.Open SQLcmd, conn, CursorType1,
  LockType1
set rs1 = Server.CreateObject
  ("ADODB.recordset")
rs1.Open "Select * from Customers",
  conn
rs1.MoveFirst
do until rs1.EOF
  Response.Write "<TABLE BORDER =
    '1' WIDTH ='100%'>"
  Response.Write "<TR><TD>" & rs1("CustName")
    & "</TD>"
  Response.Write "<TD>" & rs1("CustPhone")
    & "</TD></TR>"
  rs1.MoveNext
loop
rs.close
rs1.close
Conn.close
set rs=nothing
set rs1=nothing
set Conn=nothing
%>
</table>
</BODY>
</HTML>
```

The following snippet contains code to update a database record:

```
<%
SQLcmd = "UPDATE Customers SET CustPhone=
  "(310)222-2222"
WHERE CustName = 'John Smith'"
Set rs = Server.CreateObject
  ("ADODB.Recordset")
rs.Open SQLcmd, Conn, 3, 3
%>
```

The following snippet contains code to delete a database record:

```
<%
SQLcmd = "DELETE * FROM Customers WHERE
  CustName = 'John Smith'"
Set rs = Server.CreateObject
  ("ADODB.Recordset")
rs.Open SQLcmd, Conn, 3, 3
%>
```

Step 4: Close the Connection and Recordsets

In the final step, the connection and all its recordsets should be closed. Recordsets should be closed before closing the connection. After closing, one should also release the computer memory that was used to store these objects by setting their values to nothing. This process is sometimes termed garbage collection. The following snippet contains code to close the connection and its recordsets and also to release memory. In this snippet, the variable “Conn” has been used to represent a connection and two variables, rs and rs1, to represent two recordsets.

```
<%
rs.close
rs1.close
Conn.close
set rs=nothing
set rs1=nothing
set Conn=nothing
%>
```

SUMMARY

Progressive organizations have two major goals for their information systems. The first is to convert their existing applications to Web-based applications. The second goal is to write additional Web-based applications to take advantage of the opportunities created by intranet and the Internet.

This is an information age and the size and complexity of information continues to grow. Organizations have their important information distributed in various forms and locations. Universal data access (UDA) is a Microsoft strategy designed to provide a comprehensive means to access data from a wide range of data stores distributed across intranets or the Internet.

Microsoft has developed or patronized several technologies tied to its UDA strategy. These technologies can be grouped into three generations. The first generation of UDA technologies contains ODBC, RDO, and DAO. The second-generation UDA technology consists of OLE DB. The third generation is the latest generation of UDA technologies and contains ADO.

The ODBC provides a common interface for accessing data stored in almost any relational DBMS or even some flat-file systems. ODBC uses SQL as a standard language for accessing data. Microsoft has created two high-level programming models, DAO and RDO, to simplify the ODBC model. DAO is written to work primarily with file-server-based systems and RDO is designed for database-server systems. RDO is well suited for developing large-scale multi-tier applications.

OLE DB is a low-level programming interface to diverse data stores, including flat files, relational databases, and object-oriented databases. OLE DB provides applications with uniform access to diverse data sources. Another important advantage of the OLE DB model is its high-performance design and support for multi-tier client/server and Web-based applications.

The ADO object model is made up of five top-level objects, Connection, Recordset, Command, Record, and Stream; four subordinate collections, Parameters, Fields, Properties, and Errors; and four associated objects, Parameter, Field, Property, and Error, within its own collections. Each top-level object can exist independently of the other top-level objects. The subordinate objects/collections cannot be created independently of their parent objects.

The following steps may be used to access and manipulate a database from an ASP Web page: (a) create and open an ADO connection to a data store, (b) create and open an ADO recordset to a data store, (c) create one or more recordsets and manipulate their records, and (d) close the connection and recordsets.

ADO enjoys broad industry support because it provides a consistent, easy-to-use, high-level interface between applications and diverse data stores and does it for both traditional client/server and Web-based applications.

GLOSSARY

ADO (ActiveX Data Objects) ADO is the latest Microsoft data-access programming model. It provides a consistent high-level interface with many different types of data stores, including relational databases, flat files, e-mail files, spreadsheets, text documents, and graphics files.

ADO collections A collection consists of one or more objects referred to collectively. ADO model contains four collections: Parameters, Fields, Properties, and Errors. These collections contain Parameter, Field, Property, and Error objects, respectively.

ADO Object Model ADO object model is made up of five top-level objects (Connection, Recordset, Command, Record, and Stream), four subordinate collections (Parameters, Fields, Properties, and Errors), and four associated objects (Parameter, Field, Property, and Error) each within its own collection. Each top-level object can exist independently of the other top-level objects. The subordinate objects/collections cannot be created independently of their parent objects.

Cursor type There are four types of cursors: forward only or read only, keyset, dynamic, and static cursors. A cursor type must be set before opening a recordset.

DAO (Data Access Objects) DAO is a high-level programming model developed to simplify the ODBC programming model. DAO is designed to work primarily with file-server-based systems.

Database server system In a database server model for a Web based system, the data logic is processed on the database server, the presentation logic is processed on the client, and the business logic processing is shared between the Web server, database server, and client.

DSN connection DSN (data source name) connection between a Web server and a database server is established in two steps: (a) create an ODBC DSN and (b) execute the "Open" method of the connection object.

DSN-less connection There are two types of DSN-less connections: explicit and implicit. An explicit DSN-less connection is established through the ConnectionString property of the Connection object. An implicit DSN-less connection is established based on the Recordset object or the Command object.

File-server system In a file-server system, the client is responsible for executing data logic, presentation logic, and business logic. The file server's role is simply to provide shared access of data files to the client.

Lock type There are four cursor lock types: read only, pessimistic, optimistic, and batch optimistic. A cursor lock type must be set before opening a recordset.

MDAC (Microsoft Data Access Components) Microsoft provides MDAC in order to make universal data access possible. MDAC consists of three important technologies: ODBC, OLE DB, and ADO.

ODBC (Open Database Connectivity) ODBC technology provides a common interface to access data stored in almost any relational database management system and some flat-file systems, including ISAM/VSAM file systems.

OLE DB data consumers OLE DB data consumers are software components that consume OLE DB data. Important data consumers are high-level data access models, such as ADO.

OLE DB data providers OLE DB data providers are software components that allow one to access diverse data stores, including both relational and non-relational databases, with a standard level of uniformity and functionality.

OLE DB services OLE DB services are software components that extend the functionality of OLE DB data providers.

RDO (Remote Data Objects) RDO is a high-level programming model developed to simplify the ODBC programming model. RDO is written to work primarily with database-server-based multi-tier systems. RDO facilitates access to data stored in almost any SQL database.

Recordset A recordset or a cursor is a set of records that are the result of a SQL query, a command, or a stored procedure.

Stored procedure A stored procedure is made up of precompiled SQL statements that carry out a series of tasks. Stored procedures are stored and executed on the database server and are created to execute the data logic and some business logic.

UDA (universal data access) The UDA approach is a Microsoft strategy designed to provide a comprehensive means of accessing data from a wide range of data stores across intranets or the Internet.

Application Service Providers (ASPs)

Hans-Arno Jacobsen, *University of Toronto, Canada*

INTRODUCTION

The increase in network bandwidth, the growth of computing server performance, and the growing acceptance of the Internet as communication medium has given rise to a new software distribution model: application outsourcing and software leasing. Application outsourcing refers to the emerging trend of deploying applications over the Internet, rather than installing them in the local environment. Application outsourcing shifts the burden of installing, maintaining, and upgrading an application from the application user to the remote computing center, henceforth referred to as application service provider or ASP. Software leasing refers to the emerging trend of offering applications on a subscription basis, rather than through one of the traditional software licensing models. In the ASP model, system administration and application management is performed entirely by the provider. It thus becomes possible to charge a user on a pay-per-use basis, differentiable on a very fine-granular basis. This fine-grained differentiation can go as far as taking the specific functionality required by individual customers into account and metering, for computation consumed, the resources for exact billing. Thus, rather than selling a software license—giving a user “all-or-nothing” of a product—the software may be leased to the user, offering a “pay-by-need” and “pay-on-demand” model. The customer only pays for the actual functionality used and resources consumed.

A large spectrum of ASPs has become popular. Early models include hosting of database-backed Web space that offer customers solutions for hosting corporate or individual Web sites, including the access to database management systems for managing dynamic content and input. Other ASP models include the leasing of machines from computational server farms that are securely managed in reinforced buildings with high-capacity network links and power generators to guarantee uptime despite power failures. Either a customer deploys and manages its own set of machines or is assigned a dedicated set of machines on which its applications are run. Further prominent examples include online (financial) computing services, remote e-mail and document management, online accounting and billing, and Web information systems of all sorts.

The ASP-model also includes more complex application scenarios, however, such as the online access to enterprise resource planning systems (ERP), business administration applications, human resource management systems, customer relationship management systems, health care and insurance management systems, and system security management.

All these application scenarios offered as ASP solution are attractive for enterprises and individual customers alike who do not want to afford, cannot afford, or do not have the capacity to operate full-fledged stand-alone information technology (IT) systems of the described nature.

In this chapter, I provide a definition of the ASP model, describe its characteristics and facets, and discuss its implications. I begin by reviewing early developments and research trends; I then provide a detailed description of the application service-provisioning model and present a few detailed ASP examples, which lead to the identification of three ASP deployment models. I raise software-licensing issues and provide an analysis of existing ASP pricing models and strategies. I then discuss server-side implementation issues, involving a detailed description of privacy and security concerns. Finally, I draw conclusions and offer a view of how the ASP model is likely to evolve.

FROM EARLY DEVELOPMENTS TO RESEARCH TRENDS

The idea of interacting with a remote computer system across a network goes back to the mainframe era and the introduction of time-shared operating systems. Back then the driving force for this computing model was the investment-intensive mainframe computer systems that had to be maximally utilized to justify their large cost.

The 1960s can be considered the era of the mainframe. Combined with the concept of interactive computing, implemented through time-shared operating systems, succeeding the earlier batch-processing model, computing jobs had to be submitted and were processed by operators (with the final output delivered much later to the programmer) the idea of a remote computing utility, essentially today's ASP, was born. The mainframe became accessible through physically distributed dumb terminals connected with the computing utility over dedicated networks. The key difference between the remote computing model and the ASP model is that an ASP offers a fixed set of applications and services to its customers, whereas the remote computing model simply offers accessibility of the bare computing system to multiple users across the network.

In the 1970s, the minicomputer—a more affordable, smaller computing system—became the computer of choice for many companies and universities. Later on, in the 1980s, the personal computer became the lucrative choice, even spreading to the private sector. This turned the attention away from the initially popular remote computing model.

On one hand, more and more applications were developed for single-user, personal computers; on the other hand, the client–server computing model became popular. In the client–server model, a number of clients are served by a more powerful computing server. Clients and servers may either be computer systems (e.g., file server), but also may simply denote individual processes communicating with one another (e.g., database server, Web server, and application server).

In the late 1990s, due to the increasing spread and commercial acceptance of the Internet, advances in server technology, and steady increase in complexity of managing of (business) software systems, a model referred to as network computing model combined with a thin-client model became popular and set the stage for the then-emerging ASP model. Network computing again refers to accessing a powerful computing system across the network. A thin-client can range from a handheld device to a desktop but captures the notion of off-loading most computational and data management tasks to a remote computing system.

Many of the technical aspects of an application service provider have been thoroughly investigated in research; see, for example, Bhargava, King, and McQuay (1995); Czyzyk, Mesnier, and More (1997); Abel, Gaede, Taylor, and Zhou (1999); and Jacobsen, Guenther, and Riessen (2001). Business strategic and information economic questions have also been explored. For example, Marchand and Jacobsen (2001) analyzed, from an economic point of view, how the emerging ASP model may affect the profit opportunities of "traditional" independent software vendors. Two alternative economic scenarios can be envisioned, either competitively opposing application leasing and traditional licensing or combining both in a complementary fashion (see Marchand and Jacobsen for details).

The research projects exploring ASP models often go one step further than commercial ASPs do at present. Many research projects have explored more open and marketplace-oriented scenarios, in which a number of players interact. For example, the Middleware for Method Management project (see Jacobsen et al., 2001, for details) introduces the differentiation between the infrastructure provider, the data provider, the method provider, and the user. The infrastructure provider models the ASP. The data provider, a separate entity, publishes data sets that may serve the user community (e.g., historical stock quotes, geographic information, or consumer data.) The method provider publishes computational methods, which constitute algorithms from the target application domain of the marketplace (e.g., statistical analysis, numerical analysis, optimization schemes, or decision support algorithms.) The user, as in the commercial ASP model, executes published algorithms on published data. Method providers and data providers usually coincide with the application service provider in commercial systems. Interestingly, this infrastructure already recognized the need for letting individual users offer specific services for other market players to use. A similar vision, more targeting the corporate customer, is underlying the huge effort being put into the Web Services standard (World Wide Web Consortium, 2003).

Other research systems include the DecisionNet project (Bhargava et al., 1995), the NEOS service (Czyzyk et al., 1997), the SMART project (Abel et al., 1999), and MMM (Jacobsen, 2001). DecisionNet is an organized electronic market for decision support technologies. The NEOS service provides access to optimization software for use by researchers worldwide. The SMART project serves the government by assisting in county planning tasks and simplifying related administrative tasks. MMM is a middleware platform for mathematical method management that integrates various distributed mathematical software package providers, offering the user one unique access point in using the different systems.

Application Service Providers

Application service providers are third-party entities that manage, deploy, and host software-based services and applications for their customers from server farms and datacenters across wide area networks. Customers access the hosted application remotely and pay in a subscription-based manner. In essence, ASPs constitute a way for companies to outsource some or all aspects of their information technology operations, thus dramatically reducing their spending in this area. Services and applications offered by ASPs may be broadly categorized as follows:

- *Enterprise application ASPs* deliver high-end business applications, such as enterprise resource planning solutions. Customers are corporate clients who need these solutions but want to avoid investing in proper in-house installations.
- *Locally constrained ASPs* deliver a wide variety of (mostly bundled) application services in a local area, such as a portal for all the shops in a city or tourist information services for a region, including event registration, booking, and ordering features. These serve both the individual users as well as the local entity (e.g., shop or museum).
- *Specialized ASPs* deliver highly specialized applications addressing one specific function, such as news, sports and stock tickers, weather information, site indexing, or credit card validation. Customers are usually other

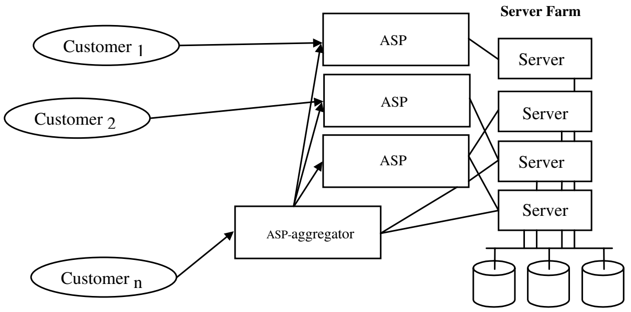

Figure 1: Application service provider architecture roles.

online service providers who bundle multiple services as one and serve one target community.

- *Vertical market ASPs* deliver applications catering to one specific industry, such as insurances, human resource management, media asset management, or health care. The customer is the corporate client.
- *Bulk-service ASPs* deliver applications for businesses in large quantities, such as e-mail, online catalog, document, or storage management.
- *ASP aggregators* combine the offerings of several ASPs and provide the user with service bundles and a single way to interact with all the aggregated ASPs.

The ASP value chain consists of many players, including the network infrastructure provider, the server farm provider, the independent software vendor, and the ASP and ASP aggregator. Figure 1 depicts a logical architecture of an ASP.

The network infrastructure provider is responsible for the network that connects customers to ASPs. The network infrastructure can be further broken down into the physical network provider, such as broadband access, phone lines, and communication infrastructure provider, and the Internet service provider, which offers services to get customers on the network. The black arrows in Figure 1 designate communication links managed by network infrastructure providers.

The server farm provider hosts the outsourced applications. The server farm consists of hundreds or more computing servers that are collectively housed. The business models for running such server farms vary. Under certain models customers bring in their own computing servers and are responsible for administering them. Other models rent a number of servers to each customer and operate them for the customer. In this case, the customer refers to the ASP operating an application. The server farm is often also referred to as a data center, because a fair amount of data management and storage is involved in most applications. In Figure 1, the server farm provider is not explicitly shown. It is responsible for the components designated as servers and as data center in the figure. The view of the server farm provider as a data center refers to ASP models in which the server farm provider takes over data backup or manages high volumes of data for the customer or for the ASP.

The independent software vendor (ISV) is responsible for the application software that is offered as outsourced solution through an ASP. Some ASPs decide to build their own software, thus avoiding the payment of license fees to the software vendor. Because the role of this player is more in the background, it is not explicitly shown in Figure 1.

The application service provider is the entity that offers the outsourced application to the customer over the network. However, the ASP must neither own the software, which it may license from an independent software vendor, nor must it own or operate the hardware, which it may lease from a server farm provider. In a further breakdown, an ASP aggregator bundles several ASPs together and offers the user one unique interface. This may be as simple as offering an ASP directory, a common log-in, and authentication, or more complex in that data can be seamlessly exchanged between the different ASPs. ASP aggregators strongly depend on open standards for accessing disparate ASPs through software integration. The emerging Web Services standards may constitute a viable solution (World Wide Web Consortium, 2003). The overall architecture of a model ASP is depicted in Figure 1, which shows the interaction of the different elements of the ASP value chain.

In the figure, an ASP is shown as a logical entity. It is associated with the software it operates for its customers and the necessary access, billing, and accounting software to run its operation. Figure 1 abstracts these functions into one component and maps them to one or more servers on the server farm. In reality, all these

Is the outsourced information highly confidential?
Does the difference of 95% versus 99% uptime make a big difference?
Is cost a major consideration and is the IT budget limited?
Is reduction of capital expenses a goal?
Dose the enterprise have remote locations that must interact with the IT system? Are there many branch offices that interact with the IT system?
Are there many (mobile) users of the IT system with a variety of client devices?
Is the lack of experienced IT staff a severe problem?
Is rapid deployment a goal?
Is the outsourced application to grow rapidly?
Are peak usage patterns expected?
Is a primary objective to focus on strategic projects rather than routine IT maintenance?

Figure 2: Factors in deciding to outsource some or all applications.

functions may operate on physically distributed computers. This achieves redundancy and fault tolerance and thus increases availability and uptime for the customer. An ASP may be a fully virtual enterprise, without any physical presence (i.e., office space).

An ASP must strategically decide to license existing applications or to build the outsourced application itself. This decision is strongly dependent on the kind of application offered. Both models can be found in practice. Existing legacy applications were never intended to be used over wide area networks by disjointed sets of users, so solutions for Web-enabling and deploying legacy applications in ASP fashion must be implemented to be used effectively in outsourcing system. Simple services, on the other hand, can easily be developed, saving the ASP expensive license and integration costs. Most ASPs are likely to use standard components, such as database management systems, in their software architectures, even for simple services. These standard components are too costly for an ASP to redevelop, so that license and integration costs are inevitable. This strategic decision by the ASP may also have an effect on customers, who may prefer to run their outsourced applications on industry-standard software. A standard ensures the customer that a switch back to an in-house operation or another ASP offering the same package can be made at any time.

The ASP model offers a number of advantages to the customer. These include a significant reduction of the total cost of ownership, because no software must be purchased and fewer IT personnel must be on site. Moreover, all IT-related tasks, such as software installation and upgrades, application maintenance, data backup, and computer system administration, are shifted to the ASP. A customer can operate with sophisticated IT applications without the huge investments in software licenses and hardware, thus drastically increasing the return of investment.

The ASP model also presents a number of disadvantages for the customer, however. These include less control over application software and the data processed, and therefore limited customization and probably less product functionality, and external dependencies on the ASP and on access to it (i.e., the network and Internet service provider.) For data storage– and data processing–intensive and nonstandard software, high switching cost is a further disadvantage to the customer. This applies equally to an application purchased for in-house use, however. Finally, the ASP model is an as yet unproven concept with little experience on either side of the relationship, little standard support, and few widely known successful applications.

For an enterprise, outsourcing part or all of its IT operation is an important strategic decision. From the previous analysis, a number of questions to guide this decision process become evident. These questions are summarized in Figure 2.

In the late 1990s, the ASP Consortium (http://www ASPstreet.com) was chartered, an industrial organization that represents the interests of ASPs and their customers. Other online resources directly related to the emerging ASP industry are the ASP Harbor (http://www Webharbour.com), ASP Island (http://www ASPIsland.com), and ASP News (http://www.ASPnews.com). These Web sites and portals are mostly commercial Web sites that collect, distribute, and sell information about ASPs.

Wireless Application Service Provider

A wireless application service provider, also known as WASP, is essentially the same as a conventional application service provider except it focuses on mobile wireless technology for service access and as a delivery mechanism. A WASP performs similar services for mobile wireless customers as the ASP does for its customers on wired lines. The wireless application service provider offers services catering to users of cellular phones, personal digital assistants, and handheld devices, and, generally, to any mobile wireless client. The service provider is more constrained in what it can offer because of the limits of the access device and great varieties in available device technology. In the business-to-consumer market, wireless application service offerings include, for example, e-mail access, unified messaging, event registration, shopping, and online banking. In the business-to-business market, wireless application services include account management and billing, backend banking, and remote sensing; in the future, this could include user location identification, system monitoring, and wireless network diagnosing. Future extensions of this model could be wireless network access providers, WASPs that offer wireless network infrastructure to customers on a pay-by-use basis in and around coffee shops, restaurants, airports, and train stations. Often, ASPs already offer wireless interaction possibilities and thus embrace both models. Because of the similarity of the WASP and ASP models, I do not discuss the WASP model further. All concepts introduced apply equally well to this kind of application service provider.

Outsourcing as a General Business Concept

Outsourcing of many business functions, from simple tasks such as bulk mailing or more complex functions such as accounting and human resource management, have been commonplace since at least the middle of the 20th century. The focus on outsourcing core IT functions and software applications is merely a special case of this broader category that has become possible because of new technology. In this chapter, the focus is on the new application service provider model enabling application outsourcing; more traditional outsourcing concepts are not covered further.

ASP EXAMPLES

In this section, I introduce a number of ASP examples. This discussion is based on existing ASP ventures. These examples have been chosen to exhibit different characteristics of ASPs that are presented more comprehensively in the following sections. The examples make no reference to specific ASP ventures, because there are too many operating ASPs, and the current ASP landscape is changing rapidly.

Income Tax ASP

The (income) tax ASP is, in the simplest instantiation, a service accessible through the Internet to complete tax forms. The yearly forms are made available on the ASP site through a browser, either based on the common HTML (hypertext markup protocol) form or based on Java applet technology. The user interface may be enhanced with features to check the entered information automatically or to guide and make the user aware of available options, essentially offering the same functionality as tax consultants or desktop tax software. The final form can then be made available as a printable document for the user to download and forward to the government tax service with supplementary information or be directly forwarded electronically to the government. In the latter case, a direct integration of the ASP with enterprise resource planning software used by the tax service can be envisioned.

Many countries are already bringing their government services, especially the revenue service, online, because it greatly facilitates the processing and distribution of the information and thus dramatically cuts costs. Moreover, private companies offer these services, combined with value-added consulting services, and forward the processed information directly to the revenue service. This example can be regarded as a successful undertaking that is changing the way people interact with their governments.

System Management ASP

The system management ASP deploys software components in the customer's computational environment that communicate autonomously with the ASP's site. In this fashion, network traffic, available disk space, system access, and, generally, any kind of computing resource activity can be closely monitored and logged. In case of a problem, or an anticipated problem, an operator is notified to take care of the problem. System intrusion detection software can be deployed in this manner as well. The local monitoring software checks for unusual system access patterns, either by forwarding network traces to the ASP's mining software or by doing the analysis locally and forwarding alert. Allen, Gabbard, and May (2003) provided a detailed discussion that investigates the outsourcing of managed IT security.

System Backup and Testing ASP

The system backup ASP offers its clients data archival services, that is, backing up disks on a defined schedule over the network, without operator intervention. Lost, overwritten, and damaged data is thus safeguarded by the ASP and can be retrieved by the client at anytime and from anywhere, over the network.

Similarly, the system-testing ASP tests a client's information system from points across the network. In many cases, a Web portal is, in manually or semiautomated fashion, subjected to loads from an outside entity; any unforeseen features, bugs, and possible errors are logged in a database and turned over to the client. Testing may include end-to-end system load measurements, monitoring of traffic, and verification of results. Because of the increase of Web-based business, this model has become a popular venture.

SOFTWARE DEPLOYMENT MODELS

The software deployment model defines where the software resides and how it is managed. In the context of application service provisioning, three models have crystallized.

Application hosting refers to the model of remotely managing a specific software package for a customer. The hosting company manages *n* applications on *n* hosts on behalf of *n* customers. Each application is given its dedicated set of resources and is physically shielded from other applications, only sharing the networking infrastructure. At one extreme of this model, the hosting company only provides the host, the network, or building infrastructure (i.e., machine rooms and physical security). Web-space hosting is a popular example of this model. Often ISP (Internet service providers), who already own appropriate data centers and server farms to start with, grow into such hosting ventures. For the hosting company it is difficult to optimally use computing resources, because a switch from one customer's system to another involves nontrivial installation steps. For example, peak load management, which shifts resources from one application to another depending on its usage pattern, is difficult to achieve for the ASP in this model. On the other hand, different hosted ventures can significantly benefit from the closeness of other hosted services, thus increasing overall efficiency of their Web-portals and decreasing perceived latency for users. For example, a big retail store whose Web site is hosted on the same server farm as an Internet advertiser will inevitably benefit from the mutual proximity. Figure 3 depicts this model logically. It shows the one-to-one correspondence between the customer and the software that the ASP operates on behalf of this customer. Each customer has a dedicated, physically separate set of computing resources. The arrows in the figure designate the network over which the customer interacts with the ASP. The figure also indicates that a single ASP manages multiple, possibly diverse, applications for different customers.

Application outsourcing refers to the model of remotely deploying one particular application, which serves many customers at the same time. This model is commonly referred to as the ASP model. Other deployment models have also been referred to as ASPs by the press, which does not differentiate carefully the various models. In this chapter, a finer grained separation is advocated. Here, in the ASP model application is offered to *n* clients. Whether

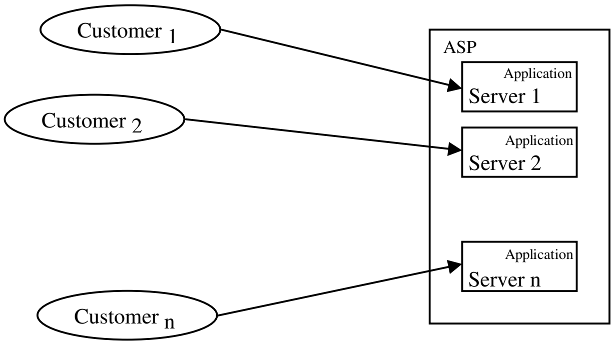

Figure 3: Application hosting deployment model.

or not this application is spread out over a number of computing nodes depends on the actual application design and implementation. The outsourced application often addresses very specific IT needs, without much customization, by many customers. Web-based e-mail services, online document management, and storage have been widely offered under such a deployment model. This approach is particularly attractive for vertical markets and applications that require little customization on a per-user basis, because in this case, the ASP has little overhead to pay. The advantage over the hosting model is that the ASP model allows computing resources to be allocated more dynamically and on demand. Server-side throughput guarantees (see Service Level Agreement later in the chapter) can thus be implemented with less investment in physical computing resources. A critical problem for this deployment model is the question of how to virtualize an application that was not intended for the use by many noninteracting customers. Standard business software has been designed for use by one customer at a time and not by *n* independent customers using it over a wide area network. Most independent software application vendors have announced their interests in this model and have started to offer their applications in such a fashion. This trend led to Web enabling of many existing applications, as well as to the redevelopment of such applications with a Web-based model in mind. Smaller and newer companies have primarily undertaken the latter.

Figure 4 depicts the application service provider deployment model. The arrows indicate network communication between customers and ASP. The difference between this model and the hosting deployment model is that here the mapping between applications managed by the ASP on behalf of its customers is not transparent. The ASP may not dedicate a physically separate server and application image for each customer; rather, the ASP may serve all customers with one application image. The customer interacts with the ASP network gateway and not the specifically dedicated resources, as in the previous model. The ASP may use less hardware to fulfill its customer needs (i.e., in Figure 4, assume *i*, the number of servers, is less than *n*, the number of servers in the hosting model).

A third model has appeared, referred to as the *application service model*. In this model, the service provider offers a service to its clients, which involves installing and maintaining software systems at the clients' site and servicing these systems and the clients' computing infrastructure across the network. Here, the service provider offers one application service to *n* clients and, additionally, manages computing systems and software at *n* client sites. Network monitoring, system administration, and system and network security constitute application services that are deployed in this manner. For the service provider this model involves great overhead, because the provider is responsible for many individually distributed, heterogeneous hardware resources. Often, a software monitor observes, at the clients' site, the state of the managed system and alerts an application service administrator preventively or in the event of problem. In a sense, this is a hybrid deployment model combining the characteristics of the previous two models. Figure 5 depicts this model logically. The components designated "ASP managed component" refer to software or hardware components that the ASP deploys on the customers site. These components monitor or control and alert the ASP in case of malfunction, emergency, or as required. These components do not exist in previous models, in which customers interact with user interface software with the remote ASP. The ASP can operate, manage, and control these components from its site over the network. These ASP-managed components are often referred to as appliances, but this term specifically refers to hardware components that are plugged into the customer's network. The mapping between customers managed and hardware required on the ASP site may correspond to any one of the previous cases.

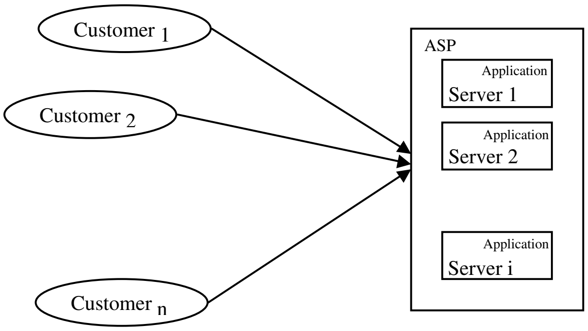

Figure 4: Application service provider deployment model.

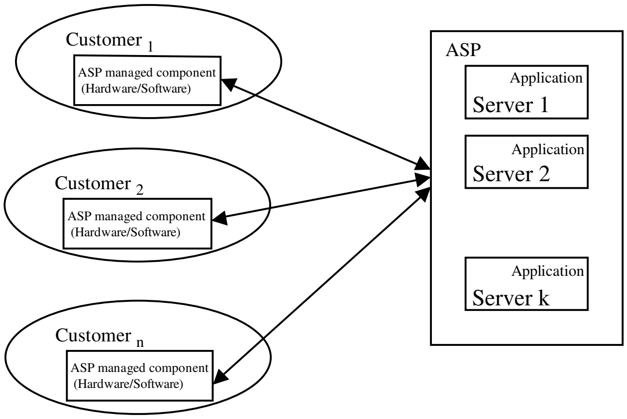

Figure 5: Application services or hybrid software deployment model.

Finally, Web services constitute services in the sense of information services, but also in the sense of human-facilitated services that are made available over the Web. In the trade press, these, too, are often referred to as application services, which is a completely different model from what has been described in this chapter thus far. The term "Web service" is in line with a set of standards (referred to as "Web Services") that is commonly used to build fully automated Web services as described here. This class of services is largely the same as the deployment of applications according to the ASP model described thus far. However, the term Web services usually refers to very specific service offers, whereas an outsourced application usually refers to a much more complex application

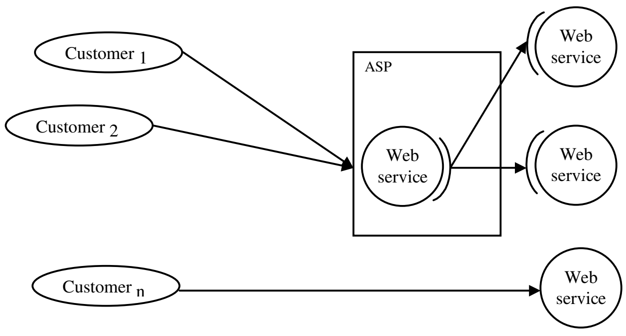

Figure 6: Web services deployment model.

offered over the network. Examples of Web services in the information technological sense are the provisioning of stock ticks, news feeds, credit card authentication, horoscopes, chat rooms, or instant messaging. Examples of Web services in the human-facilitated sense are, for example, help desks or medical and legal advice. Often a Web service is bundled, both technically and economically, into a larger Web portal offering a whole range of services to its user community. No clear-cut distinction exists between the Web service model and the application service model. Similarly, mobile services have appeared that target the mobile communication sector but essentially follow the same model.

Figure 6 shows the logical architecture of the Web service designated software deployment model. Arrows, as in the previous diagrams, designate network communication. The ASP designated component illustrates the fact that Web services are usually bundled and hardly used in isolation. The latter may also be amenable, however, for customers who directly interact with the desired Web service. The mapping between Web services and hardware to execute the service on the service deployment side depends entirely on what kind of service is offered. It is highly unlikely that a structure as found in the hosting deployment model would be propagated here. Web services may be deployed anywhere on the network and must not be physically collocated with the aggregating service. The half circles designate wrapper code that an aggregator must provide to integrate or bundle the functions of several services to offer a further new Web service. The current standardization efforts referred to as Web Services (World Wide Web Consortium, 2003) will greatly facilitate the writing of such wrapper code, because Web services conforming to this standard would expose a well-formed application programming interface.

SOFTWARE LICENSING AND DISTRIBUTION MODELS

The software licensing and distribution model defines the terms of use of the software for the customer and defines any possible obligations on the part of the software provider. Software licensing is tightly coupled with the pricing model and the service level agreement (SLA) offered by a provider. (These concepts are discussed later on in this chapter.) Four basic software licensing and distribution models broadly reflect the cases found in practice.

First, the *classical software-licensing model refers* to the case in which software is sold through a network of distribution channels to the end user, who buys and installs the software on his or her machine and uses it indefinitely. This model is not applicable in the context of application service provisioning, because the licensed application software does not reside under control by the ASP.

The *license-controlled model* refers to a refined model, whereby a customer buys and installs the software on his or her machines but is bound through a contractual agreement to pay periodic (e.g., yearly) license fees to keep using the software. In return the customer receives updates, patches, training, consulting, or new versions of the software on a regular basis. Software licenses are often designed according to the number of users working with the application (e.g., on a per-seat basis), or according to the numbers of clients interacting with an application, and on the basis of per application clients and servers deployed. Although this model already reflects a subscription-based character, it is often enforced technically by sophisticated license management software that interacts over the network with the distributor's system. This is still is not the predominant model employed by application service providers, because the customer still has most of the control over the software installed on-site.

The *leasing-based software-licensing model* refers to the model employed by application service providers. This model defines the customer's interaction with the remote application on a subscription basis and in terms of service level agreements guaranteed by the provider. The subscription mechanism defines a pricing structure based on computing resources consumed and software features used. In this model a customer interacts with an application over the network, with all management aspects of the hardware and the software being shifted to the ASP. The leased software could run entirely on the customer's machines and be managed remotely by the ASP, or part of the application could run on the customer's machine and part of it on the ASP's server farm.

Finally, a combination of the models described earlier gives rise to a further licensing and distribution model that is emerging in practice. In this model, a licensed application is offered to the client and complemented with services and extensions accessible only over the network. Examples include update distribution, library provisioning, application administration, security management, performance monitoring, and data management.

PRICING MODELS

The ASP model gives rise to the implementation of a fine-grained pricing structure that allows charging a user on a pay-per-use basis, rather than a coarse-grained structure that foresees only a limited number of prices charged for using the service. Pricing may account for the amount of system resources consumed (e.g., system interaction time, amount of data storage, CPU [computer processing unit] cycles), application functionality required, transactions executed, or simply based on a periodic or flat fee pricing model, as well as any combination of the former.

The following four pricing models can be distinguished. The flat-fee pricing model establishes a flat fee for the use of the ASP. The flat fee can be derived as a function of the size of the customer's enterprise, derived from an expected use on a per-user and per-month basis, derived from an expected transaction volume, a number of users (i.e., either named users or concurrent users), an expected usage time, or based on screen clicks. The advantage for the ASP is the simplicity to implement this model and the predictable revenue stream. The disadvantage is the invariability of the model to peak uses and customer growth (i.e., overuse). The advantage for the customer is the predictability of cost. The disadvantage for the customer is the inadaptability to underuse (i.e., paying the same price even in periods of less use).

A slightly different model, usage level-based pricing, charges a one-time setup fee and bills for certain usage levels (e.g., based on number of users using the application). Any use of the application beyond this level incurs additional charges; any use below it incurs the set charges. This model implements a predictable price structure for the customer and guarantees the ASP a usage-based remuneration, but fixed revenue if the service is underutilized by the customer. Compared with the flat-fee model, nothing changes for the customer unless the service is overused.

A usage-based pricing model bills a customer according to the resources and application features used. Implementing this kind of billing is more complicated than are the first two cases because a metering and provisioning engine must be developed for the particular hardware and software (operating system and application) used. These engines are now becoming available and are often part of new Web and application deployment infrastructures.

More difficult than metering the usage is metering of the application features used. Unless the application has been designed with this kind of deployment scenario in mind, it is difficult to offer a solution. A wrapper around the application has to be built to mediate between metering the application features and the customer interface. The disadvantage for the customer is the unpredictable price charged.

A hybrid model based on a flat fee enhanced with value-added services constitutes a further model found in practice. In addition to a flat-fee charge, the user is offered to use of value-added services that are billed according to one of the available pricing models.

Further consideration of pricing models constitutes bundling of services. This is often advocated by ASP aggregators. Several complementary services are offered as a package and are cheaper as the sum of all individual services together. A good example is the bundling of Internet access with Web hosting propagated by many ISPs today.

Furthermore, an ASP may differentiate its services by offering a variety of service-level agreements, discussed in greater detail in the next section. SLAs may account, for instance, for minimum network latency guarantees, minimum computing resource availability and throughput guarantees, and different service schedules (e.g., hotline service and data backup schedules).

Rather than selling a software license, giving a user "all or nothing" of a product, the software may be leased to the user. In contrast, under the classical software distribution model and under the software licensing model, a customer obtains the entire functionality of an application, whether or not it is actually required. Consequently, billing is much coarser grained, reflecting only the version structure of the product. A customer may, for instance, choose between a demo, a student, an advanced, and a professional version of the software, but these choices must be made up front.

Well-designed pricing models can help attract new customers and differentiate the product opening new market segments for the ASP. The right pricing model is crucial for the success of the ASP and to cover its cost. The costs for running an ASP include software license for outsourced applications, data center and network operation cost, ongoing customer support and maintenance cost, and software and infrastructure upgrade cost.

LEGAL ISSUES AND LIABILITIES

It is difficult to come up with one legal framework that determines all the responsibilities and resolves every possible conflict in application outsourcing and hosting relationships. The key problem is that the individual players may physically reside and operate in different countries bound by different legal systems but make their service available all over the Internet. Potential disputes or legal battles can severely hurt the business operation, the ASP, and the customer—as well as public opinion of the ASP model. In this section, a number of mechanisms and guidelines are discussed that can protect the customer from the ASP.

A contract with an ASP should always foresee an exit strategy that determines the conditions under which engagement with the ASP can be "legally" terminated and, in such a situation, what happens to the customer's assets (i.e., the data, business logic and process, and software that the ASP controls). This exit strategy protects the customer from a situation in which the ASP goes out of business or does not fulfill its SLA. Severe violations of SLAs may, for instance, be counteracted by a reduction in monthly payments to the ASP.

The most important rule in negotiating terms with an ASP is to retain ownership and access to all business assets outsourced to the ASP. The ASP must guarantee access to all customer data at any time and in any format requested. Copies of data should be made available regularly or, at the outer extreme, be placed in a secured location that can be physically accessed by the customer at any time. Access to data by the customer should be absolutely unconditional.

Access to critical data alone does not help to restore an IT operation once the ASP relationship has been terminated. The ASP's software is critical for processing this data. A contract with the ASP can foresee software licenses of the outsourced software for the customer and rights to operate this software in-house. This, of course, is only an option if the ASP operates standard software packages, which is not the case for all ASPs, some of which build their own solutions or integrate existing packages with value-added services. Online dispute resolution procedures have been defined by several industrial organizations in the ASP sector and for Internet-related disputes in general (WIPO Mediation and Arbitration Center, n.d.), and these may be helpful in sorting out difficulties with ASPs.

Finally, an effort toward standardization of the data formats and application programming interfaces used by ASPS may help to reduce switching cost and reduce customer lock-in, thus increasing "ASP loyalty" to a customer. This may reduce the risk of conflict in the first place.

IMPLEMENTATION ISSUES, PRIVACY, AND SECURITY CONSIDERATIONS

Service Level Agreements

An ASP customer relies on the availability of the outsourced application and the availability of network access to the application. Different customers require different classes of service, and service requirements vary among customers. For instance, customers may depend on the specific content hosted, the application or service outsourced, the time of day, or the time of year. Allocating more bandwidth and providing more server resources is a costly solution but may not resolve network congestion and server contention. On the contrary, increased resource availability attracts ever more traffic and more unrestricted use. Providing differentiated services and network access models governed by SLAs and combined with a differentiated pricing structure is the solution advocated in the service provider market today. Pricing models were discussed in the previous section. Here, I describe SLAs as related to the ASP model.

An SLA constitutes a contract between the service provider and the customer, which defines the service levels offered by the ASP to the customer. Commonly expressed in quantifiable terms, they specify levels and qualities of service that the provider guarantees and the client expects. These agreements are not unique to ASPs; many Internet service providers (ISPs) offer their customers SLAs. Also, IT departments in major enterprises have adopted the notion of defining SLAs so that services for their customers—users in other departments within the enterprise—can be quantified, justified, and ultimately compared with those provided by external ASPs. Today most service industries offer some form of SLAs.

In the ASP context, each SLA describes aspects of network and application provisioning, details the level of acceptable service, expected service, limits to the customer usage patterns, states reporting obligations, and defines conditions in case of SLA violation. An SLA contains a definition of service guarantees, which should be of an acceptable high standard and should be achievable within the pricing structure set by the service provider. Neither the customer nor the provider would not be well served by low-performance expectations, which could be achieved with ease but would not provide a sufficiently efficient and cost-effective service. Similarly, the service provider would not benefit from service levels set so high that they could not be reasonably achieved. Because network technology is rapidly changing and because the Internet's best effort service model gives rise to highly dynamic traffic patterns, SLAs cannot be defined once and for all or expressed in absolute terms. They are defined for a set period of time after which they are revisited and adapted in response to changes in technology. Because of dynamic traffic patterns, service levels are expressed as averages over time.

For ASPs service level agreements usually cover the following four areas of service levels:

1. Access to the outsourced application (i.e., network access);
2. General terms about hosting (i.e., availability of service, security, and data management);
3. Terms about the specific application or service (i.e., features supported, versions available, and upgrades administered); and
4. Customer relationship management (i.e., help desk, customization, and support).

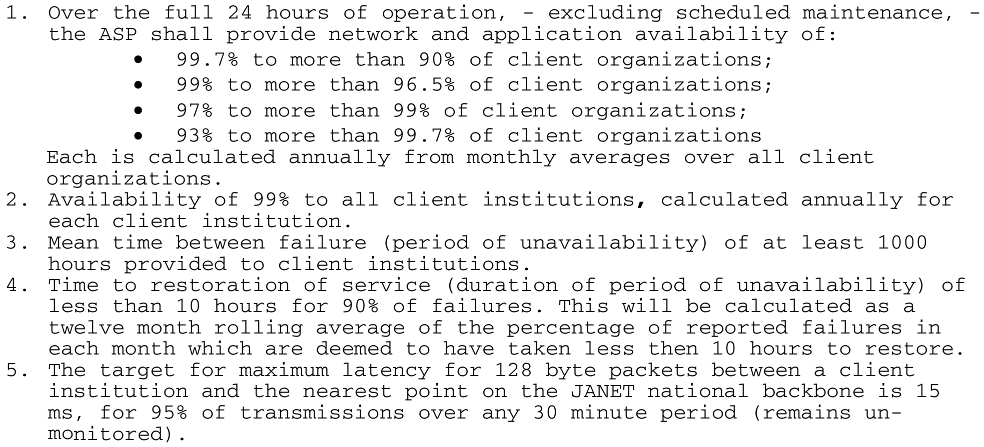
Each of these areas comprises a set of service level elements and a set of metrics to evaluate the ASP's service level guarantees and allows the customer to track its expectations and industrywide benchmarks, if available.

SLAs can be divided into technical and nontechnical service levels. A nontechnical service level guarantees a premium client a 24-hour hotline, for example, whereas a nonpremium client would only obtain a 9-to-5 weekday hotline. Various different shades of service levels are imaginable. Although nontechnical SLAs are common to all service industries, technical SLAs are more a specific characteristic of the service-provisioning model (i.e., for ISPs and ASPs alike). Technical SLAs pertain to the availability of computing and network resources that intervene in delivering the application functionality offered by the ASP to its clients. A technical SLA may guarantee the client an average throughput, an average number of transactions executed per unit of time, a bound on network bandwidth and latency. Other examples of technical SLAs are backup schedules (e.g., daily, weekly, monthly), available storage space, and security levels (e.g., encryption key strength and conformance to security standards). Example metrics that track these service levels include percentage of the time applications that are available, number of users served simultaneously, specific performance benchmarks with which actual performance is periodically compared, schedule for notification in advance of network changes that may affect users, help desk response time for various classes of problems, dial-in access availability, and usage statistics that will be provided.

Network resource guarantees, like bounds on network bandwidth and latency, are especially difficult to guarantee unless the ASP also controls the communication lines over which its service is delivered. This kind of control is unlikely in the case of Internet access. For the client, it is difficult to assess whether the promised service level has really been offered, because technical SLAs are often expressed as averages and skewed occasionally by bad user perceived latency. An extract of a real-world example of performance indicators and service levels are summarized in Figure 7.

Privacy and Security Considerations

Privacy and security is one of the primary concerns that may defeat the widespread acceptance of the ASP model. All customer application input, operational, and output



1. Over the full 24 hours of operation, - excluding scheduled maintenance, - the ASP shall provide network and application availability of:
   - 99.7% to more than 90% of client organizations;
   - 99% to more than 96.5% of client organizations;
   - 97% to more than 99% of client organizations;
   - 93% to more than 99.7% of client organizations

   Each is calculated annually from monthly averages over all client organizations.
2. Availability of 99% to all client institutions, calculated annually for each client institution.
3. Mean time between failure (period of unavailability) of at least 1000 hours provided to client institutions.
4. Time to restoration of service (duration of period of unavailability) of less than 10 hours for 90% of failures. This will be calculated as a twelve month rolling average of the percentage of reported failures in each month which are deemed to have taken less then 10 hours to restore.
5. The target for maximum latency for 128 byte packets between a client institution and the nearest point on the JANET national backbone is 15 ms, for 95% of transmissions over any 30 minute period (remains unmonitored).

Figure 7: Example of performance indicators and service levels for an Internet service provider operation.

data are available at the ASP site, potentially leaving it exposed for exploitation by the ASP, by other users, or by intruders. ASPs must implement strict security measures to

- Protect sensitive data from being stolen, corrupted, and intentionally falsified during transmission or at the remote side.
- Protect the cooperating systems from malicious use (abuse) by impersonators.
- Protect the cooperating systems from unauthorized use.
- Enforce commercial or national security concerns that may require additional steps to preserve the privacy of the data transmitted (or the encryption technology used).

To enforce these security requirements, a number of well-established techniques are available:

- Server authentication (i.e., remote site authentication ensures the client application that it is truly operating on the intended site).
- Client authentication (i.e., user authentication ensures the remote site that an authorized client is interacting).
- Integrity (i.e., noncorruption of data transferred prevents both malicious and false operation).
- Confidentiality (i.e., encrypting transferred data items prevents both malicious and false operation, as well as eavesdropping).
- Secure invocation of methods from client application to remote services, routed (i.e., delegated) through a logging facility to gather "evidence" of "who" initiated an invocation "when."
- Nonrepudiation of invoked methods to ensure liability.
- Data security to prevent sensitive or "expensive" data from being compromised at the site of computation. This may require the additional use of encryption and transformations techniques, as well as organizational means.

A detailed discussion of all mechanisms implementing these features is beyond the scope of this chapter. Except for data security, however, all these security techniques are well understood and solutions are widely deployed. The key question for an ASP user is one of trust: Why should the user entrust its sensitive and personal user or corporate data to a remote computational service (e.g., data on income, personal assets, business logic, customer information, financial data, revenue, and earnings)? Consulting groups and the trade press often note that the strongest barrier for engaging in a business relationship with an ASP is trust. Yet it is evident that for effective use of an ASP, customers must expose service input data to the ASP, where eventually it is subject to exposure, at least at the time of execution of the service's function on the data. Note that this does not refer to the risk of data being captured over the communication link. This problem is solved through cryptographic protocols that are commonplace. The data security problem is much more difficult to solve. A theoretic solution, with proven guarantees of the data remaining unknown to the ASP, is provided by Abadi and Feigenbaum (Abadi & Feigenbaum, 1990; Abadi, Feigenbaum, & Kilian, 1989) and has become know as secure circuit evaluation. Their algorithm is impractical for this scenario because it requires significant interaction between client and server to accomplish a computation. A general solution of this problem that would guarantee data security for the input, the operational, and the output data transmitted is an open research question. Approaches, such as obfuscation techniques, computing with encrypted data, computing with encrypted functions, private information retrieval, and privacy homeomorphisms are techniques that may be applied to solve this problem.

OUTLOOK

The widespread acceptance of the ASP model will depend on whether ASPs are able to ensure availability, accessibility, privacy, and security for outsourced applications and services. It will also depend on whether customers will learn to trust the model. System availability can be achieved through redundancy and replication of the service. Full accessibility of the service is strongly dependent on reliable network connections from the customer to the ASP and is less easy to guarantee by the ASP alone, unless leased communication lines are offered to access the service. Guaranteeing privacy and security of the outsourced data constitutes an open research question, with no fully satisfying solution in sight. For now, the successful ASP will offer a widely useful, highly specialized, and non-mission-critical service. Moreover, privacy guarantees and trust relationships can, for the time being, only be achieved though organizational means—for example, through the operation of ASPs by known industrial players with established brands. Because of these constraints, it is likely that the hybrid deployment model that outsources part of the software, maintains critical application components and data at the customer site, and manages these components from remote sites or, alternatively, offers additional services to complement the licensed software, will prevail.

Many enterprise resource planning (ERP) systems require significant customization to adapt the software to the business processes of the customer. Because this is a complex task to accomplish over the Web for the customer and difficult and expensive to manage on an individual basis for the ASP, it is unlikely that ASPs offering full-fledged ERP packages as leased solutions will establish themselves. If these widely accepted business software solutions establish and follow standard business process models, ASPs may be able to offer these models for a wide customer base without going through a long phase of customization.

The ASP industry is in an early stage and must still establish itself. This trend is to be expected, because the ASP model represents a paradigm shift away from the traditional application licensing and in-house management model. This emerging industry enables customers to reduce both application deployment time frames and their total cost of ownership. Although certain problems still need to be addressed, the ASP industry is successfully implementing the concept of application outsourcing and software leasing.

GLOSSARY

Appliances A prepackaged special-purpose hardware and software solution that plugs into a customer's existing IT infrastructure without much need for customization. Often, the appliance can be managed by a provider from remote.

Application hosting A computer system in a distributed environment like the Internet is often referred to as a computing host, a computing node, or simply host. Hosting refers to the provisioning of services or applications on such a computer system to make these services and applications available to authorized parties interacting in the distributed environment. Application hosting emphasizes that the hosted service is an application.

Application outsourcing The deployment of an application over a network.

Application server The system software that manages the computational transactions, business logic, and the application activation in a multitiered server configuration. The application server interacts with the database tier at one end and the client tier at the other end of the distributed application.

Application services Distinguished from applications by its smaller scope, more specific nature, and its focused functionality. An application service is seldom used in isolation; more often several application services are bundled together and offered by third-party providers that enrich their content offerings with application services.

Application service provider (ASP) The entity that manages the outsourcing of applications.

Server farm A dedicated place with many computing servers accessible through a network.

Software leasing The subscription-based offering of a software application. Often, leasing implicitly refers to a longer term relationship between the customer and the provider. Shorter term relationships are sometimes referred to as software renting, although no clear line is drawn in the context of ASPs.

Wireless application service provider (WASP) An ASP that primarily offers services to customers interacting with the ASP through wireless devices.

Web services The standard suite of protocols created by several large companies to allow applications to interoperate, discover, invoke, and integrate Web-based services across a network, primarily the Internet, is referred to as Web Services. The term Web should not be confused with the actual Web service that is created based on these standards. The Web service built in this manner is also often referred to as application service.

Authentication

Patrick McDaniel, *AT&T Labs*

AUTHENTICATION

An authentication process establishes the identity of some entity under scrutiny. For example, a traveler authenticates herself to a border guard by presenting a passport. Possession of the passport and resemblance to the attached photograph is deemed sufficient proof that the traveler is the identified person. The act of validating the passport (by checking a database of known passport serial numbers) and assessing the resemblance of the traveler is a form of authentication.

On the Internet, authentication is somewhat more complex; network entities do not typically have physical access to the parties they are authenticating. Malicious users or programs may attempt to obtain sensitive information, disrupt service, or forge data by impersonating valid entities. Distinguishing these malicious parties from valid entities is the role of authentication and is essential to network security.

Successful authentication does not imply that the authenticated entity is given access. An authorization process uses authentication, possibly with other information, to make decisions about whom to give access. For example, not all authenticated travelers will be permitted to enter the country. Other factors, such as the existence of visas, a past criminal record, and the political climate will determine which travelers are allowed to enter the country.

Although the preceding discussion focused on *entity authentication*, it is important to note that other forms of authentication exist. In particular, *message authentication* is the process by which a particular message is associated with some sending entity. This article restricts itself to entity authentication, deferring discussion of other forms to other chapters in this encyclopedia.

Meet Alice and Bob

Authentication is often illustrated through the introduction of two protagonists, Alice and Bob. In these descriptions, Alice attempts to authenticate herself to Bob. Note that Alice and Bob are often not users, but computers. For example, a computer must authenticate itself to a file server prior to being given access to its contents. Independent of whether Alice is a computer or a person, she must present evidence of her identity. Bob evaluates this evidence, commonly referred to as a credential. Alice is deemed authentic (authenticated) by Bob if the evidence is consistent with information associated with her claimed identity. The form of Alice's credential determines the strength and semantics of authentication.

The most widely used authentication credential is a password. To illustrate, UNIX passwords configured by system administrators reside in the`/etc/passwd` file. During the login process, Alice (a UNIX user) types her password into the host console. Bob (the authenticating UNIX operating system) compares the input to the known password. Bob assumes that Alice is the only entity in possession of the password. Hence, Bob deems Alice authentic because she is the only one who could present the password (credential).

Note that Bob's assertion that Alice is the only entity who could have supplied the password is not strictly accurate. Passwords are subject to *guessing* attacks. Such an attack continually retries different passwords until the authentication is successful (the correct password is guessed). Many systems combat this problem by disabling authentication (of that identity) after a threshold of failed authentication attempts. The more serious *dictionary* attack makes use of the UNIX password file itself. A salted noninvertible hash of the password is recorded in the password file. Hence, malicious parties cannot obtain the password directly from`/etc/passwd`. However, a malicious party who obtains the password file can mount a dictionary attack by comparing hashed, salted password guesses against the password file's contents. Such an attack bypasses the authentication service and, hence, is difficult to combat. Recent systems have sought to mitigate attacks on the password file by placing the password hash values in a highly restricted *shadow password* file.

Passwords are subject to more fundamental attacks. In one such attack, the adversary simply obtains the password from Alice directly. This can occur where Alice "shares" her password with others, or where she records it in some obvious place (on her PDA). Such attacks illustrate an axiom of security: A system is only as secure as the protection afforded to its secrets. In the case of authentication, failure to adequately protect credentials from misuse can result in the compromise of the system.

The definition of identity has been historically controversial. This is largely because authentication does not truly identify physical entities. It associates some secret or (presumably) unforgettable information with a virtual identity. Hence, for the purposes of authentication, any entity in possession of Alice's password is Alice. The strength of authentication is determined by the difficulty with which a malicious party can circumvent the authentication process and incorrectly assume an identity. In our above example, the strength of the authentication process is largely determined by the difficulty of guessing Alice's password. Note that other factors, such as whether Alice chooses a poor password or writes it on the front of the monitor, will determine the effectiveness of authentication. The lesson here is that authentication is as strong as the weakest link; failure to protect the password either by Alice or the host limits the effectiveness of the solution.

Authentication on the Internet is often more complex than is suggested by the previous example. Often, Alice and Bob are not physically near each other. Hence, both parties will wish to authenticate each other. In our above example, Alice will wish to ensure that she is communicating with Bob. However, no formal process is needed; because Alice is sitting at the terminal, she assumes that Bob (the host) is authentic.

On the Internet, it is not always reasonable to assume that Alice and Bob have established, or are able to establish, a relationship prior to communication. For example, consider the case where Alice is purchasing goods on the Internet. Alice goes to Bob's Web server, identifies the goods she wishes to purchase, provides her credit card information, and submits the transaction. Alice, being a cautious customer, wants to ensure that this information is only being given to Bob's Web server (i.e., authenticate the Web server). In general, however, requiring Alice to establish a direct relationship with each vendor from whom she may purchase goods is not feasible (e.g., it is not feasible to establish passwords for each Web site out of band). Enter Trent, the trusted third party. Logically, Alice appeals to Trent for authentication information relating to Bob. Trent is trusted by Alice to assert Bob's authenticity. Therefore, Bob need only establish a relationship with Trent to begin communicating with Alice. Because the number of widely used trusted third parties is small (on the order of tens), and every Web site establishes a relationship with at least one of them, Alice can authenticate virtually every vendor on the Internet.

CREDENTIALS

Authentication is performed by the evaluation of credentials supplied by the user (i.e., Alice). Such credentials can take the form of something you know (e.g., password), something you have (e.g., smartcard), or something you are (e.g., fingerprint). The credential type is specific to the authentication service and reflects some direct or indirect relationship between the user and the authentication service.

Credentials often take the form of shared secret knowledge. Users authenticate themselves by proving knowledge of the secret. In the UNIX example above, knowledge of the password is deemed sufficient evidence to prove user identity. In general, such secrets need not be statically defined passwords. For example, users in one-time password authentication systems do not present knowledge of secret text, they identify a numeric value valid only for a single authentication. Users need not present the secret directly. They need only demonstrate knowledge of it (e.g., by presenting evidence that could only be derived from it).

Secrets are often long random numbers and, thus, cannot be easily remembered by users. For example, a typical RSA private key is a 1024-digit binary number. Requiring a user to remember this number is, at the very least, unreasonable. Such information is frequently stored in a file on a user's host computer, on a PDA, or on another nonvolatile storage. The private key is used during authentication by accessing the appropriate file. However, private keys can be considered "secret knowledge" because the user presents evidence external to the authentication system (e.g., from the file system).

Credentials may also be physical objects. For example, a smartcard may be required to gain access to a host. Authenticity in these systems is inferred from possession rather than knowledge. Note that there is often a subtle difference between the knowledge- and the possession-based credentials. For example, it is often the case that a user-specific private key is stored on an authenticating smartcard. In this case, however, the user has no ability to view or modify the private key. The user can only be authenticated via the smartcard issued to the user. Hence, for the purposes of authentication, the smartcard is identity; no amount of effort can modify the identity encoded in the smartcard. Contemporary smartcards can be modified or probed. However, because such manipulation often takes considerable effort and sophistication (e.g., use of an electron microscope), such attacks are beyond the vast majority of attackers.

Biometric devices measure physical characteristics of the human body. An individual is deemed authentic if the measured aspect matches previously recorded data. The accuracy of matching determines the quality of authentication. Contemporary biometric devices include fingerprint, retina, or iris scanners and face recognition software. However, biometric devices are primarily useful only where the scanning device is trusted (i.e., under control of the authentication service). Although biometric authentication has seen limited use in the Internet, it is increasingly used to support authentication associated with physical security (i.e., governing clean-room access).

WEB AUTHENTICATION

One of the most prevalent uses of the Internet is Web browsing. Users access the Web via specialized protocols that communicate HTML and XML requests and content. The requesting user's Web browser renders received content. However, it is often necessary to restrict access to

Web content. Moreover, the interactions between the user and a Web server are often required to be private. One aspect of securing content is the use of authentication to establish the true or virtual identity of clients and Web servers.

Password-Based Web Access

Web servers initially adopted well-known technologies for user authentication. Foremost among these was the use of passwords. To illustrate the use of passwords on the Web, the following describes the configuration and use of *basic authentication* in the Apache Web server (Apache, 2002). Note that the use of basic authentication in other Web servers is largely similar.

Access to content protected by basic authentication in the Apache Web server is indirectly governed by the password file. Web-site administrators create the password file (whose location is defined by the web-site administrator) by entering user and password information using the `htpasswd` utility. It is assumed that the passwords are given to the users using an *out-of-band channel* (e.g., via e-mail, phone).

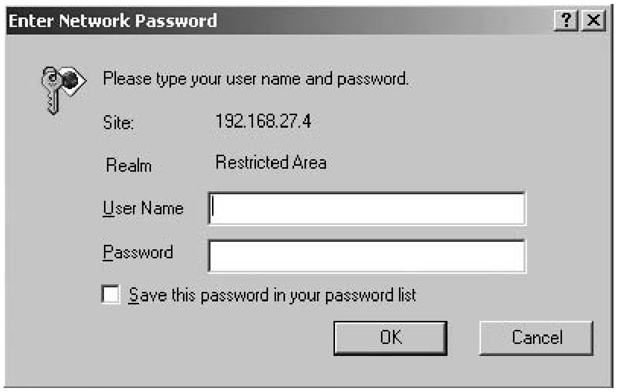
In addition to specifying passwords, the Web server must identify the subset of Web content to be password protected (e.g., a set of protected URLs). This is commonly performed by creating a `.htaccess` file in the directory to be protected. The `.htaccess` file defines the authentication type and specifies the location of the relevant password file. For example, located in the content root directory, the following `.htaccess` file restricts access to those users who are authenticated via password.

```
AuthName "Restricted Area"
AuthType Basic
AuthUserFile/var/www/webaccess
require valid-user
```

Users accessing protected content (via a browser) are presented with a password dialog (e.g., similar to the dialog depicted in Figure 1).

The user enters the appropriate username and password and, if correct, is given access to the Web content.

Because basic authentication sends passwords over the Internet in clear text, it is relatively simple to recover them by eavesdropping on the HTTP communication. Hence, basic authentication is sufficient to protect content from casual misuse but should not be used to protect valuable or sensitive data. However, as is commonly found on commercial Web sites, performing basic authentication over more secure protocols (e.g., SSL; see below) can mitigate or eliminate many of the negative properties of basic authentication.



Please type your user name and password.

Site: 192.168.27.4

Realm Restricted Area

Figure 1: Password authentication on the Web.

Many password-protected Web sites store user passwords (in encrypted form) in *cookies* the first time a user is authenticated. In these cases, the browser automatically submits the cookie to the Web site with each request. This approached eliminates the need for the user to be authenticated every time she visits the Web site. However, this convenience has a price. In most single-user operating systems, any entity using the same host will be logged in as the user. Moreover, the cookies can be easily captured and replayed back to the Web site (Fu, Sit, Smith, & Feamster, 2001).

Digest authentication uses *challenges* to mitigate the limitations of password-based authentication (Franks et al., 1999). Challenges allow authenticating parties to prove knowledge of secrets without exposing (transmitting) them. In digest authentication, Bob sends a random number (*nonce*) to Alice. Alice responds with a hash of the random number and her password. Bob uses Alice password (which only he and Alice know) to compute the correct response and compares it to the one received from Alice. Alice is deemed authentic if the computed and received responses match (because only Alice could have generated the response). Because the hash, rather than the secret, is sent, no adversary can obtain Alice's password from the response.

A number of other general-purpose services have been developed to support password maintenance. For example, RADIUS, DIAMETER, and LDAP password services have been widely deployed on the Internet. Web servers or hosts subscribing to these services defer all password maintenance and validation to a centralized service. Although each system may use different services and protocols, users see interfaces similar to those presented by basic authentication (e.g., user login above). However, passwords are maintained and validated by a centralized service, rather than by the Web server.

Single Sign-On

Basic authentication has become the predominant method of performing authentication on the web. Users often register a username and password with each retailer or service provider with which they do business. Hence, users are often faced with the difficult and error prone task of maintaining a long list of usernames and passwords. In practice, users avoid this maintenance headache by using the same passwords on all Web sites. However, this allows adversaries who gain access to the user information on one site to impersonate the user on many others.

A *single sign-on* system (SSO) defers user authentication to a single, universal authentication service. Users authenticate themselves to the SSO once per session. Subsequently, each service requiring user authentication is redirected to a SSO server that vouches for the user. Hence, the user is required to maintain only a single authentication credential (e.g., SSO password). Note that the services themselves do not possess user credentials (e.g., passwords). They simply trust the SSO to state which users are authentic.

Although single sign-on services have been used for many years (e.g., see *Kerberos*, below), the lack of universal adoption and cost of integration has made their use in Web applications highly undesirable. These difficulties have led to the creation of SSO services targeted specifically to authentication on the web. One of the most popular of these systems is the *Microsoft passport* service (Microsoft, 2002). Passport provides a single authentication service and repository of user information. Web sites and users initially negotiate secrets during the passport registration process (i.e., user passwords and Web site secret keys). In all cases, these secrets are known only to the passport servers and the registering entity.

Passport authentication proceeds as follows. Users requesting a protected Web page (i.e., a page that requires authentication) are redirected to a passport server. The user is authenticated via a passport-supplied login screen. If successful, the user is redirected back to the original Web site with an authentication *cookie* specific to that site. The cookie contains user information and site specific information encrypted with a secret key known only to the site and the passport server. The Web site decrypts and validates the received cookie contents. If successful, the user is deemed authentic and the session proceeds. Subsequent user authentication (with other sites) proceeds similarly, save that the login step is avoided. Successful completion of the initial login is noted in a session cookie stored at the user browser and presented to the passport server with later authentication requests.

Although SSO systems solve many of the problems of authentication on the Web, they are not a panacea. By definition, SSO systems introduce a single point of trust for all users in the system. Hence, ensuring that the SSO is not poorly implemented, poorly administered, or malicious is essential to its safe use. For example, passport has been shown to have several crucial flaws (Kormann & Rubin, 2000). Note that although existing Web-oriented SSO systems may be extended to support mutual authentication, the vast majority have yet to do so.

Certificates

Although passwords are appropriate for restricting access to Web content, they are not appropriate for more general Internet authentication needs. Consider the Web site for an online bookstore, *examplebooks.com*. Users wishing to purchase books from this site must be able to determine that the Web site is authentic. If not authenticated, a malicious party may impersonate *examplebooks.com* and fool the user into exposing his credit card information.

Note that most Web-enabled commercial transactions do not authenticate the user directly. The use of credit card information is deemed sufficient evidence of the user's identity. However, such evidence is typically evaluated through the credit card issuer service (e.g., checking that the credit card is valid and has not exceeded its spending limit) before the purchased goods are provided to the buyer.

The dominant technology used for Internet Web site authentication is public key certificates. Certificates provide a convenient and scalable mechanism for authentication in large, distributed environments (such as the Internet). Note that certificates are used to enable authentication of a vast array of other non-Web services. For example, certificates are often used to authenticate electronic mail messages (see *Pretty Good Privacy*, below).

Certificates are used to document an association between an identity and a cryptographic key. Keys in public key cryptography are generated in pairs: a public and a private key (Diffie & Hellman, 1976). As the name would suggest, the public key is distributed freely, and the private key is kept secret. To simplify, any data signed (using a digital signature algorithm) by the private key can be validated using the public key. A valid digital signature can be mapped to exactly one private key. Therefore, any valid signature can only be generated by some entity in possession of the private key.

Certificates are issued by *certification authorities* (CA). The CA issues a certificate by assigning an identity (e.g., the domain name of the Web site), validity dates, and the Web site's public key. The certificate is then freely distributed. A user validates a received certificate by checking the CA's digital signature. Note that most browsers are installed with a collection of CA certificates that are invariably trusted (i.e., they do not need to be validated). For example, many Web sites publish certificates issued by the Verisign CA (Verisign, 2002), whose certificate is installed with most browsers. In its most general form, a system used to distribute and validate certificates is called a *public key infrastructure*.

SSL

Introduced by Netscape in 1994, the SSL protocol uses certificates to authenticate Web content. In addition to authenticating users and Web sites, the SSL protocol negotiates an ephemeral secret key. This key is subsequently used to protect the integrity and confidentiality of all messages (e.g., by encrypting the messages sent between the Web server and the client). SSL continues to evolve. For example, the standardized and widely deployed TLS (Transport Layer Security) protocol is directly derived from SSL version 3.0.

The use of SSL is signaled to the browser and Web site through the https URL protocol identifier. For example, Alice enters the following URL to access a Web site of interest: https://www.example.com/.

In response to this request, Alice's browser will initiate an SSL handshake protocol. If the Web site is correctly authenticated via SSL, the browser will retrieve and render Web site content in a manner similar to HTTP. Authentication is achieved in SSL by validating statements signed by private keys associated with the authenticated party's public key certificate.

Figure 2 depicts the operation of the SSL authentication and key agreement process. The *SSL handshake protocol* authenticates one or both parties, negotiates the cipher-suite policy for subsequent communication (e.g., selecting cryptographic algorithms and parameters), and establishes a *master secret*. All messages occurring after

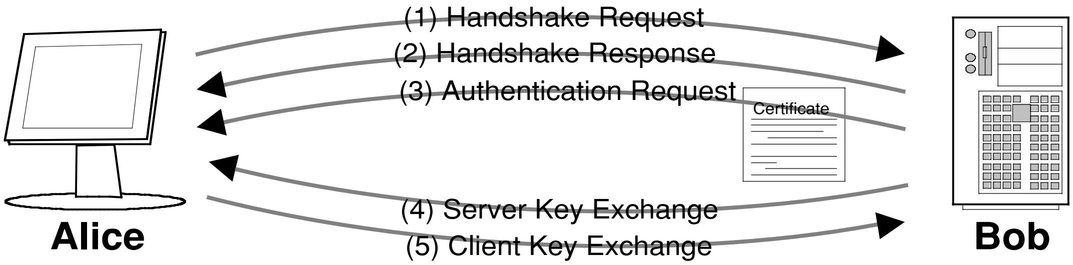


Figure 2: The SSL protocol. Alice (the client) and Bob (the server) exchange an initial handshake identifying the kind of authentication and configuration of the subsequent session security. As dictated by the authentication requirements identified in the handshake, Alice and Bob may exchange and authenticate certificates. The protocol completes by establishing a session-specific key used to secure (e.g., encrypt) later communication.

the initial handshake are protected using cryptographic keys derived from the master secret.

The handshake protocol begins with both Alice (the end-user browser) and Bob (the Web server) identifying a cipher-suite policy and session-identifying information. In the second phase, Alice and Bob exchange certificates. Note that policy will determine which entities require authentication: As dictated by policy, Alice and/or Bob will request an authenticating certificate. The certificate is validated on reception (e.g., issuance signature checked against CA's, whose certificate is installed with the browser). Note that in almost all cases, Bob will be authenticated but Alice will not. In these cases, Bob typically authenticates Alice using some external means (only when it becomes necessary). For example, online-shopping Web sites will not authenticate Alice until she expresses a desire to purchase goods, and her credit card number is used to validate her identity at the point of purchase.

Interleaved with the certificate requests and responses is the server and client key exchange. This process authenticates each side by signing information used to negotiate a session key. The signature is generated using the private key associated with the certificate of the party to be authenticated. A valid signature is deemed sufficient evidence because only an entity in possession of the private key could have generated it. Hence, signed data can be accepted as proof of authenticity. The session key is derived from the signed data, and the protocol completes with Alice and Bob sending *finished* messages.

HOST AUTHENTICATION

Most computers on the Internet provide some form of *remote access*. Remote access allows users or programs to access resources on a given computer from anywhere on the Internet. This access enables a promise of the Internet: independence from physical location. However, remote access has often been the source of many security vulnerabilities. Hence, protecting these computers from unauthorized use is essential. The means by which host authentication is performed in large part determines the degree to which an enterprise or user is protected from malicious parties lurking in the dark corners of the Internet. This section reviews the design and use of the predominant methods providing host authentication.

Remote Login

Embodying the small, isolated UNIX networks of old, *remote login* utilities allow administrators to identify the set of hosts and users who are deemed “trusted.” Trusted hosts are authenticated by source IP address, host name, and/or user name only. Hence, trusted users and hosts need not provide a user name or password.

The `rlogin` and `rsh` programs are used to access hosts. Configured by local administrators, the `/etc/hosts.equiv` file enumerates hosts/users who are trusted. Similarly, the `.rhosts` file contained in each user's home directory identifies the set of hosts trusted by an individual user. When a user connects to a remote host with a remote log-in utility, the remote log-in server (running on the accessed host) scans the `hosts.equiv` configuration file for the address and user name of the connecting host. If found, the user is deemed authentic and allowed access. If not, the `.rhosts` file of the accessing user (identified in the connection request) is scanned, and access is granted where the source address and user name is matched.

The remote access utilities do not provide strong authentication. Malicious parties may trivially forge IP addresses, DNS records, and user names (called *spoofing*). Although recent attempts have been made to address the security limitations of the IP protocol stack (e.g., IPsec, DNSsec), this information is widely accepted as untrustworthy. Remote access tools trade security for ease of access. In practice, these tools often weaken the security of network environments by providing a vulnerable authentication mechanism. Hence, the use of such tools in any environment connected to the Internet is considered extremely dangerous.

SSH

The early standards for remote access, `telnet` and `ftp`, authenticated users by UNIX password. While the means of authentication were similar to terminal log in, their use on an open network introduces new vulnerabilities. Primarily, these utilities are vulnerable to password sniffing. Such attacks passively listen in on the network for communication between the host and the remote user. Note that the physical media over which much local network communication occurs is the Ethernet. Because Ethernet is a broadcast technology, all hosts on the local network (subnet) receive every bit of transmitted data. Obviously, this approach simplifies communication eavesdropping. Although eavesdropping may be more difficult over other network media (e.g., switched networks), it is by no means impossible. Because passwords are sent in the clear (unencrypted), user-specific authentication information could be recovered. For this reason, the use of these utilities as a primary means of user access has largely been abandoned. `Ftp` is frequently used on the Web to transfer files. When used in this context, `ftp` generally operates in *anonymous* mode. `Ftp` performs no authentication in this mode, and the users are often restricted to file retrieval only.

The secure shell (SSH) (Ylonen, 1996) combats the limitations of standard tools by performing cryptographically supported host and/or user authentication. Similar to SSL, a by-product of the authentication is a cryptographic key used to obscure and protect communication between the user and remote host. SSH is not vulnerable to sniffing attacks and has been widely adopted as a replacement for the standard remote access tools.

SSH uses public key cryptography for authentication. On installation, each server host (a host allowing remote access via SSH) generates a public key pair. The public key is manually stored at each initiating host (a host from which a user will remotely connect). Note that unlike SSL, SSH uses public keys directly, rather than issued certificates. Hence, SSH authentication relies on host administrators maintaining the correct set of host keys.

SSH initiates a session in two phases. In the first phase, the server host is authenticated. The initiating host initiates the SSH session by requesting remote access. To simplify, the requesting host generates a random session key, encrypts it with a received host public key of the server, and forwards it back to the server.

The server recovers the session key using its host private key. Subsequent communication between the hosts is protected using the session key. Because only someone in possession of the host private key could have recovered the session key, the server is deemed authentic. The server transmits a short-term public key in addition to the host key. The requesting host encrypts the random value response with both keys. The use of the short-term keys prevents adversaries from recovering the content of past sessions should the host key become compromised.

The second phase of SSH session initialization authenticates the user. Dictated by the configured policy, the server will use one of the following methods to authenticate the user.

.rhosts file: As described for the *remote access* utilities above, this file simply tests whether the accessing user identifier is present in the `.rhosts` file located in the home directory of the user.

.rhosts with RSA: Similar to the above file, this requires that the accessing host be authenticated via a known and trusted RSA public key.

Password authentication: This prompts the user for a local system password. The strength of this approach is determined by the extent to which the user keeps the password private.

RSA user authentication: This works via a user-specific RSA public key. Of course, this requires that the server be configured with the public key generated for each user.

Note that it is not always feasible to obtain the public key of each host that a user will access. Host keys may change frequently (as based on an administrative policy), be compromised, or be accidentally deleted. Hence, where the remote host key is not known (and the configured policy allows it), SSH will simply transmit it during session initialization. The user is asked if the received key should be accepted. If accepted, the key is stored in the local environment and is subsequently used to authenticate the host.

Although the automated key distribution mode does provide additional protection over conventional remote access utilities (e.g., sniffing prevention), the authentication mechanism provides few guarantees. A user accepting the public key knows little about its origin (e.g., is subject to forgery, man-in-the-middle attacks, etc.). Hence, this mode may be undesirable for some environments.

One-Time Passwords

In a very different approach to combating password sniffing, the S/Key system (Haller, 1994) limits the usefulness of recovered passwords. Passwords in the S/Key system are valid only for a single authentication. Hence, a malicious party gains nothing by recovery of a previous password (e.g., via eavesdropping of a telnet log in). Although, on the surface, a one-time password approach may seem to require that the password be changed following each log in, the way in which passwords are generated alleviates the need for repeated coordination between the user and remote host.

The S/Key system establishes an ordered list of passwords. Each password is used in order and only once, then discarded. While the maintenance of the password list may seem like an unreasonable burden to place on a user, the way in which the passwords are generated makes it conceptually simple. Essentially, passwords are created such that the knowledge of a past password provides no information about future passwords. However, if one knows a secret value (called a seed value), then all passwords are easily computable. Hence, while an authentic user can supply passwords as they are needed, a malicious adversary can only supply those passwords that have been previously used (and are no longer valid).

In essence, the S/Key system allows the user to prove knowledge of the password without explicitly stating it. Over time, this relatively simple approach has been found to be extremely powerful, and it is used as the basis of many authentication services. For example, RSA's widely used SecurID combines a physical token with one-time password protocols to authenticate users (RSA, 2002).

Kerberos

The Kerberos system (Neuman & Ts'o, 1994) performs *trusted third party* authentication. In Kerberos, users, hosts, and services defer authentication to a mutually trusted key distribution center (KDC). All users implicitly trust the KDC to act in their best interest. Hence, this approach is appropriate for localized environments (e.g.,

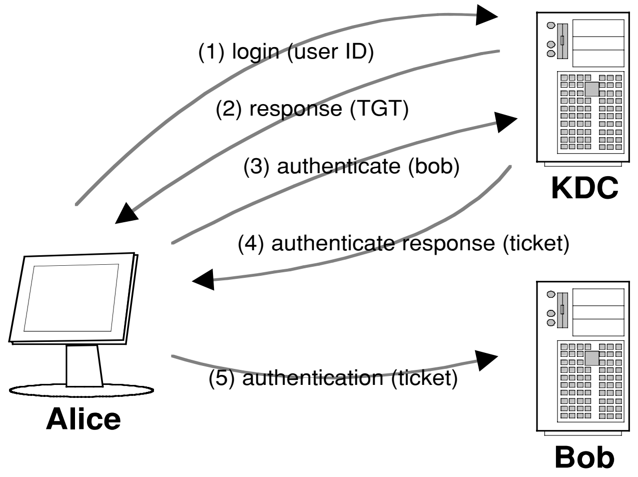

Figure 3: Kerberos authentication. Alice receives a ticket-granting ticket (TGT) after successfully logging into the Kerberos key distribution center (KDC). Alice performs mutual authentication with Bob by presenting a ticket obtained from the KDC to Bob. Note that Bob need not communicate with the KDC directly; the contents of the ticket serve as proof of Alice's identity.

campus, enterprise) but does not scale well to large, loosely coupled communities. Note that this is not an artifact of the Kerberos system but is true of any trusted third party approach; loosely coupled communities are unlikely to universally trust a single authority.

Depicted in Figure 3, the Kerberos system performs mediated authentication between Alice and Bob through a two-phase exchange with the KDC. When logging onto the system, Alice enters her user name and password.

Alice's host sends the KDC her identity. In response, the KDC sends Alice information that can only be understood by someone in possession of the password (which is encrypted with a key derived from the password). Included in this information is a ticket granting ticket (TGT) used later by Alice to initiate a session with Bob. Alice is deemed authentic because she is able to recover the TGT.

At some later point, Alice wishes to perform mutual authentication with another entity, Bob. Alice informs the KDC of this desire by identifying Bob and presenting the previously obtained TGT. Alice receives a message from the KDC containing the session key and a ticket for Bob. Encrypting the message with a key known only to Alice ensures that its contents remain confidential.

Alice then presents the ticket included in the message to Bob. Note that the ticket returned to Alice is opaque; its contents are encrypted using a key derived from Bob's password. Therefore, Bob is the only entity who can retrieve the contents of the ticket. Because later communication between Alice and Bob uses the session key (given to Alice and contained in the ticket presented to Bob), Alice is assured that Bob is authentic. Bob is assured that Alice is authentic because Bob's ticket explicitly contains Alice's identity.

One might ask why Kerberos uses a two-phase process. Over the course of a session, Alice may frequently need to authenticate a number of entities. In Kerberos, because Alice obtains a TGT at log in, later authentication can be performed automatically. Thus, the repeated authentication of users and services occurring over time does not require human intervention; Alice types in her password exactly once.

Because of its elegant design and technical maturity, the Kerberos system has been widely accepted in local environments. Historically common in UNIX environments, it has recently been introduced into other operating systems (e.g., Windows 2000, XP).

Pretty Good Privacy

As indicated by the previous discussion of trusted third parties, it is often true that two parties on the Internet will not have a direct means of performing authentication. For example, a programmer in Great Britain may not have any formal relationship with a student in California. Hence, no trusted third party exists to which both can defer authentication. A number of attempts have been made to address this problem by establishing a single public key infrastructure spanning the Internet. However, these structures require that users directly or indirectly trust CAs whose operation they know nothing about. Such assumptions are inherently dangerous and have been largely rejected by user communities.

The pretty-good-privacy (PGP) system (Zimmermann, 1994) takes advantage of informal social and organization relationships between users on the Internet. In PGP, each user creates a self-signed PGP certificate identifying a public key and identity information (e.g., e-mail address, phone number, name). Users use the key to sign the keys of those users they trust. Additionally, they obtain signatures from those users who trust them. The PGP signing process is not defined by PGP. Users commonly will exchange signatures with friends and colleagues.

The keys and signatures defined for a set of users defines a *Web of trust*. On recept of a key from a previously unknown source, an entity will make a judgment as to whether to accept the certificate based on the presence of signatures by known entities. A certificate will likely be accepted if a signature generated by a trusted party (with known and acceptable signing practices) is present. Such assessment can span multiple certificates, where signatures create trusted linkage between acceptable certificates. However, because trust is not frequently transitive, less trust is associated with long chains. PGP certificates are primarily used for electronic mail but have been extended to support a wide range of data exchange systems (e.g., Internet newsgroups).

The PGP approach and other technologies are used as the basis of S/MIME standards (Dusse, Hoffman, Ramsdell, Lundblade, & Repka, 1998). S/MIME defines protocols, data structures, and certificate management infrastructure for authentication and confidentiality of MIME (multipurpose Internet mail extensions) data. These standards are being widely adopted as a means of securing personal and enterprise e-mail.

IPsec

IPsec (Kent & Atkinson, 1998) is emerging as an important service for providing security on the Internet. IPsec is not just an authentication service but also provides a complete set of protocols and tools for securing IP-based communication. The IPsec suite of protocols provides host-to-host security within the operating system implementation of the IP protocol stack. This has the advantage of being transparent to applications running on the hosts. A disadvantage of IPsec is that it does not differentiate between users on the host. Hence, although communication passing between the hosts is secure (as determined by policy), little can be ascertained as to the true identity of users on those hosts.

The central goal of the IPsec was the construction of a general-purpose security infrastructure supporting many network environments. Hence, IPsec supports the use of an array of authentication mechanisms. IPsec authentication can be performed manually or automatically. Manually authenticated hosts share secrets distributed via administrators (i.e., configured manually at each host). Identity is inferred from knowledge of the secret. Session keys are directly or indirectly derived from the configured secret.

The Internet security association key management protocol (ISAKMP) defines an architecture for automatic authentication and key management used to support the IPsec suite of protocols. Built on ISAKMP, the Internet key exchange protocol (IKE) implements several protocols for authentication and session key negotiation. In these protocols, IKE negotiates a shared secret and policy between authenticated endpoints of an IPsec connection. The resulting IPsec Security Association (SA) records the result of IKE negotiation and is used to drive later communication between the endpoints.

The specifics of how authentication information is conveyed to a host are a matter of policy and implementation. However, in all implementations, each host must identify the keys or certificates to be used by IKE authentication. For example, Windows XP provides dialogs used to enter preshared keys. These keys are stored in the Windows registry and are later used by IKE for authentication and session key negotiation. Note that how the host stores secrets is of paramount importance. As with any security solution, users should carefully read all documentation and related security bulletins when using such interfaces.

CONCLUSION

The preceding sections described only a small fraction of a vast array of available authentication services. Given the huge number of alternatives, one might ask the question: Which one of these systems is right for my environment? The following are guidelines for the integration of an authentication service with applications and environments.

Don't try to build a custom authentication service. Designing and coding an authentication service is inherently difficult. This fact has been repeatedly demonstrated on the Internet; bugs and design flaws are occasionally found in widely deployed systems, and several custom authentication services have been broken into in a matter of hours. It is highly likely that there exists an authentication service that is appropriate for a given environment. For all of these reasons, one should use services that have been time tested.

Understand who is trusted by whom. Any authentication system should accurately reflect the trust held by all parties. For example, a system that authenticates students in a campus environment may take advantage of local authorities. In practice, such authorities are unlikely to be trusted by arbitrary endpoints in the Internet. Failure to match the trust existing in the physical world has ultimately led to the failure of many services.

Evaluate the value of the resources being protected and the strength of the surrounding security infrastructure. Authentication is only useful when used to protect access to a resource of some value. Hence, the authentication service should accurately reflect the value of the resources being protected. Moreover, the strength of the surrounding security infrastructure should be matched by the authentication service. One wants to avoid "putting a steel door in a straw house." Conversely, a weak or flawed authentication service can be used to circumvent the protection afforded by the surrounding security infrastructure.

Understand who or what is being identified. Identity can mean many things to many people. Any authentication service should model identity that is appropriate for the target domain. For many applications, it is often not necessary to map a user to a physical person or computer, but only to treat them as distinct but largely anonymous entities. Such approaches are likely to simplify authentication, and to provide opportunities for privacy protection.

Establish credentials securely. Credential establishment is often the weakest point of a security infrastructure. For example, many Web registration services establish passwords through unprotected forms (i.e., via HTTP). Malicious parties can (and do) trivially sniff such passwords and impersonate valid users. Hence, these sites are vulnerable even if every other aspect of security is correctly designed and implemented. Moreover, the limitations of many credential establishment mechanisms are often subtle. One should be careful to understand the strengths, weaknesses, and applicability of any solution to the target environment.

In the end analysis, an authentication service is one aspect of a larger framework for network security. Hence, it is a necessary to consider the many factors that contribute to the design of the security infrastructure. It is only from this larger view that the requirements, models, and design of an authentication system emerge.

GLOSSARY

Authentication The process of establishing the identity of an online entity.

Authorization The process of establishing the set of rights associated with an entity.

Certificate A digitally signed statement associating a set of attributes with a public key. Most frequently used to associate a public key with a virtual or real identity (i.e., identity certificate).

Credential Evidence used to prove identity or access rights.

Malicious party Entity on the Internet attempting to gain unauthorized access, disrupt service, or eavesdrop on sensitive communication (syn: adversary, hacker).

Secret Information only known to and accessible by a specified (and presumably small) set of entities (e.g., passwords, cryptographic keys).

Trusted third party An entity mutually trusted (typically by two end-points) to assert authenticity or authorization, or perform conflict resolution. Trusted third parties are also often used to aid in secret negotiation (e.g., cryptographic keys).

Web of trust Self-regulated certification system constructed through the creation of ad hoc relationships between members of a user community. Webs are typically defined through the exchange of user certificates and signatures within the Pretty-Good-Privacy (PGP) system.

Benchmarking Internet

Vasja Vehovar, *University of Ljubljana, Slovenia*
Vesna Dolnicar, *University of Ljubljana, Slovenia*

INTRODUCTION

Benchmarking is often defined as a total quality management (TQM) tool (Gohlke, 1998). It is also one of the most recent words introduced into the lexicon of modern management (Keegan, 1998). Only since the mid-1980s have explicit benchmarking activities emerged.

With expanded benchmarking practices, a variety of professional associations have been established: the Benchmarking Exchange, Corporate Benchmarking Services, Information Systems Management Benchmarking Consortium, Telecommunications International Benchmarking Group, and International Government Benchmarking Association, to name a few. Similarly, there exist an increasing number of professional Web sites, among them the Benchmarking Exchange, Benchmarking in Europe, Public Sector Benchmarking Service, Best Practices, the Benchmarking Network, and Benchmarking. (Uniform resource locators for these organizations and Web sites are found in the Further Reading section.) A study being conducted among the members of the Benchmarking Exchange showed that the main search engine used among practitioners is Google.com, which includes almost 1 million benchmarking-related documents (Global Benchmarking Newsbrief, 2002).

The expansion also can be observed in numerous textbooks dealing either with the general notion of benchmarking or with specific benchmarking areas. Certain textbooks have already been recognized as classics (e.g., Camp, 1989). As far as periodicals are concerned, numerous professional and community newsletters arose from practical business activities, such as *eBenchmarking Newsletters* by the Benchmarking Network (n.d.), *Benchmarking News* by the European Association of Development Agencies (n.d.), and *ICOBC & Free Newsletter* by the International Council of Benchmarking Coordinators (n.d.). Benchmarking has also become a scientific issue within the field of quality management and specialized scholarly journals appeared (e.g., *Benchmarking—an International Journal and Process Management in Benchmarking*). The online academic databases searches such as *EBSCOHost—Academic Search Premier, Emerald* and *ABI/INFORM Global, Social Science Plus* show that in 2002 each of these databases already contained a minimum of 338 and a maximum of 939 papers related to benchmarking. The number of papers that relate simultaneously to benchmarking and to the Internet is considerably lower: from 3 in *Emerald* to 33 in the *EBSCOHost* database. Papers on benchmarking can be found mostly in *Internet Research, Quality Progress*, *Computerworld* and *PC Magazine*. When Longbottom (2000) reviewed approximately 500 benchmarking-related papers published between 1995 and 2000 and referenced on online academic indices (*ANBAR and Emerald*) as well as on various Internet sites, he found that the majority (80%) could be described as practical papers discussing specific aspects of benchmarking. The remaining academic papers are a mix of theory and development.

In the Web of Science, the leading science citation database, almost 2,000 benchmarking-related papers were found in 2002. Papers in this database most often refer to the issues of improving competitive advantage or to specific areas such as health care and education. Robert C. Camp, often recognized as the founder of the benchmarking concept, was the most frequently cited author in this database, with almost 700 citations. In 2002, there were almost 200 books about benchmarking available at the *Amazon.com* Web site.

Nevertheless, benchmarking predominantly relates to the business environment, although over the past few years we can observe also an increased usage in more general context. Sometimes the notion of benchmarking even appears as a synonym for any comparison based on quantitative indicators. As an example, in some studies even the simplest comparisons based on standardized statistical indicators have been labeled "benchmarking" (i.e., Courcelle & De Vil, 2001; Petrin, Sicherl, Kukar, Mesl, & Vitez, 2000). The notion of benchmarking thus has a wide range of meanings, from a specific and well-defined business practice to almost any comparison based on empirical measures. In this chapter, we use the notion of benchmarking in a broad context, although we concentrate on a specific application: the Internet. We must recognize that the Internet is a newer phenomenon than benchmarking, at least in the sense of general usage. We are thus discussing a relatively new tool (benchmarking) in a very new area (Internet). From the aspect of the scholarly investigation, the problem cannot be precisely defined. In particular, Internet-related topics can be extremely broad, as the Internet has complex consequences on a variety of subjects, from business units to specific social segments, activities, and networks, including the everyday life of the average citizen. Additional complexity arises because the Internet is automatically associated with an array of closely related issues (i.e., the new economy, new society, new business processes, new technologies) that are not clearly separated from the Internet itself. In certain areas, the Internet may have a rich and specific meaning that radically extends beyond its mere technical essence as a network of computers based on a common communication protocol.

In this chapter, we therefore understand benchmarking in its broadest sense but limit the scope of study, as much as possible, to its relation to the Internet and not to related technologies and the corresponding social and business ramifications. In particular, we limit this discussion to business entities and national comparisons.

In the following sections, we describe the notion of benchmarking in a business environment and also in a more general context, such as sectoral benchmarking and benchmarking of framework conditions. Next, we concentrate on benchmarking of Internet-related issues, particularly with regard to the performance of various countries. Key methodological problems are also discussed with specific attention to the dimension of time.

BUSINESS BENCHMARKING

A relatively sharp distinction exists between benchmarking at the company level and other types of benchmarking, which we consider extensions of the technique and discuss later in the chapter. First, we examine additional details related to the business benchmarking process.

The Concept of Benchmarking

The common denominator of various definitions of benchmarking is the concept of a "proactive, continuous process, which uses external comparisons to promote incremental improvements in products, processes, and services, which ultimately lead to competitive advantage through improved customer satisfaction, and achieving superior performance" (Camp, 1989, p. 3). The majority of authors also distinguish between *benchmarking* and *benchmarks*. The latter are measurements that gauge the performance of a function, operation, or business relative to others (i.e., Bogan & English, 1994, pp. 4–5). Similarly, Camp (1989) defined benchmark as a level of service provided, a process or a product attribute that sets the standard of excellence, which is often described as a "best-in-class" achievement. Benchmarking, in contrast to benchmarks, is the ongoing search for best practices that produce superior performance when adapted and implemented in an organization (Bogan & English, 1994). The *benchmarking process* is thus a systematic and continuous approach that involves identifying a benchmark, comparing against it, and identifying practices and procedures that will enable an organization to become the new best in class (Camp, 1989; Spendolini, 1992).

In general, two types of benchmarking definitions can be found. Some definitions are limited only to the measuring and comparing while the others focus also on implementation of change and the monitoring of results. Within this context Camp (1989, pp. 10–13) distinguished between *formal* and *working* definitions, with the latter emphasizing the decision-making component and the former relating to the measurement process alone.

As already noted, benchmarking is basically a TQM tool (Codling, 1996; Czarnecki, 1999; Gohlke, 1998). If quality management is the medicine for strengthening organizations, benchmarking is the diagnosis (Keegan, 1998, pp. 1–3). Although benchmarking readily integrates with strategic initiatives such as continuous improvement and TQM, it is also a discrete process that delivers value to the organization itself (American Productivity and Quality Center [APQC], 2002). At the extreme side, Codling (1996, pp. 24–27) did not classify benchmarking within the TQM framework at all but indicated that they are two separate processes that do not exist within a simple hierarchical relationship but are equal concepts with considerable overlap. We add that apart from TQM, benchmarking also integrates with reengineering (Bogan & English, 1994) and the Six Sigma approach (Adams Associates, 2002).

In the late 1970s, Xerox developed a well-known benchmarking project, considered a pioneer in the process (Rao et al., 1996). Xerox defined benchmarking as "a continuous process of measuring products, services, and practices against the toughest competitors or those companies recognized as industry leaders" (Camp, 1989, p. 10). Codling (1996) noted, however, that in the 1950s, well before the Xerox project, to U.K. organizations, Profit Impact of Marketing Strategy (PIMS) and the Center for Interfirm Comparison (CIFC) conducted activities that could be defined as benchmarking. PIMS and CIFC systematically gathered information on companies' performance and compared these data with those from similar businesses. Early seeds of benchmarking can be also found in the Japanese automotive industry when Toyota systematically studied U.S. manufacturing processes at General Motors, Chrysler, and Ford in the 1950s. Toyota then adopted, adapted, and improved upon their findings. All these examples confirm that companies actually used benchmarking well before 1970s, most often using the methods of site visits, reverse engineering, and competitive analysis (Rao et al., 1996).

The emphasis on formal benchmarking processes changed markedly only in 1990s, not only in the business sector, but also in regional and public sectors, particularly in Australia, New Zealand, and the United Kingdom. The initial understanding of benchmarking was rapidly extended in numerous directions. Modern benchmarking thus refers to complex procedures of evaluation, comprehension, estimation, measurement and comparison. It covers designing, processing, and interpreting of the information needed for a improved decision making. This relates not only to businesses but also to the performance of other entities, including countries. As a typical example, in the second benchmarking report comparing the performance of Belgium with other countries, Courcelle and De Vil (2001, p. 1) defined benchmarking as a continuous, systematic process for comparing performances against the best performers in the world.

Company Benchmarking

As noted earlier, benchmarking is usually a part of the quality management concept directed toward making products or services "quicker, better and cheaper" (Keegan, 1998, p. 12). The APQC (2002) suggested using benchmarking to improve profits and effectiveness, accelerate and manage change, set stretch goals, achieve breakthroughs and innovations, create a sense of urgency, overcome complacency or arrogance, see "outside the box," understand world-class performance and make better informed decisions. Within the business environment, benchmarking is most often performed in the fields of customer satisfaction, information systems, employee training, process improvement, employee recruiting, and human resources.

The literature describes many types of benchmarking processes. Camp (1995, p. 16) distinguished between four types of benchmarking: internal, competitive, functional, and generic. Similarly, Codling (1996, pp. 8–13) differentiated three types or perspectives on benchmarking: internal, external, and best practice. Bogan and English (1994, pp. 7–9) also presented three distinct types of benchmarking: process, performance, and strategic benchmarking (see also Keegan, 1998, pp. 13–16).

Benchmarking procedures are usually formalized in 4 to 12 stages (APQC, 2002; Bogan & English, 1994; Camp, 1995; Codling, 1996; Longbottom, 2000; Keegan, 1998; Spendolini, 1992). As Bogan and English (1994, p. 81) stated, the differences among benchmarking processes are often cosmetic. Most companies employ a common approach that helps them plan the project, collect and analyze data, develop insights, and implement improvement actions. Each company breaks this process into a different number of steps, however, depending on how much detail it wishes to describe at each step of the template. This does not mean that some companies exclude some steps, but in practice certain steps may naturally combine into one (Codling, 1996, p. xii). The four major stages that appear to be common to all classifications are as follows:

1. *Planning*. This step involves selection of the broad subject area to be benchmarked, defining the process, and other aspects of preparation. During the planning stage, organizations perform an internal investigation, identify potential competitors against which benchmarking may be performed, identify key performance variables, and select the most likely sources of data and the most appropriate method of data collection.
2. *Analysis*. This step involves collection of data (e.g., from public databases, professional associations, surveys and questionnaires, telephone interviews, benchmarking groups), determination of the gap between the organization's performance and that of the benchmarks, exchange of information, site visits to the benchmarked company, and observations and comparisons of process. A structured questionnaire asking for specific benchmarks, addressed to the similar or competitive business entities, is often a crucial step in collecting the data.
3. *Action*. This step involves communication throughout the organization of benchmarking results, adjustment of goals, adaptation of processes, and implementation of plans for improvement.
4. *Review*. This step involves review and repetition of the process with the goal of continuous improvement.

Another classification of the benchmarking process relates to the maturity of the company. In the early phase of the process, a company applies *diagnostic benchmarking*. The second phase is *holistic benchmarking,* in which the business as a whole is examined, identifying key areas for improvement. In the third, mature phase, the company graduates to *process benchmarking,* focusing on specific processes and chasing world-class performance (Keegan, 1998; O'Reagain & Keegan, 2000).

From these descriptions, it is clear that benchmarking activities are performed in a dialogue with competitors. As Czarnecki (1999, pp. 158, 254) pointed out, however, such a relationship does not happen overnight. Traditional barriers among competing companies must come down, and cooperation must be clearly demonstrated. Today's companies realize that to get information, they also have to give information.

Of course, for a successful implementation of change, it is important to build on the managerial foundation and culture rather than blindly adopting another organization's specific process. Edwards Deming, sometimes referred to as the father of the Japanese postwar industrial revival, illustrated this in his well-known saying that "to copy is too risky, because you don't understand why you are doing it. To *adapt* and not *adopt* is the way" (Keegan, 1998). Bogan and English (1994) pointed out that one company's effective benchmarking process design may fail at another organization with different operating concerns.

EXTENSIONS OF BENCHMARKING

Many authors (Keegan, 1998; O'Reagain & Keegan, 2000) strictly distinguish between benchmarking at the organizational (company, enterprise) level, benchmarking at the sector level, and, more generally, benchmarking of framework conditions. These extensions of benchmarking are the main focus in this section.

(Public) Sector Benchmarking

Public sector benchmarking is a natural extension of company benchmarking. Similar principles can be applied to the set of enterprises that make up an industry. Sector benchmarking thus focuses on the factors of competitiveness, which are specific to a particular industry (O'Reagain & Keegan, 2000). The usual aim here is to monitor the key factors that determine the ability of the sector to respond to continually changing international competitiveness.

During the past few decades, the notion of benchmarking extended also to a variety of nonindustrial fields, particularly to the public sector and especially to the social and welfare agencies in the health and education sector (Codling, 1996, p. 6). Of course, the goals of a public sector organization differ from those of a commercial company (O'Reagain & Keegan, 2000). For public sector organizations, benchmarking can serve as the surrogate for the competitive pressures of the market place by driving continuous improvement in value for money for taxpayers. Benchmarking can help public sector bodies to share best practices systematically with the private sector and with public bodies (e.g., government), as well as with other countries (Cabinet Office, 1999; Keegan, 1998, pp. 126–128).

A typical example of this type of benchmarking is the intra-European Union (EU) and EU—U.S. study on the performance of the national statistical offices. The comparisons of explicit benchmarks related to consideration of the time lag between data collection and the release of the economic statistics, which showed considerable lag within the EU statistical system (Statistics Sweden and Eurostat, 2001, p. 12). The study also showed, however, that in the EU international harmonization of economic statistics has been an important priority over the last decade. Further harmonization on a global level (guided by the United Nations, International Monetary Fund, and Organization for Economic Co-operation and Development [OECD]) is regarded as a much more important part of the statistical work in Europe compared with the United States, where complying with international standards has been of less importance.

Recognition that award models derived for commercial organizations can be equally applied to public sector organizations has also increased in recent years. To provide a consistent approach to assessment, some authors suggest the use of the European Foundation for Quality Management (EFQM) model for business excellence (e.g., Cabinet Office, 1999; Keegan, 1998, pp. 45–47). Keegan (1998, pp. 126–130) also mentioned "Hybrid Benchmarking," a technique that compares performance against others in both private and public sectors. Here the sources of information are similar work areas within the organization of the public sector (government departments and other public bodies) and the private sector.

Framework Conditions Benchmarking

The benchmarking method traditionally has been applied at the organizational and sector levels to evaluate the performance of the management processes, but it has been extended to the identification and the evaluation of key factors and structural conditions affecting the entire business environment. This extension is usually called the framework conditions benchmarking (Courcelle & De Vil, 2001, p. 2).

Benchmarking of framework conditions typically applies to those key elements that affect the attractiveness of a region as a place to do business. These elements can be benchmarked on a national or regional level: macroeconomic environment, taxation, labor market, education, transportation, energy, environment, research and development, foreign trade, and direct investment, as well as information and communication technology (ICT) (Courcelle & De Vil, 2001; Keegan, 1998, pp. 20–21).

Benchmarking of framework conditions therefore usually involves regions or states comparing the regulations, processes and policies that affect the business environment. Benchmarking of framework conditions usually provides an instrument for evaluating the efficiency of public policies and for identifying steps to improve them by reference to worldwide best practice (European Conference of Ministers of Transport, 2000, p. 12).

The philosophy and practice of benchmarking are roughly similar in different domains of application. However, there is an important difference in the feasibility of using results in the case of the framework conditions benchmarking, because the political power to implement changes is often lacking. Therefore one of the most important elements of the benchmarking best practice may be missing.

Benchmarking on the (Inter)national Level

In recent years, the notion of benchmarking has become extremely popular in the evaluation and comparison of countries. Theoretically, this type of benchmarking arises from benchmarking framework conditions; however, two specifics are worth noting.

Standardized comparative indicators have existed for centuries, yet the explicit label of benchmarking strongly emerged for these comparisons only with the rise of the Internet and with recent comparisons of ICT developments. Often, such notion of benchmarking for country comparisons is relatively isolated from the rich theory and practice of benchmarking. Today, we can observe national reports based on simple comparisons of indicators that are referred to as benchmarking studies; these include *Benchmarking the Framework Conditions: A Systematic Test for Belgium* (Courcelle & De Vil, 2001) and *Benchmarking Slovenia: Evaluation of Slovenia's Competitiveness, Strengths and Weaknesses* (Petrin et al., 2000). The essence of the benchmarking concept are evident in these studies because the indicators are compared with leading, comparable, or competitive countries.

Similarly, within the European Union, the notion of benchmarking has become a standard term for comparisons of the member states. Typical examples of such research are the periodic benchmark studies on the gross domestic products per capita and per employed person. In a more advanced setting, benchmarking refers to a complex process of establishing and monitoring the standardized set of indicators of the information society (e.g., Conseil de l'Union européenne, 2000).

BENCHMARKING INTERNET

Internet and Company Benchmarking

The Internet is rapidly being integrated into every facet of organizations' overall strategy and operation. Many organizations have expanded their direct-to-consumer business model, employing multiple Internet strategies to customize customer information, track customer development trends and patterns, and increase customer savings as a means to build strong relationships with their customers (Best Practices, 2000, 2001; Martin, 1999). These changes have had a major impact on the benchmarking process as well.

ICT systems are not only being benchmarked, they are also the key enablers of successful benchmarking. Current ICT systems permit users to generate, disseminate, analyze, and store vast amounts of information quickly and inexpensively. When poorly managed, however, ICT can annoy customers, slow cycle times, saddle the corporation with excessive costs, and damage productivity—all to the disadvantage of the organization (Best Practices, 2001; Bogan & English, 1994, pp. 171, 188). The benchmarks that provide the comparative insight into the role of the ICT are thus extremely important, particularly because the implementation of the ICT requires long-term strategic planning and significant investment.

The process of the Internet benchmarking on the organizational level still lacks a set of universally recognized benchmarks. Nevertheless, on the basis of several sources (e.g., Benchmark Storage Innovations, 2002; Bogan & English, 1994; Haddad, 2002; Tardugno, DiPasquale, & Matthews, 2000) we can broadly classify these benchmarks into three categories.

First, when benchmarking features and functionality, indicators usually measure the following:

- Characteristics of software and hardware (e.g., server, database, multimedia, networks, operating systems and utilities, security infrastructures, videoconference systems, corporate intranet and extranet, type of Internet connection and connection, download and upload speed)
- Purchase of new technology (e.g., share of new computers according to the number of all computers)
- Costs of technology and the organization's budget for ICT
- Software and network security administration
- Computer system performance (processing speeds, central processing unit efficiency, CD-ROM drive access speeds, performance analysis of networking and communications systems, reliability and performance modeling of software-based systems, error rates)

Second, while exploring the measures related to the use of ICT, an organization can measure the processes related to the outside environment, including its clients (customer-oriented benchmarks), or it can evaluate the use of ICTs within the organization (employee-oriented benchmarks). Customer-oriented benchmarks reflect the following:

- The extent to which ICTs have been incorporated into economic activity, such as use of the Internet in a company's transactions (i.e., electronic commerce)
- Types of e-business processes (such as Web sites with no transactions, Web-based e-commerce, electronic marketplace, etc.)
- The characteristics of strategic information technology projects (e.g., mobile or wireless commerce offerings; electronic supply chains; participation in electronic marketplaces; the organization's Web site capacity, performance, and usability; customer service and support infrastructure; creation of "localized" Web sites for customers in other countries, etc.)

Employee-oriented benchmarks typically examine the following:

- Key applications running in the organization
- Number of employees that use ICTs and the technical skills evolved
- Level of training provided for employees to use ICTs effectively
- Information system indicators reflecting organizational learning and continuous improvement
- Diffusion of telework
- New product development times
- Employee suggestion and process improvement rates
- Use of software (e.g., databases and telecommunication networks) by employees
- ICT usability

Third, when an organization explores the benefits attributed to the employment of Internet and other ICTs, it typically observes the following benchmarks:

- Increased efficiency, productivity, and performance of the organization
- Improved workstation comfort and job satisfaction
- Fewer problems in the production stage
- Broader customer base in existing and international markets
- More effective communication with customers, employees, and suppliers
- Fewer customer complaints
- Increased customer loyalty
- Better financial management
- Better integration of business processes

Measurement instruments and indicators used in the benchmarking process depend on the type of organization, its communication and business processes, the social context within which it operates, the characteristics of the employees and clients, and so on. Consequently, when evaluating features, functionality, use, and benefits of ICT, different practitioners focus on different benchmarks. In addition, most of the benchmarks described here can be measured from different perspectives; for example, a practitioner may concentrate on extent, intensity,

Table 1 Internet Benchmarks

	A[a]	B[b]	C[c]	D[d]	E[e]	F[f]	G[g]	H[h]
ICT Infrastructure								
Number of Internet hosts	x		x	x			x	x
Percentage of computers connected to the Internet			x					
Households with access to the Internet		x		x			x	
Wireless Internet access						x		
Number of Web sites								x
Price and quality of Internet connection			x				x	
Cable modem lines per 100 inhabitants				x				
Digital subscriber lines (DSL) per 100 inhabitants				x				
Network Use								
Percentage of population that (regularly) uses the Internet	x	x	x		x	x	x	x
Internet subscribers per 100 inhabitants				x			x	
Cable modem, DSL, and Internet service provider (ISP) dial-up subscribers				x				
Hours spent online per week					x			
Mobile and fixed Internet users						x		
Primary uses of the Internet					x			
Primary place of access					x			
Perception of broadband Internet access			x					
Secure Networks and Smartcards								
Number of (secure) Web servers per million inhabitants		x		x			x	x
Percentage of Internet users with security problems		x		x				
Faster Internet for Researchers and Students								
Speed of interconnections within national education networks		x						
E-commerce								
Internet access costs		x	x	x				x
Percentage of companies that buy and sell over the Internet		x		x		x		
Percentage of users ordering over the Internet				x		x		x
Business-to-consumer e-commerce transactions (% of gross domestic product)			x			x		x
Average annual e-commerce/Web spending per buyer						x		
Internet sales in the retail sector (%)				x				
Consumer Internet purchases by product				x	x	x		
Payment methods						x		
Future e-commerce plans						x		
Business intranet sophistication			x					
Online ad placement by type of site					x			
Internet advertising revenues—source comparison					x			
Domestic venture capital investment in e-commerce			x					
Competition in dot-com market			x					
Prevalence of Internet startups			x					
Use of Internet-based payment systems			x					
Sophistication of online marketing			x					
Price as barrier of e-commerce								x
Networked Learning								
Computers connected to Internet per 100 pupils		x						
Computers with high-speed connections per 100 pupils		x						
Internet access in schools		x	x					
Teachers using the Internet for noncomputing teaching		x						
Working in the Knowledge-Based Economy								
Percentage of workforce using telework		x						
Computer workers as a percentage of total employment				x				
Participation for All								
Number of public Internet points (PIAP) per 1,000 inhabitants		x						
Availability of public access to the Internet			x					

Table 1 (Continued)

	A[a]	B[b]	C[c]	D[d]	E[e]	F[f]	G[g]	H[h]
Central government Web sites that conform to the Web Accessibility Initiative (WAI)		x						
Government Online								
Percentage of basic public services available online		x	x					
Public use of government online services		x						
Percentage of online public procurement		x						
Government effectiveness in promoting the use of information and communication technology			x					
Business Internet-based interactions with government			x					
Health Online								
Percentage of health professionals with Internet access		x						
Use of different Web content by health professionals		x

quality, efficiency, mode of use, familiarity, or readiness of the certain component.

Internet and Sector Benchmarking

Sector benchmarking focuses on the factors of competitiveness, specific to a particular industry. Because of its powerful impact—which is sometimes unclear or even contradictory—it is particularly important that Internet is benchmarked within the whole sectors. The need for this practice is especially crucial in ICT-related sectors.

Typically, telecommunication companies have used benchmarking to evaluate digital versus analog technology. Benchmarks included one-time costs, maintenance costs per line, minutes of downtime per line per month, and various performance measures for processing time and failures (Bogan & English, 1994, p. 171). The Internet is being benchmarked beyond the ICT sector, however. New technologies, especially Internet-based information and service delivery, offer immense possibilities to meet a range of sector objectives. If appropriately deployed, ICT can help facilitate crucial economic and social development objectives in all sectors (World Bank Group, 2001, p. 67).

Internet and Framework Conditions Benchmarking

Framework conditions benchmarking focuses on improving the external environment in which organizations operate. One of the key elements affecting the national or regional business environment is the presence and nature of ICT. Lanvin (2002, p. xi) thus raised an important question: whether societies with different levels of development can turn the ICT revolution into an instrument that reduces the risk of marginalization and alleviates poverty. The realities in this broad and complex area require a clear assessment of how well equipped a region or country is to face the challenges of the information-driven economy (Lanvin, 2002, p. xi). So, before an action is taken, the so-called digital divide among less developed countries and the most developed countries or regions must be estimated. In other words, only when standardized indicators are available can the challenge of bridging the global digital divide be addressed.

INTERNATIONAL COMPARISONS

In this section, the key Internet indicators related to country comparisons are presented, together with their methodological specifics. The international organizations and projects that collect or present these data are briefly introduced.

Standardized Internet Benchmarks

From a technological perspective, the Internet is a global network of computers with a common communicating protocol. The corresponding social consequences of this phenomenon are extremely complex, however so we cannot avoid the benchmarks that relate not only to the Internet but also those linked to other ICT and to society. Of course, the line between the Internet and more general ICT benchmarks may be relatively vague. We limit the discussion here only to those benchmarks that are closely linked to the Internet.

In recent years, there has been a great deal of conceptual discussion about measuring Internet and the information society. The rapidly changing phenomena in this area have also challenged the process of scientific production, particularly in the social sciences, as well as the production of official statistical indicators. In last few years, however, the key Internet-related benchmarks converged to form relatively simple and commonsense standardized indicators (Table 1). This simplification corresponds to a relative loss of the enthusiasm for the so-called new economy, information society, and new business models that has recently occurred.

The quest for standardized indicators for Internet benchmarking has perhaps been strongest in the EU. In part, this is because the EU's official and ambitious goal is to surpass the United States within the next decade as the technologically most advanced society. In addition, the EU urgently needs valid comparisons among its 15 members as well as the 10 countries that will join in 2004. In addition to official EU documents regulating the standards for information society benchmarks (Benchmarking eEurope, 2002), a variety of research projects have emerged, one of the most comprehensive of which is the EU research program Statistical Indicators Benchmarking the Information Society (SIBIS, 2002). The conceptual framework for statistical measurements used by SIBIS was extensively developed for all key areas of the ICT-related phenomena—from e-security and e-commerce to e-learning, e-health, and e-government.

Currently, of course, only a small portion of the proposed indicators is being collected. Table 1 roughly summarizes only the key and most often applied benchmarks in the field of Internet-related country comparisons. In compiling the list, we sought a balance between Internet and the related ICT benchmarks and tried to avoid more general ICT indicators, such as those from the broad field of telecommunications.

The columns in Table 1 relate to the selected organizations that have published these data. Of course, the work of many other organizations was omitted because of space limitations and the scope of this chapter. Only the key international bodies and projects that systematically collect and present Internet benchmarks are listed. In addition, we also included two examples of the private companies, NUA (http://www.nua.com), which was one of the first to collect secondary data on worldwide Internet users (column E), and the International Data Corporation (IDC; http://www.idc.com), the leading global consulting agency specializing in international ICT studies (column F). In the last column (column H), the example of the benchmarks included in a typical national report (e.g., Belgium) on ICT is presented (Courcelle & De Vil, 2001). We now briefly describe the sources of the data in the Table 1.

European Information Technology Observatory (EITO)

This broad European initiative has as its objective the provision of an extensive overview of the European market for ICT within a global perspective. EITO publishes a yearbook that presents the most comprehensive and up-to-date data about the ICT market in Europe, together with the global benchmarks, particularly those related to United States and Japan (EITO, 2002). The majority of benchmarks that measure financial aspects (e.g., ICT investments) rely on data gathered by IDC. From the beginning the EITO has been strongly supported by the European Commission, Directorate General Enterprise, and Information Society, and since 1995 also by the Directorate for Science, Technology and Industry of the OECD in Paris (EITO, 2002). The annual EITO reports include the key benchmarks and also in-depth discussion of the contemporary ICT issues.

Benchmarking *e*Europe

This is the official European Union benchmarking project in the filed of ICT, begun in November 2000, when the European Council identified 23 indicators to benchmark the progress of the *eEurope Action Plan.* Indicators measure many aspects of ICTs, including e-commerce, e-government, e-security, e-education, and e-government. The facts and figures from this benchmarking program will be used to evaluate the net impact of *e*Europe and the information society, to show the current levels of activity in key areas, and to shape future policies by informing policy makers (Benchmarking *e*Europe, 2002).

The Global Information Technology Report (GITR) 2001–2002

Readiness for the Networked World is a project supported by the Information for Development Program (*info*Dev, http://www.infodev.org), a multidonor program administered by the World Bank Group (Lanvin, 2002, p. xi; World Bank Group, 2001, p. iii). At the core of the GITR is the *Networked Readiness Index,* a major comparative assessment of countries' capacity to exploit the opportunities offered by ICTs. *The Networked Readiness Index* provides a summary measure that ranks 75 countries on their relative ability to leverage their ICT networks.

Organization for Economic Co-operation and Development

The OECD groups 30 countries sharing a commitment to democratic government and the market economy. With active relationships with some 70 other countries, nongovernmental organizations, and civil societies, the OECD has a global reach. Best known for its country surveys and reviews, its work covers economic and social issues from macroeconomics to trade, education, development, and science and innovation. The OECD produces internationally agreed upon instruments to promote rules of the game in areas in which multilateral agreement is necessary for individual countries to make comparisons and progress in a global economy. Within OECD, the Statistical Analysis of Science, Technology and Industry is also conducted, together with the development of the international statistical standards for this field. Among other responsibilities, the OECD's work in this area seeks ways of examine and measure advances in science and technology and reviews recent developments in information and communication technologies (OECD, n.d.). Several internationally comparable indicators are formed within the field of the information economy, such as resources and infrastructure for the information economy, the diffusion of Internet technologies and electronic commerce, ICTs (software and hardware). The OECD also established The Committee for Information, Computer and Communications Policy (ICCP), which addresses issues arising from the digital economy, the developing global information infrastructure, and the evolution toward a global information society. In 2002, OECD published the *OECD Information Technology Outlook,* which provides a comprehensive analysis of ICTs in the economy, ICT globalization, the software sector, e-commerce, ICT skills, the digital divide, technology trends, and information technology policies.

NUA Internet Surveys

As a global resource on Internet trends, demographics, and statistics, NUA offers news and analysis updated weekly. It compiles and publishes Internet-related survey information from throughout the world. NUA is particularly known for its unique "How Many Online?" feature, which offers an estimate of the global Internet user population based on extensive examination of surveys and reports from around the world (NUA, n.d.). The value and importance of this work rapidly diminishes as more reliable and standardized indicators have begun to appear.

International Data Corporation (IDC)

IDC is a commercial company and the world's leading provider of technology intelligence, industry analysis, market data, and strategic and tactical guidance to builders, providers, and users of IT (IDC, n.d.). Thus, IDC is perhaps the most reliable global source for the number of personal computers sold in certain country or region. In addition to individual research projects and more than 300 continuous information services, IDC also provides a specific Information Society Index (ISI), which is based on four infrastructure categories: computer, information, Internet, and social infrastructures. The ISI is designed for use by governments to develop national programs that will stimulate economic and social development. It is also a tool for IT, dot-coms, and asset management and telecommunications companies with global ambitions to assess the market potential of the various regions and countries of the world (IDC, 2002a, 2002b).

International Telecommunication Union (ITU)

Headquartered in Geneva, Switzerland, ITU is an international organization within the United Nations System in which governments and the private sector coordinate global telecom networks and services. Established in 1865, ITU is the one of the world's oldest international organization. ITU's membership includes almost all countries and more than 500 private members from telecommunication, broadcasting, and IT sectors. ITU regularly publishes key telecommunication indicators, including the Internet-related benchmarks (ITU, n.d.).

Benchmarking Belgium

Benchmarking Belgium (Courcelle & De Vil, 2001) is a typical national ICT benchmarking study with the goal of comparing ICT developments in Belgium with comparable countries.

Other organizations also provide international Internet-related benchmark indicators. The indicators are usually similar to those already covered in Table 1, however. A brief listing of the most important of these follows.

The *Human Development Report*, commissioned by the United Nations Development Programme (UNDP), covers more than 100 countries annually. In 2001, the report was titled *Making New Technologies Work for Human Development*. It presents statistical cross-country comparisons that have been built up through cooperation of many organizations (e.g., several UN agencies, OECD, ITU, the World Bank). Report contains many composite indexes, such as the technology achievement index designed to capture the performance of countries in creating and diffusing technology and in building a human skills base (UNDP, 2001).

United Nations Industrial Development Organization (UNIDO) benchmarked a set of industrial performance and capability indicators and ranked 87 countries. *The Industrial Development Report 2002/2003* is intended to help policy makers, business communities, and support institutions assess and benchmark the performance of their national industries and analyze their key drivers (UNIDO, 2002).

Benchmarking is also relevant to the United Nations Educational, Scientific and Cultural Organization (UNESCO), particularly within the field of higher education. UNESCO has established Observatory of the Information Society with the objectives of raising awareness on the constant evolution of ethical, legal, and societal challenges brought about by new technologies. It aims to become a public service that provides updated information on the evolution of the information society at the national and international levels (WebWorld, 2002).

In 2001 The World Bank Group gathered data that allow comparisons for almost all existing countries available in the World Development Indicators database. Included are also indicators that measure infrastructure and access, expenditures, and business and government environment in relation to ICT.

In the United Kingdom, the Department of Trade and Industry (DTI) has sponsored research on levels of ownership, usage, and understanding of ICTs by companies of all sizes and within all sectors in benchmarked countries. The report Business in the Information Age benchmarks businesses in the United Kingdom against those in several European countries, the United States, Canada, Japan, and Australia (DTI, 2002). Also in the United Kingdom, the Office of Telecommunications (2002) issued the International Benchmarking Study of Internet Access, covering both basic dial-up access and broadband services (i.e., DSL and cable modem).

The number of institutions that publish some Internet-related measurements on international level is higher each year. It is hoped that this will also lead to accelerated establishment of standardized instruments for statistical comparisons.

Technical Measurements

The benchmarks presented in Table 1 included almost none of the performance metrics of ICT infrastructure, although they are extremely important Internet benchmarks. The technical benchmarks related to the ICT infrastructure predominantly include specific information on computers. Also relevant are the characteristics of modems and the type of Internet connection. Here, some of the most interesting benchmarks also overlap with those already outlined in the Internet and Company Benchmarking section (i.e., the type of software and hardware).

One of the central devices for the Internet technical measurement is the Internet host, where the measurements relate to corresponding speed, access, stability, and trace-route. The speed is usually expressed in the amount of information transmitted per second. Beside technical characteristics of modems and computers, the processing speed is determined by network speed between the hosts, which depends on the Internet service providers' and national communication infrastructures. In particular, the *capacity* of the total national communication links is often used as an important benchmark for the country comparisons. The access and stability are related concepts; *stability* is checked on a local level and is defined in terms of host's interruptions. The *access* stands for stability on a global level; it tells us how accessible the host is from one or more points in the Internet network. Also important are the *trace-route* reports, in which we can observe the path where data packets travel as they leave the user's computer system. More direct routes to the key international communication nodes may indicate better national infrastructure.

THE METHODOLOGICAL PROBLEMS

Of course, because of their newness, all Internet benchmarks are relatively unstable and typically face severe methodological problems. This is understandable, because these phenomena occurred relatively recently and therefore little time has been available for the discussion of methodological issues. Often, they also exhibit extremely high annual growth rates, measured in tens of percentages. In addition, the new technological improvements continuously change the nature of these phenomena and generate a permanent quest for new indicators. As a consequence, in mid-1990s this rapid development almost entirely eliminated the official statistics from this area. Instead, the private consulting agencies took the lead in ICT measurements. Thus, for example, the IDC produces many key internationally comparable data on the extent and structure of the ICT sectors.

In last few years, the efforts in official statistics and other noncommercial entities took some important steps toward compatibility. The activities within OECD particularly in Scandinavian countries, Australia, Canada, and the United States, have been particularly intensive. The United States took the lead in many respects, what was due not so much to the early Internet adoption but to early critical mass achieved in that country. In the United States, there were already millions of the Internet users by mid-1990s, a fact that many commercial organizations considered worthy of research. The U.S. government also reacted promptly, so, for example, in addition to numerous commercial measurements, official U.S. Census Bureau figures are available for business-to-customer and business-to-business sales from the end of the 1990s. The EU, in comparison, is only in the process of establishing these measurements for 2003. With respect to more sociological benchmarks, the National Telecommunications and Information Administration (2002) conducted pioneering research on the digital divide. The Pew Research Center (n.d.), a U.S. nonprofit organization, conducts important research that sets standards for sociological Internet benchmarks.

In the reminder of this section, we discuss some typical methodological problems related to the Internet benchmarks. The discussion is limited to the two most popular benchmarks in the field of Internet-related national performance: the number of Internet users and the number of Internet hosts. We believe that the methodological problems are very much typical for other indicators listed in Table 1.

Number of Internet Users

The number of Internet users heavily depends on the definition applied, an issue for which three methodological problems can be cited.

1. The Specification of Time

When defining the Internet user, usage during the last three months is often applied (NUA, 2002). Even more often, the Internet user is defined with simple self-classification, in which a question such as "Do you currently use the Internet" is asked on a survey. Experience shows that a positive answer to this question results in about 3–5% overestimation compared with questions asked among monthly users (e.g., people who claim to use the Internet on a monthly basis). Typically, usage during the last three months reveals up to a third more users compared with the category of monthly users. In the case of weekly users, which is another important benchmark, the figure shrinks to about one fifth compared with monthly Internet users. A huge variation thus exists in the number of Internet users only because of the specified frequency of usage. In addition, when asking for the Internet usage from each location separately (e.g., home, school, job), the figure increases considerably compared with asking a general question that disregards location. The timing of the survey has also a considerable impact: February figures can dramatically differ from the November figures of the same year. Unfortunately, the explicit definitions (e.g., working, timing) applied are typically not clearly stated when numbers of Internet users are published.

2. The Base and Denominator for Calculating Percentages

The number of Internet users is often observed as a share within the total population. This may be a rather unfair comparison because of populations' varying age structures and may produce artificially low figures for certain countries. Instead, often only the category 18+ is included in research, particularly in the United States. In Europe, users older than 15 years (15+) have become the standard population. The population aged 15 to 65 is also used as a basis for calculations, whereas media studies usually target the population aged 12 to 65 or 10 to 75. For a country with Internet penetration reaching about a quarter of the population, discrepancies arising from varying target populations (e.g., the basis in the denominator) vary dramatically, from the lowest Internet penetration of 20% in the population 15+ to the highest penetration of 30% in the population aged 15 to 65.

3. Internet Services Used

When asking about the Internet usage, typically only the Internet is mentioned in the survey question. Increasingly often the definition explicitly includes also the usage of the e-mail. However, here we instantly face the problem of non-Internet-based email systems. Some other definitions also include Wireless Application Protocol and other mobile Internet access methods as well as WebTV. No common international standards have been accepted. An attempt to establish such guidelines may be jeopardized with the emerging and unpredictable devices that will enable the access to the Internet. In the future, the definitions will have to become much more complex, so the potential danger for improper comparisons will also increase. The development of the standardized survey question is thus extremely important.

In addition to the these three problems, we should add that the number of Internet users is typically obtained from some representative face-to-face or telephone survey, which creates an additional and complex set of methodological problems related to the quality of survey data (sample design issues, nonresponse problems, etc.).

Another approach to estimate the number of Internet users is through models in which the number of Internet hosts and other socioeconomic parameters (i.e., educational statistics, gross domestic product) come as an input. This may be a problematic practice. A much more promising approach are so-called PC-meter measurements, in which the representative sample of Internet users is determined by installing a tracking software that records a person's Internet-related activities (e.g., Nielsen-Netratings, MediaMatrix). Despite serious methodological problems—particularly due to the non-household-PC access (i.e., business, school) and non-computer access (i.e., mobile)—this approach seems to be one of the most promising. The key advantage here is that it is not based on a survey question but on real-time observations. Another advantage is the convenience arising from the fact that the leading PC-meter companies already perform these measurements on a global level.

Number of Internet Hosts

The number of Internet hosts is perhaps the most commonly used Internet benchmarks. The reason for this is a relative easiness of its calculation and the regular frequency of these measurements. The Network Wizards (http://www.nw.com/) and Réseaux IP Européens (RIPE) (http://www.ripe.net/) are typical examples of the organizations that gather these kinds of statistics. There are severe methodological problems related to these measurements, however.

Device

The term "host" usually relates to a device that is linked to the Internet and potentially offers some content to the network. It also relates to a device with which users access the Internet. During an Internet session, each device has its Internet protocol (IP) number. The device is typically a computer; however, it can also be a modem used for a dial-up access. In the future, other devices—mobile phones, televisions, and perhaps even home appliances such as refrigerators—will also have IP numbers. National differences in the structure of those devices may post severe problems for international comparisons. Some other national specifics may also have some impact, such as a relatively large number of IP numbers partitioned on one server.

Dial-Up Modems

The most critical type of the host device is a dial-up modem, which usually serves about 100 users (e.g., households or companies) monthly. As a consequence, in each session the dial-up user connects to the Internet through a different and randomly selected modem (IP number). In countries with larger numbers of dial-up access users, the host count may underestimate the reach of the Internet.

Proxy Servers

In businesses and organizations, one computer or server may be used as the proxy host for Internet access for all computers within the local network. All the users (e.g., employees) may appear to use the same host number. Countries with a large number of such local networks may underestimate their Internet penetration.

Domain Problems

In host count statistics, all the hosts under a country's national domain are attributed to that country. The countries with restrictive domain-registration policies force their subjects to register their domains abroad, however. Consequently, a considerable number of hosts may be excluded from the national domain count. The Slovenian example is typical. Until 2003, only a company's name and trademark could receive the national domain name ".si," so up to one third of all hosts are registered under ".com," ".net," and other domains. It is true that with some additional procedures, the hosts can be reallocated to the proper country, as is typically done for the OECD. This requires additional resources, however, and is not available in the original host count data.

Technical Problems

The host count measurements are basically performed with a method "pinging" in which the computer signal is sent to a certain host number. Because of increased security protection for the local networks, the methodologies must be permanently adopted. Thus, for example, a few years ago the Network Wizards (NW) had to break the original time series of its measurements with a completely new measurement strategy. The differences between RIPE and NW are also considerable for certain countries. Local measurements can be somewhat helpful here; however, the regional or national partner may not report regularly, so a large dropout rate may result, as was often the case with RIPE data for Italy. There is also the problem of global commercial hosting, in which businesses from one country run their Web activities in the most convenient commercial space found in another country.

In the future, the host count measurement will have to upgrade measurement techniques continuously, and there will always remain certain limitations when inferring national Internet development from host count statistics.

These methodological problems related to Internet users and hosts also affect other benchmarks listed in Table 1. Thus, a general warning should be raised when using this kind of data. In particular, the methodological description must be closely observed.

Despite severe methodological problems, the national benchmarks in Table 1 offer reasonable and consistent results. Of course, with certain countries additional factors must be considered in the interpretation of data. In the future, because of the increased need for standardized, stable, and longitudinal benchmarks, we can expect that at least some of them will become standard. Another reason for this is that many phenomena have already profiled themselves and settled down in a stable and standardized form. For others, and particularly for new methods, users may have to struggle through the certain period of ambiguity during which no standardized or official indicators are available.

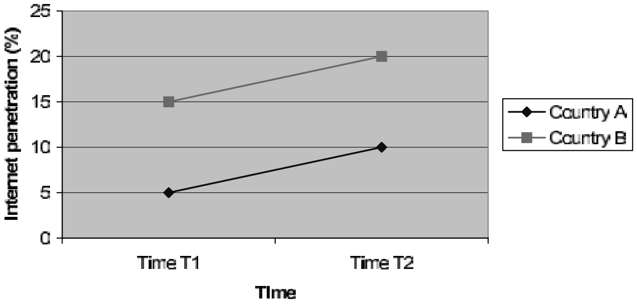

Figure 1: Internet penetration in Time 1 and in Time 2.

THE DIMENSION OF TIME

Benchmark comparisons are usually performed within time framework, so this benchmarking dimension is of great significance. Observing benchmarks through time can be extremely problematic because the straightforward comparisons of fixed benchmarks may not suffice in a rapidly changing environment.

As an example, the increase in Internet penetration from 5% in Time T1 to 10% in Time T2 for Country A demonstrates the same absolute increase in penetration as experienced by Country B with the corresponding increase from 15% (T1) to 20% (T2). In an absolute sense, one could say there had been an identical increase in Internet penetration (e.g., 5%). Similarly, the gap between the countries remains the same (e.g., 15 − 5 = 10% in time T1 and 20 − 10 = 10% in time T2).

In a relative sense, however, the increase in Country A from T1 to T2 was considerably higher:—(10 – 5)/10 = 50%, compared with (15 – 10)/15 = 33% in Country B. Similarly, the amount of the relative difference between the countries dramatically shrunk from (15 − 5)/15 = 75% at T1 compared with (20 – 10)/20 = 50% in T2. Correspondingly, at T1 Country A reached 15 – 5/15 = 33% of the Internet penetration of country B, whereas at T2 it already had reached (20 − 10)/20 = 50% of the penetration in Country B.

It is only a matter of subjective interpretation whether the differences in Internet penetration between the two countries remained the same (e.g., 5%) or decreased (e.g., Country A is reaching 50% of the penetration of Country B at T2 instead of only 33% at T1). Paradoxically, as will be shown later, the gap from T1 to T2 between these two countries most likely increased.

Of course, these differences may seem trivial because they refer to the usual statistical paradoxes, which can be dealt with a clear conceptual approach about what to benchmark together with some common sense judgment. It is much more difficult to comprehend and express the entire time dimension of the comparison in this example. The fact is that all the information regarding the time lag between the countries cannot be deduced directly from these data (Figure 1). To evaluate the entire time dimension, one would need the diffusion pattern of the Internet penetration or at least some assumptions about it. Typically, we assume that at T2 Country A will follow the pattern of Country B (Sicherl, 2001). For Figure 1 we could thus deduce, using a simple linear extrapolation, that Country A would need 2 × (T2 – T1) time units (i.e. years) to reach the penetration of the country B at T2, what is usually labeled as a time distance between the two countries.

It is also possible, however, that at T1 Country A will need, for example, 3 years to reach the penetration of Country B at T1, whereas at T2, Country A may need 5 years to reach Country B’s penetration at T2. Such an increase in lag time is expected for Internet penetration because its growth is much higher during the introductory period. Typically, much less time is needed for an increase in penetration from 5 to 10% compared with an increase from 55 to 60%. The opposite may also be true, however, as the differences in time may shrink from 3 years at T1 to 2 years at T2; it depends on the overall pattern of the Internet diffusion process.

Figure 2 demonstrates these relationships for the case of the two-dimensional presentation of the host density (the number of Internet hosts per 10,000 habitants) for Slovenia and the EU average (1995–2001). We expressed the Slovenian relative host density as the percentage of the density reached in the EU as the first dimension. The other dimension expresses the differences in terms of time distance, that is, the number of years Slovenia would need to catch up to the EU average. The method of time distance, which extrapolates the existing growth to the future, was applied here (Sicherl, 2001). In July 1995, Slovenia reached almost 40% of the EU average and in January 1997, it reached almost 90%, whereas in January 2001, it returned to 40% of the EU average. On the other hand, the corresponding time lag increased from about 1 year in 1995 to more than 3 years in 2001. The same figure for the relative benchmark (e.g., 40% in 1995 and

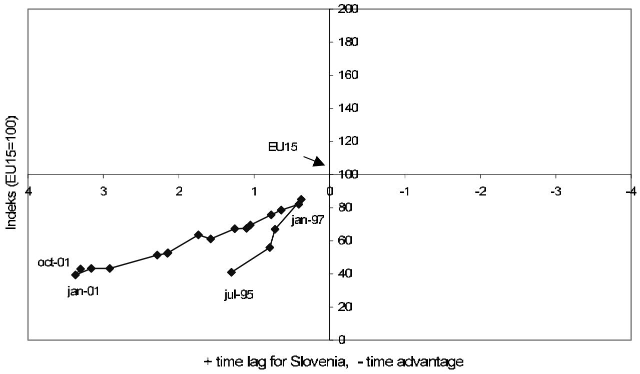

Figure 2: Host density in Slovenia and EU (1995–2002). Source: Sicherl (2001)

in 2001) has thus a dramatically different interpretation in terms of the time distance (e.g. 1 year and 3 years). The discrepancy can be explained by the fact that it was much easier to expand growth in 1995 when yearly growth rates in hosts' density were over 100% and the EU average was around 20 hosts per 10,000 habitants, compared to 2001 when the yearly growth rate were only around 10% or even stagnating, and the average of the host density was 40 hosts per 10,000 inhabitants.

Obviously, the Internet benchmarks should be observed within the framework of changing penetration patterns. Any benchmark that relies only on the comparisons of absolute or relative achievements may not be exhaustive in explaining the phenomena. It can be even directly misleading. This example illustrates that benchmark researchers must take the time dimension into careful consideration.

CONCLUSION

The basic concept of benchmarking relates to comparisons of performance indicators with a common reference point. Historically, such comparisons have been performed since the time of the ancient Egyptians. The systematic collection of the benchmarks also existed from the early days of the competitive economy, when companies compared their business practices with those of competitors. The explicit notion of benchmarking arose only in the late 1970s with the pioneering work of Xerox, however, and interest in the field exploded in the 1990s. Today benchmarking is an established discipline with professional associations, awards, codes of conduct, conferences, journals, and textbooks, and companies around the world are involved in the practice.

There are no doubts that modern benchmarking arose from a business environment where all the basic methodology and the standard procedures were developed. However, during past years the notion of benchmarking has expanded to sector benchmarking as well as to the governmental and nonprofit sector. In last few years it has also become popular for the national comparisons in the field of ICT. A number of international studies have been labeled as benchmarking, although little benchmarking theory was actually applied (Courcelle & De Vil, 2001; Petrin et al., 2000). The EU adopted benchmarking for ICT comparisons of member and candidate nations in a formal manner. In this case, statistical data are used for systematic year-by-year comparisons according to 23 Internet benchmarks.

The speed of changes in the field of ICT creates severe methodological problems for the Internet benchmarks. With the dramatic rise of the Internet in mid-90s only private companies had sufficient flexibility to provide up-to-date ICT indicators. As a consequence, even today, for the ICT international comparisons the data from private agencies are often used. In particular, this holds true for the scope and structure of the ICT spending. Only in recent years have the official statistics and other international bodies recovered from this lag and presented their own methodological outlines. Here, the work within EU and particularly within the OECD should be emphasized.

The contemporary Internet indicators used for the international comparisons of the countries' performance have stabilized only in recent years. After many theoretical discussions about the complexity of the information society, relatively simple indicators became the standards for the national ICT benchmarking. Among the key indicators in this field are the Internet penetration, the host density, and the share of Internet transactions among all commercial transactions of consumers and companies as well as within the government–citizen relations.

GLOSSARY

Benchmark A reference point, or a unit of measurement, for making comparisons. A benchmark is a criterion for success, an indicator of the extent to which an organization achieves the targets and goals defined for it.

Benchmarking A process whereby a group of organizations, usually in the same or similar domains, compare their performance on a number of indicators. The aim of the exercise is for participants to learn from each other and to identify good practice with a view toward improving performance in the long run.

Biometric Authentication

James. L. Wayman, *San Jose State University*

INTRODUCTION

"Biometric authentication" is the automatic identification or identity verification of living humans based on behavioral and physiological characteristics (Miller, 1989). The field is a subset of the broader field of human identification science. Example technologies include, among others, fingerprinting, hand geometry, speaker verification, and iris recognition. At the current level of technology, DNA analysis is a laboratory technique requiring human processing, so it not considered "biometric authentication" under this definition. Some techniques (such as iris recognition) are more physiologically based, some (such as signature recognition) more behaviorally based, but all techniques are influenced by both behavioral and physiological elements.

Biometric authentication is frequently referred to as simply "biometrics," although this term has historically been associated with the statistical analysis of general biological data (*Webster's New World Dictionary,* 1966). The word biometrics is usually treated as singular. In the context of this chapter, biometrics deals with computer recognition of patterns created by human behavior and physiology and is usually associated more with the field of computer engineering than with biology.

APPLICATIONS

The perfect biometric measure would be

- Distinctive: different across users,
- Repeatable: similar across time for each user,
- Accessible: easily displayed to a sensor,
- Acceptable: not objectionable to display by users, and
- Universal: possessed by and observable on all people.

Unfortunately, no biometric measure has all of these attributes: There are great similarities among different individuals, measures change over time, some physical limitations prevent display, "acceptability" is in the mind of the user, and not all people have all characteristics. Practical biometric technologies must compromise on every point. Consequently, the challenge of biometric deployments is to develop robust systems to deal with the vagaries and variations of human beings.

There are two basic applications of biometric systems:

1. To establish that a person is enrolled in a database.
2. To establish that a person is not enrolled in a database.

Immigration systems, amusement parks, and health clubs use biometrics in the first application: to link users to their enrolled identity. Social service, drivers' licensing, and national identification systems use biometrics primarily in the second application: to establish that prospective participants are not already enrolled. Although hybrid systems—using "negative identification" to establish that a user is not already enrolled, then using "positive identification" to recognize enrolled individuals in later encounters—are also possible, they are not common. The largest biometric systems in place, worldwide, are for purely negative identification.

The key to all of these of systems is the "enrollment" process, in which a user presents for the first time one or more biometric measures to be processed and stored by the system. Systems of the first type, called "positive identification systems" do not necessarily require centralized databases but can use distributed storage, such as on individual computers or machine-readable cards. Systems of the second type, called "negative identification systems," require a centralized database or its equivalent.

For positive identification systems using distributed storage, the submitted sample can be compared only to a single template on the storage media. This is called "one-to-one" verification. Positive identification systems using a centralized database may require users to enter an identification number or name (perhaps encoded on a mag-stripe card) to limit the size of the required search to only a portion of the entire database. If the identifying number or name is unique to each enrolled individual, this form of positive verification can also be "one-to-one," even though the centralized database contains many enrolled individuals.

Large-scale negative identification systems generally partition the database using factors such as gender or age so that not all centrally stored templates need be examined to establish that a user is not in the database. Such systems are sometimes loosely called "one-to-N," where *N* represents only a small portion of the enrolled users. In the general case, however, both positive and negative identification systems search one or more submitted samples against many stored templates or models.

All biometric systems can only link a user to an enrolled identity at some incomplete level of certainty. A biometric system can neither verify the truth of the enrolled identity nor establish the link automatically with complete certainty. If required, determining a user's "true" identity is done at the time of enrollment through trusted external documentation, such as a birth certificate or driver's license. When the user is later linked to that enrolled identity through a biometric measure, the veracity of that identity is only as reliable as the original documentation used for enrollment.

All biometric measures may change over time, due to aging of the body, injury, or disease. Therefore, reenrollment may be required. If "true" identity or continuity of identity is required by the system, reenrollment must necessitate presentation of trusted documentation. Not all systems, however, have a requirement to know a user's "true" identity. Biometric measures can be used as identifiers in anonymous and pseudo-anonymous systems.

Although biometric technologies are not commonly used with Internet transactions today, future uses would most likely be in the first application: to establish that a person is enrolled in a database and, therefore, has certain attributes and privileges within it, including access authorization. The argument can be made that biometric measures more closely link the authentication to the human user than passwords, personal identification numbers (PINs), PKI codes, or tokens, which authenticate machines. Consequently, the focus and terminology of this chapter is on applications of the first type, "positive identification."

HISTORY

The science of recognizing people based on physical measurements owes to the French police clerk Alphonse Bertillon, who began his work in the late 1870s (Beavan, 2001; Cole, 2002). The Bertillon system involved at least 11 measurements, such as height, the length and breadth of the head, and length of the ring and middle fingers. Categorization of iris color and pattern was also included in the system. By the 1880s, the Bertillon system was in use in France to identify repeat criminal offenders. Use of the system in the United States for the identification of prisoners began shortly thereafter and continued into the 1920s. Extreme claims of accuracy were made for the system, based on the unsupportable hypothesis that the various measures were statistically independent (Galton, 1890; Galton, 1908).

Although research on fingerprinting by a British colonial magistrate in India, William Herschel, began in the late 1850s, knowledge of the technique did not become known in the Western world until the 1880s (Faulds, 1880; Herschel, 1880) when it was popularized scientifically by Sir Francis Galton (1888) and in literature by Mark Twain (1992/1894). Galton's work also included the identification of persons from profile facial measurements.

By the mid-1920s, fingerprinting had completely replaced the Bertillon system within the U.S. Bureau of Investigation (later to become the Federal Bureau of Investigation). Research on new methods of human identification continued, however, in the scientific world. Handwriting analysis was recognized by 1929 (Osborn, 1929), and retinal scanning was suggested in 1935 (Smith & Goldstein, 1935).

None of these techniques was "automatic," however, so none meets the definition of "biometric authentication" used in this chapter. Automatic techniques require automatic computation. Work in automatic speaker identification can be traced directly to experiments with analog computers done in the 1940s and early 1950s (Chang, Pihl, & Essignmann, 1951). With the digital revolution beginning in the 1950s, a strong tool for human identification through pattern matching became available: the digital computer. Speaker (Atal, 1976; Rosenberg, 1976) and fingerprint (Trauring, 1963a) pattern recognition were among the first applications in digital signal processing. By 1961, a "wide, diverse market" for computer-based fingerprint recognition was identified, with potential applications in "credit systems," "industrial and military security systems," and "personal locks" (Trauring, 1963b). Computerized facial recognition followed (Kanade, 1977). By the mid-1970s, the first operational fingerprint and hand geometry systems (Raphael & Young, 1974) were fielded, and formal biometric system testing had begun (National Bureau of Standards, 1977). Iris recognition systems became available in the mid-1990s (Daugman, 1993). Today there are close to a dozen approaches used in commercially available systems (see Table 1).

SYSTEM DESCRIPTION

Given the variety of applications and technologies, it might seem difficult to draw any generalizations about biometric systems. All such systems, however, have many elements in common. Figure 1 shows a general biometric system consisting of data collection, transmission, signal processing, storage, and decision subsystems (Wayman, 1999). This diagram accounts for both enrollment and operation of positive and negative identification systems.

Data Collection

Biometric systems begin with the measurement of a behavioral or physiological characteristic. Because biometric data can be one- (speech), two- (fingerprint), or multidimensional (handwriting dynamics), it generally does not involve "images." To simplify the vocabulary used in this chapter, I refer to raw signals simply as "samples."

Key to all systems is the underlying assumption that the measured biometric characteristic is both distinctive among individuals and repeatable over time for the same individual. The problems in measuring and controlling these variations begin in the data collection subsystem.

The user's characteristic must be presented to a sensor. The act of presenting a biometric measure to a sensor introduces a behavioral component to every biometric method because the user must interact with the sensor in the collection environment. The output of the sensor, which is the input sample on which the system is built, is the combination of (a) the biometric measure, (b) the way the measure is presented, and (c) the technical characteristics of the sensor. Both the repeatability and the distinctiveness of the measurement are negatively affected by changes in any of these factors. If a system is to communicate with other systems, the presentation and sensor characteristics must be standardized to ensure that biometric characteristics collected with one system will match those collected on the same individual by another system.

Transmission

Some, but not all, biometric systems collect data at one location but store or process it (or both) at another. Such systems require data transmission over a medium such as the Internet. If a great amount of data is involved, compression may be required before transmission or storage to conserve bandwidth and storage space. Figure 1 shows compression and transmission occurring before the signal processing and image storage. In such cases, the transmitted or stored compressed data must be expanded before further use. The process of compression and expansion generally causes quality loss in the restored signal, with loss increasing with increasing compression ratio. Interestingly, limited compression may actually improve the performance of the pattern recognition software as information loss in the original signal is generally in the less repeatable high-frequency components. The compression

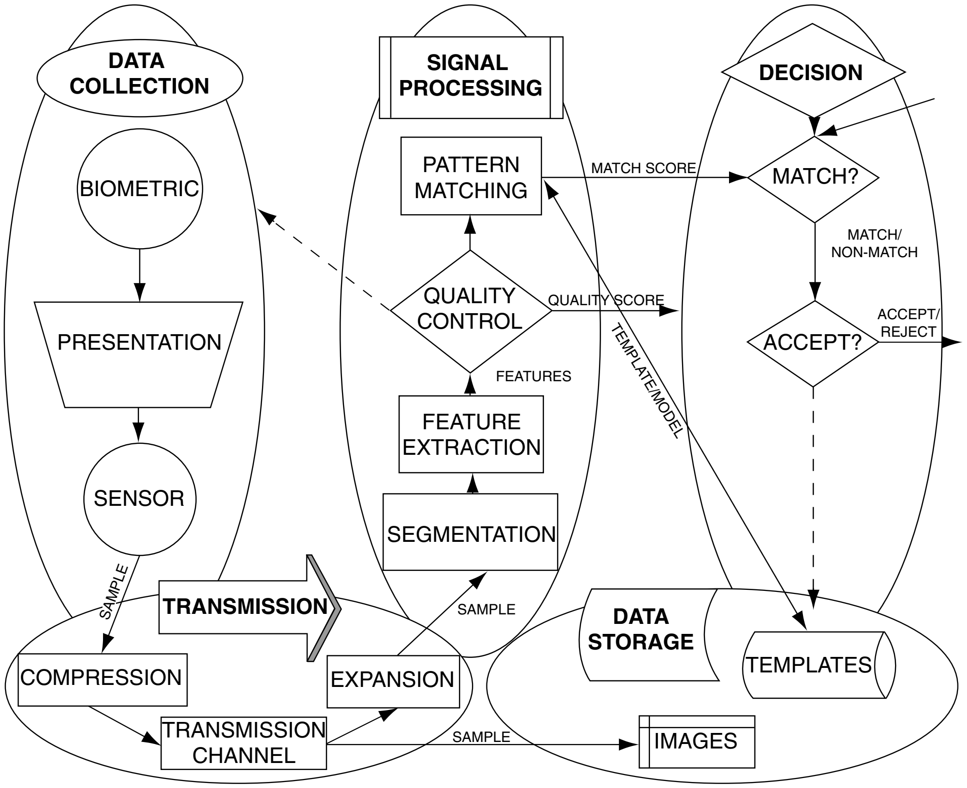

Figure 1: Example biometric system.

technique used will depend on the biometric signal. An interesting area of research is in finding, for a given biometric technique, compression methods that have a minimal impact on the subsequent signal processing activities.

If a system is to allow sharing of data at the signal level with other systems, compression and transmission protocols must be standardized. Standards currently exist for the compression of fingerprint (Wavelet Scalar Quantization, 1993), facial (Information Technology, 1993), and voice (Cox, 1997) data.

Signal Processing

The biometrics signal processing subsystem comprises four modules: segmentation, feature extraction, quality control, and pattern matching. The segmentation module must determine if biometric signals exist in the received data stream (signal detection) and, if so, extract the signals from the surrounding noise. If the segmentation module fails to detect or extract a biometric signal, a "failure-to-acquire" has occurred.

The feature extraction module must process the signal in some way to preserve or enhance the between-individual variation (distinctiveness) while minimizing the within-individual variation (nonrepeatability). The output of this module is numbers, vectors, or distribution parameters that, although called biometric "features," may not have direct physiological or behavioral interpretation. For example, mathematical output from facial recognition systems does not indicate directly the width of the lips or the distances between the eyes and the mouth.

The quality control module must do a statistical "sanity check" on the extracted features to make sure they are not outside population statistical norms. If the sanity check is not successfully passed, the system may be able to alert the user to resubmit the biometric pattern. If the biometric system is ultimately unable to produce an acceptable feature set from a user, a "failure-to-enroll" or a "failure-to-acquire" will be said to have occurred. Failure-to-enroll or acquire may be due to failure of the segmentation algorithm, in which case no feature set will be produced. The quality control module might even affect the decision process, directing the decision subsystem to adopt higher requirements for matching a poor quality input sample.

The pattern matching module compares sample feature sets with enrolled templates or models from the database and produces a numerical "matching score." When both template and features are vectors, the comparison may be as simple as a Euclidean distance. Neural networks might be used instead. Regardless of which pattern matching technique is used, templates or models and features from samples will never match exactly because of the repeatability issues. Consequently, the matching scores determined by the pattern matching module will have to be interpreted by the decision subsystem.

In more advanced systems, such as speaker verification, the enrollment "templates" might be "models" of the signal generation process—very different data structures than the observed features. The pattern matching module determines the consistency of the observed features with the stored generating model. Some pattern matching modules may even direct the adaptive recomputation of features from the input data.

Decision

The decision subsystem is considered independently from the pattern matching module. The pattern matching module might make a simple "match" or "no match" decision based on the output score from the pattern matcher. The decision module might ultimately "accept" or "reject" a user's claim to identity (or nonidentity) based on multiple attempts, multiple measures or a measure-dependent decision criteria. For instance, a "three-try" decision policy will accept a user's identity claim if a match occurs in any of three attempts.

The decision module might also direct operations to the stored database, allowing enrollment templates to be stored, calling up additional templates for comparison in the pattern matching module, or directing a database search.

Because input samples and stored templates will never match exactly, the decision modules will make mistakes—wrongly rejecting a correctly claimed identity of an enrolled user or wrongly accepting the identity claim of an impostor. Thus, there are two types of errors: false rejection and false acceptance. These errors can be traded off against one another to a limited extent: decreasing false rejections at the cost of increased false acceptances and vice versa. In practice, however, inherent within-individual variation (nonrepeatability) limits the extent to which false rejections can be reduced, short of accepting all comparisons. The decision policies regarding "match–no match" and "accept–reject" criteria specific to the operational and security requirements of the system and reflect the ultimate cost of errors of both types.

Because of the inevitability of false rejections, all biometric systems must have "exception handling" mechanisms in place. If exception handling mechanisms are not as strong as the basic biometric security system, vulnerability results. An excessively high rate of false rejections may cause the security level of the exception handling system to be reduced through overload.

The false acceptance rate, on the other hand, measures the percentage of impostors who are able to access the system. The complement of the false acceptance rate is the percentage of impostors who are intercepted. So a 20% false acceptance rate means that 80% of impostors are intercepted. Depending on the application, this may be high enough to serve as a sufficient deterrent to prevent impostors from attempting access through the biometric system. The exception handling mechanism might become a more appealing target for those seeking fraudulent access. Consequently, the security level of a biometric system in a positive identification application may be more dependent on the false rejection rate than the false acceptance rate.

Storage

The remaining subsystem to be considered is that of storage. The processed features or the feature generation model of each user will be stored or "enrolled" in a database for future comparison by the pattern matcher to

Table 2 Biometric Template Sizes

DEVICE	SIZE IN BYTES
Fingerprint	200–1,000
Speaker	100–6,000
Finger geometry	14
Hand geometry	9
Face	100–3,500
Iris	512

incoming feature samples. This enrollment data is called a "template" if it is of the same mathematical type as the processed features and a "model" if it gives a mathematical explanation of the feature generating process. For systems only performing positive identification, the database may be distributed on magnetic strip, optically read, or smart cards that each enrolled user carries. Depending on system policy, no central database for positive identification systems need exist, although a centralized database can be used to detect counterfeit cards or to reissue lost cards without recollecting the biometric measures.

The original biometric measurement, such as a fingerprint pattern, is generally not reconstructable from the stored templates. Furthermore, the templates themselves are created using the proprietary feature extraction algorithms of the system vendor. If it may become necessary to reconstruct the biometric patterns from stored data (to support interoperability with systems from other vendors, for example), raw (although possibly compressed) data storage will be required. The storage of raw data allows changes in the system or system vendor to be made without the need to recollect data from all enrolled users. Table 2 shows some example template sizes for various biometric devices.

PERFORMANCE TESTING

Biometric devices and systems might be tested in many different ways. Types of testing include the following:

- Technical performance;
- Reliability, availability, and maintainability [RAM];
- Vulnerability;
- Security;
- User acceptance;
- Human factors;
- Cost–benefit; and
- Privacy regulation compliance.

Technical performance has been the most common form of testing in the last three decades, and "best practices" have been developed (Mansfield & Wayman, 2001). These tests generally measure failure-to-enroll, failure-to-acquire, false acceptance, false rejection, and throughput rates. Failure-to-enroll rate is determined as the percentage of all persons presenting themselves to the system in "good faith" for enrollment who are unable to do so because of system or human failure. Failure-to-acquire rate is determined as the percentage of "good faith" presentations by all enrolled users that are not acknowledged by the system. The false rejection rate is the percentage of all users whose claim to identity is not accepted by the system. This will include failed enrollments and failed acquisitions, as well as false nonmatches against the user's stored template. The false acceptance rate is the rate at which "zero-effort" impostors making no attempt at emulation are incorrectly matched to a single, randomly chosen false identity. Because false acceptance–rejection and false match–nonmatch rates are generally competing measures, they can be displayed as "decision error trade-off" (DET) curves.

The throughput rate is the number of persons processed by the system per minute and includes both the human–machine interaction time and the computational processing time of the system.

Types of Technical Tests

There are three types of technical tests: technology, scenario, operational (Phillips, Martin, Wilson, & Przybocki, 2000).

Technology Test

The goal of a technology test is to compare competing algorithms from a single technology, such as fingerprinting, against a standardized database collected with a "universal" sensor. There are competitive, government-sponsored technology tests in speaker verification (National Institute of Standards and Technology, 2003), facial recognition (Philips, Grother, Michaels, Blackburn, Tabassi, & Bone, 2003), and fingerprinting (Maio, Maltoni, Wayman, & Jain, 2000).

Scenario Test

Although the goal of technology testing is to assess the algorithm, the goal of scenario testing is to assess the performance of the users as they interact with the complete system in an environment that models a "real-world" application. Each system tested will have its own acquisition sensor and so will receive slightly different data. Scenario testing has been performed by a number of groups, but few results have been published openly (Bouchier, Ahrens, & Wells, 1996; Mansfield, Kelly, Chandler, & Kane, n.d.; Rodriguez, Bouchier, & Ruehie, M., 1993).

Operational Test

The goal of operational testing is to determine the performance of a target population in a specific application environment with a complete biometric system. In general, operational test results will not be repeatable because of unknown and undocumented differences between operational environments. Furthermore, "ground truth" (i.e., who was actually presenting a "good faith" biometric measure) will be difficult to ascertain. Because of the sensitivity of information regarding error rates of operational systems, few results have been reported in the open literature (Wayman, 2000b).

Regardless of the type of test, all biometric authentication techniques require human interaction with a data collection device, either standing alone (as in technology

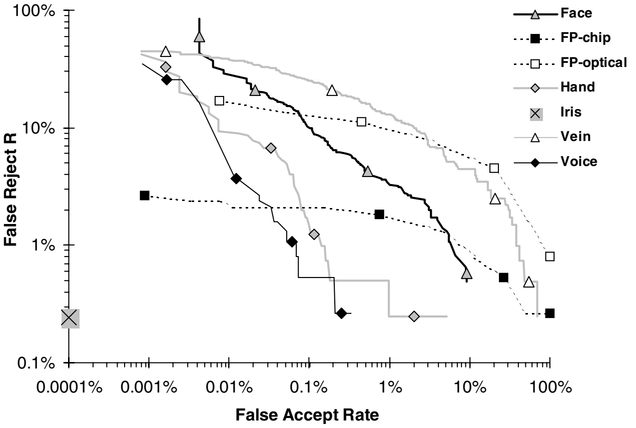

Figure 2: Detection error trade-off curve: Best of three attempts.

testing) or as part of an automatic system (as in scenario and operational testing). Consequently, humans are a key component in all system assessments. Error, failure-to-enroll or acquire, and throughput rates are determined by the human interaction, which in turn depends on the specifics of the collection environment. Therefore, little in general can be said about the performance of biometric systems or, more accurately, about the performance of the humans as they interact with biometrics systems.

The National Physical Lab Tests

A study by the U.K. National Physical Laboratory in 2000 (Mansfield et al., 2001b) looked at eight biometric technologies in a scenario test designed to emulate access control to computers or physical spaces by scientific professionals in a quiet office environment.

The false accept–false reject DET under a "three-tries" decision policy for this test is shown in Figure 2. The false rejection rate includes "failure-to-enroll/acquire" rates in its calculation.

Throughput Rates

The National Physical Laboratory study (Mansfield et al., n.d.) also established transaction times for various biometric devices in an office, physical access control setting, shown as Table 3.

In Table 3, the term "PIN" indicates whether the transaction time included the manual entry of a four-digit identification number by the user. These times referred only to the use of the biometric device and did not include actually accessing a restricted area.

Table 3 Transaction Times in Office Environment

TRANSACTION TIME				
DEVICE	MEAN	MEDIAN	MINIMUM	PIN?
Face	15	14	10	No
Fingerprint—optical	9	8	2	No
Fingerprint—chip	19	15	9	No
Hand	10	8	4	Yes
Iris	12	10	4	Yes
Vein	18	16	11	Yes
Speaker	12	11	10	No

Biometric Forgeries

It has been well known since the 1970s that all biometric devices can be fooled by forgeries (Beardsley, 1972). In a positive identification system, "spoofing" is the use of a forgery of another person's biometric measures. (In a negative identification system, "spoofing" is an attempt to disguise one's own biometric measure.) Forging biometric measures of another person is more difficult than disguising one's own measures, but is possible nonetheless. Several studies (Blackburn et al., 2001; Matsumoto et al., 2002; Thalheim, Krissler, & Ziegler, 2002; van der Putte & Keuning, 2002) discuss ways by which facial, fingerprint and iris biometrics can be forged. Because retinal recognition systems have not been commercially available for several years, there is no research on retina forgery, but it is thought to be a difficult problem. Speaker recognition systems can make forgery difficult by requesting the user to say randomly chosen numbers. The current state of technology does not provide reliable "liveness testing" to ensure that the biometric measure is both from a living person and not a forgery.

EXAMPLE APPLICATIONS

Most successful biometric programs for positive identification have been for physical access control. In this section, I consider two such programs, one at Walt Disney World and the other the U.S. INSPASS program.

Disney World

The Walt Disney Corporation needed to link guests to season passes without inconveniencing passholders on visits to their four Orlando parks (Disney World, Epcot, Animal Kingdom, and MGM Studio Tour) and two water parks (Blizzard Beach and Typhoon Lagoon) (Levin, 2002). The challenge was to create a verification component with minimum impact on existing systems and procedures. Alternatives to biometrics existed for Disney. They considered putting photos on the passes, then checking photos against passholders. This approach required human inspectors at all the entrances. Disney could have put names on passes at the point of sale, then checked passes against photo identification presented by the pass holders at the entrance to the parks, but this would have required disclosure of the passholders' identities.

Automatic, anonymous authentication of the passholders might have been accomplished by requiring passholders to enter an identifying number of some sort upon entrance to the parks. That number would be chosen at the time of sale or first use of the pass and could be chosen by the passholder. The concerns with this approach are twofold: forgotten numbers and the increased guest processing time. Disney seeks to make parks as accessible as possible, and use of key pads could create accessibility problems. Disney ultimately decided to use biometric authentication, taking the shapes of right index and middle finger on all passholders. Finger shape only is recorded.

Fingerprints are not imaged. The template is established when the holder places the fingers in the imaging device upon first use of the pass at the park entrance. This first user becomes the "authorized holder" of the pass. The template is stored centrally in the Disney access control system and is linked to the pass number encoded on a magnetic stripe on the pass. Upon subsequent uses, the card number allows the recall of the stored finger geometry, which is then compared with that presented by the guest to determine if the guest matches the original holder of the pass. A failure of the system to authenticate the guest is assumed to be a system error and a guest relations officer is on hand to resolve the issue quickly. Disney considers the system to be quite successful.

INSPASS

Frequent travelers to the United States can bypass immigration lines if they hold a card issued by the Immigration and Naturalization Service's (INS) Passenger Accelerated Service System (INSPASS). The system is currently in place at Kennedy, Newark, Los Angeles, Miami, San Francisco, Detroit, and Washington Dulles airports, as well as in Vancouver, and Toronto airports in Canada. Users give measurements of their hand geometry at the INSPASS kiosk to verify that they are the correct holder of the card. The passport number on the card can then be trusted by the INS to be that of the holder and the border crossing event is automatically recorded.

At the nine airports with INSPASS, there are more than 21 kiosks, and more than 20,000 automated immigration inspections were conducted on average each month in 2000. About 72% of these inspections were for U.S. citizens, but any citizen of any country on the U.S. "visa waver program" can apply for and receive an INSPASS card. In 2000, there were more than 45,000 active enrollees, and each traveler used INSPASS about four times annually, on average. As of this writing, INSPASS is temporarily on hiatus at some airports, pending the creation of a thorough business plan for the system by the INS Office of Inspections.

Use of INSPASS is entirely voluntary. Applicants attest that they have no drug or smuggling convictions and supply fingerprints, along with their hand geometry, at the time of enrollment. A passport is also required as proof of "true" identity. The INS considers the INSPASS holders to be low-risk travelers already well-known to the system and therefore affords them the special privilege of entering the United States without a face-to-face meeting with an immigration officer. Those not using INSPASS have passports inspected by an immigration officer, whose duty it is to ferret out those entering illegally or on forged or stolen passports. Immigration officers are also charged with prescreening all arrivals for customs, agriculture, and State Department–related issues. Returning U.S. citizens not holding INSPASS cards must answer questions such as length of trip, travel destinations, and purpose of travel. Non-U.S. citizens arriving without an INSPASS must answer an even more extensive series of questions about length of stay, intent of visit, and destinations within the United States. In effect, INSPASS substitutes the possession of card for the passport and substitutes presentation of the hand geometry for the usual round of border crossing questions. Analyses of the error rates for this system are given in Wayman (2000b).

BIOMETRICS AND PRIVACY

The concept "privacy" is highly culturally dependent. Legal definitions vary from country to country and, in the United States, even from state to state (Alderman & Kennedy, 1995). A classic definition is the intrinsic "right to be let alone," (Warren & Brandeis, 1980), but more modern definitions include informational privacy: the right of individuals "to determine for themselves when, how and to what extent information about them is communicated to others" (Westin, 1967). The U.S. Supreme Court has recognized both intrinsic (*Griswald v. Connecticut,* 1967) and informational (*Whalen v. Roe,* 1977) privacy. Both types of privacy can be affected positively or negatively by biometric technology.

Intrinsic (or Physical) Privacy

Some people see the use of biometric devices as an intrusion on intrinsic privacy. Touching a publicly used biometric device, such as a fingerprint or hand geometry reader, may seem physically intrusive, even though there is no evidence that disease can spread any more easily by these devices than by door handles. People may also object to being asked to look into a retinal scanner or to stand still while giving an iris or facial image. Not all biometric methods require physical contact. A biometric application that replaced the use of a keypad with the imaging of an iris, for instance, might be seen as enhancing of physical privacy.

If biometrics are used to limit access to private spaces, then biometrics can be more enhancing to intrinsic privacy than other forms of access control, such as keys, which are not as closely linked to the holder.

There are people who object to use of biometrics on religious grounds: Some Muslim women object to displaying their face to a camera, and some Christians object to hand biometrics as "the sign of the beast" (Revelations, 13:16–18). It has been noted (Seildarz, 1998), however, that biometrics are the marks given an individual by God.

It can be argued (Baker, 2000; Locke, 1690) that a physical body is not identical to the person that inhabits it. Whereas PINs and passwords identify persons, biometrics identifies the body. Some people are uncomfortable with biometrics because of this connection to the physical level of human identity and the possibility of nonconsentual collection of some biometric measures. Biometric measures could allow linking of the various "persons" or psychological identities that each of us choose to manifest in our separate dealings within our social structures. Biometrics, if universally collected without adequate controls, could aid in linking my employment records to my health history and church membership. This leads us to the concept of "informational privacy."

Informational Privacy

With notably minor qualifications, biometric features contain no personal information whatsoever about the user. This includes no information about health status, age, nationality, ethnicity, or gender. Consequently, this also limits the power of biometrics to prevent underage access to pornography on the Internet (Woodward, 2000) or to detect voting registration by noncitizens (Wayman 2000a).

No single biometric measure has been demonstrated to be distinctive or repeatable enough to allow the selection of a single person out of a very large database. (All automatic large-scale civilian fingerprint systems, for instance, require images from multiple fingers of each user for unique identification. Law enforcement automatic fingerprint identification systems (AFIS) require human intervention to identify an individual from "latent" fingerprint images left at crime scenes.) When aggregated with other data, however, such as name, telephone area code, or other even weakly identifying attributes, biometric measures can lead to unique identification within a large population. For this reason, databases of biometric information must be treated as personally identifiable information and protected accordingly.

Biometrics can be directly used to enhance informational privacy. Use to control access to databases containing personal and personally identifiable data can enhance informational privacy. The use of biometric measures, in place of name or social security number, to ensure that personal data is anonymous, is privacy enhancing.

Biometric measures are private but not secret. The U.S. Supreme Court has ruled that "Like a man's facial characteristics, or handwriting, his voice is repeatedly produced for others to hear" (*U.S. v. Dionisio,* 1973). Therefore, the court concluded, no can reasonably expect that either his or her voice or face "will be a mystery to the world." The theft of biometric measures through reproduction, theft of identity at biometric enrollment, or theft of biometrically protected identity by data substitution through reenrollment could all have grave repercussions for both intrinsic and informational privacy.

STANDARDS

Biometric methods, such as fingerprinting, face, and speaker recognition, were developed independently, by different academic traditions and for different applications. It has only been within the last decade that the commonality as automatic human identification methods has even been recognized, so it should come as no surprise that common standards have been slow to develop.

Furthermore, there has been little need for interoperability among these systems. In fact, the lack of interoperability within and across technologies has been touted as a privacy-preserving asset of biometric systems (Woodward, 1999). Consequently, there has been no motivation for the tedious standards development process required to promote interoperability. A notable exception is in automatic fingerprint identification systems (AFIS), for which law enforcement has long needed the capability of interjurisdictional fingerprint exchanges. In this case, some American National Standards Institute (ANSI), National Institute of Standards and Technology (NIST), and Criminal Justice Information Services (CJIS) recognized standards do exist. These have been accepted as de facto international standards.

In 2002, the International Standards Organization/International Electrotechnical Commission Joint Technical Committee 1 formed Standing Committee 37 to create international standards for biometrics. Early work by SC37 has focused on "harmonized vocabulary and definitions," "technical interfaces," "data interchange formats," "application profiles," "testing and reporting," and "cross jurisdictional and societal aspects."

Fingerprint Standards

The CJIS (1999) report Interim IAFIS Fingerprint Image Quality Specifications for Scanners specifies technical requirements (signal-to-noise ratio, gray scale resolution, etc.) for the scanning of fingerprint images for transmission to the FBI. This standard, commonly known as "Appendix F/G," was developed for "flat bed scanners" used for the digital imaging of inked fingerprint cards. It has been applied, with difficulty, as a standard for fingerprint sensors used in large-scale biometric fingerprint systems. Fingerprint devices not used for large-scale searches, such as those for computer or facilities access control, commonly do not meet "Appendix F/G" technical standards.

Fingerprint images, even when compressed, are around 15 kBytes in size. As shown in Table 2, templates extracted using proprietary algorithms are much smaller. The requirement to store fingerprint information on interoperable ID cards has lead to some efforts at template standardization the American Association of Motor Vehicle Administrators (AAMVA, 2000), motivated by the need for cross-jurisdictional exchange of fingerprint data for driver identification, has published a standard for drivers licenses and identification cards, which includes a section on fingerprint minutiae extraction and storage. Although this standard has never been tested or implemented, it is hoped that it will provide a possible solution to fingerprint system interoperability.

Facial Image Standards

Compression standards for facial imaging have already been mentioned (Information Technology, 1993). NIST has a document "Best Practice Recommendations for the Capture of Mugshots" (NIST, 1993), that has application to facial recognition when "mug shot" type photos are used.

BioAPI

Beyond the issue of interoperability standards is that of software protocol conventions. In the past, each vendor has used its own platform-specific software to support its own data collection, feature extraction, and storage and matching operations. This has caused major headaches for system integrators who try to use biometric devices in larger or more general access control and information retrieval systems. The integrators have been forced to learn and handle the idiosyncratic software of each biometric vendor. During the last 5 years, under the sponsorship of both the U.S. Department of Defense (Human Authentication-Application Programming Interface Steering Group, 1998) and NIST, common software standards have been emerging. This effort is currently known as the "Biometric Applications Programming Interface" (BioAPI Consortium, 2001). This standard specifies exactly how information will be passed back and forth between the larger system and the biometric subsystems. It will allow system integrators to establish one set of software function calls to handle any biometric device within the system.

CBEFF

Closely related to the BioAPI effort is the Common Biometric Exchange File Format (CBEFF) working group sponsored by NIST and the National Security Agency (NIST, 2001). This group has developed a standard "packaging" protocol for transferring biometric templates and samples between applications. Recently, this work is being extended by the Organization for the Advancement of Structured Information Standards (http:// www.oasis-open.org) to an extensible markup language (XML) format for biometric transmission over the Internet.

ANSI X9.84

The ANSI X9.84–2001 standard for Biometric Information Management and Security (ANSI, 2001) is a comprehensive document describing proper architectures and procedures for the financial industry when using biometrics for secure remote electronic access or local physical access control. The standard discusses security requirements for the collection, distribution, and processing of biometric data; uses of biometric technology; techniques for secure transmission of biometric data; and requirements for data privacy.

POTENTIAL INTERNET APPLICATIONS

There have been few direct applications of biometrics to the Internet. Biometrics can and are being used to control local network and PC log-on, however. Many commercial devices are available for this application, including fingerprint, keystroke, speaker, and iris recognition. Some of these products have in the past been marketed at office-supply chain stores. Users enroll biometric data on their local network or own PC. At log-on, submitted biometric data is compared locally with that locally stored. This model can be extended to include biometric authorization for access to computer files and services. No biometric data ever leaves the PC or local network.

How might biometrics be used directly over the Internet? One model requires users to supply biometric data over the internet when registering at a Web site. Of course, such a system has no way of determining the true identity of the user or even whether the biometric data supplied really belongs to the registrant. But once enrolled, the Web site could determine whether the user's browser had access to the same biometric measures given at enrollment. This might indicate continuity of the person at the browser or across browsers.

Recognizing the weakness of such a system, one speaker verification company established a business model of "out-of-band" registration over the telephone. Those registering would speak to a human operator, who would collect identification information, then switch the registrant to a computer for collecting speech samples. When registered users wished to access a controlled Web site, they would telephone the speaker verification company, verify their voice, and be issued an alphanumeric "volatile pass code" that would allow access to the requested site if promptly submitted over the internet.

A third model would be a centralized "biometric certification authority" (BCA), operated either by government or a commercial entity. Users would enroll a biometric measure in person, or possibly through an "out-of-band" mechanism such as the mail. Depending on the purpose of the system, users might be required to present proof of identity, credit card information, or the like. After registration, users wishing to access biometrically controlled Web sites would submit their biometric measures over the Internet to the BCA, which would verify identity to the Web site being accessed. Fear of centralized biometric databases in the hands of either business or government has inhibited implementation of this model.

Given the nonrevocability of biometric information, its "private but not secret" status, and the need for in-person registration when applied to user identification, it is not clear that biometrics has a secure place in Internet communication or commerce.

Commonsense Rules for Use of Biometrics

From what has been discussed thus far, we can develop some commonsense rules for the use of biometrics for access control and similar positive identification applications.

- Never participate in a biometric system that allows either remote enrollment or reenrollment. Such systems have no way of connecting a user with the enrolled biometric record, so the purpose of using biometrics is lost.
- Biometric measures can reveal people's identity only if they are linked at enrollment to their name, social security number, or other closely identifying information. Without that linkage, biometric measures are anonymous.
- Remember that biometric measures cannot be reissued if stolen or sold. Do not enroll in a nonanonymous system unless you have complete trust in the system administration.
- All biometric access control systems must have "exception handling" mechanisms for those that either cannot enroll or cannot reliably use the system. If you are uncomfortable with enrolling in a biometric system for positive identification, insist on routinely using the "exception handling" mechanism instead.
- The safest biometric systems are those in which each user controls his or her own template.
- Because biometric measures are not perfectly repeatable, are not completely distinctive, and require specialized data collection hardware, biometric systems are not useful for tracking people. Anyone who really wants to physically track you will use your credit card, phone records, or cell phone emanations instead. Anyone wanting to track your Internet transactions will do so with cookies or Web logs.

CONCLUSION

Automated methods for human identification have a history predating the digital computer age. For decades, mass adoption of biometric technologies has appeared to be just a few years away (Raphael & Young, 1974; The Right Biometric, 1989), yet even today, difficulties remain in establishing a strong business case, in motivating consumer demand, and in creating a single system usable by all sizes and shapes of persons. Nonetheless, the biometric industry has grown at a steady pace as consumers, industry, and government have found appropriate applications for these technologies. Testing and standards continue to develop, and the privacy implications continue to be debated. Only time will tell if biometric technologies will extend to the Internet on a mass scale.

GLOSSARY

Biometrics The automatic identification or identity verification of living humans based on behavioral and physiological characteristics.

Biometric measures Numerical values derived from a submitted physiological or behavioral sample.

Decision A determination of probable validity of a user's claim to identity or nonidentity in the system.

Enrollment Presenting oneself to a biometric system for the first time, creating an identity within the system, and submitting biometric samples for the creation of biometric measures to be stored with that identity.

Failure-to-acquire rate The percentage of transactions for which the system cannot obtain a usable biometric sample.

Failure-to-enroll rate The percentage of a population that is unable to give repeatable biometric measures on any particular device.

False accept rate (FAR) The expected proportion of transactions with wrongful claims of identity (in a positive ID system) or nonidentity (in a negative ID system) that are incorrectly confirmed. In negative identification systems, the FAR may include the failure-to-acquire rate.

False match rate (FMR) The expected probability that an acquired sample will be falsely declared to match to a single, randomly selected, nonself template or model.

False non-match rate (FNMR) The expected probability that an acquired sample will be falsely declared not to match a template or model of that measure from the same user.

False reject rate (FRR) The expected proportion of transactions with truthful claims of identity (in a positive ID system) or nonidentity (in a negative ID system) that are incorrectly denied. In positive identification systems, the FRR will include the failure-to-enroll and the failure-to-acquire rates.

Features A mathematical representation of the information extracted from the presented sample by the signal processing subsystem that will be used to construct or compare against enrolment templates (e.g., minutiae coordinates, principal component coefficients and iris codes are features).

Genuine claim of identity A truthful positive claim by a user about identity in the system. The user truthfully claims to be him- or herself, leading to a comparison of a sample with a truly matching template.

Impostor claim of identity A false positive claim by a user about identity in the system. The user falsely claims to be someone else enrolled in the system, leading to the comparison of a sample with a nonmatching template.

Identifier An identity pointer, such as a biometric measure, PIN (personal identification number), or name.

Identify To connect a person to an identifier in the database.

Identity An information record about a person, perhaps including attributes or authorizations or other pointers, such as names or identifying numbers.

Identification The process of identifying, perhaps requiring a search of the entire database of identifiers; consequently, the process of connecting a person to a pointer to an information record.

Matching score A measure of similarity or dissimilarity between a presented sample and a stored template.

Models Mathematical representation of the generating process for biometric measures.

Negative claim of identity The claim (either implicitly or explicitly) of a user not to be known to or enrolled in the system. Enrollment in social service systems open only to those not already enrolled is an example.

Positive claim of identity The claim (either explicitly or implicitly) of a user to be enrolled in or known to the system. An explicit claim might be accompanied by a claimed identifier in the form of a name or identification number. Common access control systems are an example.

Sample A biometric signal presented by the user and captured by the data collection subsystem (e.g. fingerprint, face samples, and iris images are samples).

Template A user's stored reference measure based on features extracted from samples.

Transaction An attempt by a user to validate a claim of identity or nonidentity by consecutively submitting one or more samples, as allowed by the system policy.

Verification Proving as truthful a user's positive claim to an identity in the system by comparing a submitted biometric sample to a template or model stored at enrollment.

Bluetooth™—A Wireless Personal Area Network

Brent A. Miller, *IBM Corporation*

INTRODUCTION

Launched in May 1998, Bluetooth™ wireless technology rapidly has become one of the most well-known means of communication in the information technology industry. The unusual name *Bluetooth* itself has garnered much attention (I discuss the origins of this name later), but the main reason for the focus that the technology receives from so many companies and individuals is the new capabilities that it brings to mobile computing and communication.

This chapter discusses many facets of Bluetooth wireless technology—its origins, the associated Bluetooth Special Interest Group, its applications, especially in personal-area networks, how it works, and how it relates to other wireless technologies. I also present numerous references where more information can be found about this exciting new way to form wireless personal area networks (WPANs) that allow mobile devices to communicate with each other.

BLUETOOTH WIRELESS TECHNOLOGY

Bluetooth wireless technology uses radio frequency (RF) to accomplish wireless communication. It operates in the 2.4-GHz frequency spectrum; the use of this frequency range allows Bluetooth devices to be used virtually worldwide without requiring a license for operation. Bluetooth communication is intended to operate over short distances (up to approximately 100 m, although the nominal range used by most Bluetooth devices is about 10 m). Restricting communication to short ranges allows for low-power operation, so Bluetooth technology is particularly well suited for use with battery-powered personal devices that can be used to form a WPAN. Both voice and data can be carried over Bluetooth communication links, making the technology suitable for connecting both computing and communication devices, such as mobile phones, personal digital assistants (PDAs), pagers, and notebook computers. Table 1 summarizes these key attributes of Bluetooth wireless technology.

Bluetooth wireless technology originally was designed for cable replacement applications, intended to remove the need for a cable between any two devices to allow them to communicate. For example, a cable might be used to connect two computers to transfer files, to connect a PDA cradle to a computer to synchronize data, or to connect a headset to a telephone for hands-free voice calls. This sort of wired operation can often be cumbersome, because the cables used are frequently special-purpose wires intended to connect two specific devices; hence, they are likely to have special connectors that make them unsuitable for general-purpose use. This can lead to “cable clutter”—the need for many cables to interconnect various devices. Mobile users may find this especially burdensome because they need to carry their device cables with them to connect the devices when they are away from home, and even with a large collection of cables, it is unlikely that all of the devices can be plugged together. Nonmobile environments, too, can suffer from cable clutter. In a home or office, wires used to connect, say, computer peripherals or stereo speakers limit the placement of these items, and the cables themselves become obstacles.

Bluetooth technology attempts to solve the problem of cable clutter by defining a standard communication mechanism that can allow many devices to communicate with each other without wires. The next section explores the genesis and evolution of Bluetooth wireless communication.

Origins

The genesis of Bluetooth wireless technology generally is credited to Ericsson, where engineers were searching for a method to enable wireless headsets for mobile telephones. Realizing that such a short-range RF technology could have wider applications, and further realizing that its likelihood for success would be greater as an industry standard rather than a proprietary technology, Ericsson approached other major telephone, mobile computer, and electronics companies about forming an industry group to specify and standardize a general-purpose, short-range, low-power form of wireless communication. This small group became the Bluetooth Special Interest Group (SIG), discussed later.

Of special interest to many is the name “Bluetooth.” Such a name for an industry initiative is unusual. A two-part newsletter article (Kardach, 2001) offers a full explanation of the name’s origin; the salient points follow here. Some of the first technologists involved in early

Table 1 Key Bluetooth Technology Characteristics

CHARACTERISTIC	BLUETOOTH TECHNOLOGY ATTRIBUTES
Medium	Radio frequency (RF) in the 2.4-GHz globally unlicensed spectrum
Range	Nominally 10 m; optionally up to 100 m
Power	Low-power operation, suitable for battery-powered portable devices
Packet types	Voice and data
Types of applications	Cable replacement, wireless personal-area networks
Example applications	Network access, wireless headsets, wireless data transfer, cordless telephony, retail and m-commerce, travel and mobility, and many other applications

discussions about a short-range wireless technology were history buffs, and the discussion at some point turned to Scandinavian history. A key figure in Scandinavian history is 10th-century Danish king Harald Blåtand, who is credited with uniting parts of Scandinavia. It is said that a loose translation of his surname to English produces "blue tooth." Those involved in early discussions of this technology recognized that it could unite the telecommunications and information technology (IT) industries, and hence they referred to it as "Bluetooth," after King Harald. At that time, Bluetooth was considered a temporary "code name" for the project. When the time came to develop an official name for the technology and its associated special interest group, the name Bluetooth was chosen after considering several alternatives. Today this is the trademarked name of the technology and the incorporated entity (the Bluetooth SIG, discussed next) that manages it. In fact, the SIG publishes rules and guidelines (Bluetooth SIG, 2002a) for using the term.

The Bluetooth Special Interest Group

Formed in early 1998 and announced in May of that year, the Bluetooth SIG originally was a rather loosely knit group of five companies: Ericsson, Intel, IBM, Nokia and Toshiba. These companies established themselves as Bluetooth SIG promoter members and formed the core of the SIG. Other companies were invited to join as adopter members, and the SIG's membership grew rapidly. The promoter companies, along with a few invited experts, developed the original versions of the Bluetooth specification (detailed later).

In December 1999, four additional companies—3Com, Lucent, Microsoft, and Motorola—were invited to join the group of promoter companies (later Lucent's promoter membership was transferred to its spin-off company, Agere Systems). By this time, the SIG's membership had grown to more than 2,000 companies. In addition to promoters and adopters, a third membership tier, called associate member, also was defined. Companies may apply to become associate members, who must pay membership fees. Adopter membership is free and open to anyone. In general, promoter and associate members develop and maintain the Bluetooth specification; adopter members may review specification updates before their public availability.

The SIG's original purpose was to develop the Bluetooth specification, but it has taken on additional responsibilities over time. In 2001, the SIG incorporated and instituted a more formal structure for the organization, including a board of directors that oversees all operations, a technical organization led by the Bluetooth Architecture Review Board (BARB), a marketing arm and a legal group. The SIG continues to develop and maintain the specification and promote the technology, including sponsoring developers conferences and other events. One important function of the SIG is to manage the Bluetooth qualification program, in which products are tested for conformance to the specification. All Bluetooth products must undergo qualification testing. The SIG's official Web site (Bluetooth SIG, 2002b) offers more details about the organization and the qualification program.

Wireless Personal Area Networks

A *personal area network* (PAN) generally is considered to be a set of communicating devices that someone carries with her. A wireless PAN (WPAN), of course, is such a set of devices that communicate without cables, such as through the use of Bluetooth technology. One can imagine a "sphere" of connectivity that surrounds a person and moves with her or him, so that all of the devices in the WPAN remain in communication with one another.

WPANs need only short-range communication capability to cover the personal area, in contrast with local area (LAN) or wide area networks (WAN), which need to communicate across greater distances using established infrastructure. One source (Miller, 2001) contrasts PANs, LANs, and WANs, particularly Bluetooth technology as a WPAN solution versus Institute of Electrical and Electronics Engineers (IEEE, 1999) 802.11 WLAN technology.

The usefulness of a WPAN derives primarily from the ability of individual devices to communicate with each other in an ad hoc manner. Each device still can specialize in certain capabilities but can "borrow" the capabilities of other devices to accomplish certain tasks. For example, a PDA is useful for quickly accessing personal information, such as appointments and contacts. A mobile telephone can be used to contact people whose information is stored in the PDA. Hence, a user might look up the telephone number of an associate and then dial that number on the mobile phone. With a WPAN, however, this process can be automated: Once the telephone number is accessed, the PDA software could include an option to dial the specified phone number automatically on the mobile telephone within the WPAN, using wireless communication links to transmit the dialing instructions to the phone. When combined with a wireless headset in the same WPAN, this could enable a more convenient device usage model for the user, who might never need to handle the mobile telephone at all (it could remain stored in a briefcase). Moreover, the user interface of the PDA is likely to be easier to use than a telephone keypad for retrieving contact information. This allows each of the devices (PDA, mobile phone, and wireless headset in this example) to be optimized to perform the specific tasks that they do best. The capabilities of each device are accessed from other devices via the WPAN. This often is preferred over an alternative usage model, the "all-in-one" device (imagine a PDA that also functions as a mobile telephone). Such multifunction devices might tend to be cumbersome and are more difficult to optimize for specific functions.

Because it was developed primarily to replace cables that connect mobile devices, Bluetooth wireless communication is an ideal WPAN technology. Indeed, most of the popular usage scenarios for Bluetooth technology originate in a WPAN of some sort, connecting personal devices to each other or to other networks in proximity. The use of Bluetooth communication links in WPANs is illustrated next, in an examination of various Bluetooth applications.

Bluetooth Applications

Because Bluetooth technology primarily is about replacing cables, many of its applications involve well-known usage scenarios. The value that Bluetooth communication adds to these types of applications derives from the ability to accomplish them without wires, enhancing mobility and convenience. For example, dial-up networking is a task commonly performed by many individuals, especially mobile professionals. One of the original usage scenarios used to illustrate the value of Bluetooth technology involves performing dial-up networking wirelessly—with the use of a mobile computer and a mobile phone, both equipped with Bluetooth communication, dial-up networking no longer is constrained by cables. This application and others are detailed next.

Basic Cable Replacement Applications

These applications comprise the original set of usage models envisioned for Bluetooth wireless technology. When the SIG was formed and the technology began to be popularized, these applications were touted as the most common ways in which Bluetooth wireless communication would be used. Although many other, perhaps more sophisticated, applications for Bluetooth technology have been discovered and envisioned, these original usage models remain as the primary application set. Nearly all of these early applications involve a mobile computer or a mobile telephone, and for the most part, they involve performing typical existing tasks wirelessly.

One such application, already mentioned, is dial-up networking. In this application, a Bluetooth communication link replaces the wire (typically a serial cable) between a computer and a telephone. When the telephone also is a mobile device, the network connection can be entirely wireless; a Bluetooth wireless link exists between the computer and the telephone, and a wide-area communications link (using typical cellular technology, such as the global system for mobile communication [GSM], time division/demand multiple access [TDMA], or others) carries the network traffic, using the mobile telephone as a wireless modem. Figure 1 depicts this usage model.

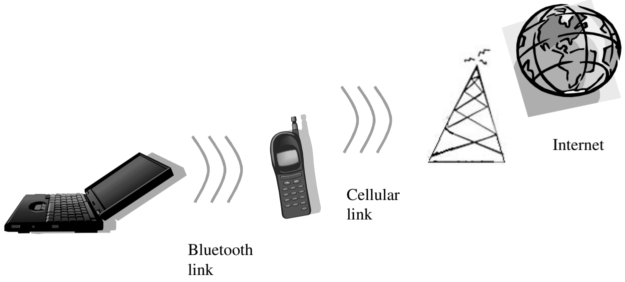

Figure 1: Dial-up networking illustration.

A variant of this application uses direct (rather than dial-up) connection to a network such as the Internet. In this case, the Bluetooth link allows a computer to connect to a network such as a LAN without using a cable. Together, these two applications (wireless dial-up networking and wireless LAN access) form a usage model that the SIG calls the *Internet Bridge*. Both applications involve access to a network, using existing protocols, with the main benefit being the ability to access the network without the cables that typically are required to connect the network client computer.

Another type of cable replacement application involves data transfer from one device to another. One of the most common such usage models is transferring files from one computer to another. This can be accomplished with removable media (diskettes, CDs), with cables (over a network or via a direct connection) or wirelessly (using infrared or Bluetooth communication, to name two ways). Infrared file transfer is not uncommon, but it requires the two devices to have a line of sight between them. Bluetooth file transfer operates similarly to that of IrDA® infrared file transfer (in fact, the Bluetooth protocol stack, discussed later, is designed such that the same application can be used over either transport medium). Bluetooth communication, being RF-based, does not require a line of sight between the two devices, however. Moreover, through the use of standard data formats, such as *vCard* (Internet Mail Consortium, 1996a), *vCal* (Internet Mail Consortium, 1996b), and others, objects other than files can be exchanged between devices using Bluetooth links in a manner similar to that used with IrDA. So, for example, electronic business cards, calendar appointments, and contact information can be shared wirelessly among devices.

Building on this capability to exchange data objects is the application that allows these same objects to be synchronized. This means that data sets on two devices reflect the same information at the point in time when they are synchronized. Hence, in addition to simply sending a copy of contact information or a calendar appointment from one device to another, the full address book or calendar can be synchronized between the two devices so that they have the same set of contacts or appointments. This allows a user to enter information on any convenient device and then have that information reflected on other devices by synchronizing with those devices. In addition to the benefit of performing these tasks wirelessly, by using standard protocols and data formats information can be exchanged easily among many kinds of devices. Specialized cables to connect two computers, or custom cradles to connect a PDA to a computer, are not needed once Bluetooth technology enters the picture. Instead, the same data can be exchanged and synchronized to and from notebook computers, PDAs, mobile phones, pagers, and other devices. This illustrates a hallmark of the value of Bluetooth technology: a single standard wireless link can replace many cables of various types, allowing devices that otherwise might not be able to be connected to communicate easily.

Another data transfer application is related to those just described, but it has a distinguished usage model because of the kind of data it transfers, namely, image data. The SIG calls this usage model the *instant postcard,* and it involves transferring pictures from one device to another. One reason that this application is separately described is because it involves the use of a digital camera. Today, when a camera captures new images, they typically are loaded onto a computer of some sort (or perhaps a television or similar video device) to be displayed. Through the use of Bluetooth wireless technology, this image transfer can be accomplished more easily, but once again, this standard form of wireless link enables the same data to be transferred to other types of devices. For example, rather than uploading photos to a computer, the photos might be transferred to a mobile phone. Even if the phone's display is not suitable for viewing the photo, it still could be e-mailed to someone who could view it on his computer or other e-mail device.

Until now this chapter has focused on applications involving data, but Bluetooth wireless technology also is designed to transport voice traffic (audio packets), and some of the cable replacement applications take advantage of this fact. The most notable of these is the wireless headset. Cabled headsets that connect to a mobile phone are widely used today to allow hands-free conversations. Bluetooth technology removes the cable from the headset to the telephone handset, enabling wireless operation that can allow the phone to be stowed away in a briefcase, pocket, or purse. In fact, as noted earlier, this particular application was the basis for the invention of Bluetooth technology. As with the previously discussed applications, however, once a standard wireless link is established, additional ways to connect other kinds of devices present themselves. For example, the same Bluetooth headset used with a mobile phone might also be used with a stationary telephone (again to allow hands-free operation and increased mobility), as well as with a computer (to carry audio traffic to and from the computer). Furthermore, although Bluetooth wireless communication was not originally designed to carry more complex audio traffic (such as digital music), advances are being made that will allow it to do so. With this capability, the same wireless headset also could be used with home entertainment systems, car audio systems, and personal music players. Hence, the Bluetooth SIG dubs this usage model the *ultimate headset.*

A variation on the wireless headset usage model is what the SIG calls the *speaking laptop.* In this application, Bluetooth links carry audio data in the same manner as for the headset application, but in this case the audio data is routed between a telephone and a notebook computer's speaker and microphone, rather than to a headset. One usage scenario enabled with this application is that of using the notebook computer as a speakerphone: A call made to or from a mobile telephone can be transformed into a conference call ("put on the speaker") by using the speaker and microphone built into nearly all portable (and desktop) computers.

Cordless telephony is another application for Bluetooth technology. With a Bluetooth voice access point, or cordless telephone base station, a standard cellular mobile telephone also can be used as a cordless phone in a home or office. The Bluetooth link carries the voice traffic from the handset to the base station, with the call then being carried over the normal wired telephone network. This allows mobile calls to be made without incurring cellular usage charges. In addition, two handsets can function as walkie-talkies, or an intercom system, using direct Bluetooth links between them, allowing two parties to carry on voice conversations in a home, office, or public space without any telephone network at all. Because a single mobile telephone can be used as a standard cellular phone, a cordless phone, and an intercom, the SIG calls this cordless telephony application the *three-in-one phone* usage model.

Additional Applications

Although Bluetooth wireless technology was developed especially for cable-replacement applications such as those just cited, many observers quickly realized that Bluetooth communication could be used in other ways, too. Here I describe a few of the many potential applications of Bluetooth technology, beginning with those that the SIG already is in the process of specifying.

The Bluetooth SIG focused primarily on the cable replacement applications already discussed in the version 1.x specifications that it released. The SIG also is developing additional profiles (detailed later) for other types of Bluetooth applications. Among these are more robust personal area proximity networking, human interface devices, printing, local positioning, multimedia, and automotive applications.

Bluetooth personal area networking takes advantage of the ability of Bluetooth devices to establish communication with each other based on their proximity to each other, so that ad hoc networks can be formed. The *Bluetooth Network Encapsulation Protocol* (BNEP) allows Ethernet packets to be transported over Bluetooth links, thus enabling many classic networking applications to operate in Bluetooth piconets (piconets are discussed at length in the section Bluetooth Operation). This capability extends the Bluetooth WPAN to encompass other devices. An example is the formation of an ad hoc Bluetooth network in a conference room with multiple meeting participants. Such a network could facilitate collaborative applications such as white-boarding, instant messaging, and group scheduling. Such applications could allow group editing of documents and scheduling of follow-up meetings, all in real time. Nonetheless, it should be noted that although this scenario resembles classic intranet- or Internet-style networking in some respects, Bluetooth personal area networking is not as robust a solution for true networking solutions as is a WLAN technology, such as IEEE 802.11 (described in the section Related Technologies).

Replacing desktop computer cables with Bluetooth communication links fundamentally is a cable replacement application (dubbed the *cordless computer* by the SIG), and this was one of the originally envisioned Bluetooth usage scenarios, but the original specifications did not fully address it. The new *Human Interface Device* (HID) specification describes how Bluetooth technology can be used in wireless computer peripherals such as keyboards, mice, joysticks, and so on. The Bluetooth printing profiles specify methods for wireless printing using Bluetooth communication, including "walk up and print" scenarios that allow immediate printing from any device, including mobile telephones and PDAs, as well as notebook computers, to any usable printer in the vicinity. This application of Bluetooth technology can obviate the need for specialized network print servers and their associated configuration and administration tasks.

Another application that can be realized with Bluetooth wireless technology is *local positioning.* Bluetooth technology can be used to augment other technologies, such as global positioning systems (GPS), especially inside buildings, where other technologies might not work well. Using two or more Bluetooth radios, local position information can be obtained in several ways. If one Bluetooth device is stationary (say, a kiosk), it could supply its position information to other devices within range. Any device that knows its own position can provide this information to other Bluetooth devices so that they can learn their current position. Sophisticated applications might even use signal strength information to derive more granular position information. Once position information is known, it could be used with other applications, such as maps of the area, directions to target locations, or perhaps even locating lost devices. *The Bluetooth Local Positioning Profile* specifies standard data formats and interchange methods for local positioning information.

Multimedia applications have become standard on most desktop and notebook computers, and the Bluetooth SIG is pursuing ways by which streamed multimedia data, such as sound and motion video, could be used in Bluetooth environments. The 1 Mbps raw data rate of version 1 Bluetooth radios is not sufficient for many sorts of multimedia traffic, but the SIG is investigating methods for faster Bluetooth radios that could handle multimedia applications. The SIG also is developing profiles for multimedia data over Bluetooth links.

Another emerging application area is that of automotive Bluetooth applications. Using Bluetooth communication, wireless networks could be formed in cars. Devices from the WPAN could join the automobile's built-in Bluetooth network to accomplish scenarios such as the following:

- Obtaining e-mail and other messages, using a mobile phone as a WAN access device, and transferring those messages to the car's Bluetooth network, where they might be read over the car's audio system using text-to-speech technology (and perhaps even composing responses using voice recognition technology)
- Obtaining vehicle information remotely, perhaps for informational purposes (for example, querying the car's current mileage from the office or home) or for diagnostic purposes (for example, a wireless engine diagnostic system for automobile mechanics that does not require probes and cables to be connected to the engine)
- Sending alerts and reminders from the car to a WPAN when service or maintenance is required (for example, e-mail reminders that an oil change is due or in-vehicle or remote alerts when tire pressure is low or other problems are diagnosed by the vehicle's diagnostic systems)

The SIG, in conjunction with automotive industry representatives, is developing profiles for Bluetooth automotive applications. This area is likely to prove to be an exciting and rapidly growing domain for the use of Bluetooth wireless technology.

These new applications comprise only some of the potential uses for Bluetooth wireless technology. Many other domains are being explored or will be invented in the future. Other noteworthy applications for Bluetooth wireless communications include mobile e-commerce, medical, and travel technologies. Bluetooth devices such as mobile phones or PDAs might be used to purchase items in stores or from vending machines; wireless biometrics and even Bluetooth drug dispensers might appear in the future (the 2.4-GHz band in which Bluetooth operates is called the industrial, scientific, and medical band); and travelers could experience enhanced convenience by using Bluetooth devices for anytime, anywhere personal data access and airline and hotel automated check-in. In fact, this latter scenario, including the use of a Bluetooth PDA to unlock a hotel room door, has already been demonstrated (InnTechnology, 2000).

The Bluetooth Protocol Stack

A complete discussion of the Bluetooth protocol stack is outside the scope of this article. Numerous books, including Miller and Bisdikian (2000) and Bray and Sturman (2000) offer more in-depth discussions of Bluetooth protocols. Here we present an overview of Bluetooth operation and how the various protocols may be used to accomplish the applications already discussed. A typical Bluetooth stack is illustrated in Figure 2. Each layer of the stack is detailed next.

Radio, Baseband, and Link Manager

These three protocol layers comprise the *Bluetooth module.* Typically, this module is an electronics package containing hardware and firmware. Today many manufacturers supply Bluetooth modules.

The *radio* consists of the signal processing electronics for a transmitter and receiver (transceiver) to allow RF communication over an *air-interface* between two Bluetooth devices. As noted earlier, the radio operates in the 2.4-GHz spectrum, specifically in the frequency range 2.400–2.4835 GHz. This frequency range is divided into

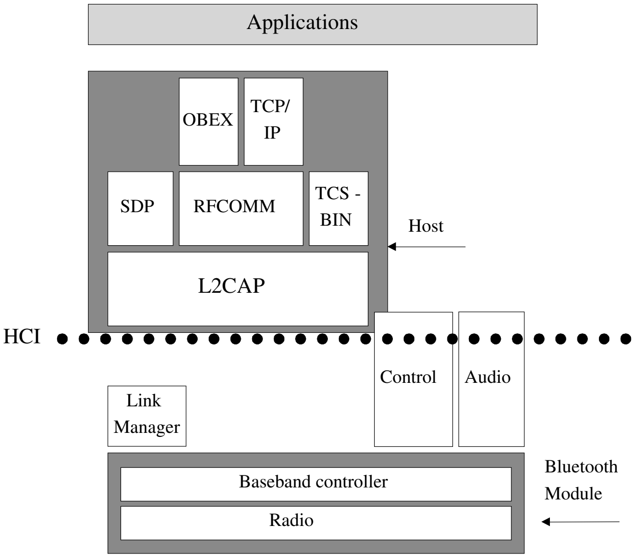

Figure 2: The Bluetooth protocol stack.

79 channels (along with upper and lower guard bands), with each channel having a 1-MHz separation from its neighbors. *Frequency hopping* is employed in Bluetooth wireless communication; each packet is transmitted on a different channel, with the channels being selected pseudo-randomly, based on the clock of the master device (master and slave devices are described in more detail later). The receiving device knows the frequency hopping pattern and follows the pattern of the transmitting device, hopping to the next channel in the pattern to receive the transmitted packets.

The Bluetooth specification defines three classes of radios, based on their maximum power output:

- 1 mW (0 dBm)
- 2.5 mW (4 dBm)
- 100 mW (20 dBm)

Increased transmission power offers a corresponding increase in radio range; the nominal range for the 0-dBm radio is 10 m, whereas the nominal range for the 20-dBm radio is 100 m. Of course, increased transmission power also requires a corresponding increase in the energy necessary to power the system, so higher power radios will draw more battery power. The basic cable replacement applications (indeed, most Bluetooth usage scenarios described here) envision the 0-dBm radio, which is considered the standard Bluetooth radio and is the most prevalent in devices. The 0-dBm radio is sufficient for most applications, and its low power consumption makes it suitable for use on small, portable devices.

Transmitter and receiver characteristics such as interference, tolerance, sensitivity, modulation, and spurious emissions are outside the scope of this chapter but are detailed in the Bluetooth specification (Bluetooth SIG, 2001a).

The *baseband controller* controls the radio and typically is implemented as firmware in the Bluetooth module. The controller is responsible for all of the various timing and raw data handling aspects associated with RF communication, including the frequency hopping just mentioned, management of the time slots used for transmitting and receiving packets, generating air-interface packets (and causing the radio to transmit them), and parsing air-interface packets (when they are received by the radio). Packet generation and reception involves many considerations, including the following:

- Generating and receiving packet payload
- Generating and receiving packet headers and trailers
- Dealing with the several packet formats defined for Bluetooth communication
- Error detection and correction
- Address generation and detection
- Data whitening (a process by which the actual data bits are rearranged so that the occurrence of zero and one bits in a data stream is randomized, helping to overcome DC bias)
- Data encryption and decryption

Not all of these operations are necessarily performed on every packet; there are various options available for whether or not a particular transformation is applied to the data, and in some cases (such as error detection and correction), there are several alternatives that may be employed by the baseband firmware.

The *link manager,* as its name implies, manages the link layer between two Bluetooth devices. Link managers in two devices communicate using the *link manager protocol* (LMP). LMP consists of a set of commands and responses to set up and manage a baseband link between two devices. A link manager on one device communicates with a link manager on another device (indeed, this is generally the case for all the Bluetooth protocols described here; a particular protocol layer communicates with its corresponding layer in the other device, using its own defined protocol. Each protocol is passed to the next successively lower layer, where it is transformed to that layer's protocol, until it reaches the baseband, where the baseband packets that encapsulate the higher layer packets are transmitted and received over the air interface). LMP setup commands include those for authenticating the link with the other device; setting up encryption, if desired, between the two devices; retrieving information about the device at the other end of the link, such as its name and timing parameters; and swapping the master and slave roles (detailed later) of the two devices. LMP management commands include those for controlling the transmission power; setting special power-saving modes, called hold, park, and sniff; and managing quality-of-service (QoS) parameters for the link. Because LMP messages deal with fundamental characteristics of the communication link between devices, they are handled in an expedited manner, at a higher priority than the normal data that is transmitted and received.

Control and Audio

The *control* and *audio* blocks in Figure 2 are not actual protocols. Instead, they represent means by which the upper layers of the stack can access lower layers. The control functions can be characterized as methods for inter-protocol-layer communication. These could include requests and notifications from applications, end users, or protocol layers that require action by another protocol layer, such as setting desired QoS parameters, requests to enter or terminate power-saving modes, or requests to search for other Bluetooth devices or change the discoverability of the local device. Often, these take the form of a user-initiated action, via an application, that requires the link manager (and perhaps other layers) to take some action.

The audio block in Figure 2 represents the typical path for audio (voice) traffic. Recall that Bluetooth wireless technology supports both data and voice. Data packets traverse through the L2CAP layer (described later), but voice packets typically are routed directly to the baseband, because audio traffic is isochronous and hence time critical. Audio traffic usually is associated with telephony applications, for which data traffic is used to set up and control the call and voice traffic serves as the content of the call. Audio data can be carried over Bluetooth links in two formats:

- Pulse code modulation (PCM), with either a-law or μ-law logarithmic compression
- Continuous variable slope delta (CVSD) modulation, which works well for audio data with relatively smooth continuity, usually the case for typical voice conversations

Host-Controller Interface (HCI)

The HCI is an optional interface between the two major components of the Bluetooth stack: the *host* and the *controller*. As shown in Figure 2 and described earlier, the radio, baseband controller, and link manager comprise the module, which is often, but not necessarily, implemented in a single electronics package. Such a module can be integrated easily into many devices, with the remaining layers of the stack residing on the main processor of the device (such as a notebook computer, mobile phone, or PDA). These remaining layers (described next) are referred to as the host portion of the stack.

Figure 2 illustrates a typical "two-chip" solution in which the first "chip" is the Bluetooth module and the second "chip" is the processor in the device on which the host software executes. (The module itself might have multiple chips or electronic subsystems for the radio, the firmware processor, and other external logic.) In such a system, the HCI allows different Bluetooth modules to be interchanged in a device, because it defines a standard method for the host software to communicate with the controller firmware that resides on the module. So, at least in theory, one vendor's Bluetooth module could be substituted for another, so long as both faithfully implement the HCI. Although this is not the only type of partitioning that can be used when implementing a Bluetooth system, the SIG felt it was common enough that a standard interface should be defined between the two major components of the system. A Bluetooth system could be implemented in an "all-in-one" single module, where the host and controller reside together in the same physical package (often called a "single-chip" solution), although in this case, the HCI might still be used as an internal interface. When the two-chip solution is used, the physical layer for the HCI (that is, the physical connection between the host and the controller) could be one of several types. The Bluetooth specification defines three particular physical layers for the HCI:

- Universal serial bus (USB)
- Universal asynchronous receiver/transmitter (UART)
- RS-232 serial port

Other HCI transports could be implemented; the Bluetooth specification currently contains details and considerations for these three.

Logical Link Control and Adaptation Protocol (L2CAP)

The Logical Link Control and Adaptation Protocol (L2CAP) layer serves as a "funnel" through which all data traffic flows. As discussed earlier, voice packets typically are routed directly to the baseband, whereas data packets flow to and from higher layers, such as applications, to the baseband via the L2CAP layer.

The L2CAP layer offers an abstraction of lower layers to higher layer protocols. This allows the higher layers to operate using more natural data packet formats and protocols, without being concerned about how their data is transferred over the air-interface. For example, the Service Discovery Protocol layer (discussed next) defines its own data formats and protocol data units. At the SDP layer, only the service discovery protocol needs to be handled; the fact that SDP data must be separated into baseband packets for transmission and aggregated from baseband packets for reception is not a concern at the SDP layer, nor are any of the other operations that occur at the baseband (such as encryption, whitening, and so on). This is accomplished because the L2CAP layer performs operations on data packets. Among these operations are segmentation and reassembly, whereby the L2CAP layer breaks higher layer protocol data units into L2CAP packets, which in turn can be transformed into baseband packets; the L2CAP layer conversely can reassemble baseband packets into L2CAP packets that in turn can be transformed into the natural format of higher layers of the stack.

An L2CAP layer in one Bluetooth stack communicates with another, corresponding L2CAP layer in another Bluetooth stack. Each L2CAP layer can have many channels. L2CAP channels identify data streams between the L2CAP layers in two Bluetooth devices. (L2CAP channels should not be confused with baseband channels used for frequency hopping. L2CAP channels are logical identifiers between two L2CAP layers.) An L2CAP channel often is associated with a particular upper layer of the stack, handling data traffic for that layer, although there need not be a one-to-one correspondence between channels and upper-layer protocols. An L2CAP layer might use the same protocol on multiple L2CAP channels. This illustrates another data operation of the L2CAP layer: protocol multiplexing. Through the use of multiple channels and a protocol identifier (called a *protocol-specific* *multiplexer,* or PSM), L2CAP allows various protocols to be multiplexed (flow simultaneously) over the air-interface. The L2CAP layer sorts out which packets are destined for which upper layers of the stack.

Service Discovery Protocol (SDP)

The SDP layer provides a means by which Bluetooth devices can learn, in an ad hoc manner, which services are offered by each device. Once a connection has been established, devices use the SDP to exchange information about services. An SDP client queries an SDP server to inquire about services that are available; the SDP server responds with information about services that it offers. Any Bluetooth device can be either an SDP client or an SDP server, acting in one role or the other at different times.

SDP allows a device to inquire about specific services in which it is interested (called *service searching*) or to perform a general inquiry about any services that happen to be available (called *service browsing*). A device can perform an SDP service search to look for, say, printing services in the vicinity. Any devices that offer a printing service that matches the query can respond with a "handle" for the service; the client then uses that handle to perform additional queries to obtain more details about the service. Once a service is discovered using SDP, other protocols are used to access and invoke the service; one of the items that can be discovered using SDP is the set of protocols that are necessary to access and invoke the service.

SDP is designed to be a lightweight discovery protocol that is optimized for the dynamic nature of Bluetooth piconets. SDP can coexist with other discovery and control protocols; for example, the Bluetooth SIG has published a specification for using the UPnP discovery and control technology over Bluetooth links.

RFCOMM

As its name suggests, the RFCOMM layer defines a standard communications protocol, specifically one that emulates serial port communication (the "RF" designates radio frequency wireless communication; the "COMM" portion suggests a serial port, commonly called a COM port in the personal computer realm). RFCOMM emulates a serial cable connection and provides the abstraction of a serial port to higher layers in the stack. This is particularly valuable for Bluetooth cable replacement applications, because so many cable connections—modems, infrared ports, camera and mobile phone ports, printers, and others—use some form of a serial port to communicate.

RFCOMM is based on the European Telecommunications Standards Institute (ETSI) TS07.10 protocol (ETSI, 1999), which defines a multiplexed serial communications channel. The Bluetooth specification adopts much of the TS07.10 protocol and adds some Bluetooth adaptation features. The presence of RFCOMM in the Bluetooth protocol stack is intended to facilitate the migration of existing wired serial communication applications to wireless Bluetooth links. By presenting higher layers of the stack with a virtual serial port, many existing applications that already use a serial port can be used in Bluetooth environments without any changes. Indeed, many of the cable replacement applications cited earlier, including dial-up networking, LAN access, headset, and file and object exchange, use RFCOMM to communicate. Because RFCOMM is a multiplexed serial channel, many serial data streams can flow over it simultaneously; each separate serial data stream is identified with a *server channel,* in a manner somewhat analogous to the channels used with L2CAP.

Telephony Control Specification-Binary (TCS-BIN)

The TCS-BIN is a protocol used for advanced telephony operations. Many of the Bluetooth usage scenarios involve a mobile telephone, and some of these use the TCS-BIN protocol. TCS-BIN is adopted from the ITU-T Q.931 standard (International Telecommunication Union, 1998), and it includes functions for call control and managing wireless user groups. Typically, TCS-BIN is used to set up and manage voice calls; the voice traffic that is the content of the call is carried over audio packets as described earlier. Applications such as the three-in-one phone usage model use TCS-BIN to enable functions such as using a mobile phone as a cordless phone or an intercom. In these cases, TCS-BIN is used to recognize the mobile phone so that it can be added to a wireless user group that consists of all the cordless telephone handsets used with a cordless telephone base station. TCS-BIN also is used to set up and control calls between the handset and the base station (cordless telephony) or between two handsets (intercom).

TCS-BIN offers several advanced telephony functions; devices that support TCS-BIN can obtain knowledge of and directly communicate with any other devices in the TCS-BIN wireless user group, essentially overcoming the master-slave relationship of the underlying Bluetooth piconet (detailed later). It should be noted that not all Bluetooth telephony applications require TCS-BIN; an alternative method for call control is the use of AT commands over the RFCOMM serial interface. This latter method is used for the headset, dial-up networking, and fax profiles.

Adopted Protocols

Although several layers of the Bluetooth protocol stack were developed specifically to support Bluetooth wireless communication, other layers are adopted from existing industry standards. I already have noted that RFCOMM and TCS-BIN are based on existing specifications. In addition to these, protocols for file and object exchange and synchronization are adopted from the Infrared Data Association (IrDA), and Internet networking protocols are used in some applications.

The IrDA's *object exchange* (OBEX) protocol is used for the file and object transfer, object push, and synchronization usage models. OBEX originally was developed for infrared wireless communication, and it maps well to Bluetooth wireless communication. OBEX is a relatively lightweight protocol for data exchange, and several well-defined data types—including electronic business cards, e-mail, short messages, and calendar items—can be carried within the protocol. Hence, the Bluetooth SIG adopted OBEX for use in its data exchange scenarios; by doing so, existing infrared applications can be used over Bluetooth links, often with no application changes.

Figure 3: The Bluetooth profiles.

In addition, the *infrared mobile communications* (IrMC) protocol is used for the synchronization usage model. Typically, infrared communication occurs over a serial port, so the adopted IrDA protocols operate over RFCOMM in the Bluetooth protocol stack.

Networking applications such as dial-up networking and LAN access use standard Internet protocols, including point-to-point protocol (PPP), Internet protocol (IP), user datagram protocol (UDP), and transmission control protocol (TCP). As shown in Figure 2, these protocols operate over the RFCOMM protocol. Once a Bluetooth RFCOMM connection is established between two devices, PPP can be used as a basis for UDP–IP and TCP–IP networking packets. This enables typical networking applications, such as network dialers, e-mail programs, and browsers, to operate over Bluetooth links, often with no changes to the applications.

Bluetooth Profiles

I have presented an overview of the Bluetooth protocols, which are specified in Bluetooth SIG (2001a), the first volume of the Bluetooth specification. The Bluetooth SIG also publishes a second volume of the specification (Bluetooth SIG, 2001b), which defines the Bluetooth *profiles*. Profiles offer additional guidance to developers beyond the specification of the protocols. Essentially, a profile is a formalized usage case that describes how to use the protocols (including which protocols to use, which options are available, and so on) for a given application. Profiles were developed to foster interoperability; they provide a standard basis for all implementations, to increase the likelihood that implementations from different vendors will work together, so that end users can have confidence that Bluetooth devices will interoperate with each other. In addition to the profile specifications, the SIG offers other mechanisms intended to promote interoperability; among these are the *Bluetooth Qualification Program* (a definition of testing that a Bluetooth device must undergo) and *unplugfests* (informal sessions where many vendors can test their products with each other); detailed discussions of these programs are outside the scope of this chapter, but more information is available on the Bluetooth Web site (Bluetooth SIG, 2002b).

Our earlier discussion of Bluetooth applications presented several usage models for Bluetooth wireless communication. Many of these applications have associated profiles. For example, the dial-up networking profile defines implementation considerations for the dial-up networking application. Most of the applications cited here have associated profiles, and many new profiles are being developed and published by the SIG; the official Bluetooth Web site (Bluetooth SIG, 2002b) has a current list of available specifications. In addition, there are some fundamental profiles that describe basic Bluetooth operations that are necessary for most any application. The version 1.1 profiles are illustrated in Figure 3. This figure shows the relationship among the various profiles, illustrating how certain profiles are derived from (and build upon) others.

The leaf nodes of the diagram consist of profiles that describe particular applications—file and object transfer, object push, synchronization, dial-up networking, fax, headset, LAN access, cordless telephony, and intercom. The telephony (TCS-BIN) profile includes elements that are common to cordless telephony and intercom applications; similarly, the generic object exchange profile describes the common elements for its children, and the serial port profile defines operations used by all applications that use the RFCOMM serial cable replacement protocol. Note that the generic object exchange profile derives from the serial port profile; this is because OBEX operates over RFCOMM in the Bluetooth protocol stack.

The two remaining profiles describe fundamental operations for Bluetooth communication. The service discovery application profile describes how a service discovery application uses the service discovery protocol (described earlier). The generic access profile is common to all applications; it defines the basic operations that Bluetooth devices use to establish connections, including how devices become discoverable and connectable, security considerations for connections, and so on. The generic access profile also includes a common set of terminology used in other profiles; this is intended to reduce ambiguity in the specification. The generic access and service discovery application profiles are mandatory for all Bluetooth devices to implement, because they form the basis for interoperable devices. Other works, including Miller and Bisdikian (2000), delve more deeply into the Bluetooth profiles.

Bluetooth Operation

Having discussed WPANs, Bluetooth applications, protocols, and profiles, I now turn our attention to some of the fundamental concepts of Bluetooth operation, illustrating an example flow for a Bluetooth connection.

At the baseband layer, Bluetooth operates on a master–slave model. In general, the *master* device is the one that initiates communication with one or more other devices. *Slaves* are the devices that respond to the master's queries. In general, any Bluetooth device can operate as either a master or a slave at any given time. The master and slave roles are meaningful only at the baseband layer; upper layers are not concerned with these roles. The master device establishes the frequency hopping pattern for communication with its slaves, using its internal clock values to generate the frequency hopping pattern. Slaves follow the frequency hopping pattern of the master(s) with which they communicate.

When a master establishes a connection with one or more slaves, a *piconet* is formed. To establish the connection, a master uses processes called *inquiry* and *paging.* A master can perform an inquiry operation, which transmits a well-defined data sequence across the full spectrum of frequency hopping channels. An inquiry effectively asks, "Are there any devices listening?" Devices that are in *inquiry scan* mode (a mode in which the device periodically listens to all of the channels for inquiries) can respond to the master's inquiry with enough information for the master device to address the responding device directly. The inquiring (master) device may then choose to page the responding (slave) device. The page also is transmitted across the full spectrum of frequency hopping channels; the device that originally responded to the inquiry can enter a *page scan* state (a state in which it periodically listens to all of the channels for pages), and it can respond to the page with additional information that can be used to establish a baseband connection between the master and the slave. The master can repeat this process and establish connections with as many as seven slaves at a time. Hence, a piconet consists of one master and up to 7 active slaves; additional slaves can be part of the piconet, but only seven slaves can be active at one time. Slaves can be "parked" (made inactive) so that other slaves can be activated. Figure 4 illustrates a typical Bluetooth piconet. Note that a device could be a slave in more than one piconet at a time, or it could be a master of one piconet and a slave in a second piconet. In these cases, the device participating in multiple piconets must use the appropriate frequency hopping pattern in each piconet, so it effectively must split its time among all the piconets in which it participates. The Bluetooth specification calls such interconnected piconets *scatternets*.

Once a piconet is formed (a baseband connection exists between a master and one or more slave devices), higher layer connections can be formed, and link manager commands and responses may be used to manage the link. At some point, it is likely that an L2CAP connection will be formed for data packets (even if the main content for a link is voice traffic, an L2CAP data connection will be needed to set up and manage the voice links). A Bluetooth device can have one data (L2CAP) connection and up to three voice connections with any other Bluetooth device at a given time (recall, however, that L2CAP connections can be multiplexed, so many different data streams can flow over the single L2CAP connection). Once an L2CAP connection is established, additional higher layer connections can be established. If the devices are not familiar to each other already, it is likely that an SDP connection will be used to perform service discovery. RFCOMM and TCS-BIN connections also might be made, depending on the application. From here, applications can manage voice and data packets to accomplish their usage scenarios, which might be those defined by Bluetooth profiles or other ways to use Bluetooth wireless communication to accomplish a given task. Additional details about fundamental Bluetooth operations and connection establishment, including the various types of packets, master–slave communication protocols, and timing considerations, are outside the scope of this chapter but are detailed in works such as Miller and Bisdikian (2000) and Bray and Sturman (2000).

An additional noteworthy aspect of Bluetooth operation is security. In the wireless world, security justifiably is a key concern for device manufacturers, device deployers and end users. The Bluetooth specification includes security measures such as authentication and encryption. At the time that a link is established, Bluetooth devices may be required to authenticate themselves to each other. Once a link has been established, the data traffic over that

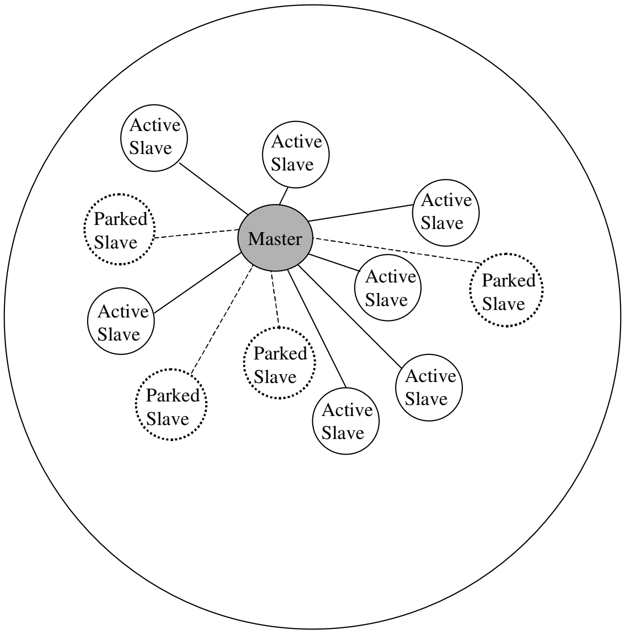

Figure 4: Example of a Bluetooth piconet.

link may be required to be encrypted. The methods used for authentication and encryption are detailed in the specification, and the Bluetooth profiles discuss what security measures should be employed in various circumstances (for example, the file transfer profile requires that both authentication and encryption be supported, and it recommends that they be used). Applications are free to impose additional security restrictions beyond those that are provided in the specification. For example, applications might choose to expose data or services only to authorized users or to implement more robust user authentication schemes. Details of the operation of Bluetooth security features are outside the scope of this chapter but are detailed in works such as Miller and Bisdikian (2000) and Bray and Sturman (2000).

Related Technologies

Other sources, including other chapters in this encyclopedia (see the "Cross References" section), discuss related wireless communication technologies in some depth. Here I briefly describe two particularly interesting related technologies, IrDA and IEEE 802.11 WLANI. I also comment on the IEEE 802.15.1 WPAN standard.

IrDA technology (IrDA 2002) uses infrared optical links, rather than RF links, to accomplish wireless communication between two devices. IrDA ports are common on many portable computing and communication devices and often are found on the same sorts of devices that are good candidates for using Bluetooth technology. IrDA and Bluetooth technologies share several aspects:

- Both are for short-range communication.
- Both use low-power transmission.
- Both are useful for cable-replacement applications.

Some differences between the two technologies are the following:

- IrDA typically uses less power than Bluetooth radios.
- IrDA data rates typically are greater than those of Bluetooth wireless communication.
- IrDA technology, because it uses optical communication, requires a "line of sight" between the two devices, whereas Bluetooth technology, because it uses RF communication, can penetrate many obstacles that might lie between two devices.

As already noted, many IrDA applications are well suited for use with Bluetooth links, and the Bluetooth SIG adopted the OBEX and IrMC protocols from the IrDA specification for use in the Bluetooth specification to foster the use of common applications for either technology. For certain applications in certain situations, one technology or the other might be the most suitable to use. A more detailed comparison of the two technologies can be found in Suvak (1999).

Many articles (e.g., Miller, 2001) have dealt with the relationship between IEEE 802.11 WLAN (IEEE, 1999) and Bluetooth WPAN technologies. Often, these two technologies are portrayed as being in competition with one another, with the proposition that one will "win" at the expense of the other. In fact, I believe, as many do, that these two technologies are complementary. Indeed, they are optimized for different purposes and applications. IEEE 802.11 is for WLAN applications, whereas Bluetooth technology is aimed at WPAN applications. Similarities between the two technologies include the following:

- Both operate in the 2.4-GHz RF spectrum. (The IEEE 802.11 standard actually includes two variants, 802.11a and 802.11b. Here I focus primarily on 802.11b. IEEE 802.11a operates in the 5-GHz spectrum.)
- Both use spread spectrum to communicate.
- Both can be used to access networks.

There are, however, distinct differences between the two technologies, including the following:

- IEEE 802.11 has a longer range (nominally 100 m) versus the typical nominal range of 10 m for Bluetooth wireless communication.
- IEEE 802.11 permits a much faster data rate (about 11 Mbps for 802.11b, even faster for 802.11a) than does Bluetooth technology (about 1 Mbps).
- The topology, higher data rate, and longer range of IEEE 802.11 WLAN technology inevitably lead to higher power consumption on average, making it less suitable for small portable personal devices with limited battery power.
- IEEE 802.11 is intended to be used for Ethernet-style networking applications in a LAN environment—it is a typical LAN without the wires—whereas Bluetooth is optimized for WPAN applications, notably cable replacement.

Indeed, the IEEE distinguishes between WLAN and WPAN technologies and has a separate standard, IEEE 802.15.1 (IEEE, 2001) for WPAN applications. In fact, this IEEE 802.15.1 standard is based on the Bluetooth specification, and it essentially adopts a subset of the Bluetooth technology as the IEEE standard. Using Bluetooth wireless technology as the basis for the IEEE WPAN standards offers further evidence that Bluetooth and IEEE 802.11 technologies can complement each other, as does the fact that the Bluetooth SIG and the IEEE work together on certain issues, including pursuing methods by which the RF interference between the two technologies can be minimized.

CONCLUSION

This introduction to Bluetooth wireless technology has touched on what can be done with the technology (Bluetooth applications), how it began and how it now is managed (the Bluetooth SIG), how it works (Bluetooth protocols, profiles, and operation), and how it relates to some other wireless communication technologies. The chapter focused on the application of Bluetooth wireless communication as a WPAN technology for connecting personal portable devices. I have presented several references where this topic is explored in greater detail.

With tremendous industry backing, a design to work with both voice and data, the ability to replace cumbersome cables, and many new products being deployed on a regular basis, Bluetooth wireless technology is poised to become an important way for people to communicate for the foreseeable future. From its genesis as a method to provide a wireless headset for mobile phones, this technology named for a Danish king continues to spread across the planet.

GLOSSARY

Bluetooth wireless technology Name given to a wireless communications technology used for short-range voice and data communication, especially for cable-replacement applications.

Bluetooth SIG The Bluetooth Special Interest Group, an industry consortium that develops, promotes, and manages Bluetooth wireless technology, including the Bluetooth qualification program and the Bluetooth brand.

Frequency-hopping spread spectrum A method of dividing packetized information across multiple channels of a frequency spectrum that is used in Bluetooth wireless communication.

IEEE 802.11 A wireless local-area network standard developed by the Institute for Electrical and Electronics Engineers that is considered complementary to Bluetooth wireless technology.

IEEE 802.15.1 A wireless personal area network standard developed by the Institute for Electrical and Electronics Engineers that is based on Bluetooth wireless technology.

Infrared Data Association (IrDA) An industry consortium that specifies the IrDA infrared communication protocols, some of which are used in the Bluetooth protocol stack.

Piconet A Bluetooth wireless technology term for a set of interconnected devices with one master and up to seven active slave devices.

Profile In Bluetooth wireless technology, a specification for standard methods to use when implementing a particular application, with a goal of fostering interoperability among applications and devices.

Radio frequency (RF) Used in the Bluetooth specification to describe the use of radio waves for physical layer communication.

Wireless personal area network (WPAN) A small set of interconnected devices used by one person.

Business Plans for E-commerce Projects

Amy W. Ray, *Bentley College*

INTRODUCTION AND BACKGROUND

Numerous excellent resources exist to help would-be entrepreneurs with the technical aspects of writing a business plan, many of which are referenced here. Many articles have also been written on financial management of e-businesses, but most of these are targeted to helping venture capitalists (VCs) rather than entrepreneurs. Would-be entrepreneurs should begin by taking one step back from the actual preparation of a written business plan to consider the types of funding available for start-up e-businesses. Deciding how best to fund a start-up company is the first important issue faced by entrepreneurs, yet the consequences of specific choices are often overlooked—the people who fund the company will invariably have a major impact on how the company is ultimately managed.

Although there are numerous benefits to actually writing a business plan, most formal business plans are executed as a requirement for obtaining external funding, and the primary source of funding for e-businesses is venture capital. In fact, Venture Economics, a New York-based consulting firm, notes that about $240 billion has been poured into venture funds since the beginning of 1998 (Healy, 2002). This number does not include the significant contributions from VCs beyond the large, centrally managed venture funds. Accordingly, the benefits and challenges of using venture capital as a primary source of start-up funding are discussed here. Through consulting engagements with numerous start-up companies, the number one problem this author sees is that entrepreneurs fail to recognize that differences between their motivations for starting businesses and the investors' motivation for funding them. Publicly available examples are used throughout this chapter to help explain the additional volatility that entrepreneurs face when using venture capital to fund their e-business start-up companies.

Beginning of the Dot-com Gold Rush

The mid-1990s marked the beginning of the dot-com gold rush, a period of time when investors eagerly supplied capital to any entrepreneur willing to brave the mysterious world of electronic commerce and build a business-to-consumer (B2C) company presence on the Internet. All would-be entrepreneurs needed were the words "online," "dot-com," or "electronic commerce" in their business plans to spark significant interest. Traditional concerns regarding the potential to generate revenues—typically measured by the existence of current sales—were temporarily suspended, as investors believed that the Internet held limitless potential and that existing business methods for sales held little predictive value for the success of an e-business. Essentially, as recently as 1993 the boundaries of this new frontier were completely unknown and every investment was a tremendous leap of faith. Yet many investors readily made this leap, believing that the payoff would be worth it.

Since 1993, we have learned a great deal about the Internet's role in business, including the fact that many of the keys to success for an e-business venture are the same as the keys to success for most traditional business ventures. "Just because you're part of the Net doesn't mean that the laws of economics have been repealed. You've got to have a real business," says Bill Reichart, the current President of Garage Technology Ventures (Aragon, 2000). The challenge is in finding the right balance between traditional and new business measures and methods. Many e-business ventures that were started in the mid-1990s continue to flourish, but many more ventures have come and gone. What we hear about most in the popular press are the spectacular failures of the dot-com companies, often dubbed "dot-bombs." In fact, whole Web sites have been dedicated to documenting these failures. Table 1 lists some of the failed companies' documentation sites, still up and running in September 2002. It is interesting to note

Table 1 Listing of Dot-com Failure Web Sites

HOOVERS	http://www.hoovers.com/news/detail/0,2417,11_3583,00.html
ITWATCHDOG	http://www.itwatchdog.com/NewsFeeds/DotcomDoom.html
PLANETPINKSLIP	http://www.planetpinkslip.com/
DOTCOMSCOOP	http://www.dotcomscoop.com
WEBMERGERS	http://www.webmergers.com/

that at one time many more documentation sites existed, but many of them ceased to exist as the economy slowed considerably during the third quarter of 2001 and continued to decline for several months afterward.

Studying past failure is an important part of increasing future likelihood of success, lest history repeat itself. Many articles have documented the explosion of e-business failures, with particular emphasis given to the myriad new but bad ideas that have been funded. However, that's not the entire story, or even the most interesting bit of the story. In this chapter, a brief discussion of other major reasons for dot-com failures precedes the discussion of keys to business plan success. Specifically, this chapter focuses on two additional key factors in numerous dot-com failures. First, the rapidly changing interests of investing firms are discussed. That is followed by a discussion of failed frontrunners with new and good business ideas that just lost their balance on the steep learning curve of new customer issues and/or business infrastructure requirements for e-business success.

Changing Interests of Investing Firms

Beginning in the mid-1990s, numerous investors eagerly sought electronic commerce ventures and were especially interested in funding B2C start-ups. The prospect of potentially reaching any consumer around the world without the cost of setting up physical shops seemed to hold unlimited profit potential. In fact, for a short period of time it seemed that the ultimate goal was to find and fund purely virtual companies, or companies completely independent of physical constraints. One of the first successful virtual companies is Tucows (http://www.tucows.com). Scott Swedorski, a young man who was very good at developing Winsock patches for Microsoft products, started Tucows in 1993. Mr. Swedorski developed a Web site and posted software patches as freeware. The Web site became so successful among software developers that advertisers rushed to place banner advertisements on the Web site. It is interesting to note that not only is Tucows one of the first successful virtual companies, it is also one of a very few companies that successfully used banner advertising as a sustainable business model. Indeed, Tucows is the exception, not the norm. Mr. Swedorski recognized a unique market need and fulfilled it, using the Internet.

In contrast, many new e-business start-ups have been driven more by a desire to identify new Internet markets rather than by an existing need. That is one valuable lesson from the Tucows example. Another lesson is that Tucows did not need venture capital funding because the company grew as a result of meeting a need in a new way. There is much less risk all around if an entrepreneur with a good idea can start small and grow the business slowly. Entrepreneurs who want to start big usually require venture capital. Invariably, this means that entrepreneurs will relinquish control of company management. It also means that overall the financial stakes are higher.

Two examples of start-up failures are briefly documented here to illustrate the related risks of starting big and using venture capital. Please note, however, that these examples are not intended to represent an indictment of VCs. Rather, it is a call to attention of the challenges of using venture capital that are generally overlooked.

Pets.com started off as a good idea—one-stop online shopping for pet supplies, from food to beds to routine medications. Pets.com was started late in the 1990s, a time when VCs were pushing managers to establish brand recognition at all costs. During this period, it was common for VCs to give large sums of money to start-up managers and tell them to spend aggressively on advertising campaigns designed to establish significant brand recognition as quickly as possible. During 1998 and 1999, the spectacular successes of a few firms with this strategy further encouraged other firms to push the limits on advertising campaigns. For example, exorbitant spending by the start-ups monster.com and hotjobs.com during the Superbowl in 1999 proved to be very successful. There was little reason to believe that it wouldn't work for other companies, such as Pets.com. Yet in the fiscal year ending September 30, 1999, Pets.com made $619,000 in revenues and spent $11,815,000 on marketing and sales. They were arguably successful in establishing brand recognition, as most people today would still recognize the Pets.com sock puppet, but the cost was too high. In the year 2000, they went public, but despite their brand recognition, consumers did not come in as quickly as as needed to build revenues. Consequently, they closed their doors the same year they went public.

The role of VCs in the failure of Pets.com and similar companies during the late 1990s is often overlooked in the retelling of the stories but was, in fact, key to those failures. Instead of fostering the vision of a sustainable business model, many VCs pushed artificial company growth purely through venture spending, with the goal of taking the company public as quickly as possible. Once such companies went through their initial public offering and public investors started to buy, the original VCs often sold their shares. Thus, it was traditional investors, not the VCs, who were left holding the losses. Traditional investors have learned the hard way that revenues matter, even for young companies. At the same time, for would-be entrepreneurs interested in seeking venture capital, such stories provide important lessons: Logistics and transportation issues probably would not have spun so far out of control if companies had started smaller, and brand recognition is not the only thing that matters.

It is important to keep in mind the focus of high risk investors such as VCs: They are willing to make higher risk investments with the hope of fast and significant payoffs. Unfortunately, this translates into an environment where some of those investors are willing to sacrifice the long-term future of a start-up company for their own profitability. Accordingly, it is very important that entrepreneurs check the track records of different investors before deciding whom to approach for funding.

VCs also played a major role in the failure of companies that never went public simply by shifting their interest to other types of start-ups before their previous start-up investments had stabilized. Streamline.com was an online grocery company that had a business model superior to most of their competitors' in terms of provisions for customer value and service. One of their primary problems was that they underestimated logistics and transportation costs, and they also found that competing with large grocery stores for top-quality products from food production companies was difficult. By the time that they began to learn from these issues, the VCs decided against further financing of the business, as their interests had shifted to other, newer types of emerging e-commerce companies.

The initial enthusiasm for B2C start-ups in the mid-1990s was replaced in the late 1990s with interest in the business-to-business (B2B) space. Investors began to realize that the profit potential in the B2B space was much greater because of larger transaction size and volume and greater customer reliability (businesses instead of individuals). Soon after B2B business plans became the favored choice for VCs, investors began to realize that a lot of work on Internet infrastructure was needed in order to truly exploit the Internet's potential. Thus, companies building software applications and other support mechanisms for strengthening the Internet's infrastructure replaced B2B investments as the favored business plans to invest in.

Within the span of 5 years or so, the interests of investors moved from B2C, to B2B, to Internet infrastructure business plans. This was taking place at the same time entrepreneurs were receiving large sums of money to build artificial growth. The result was that a number of companies with sound business plans grew too quickly to be sustainable on their own revenues, yet venture backing stopped, as VCs moved on to what they deemed to be more exciting categories of business plans. Streamline.com is but one example of a B2C company that started to show signs of progress as interest in financing shifted from B2C to what were considered potentially more lucrative ventures.

The moral of the story is that entrepreneurs looking for venture backing need to understand trends in business as well as what investments are favored by venture firms. Entrepreneurs willing to start smaller and grow more slowly can maintain control of the company's management and can move along the learning curve at a more reasonable pace. On the other hand, entrepreneurs with clear ideas for fulfilling significant and known market needs with electronic commerce businesses should genuinely consider venture capital as a funding option.

Confounding Organizational Issues

In the previous section, Streamline.com was mentioned as a firm that could not attract additional rounds of funding as they were learning how to manage their operations. Many online stores, such as Streamline.com and Amazon.com, started off believing they would compete directly with physical stores. Indeed, during the mid-1990s there was much discussion regarding anticipated changes in profits of physical stores and anticipated changes in consumer behavior. In the end, it became clear that most consumers were primarily interested in online shopping as an additional convenience rather than as an exclusive alternative to shopping in physical stores. This meant that online stores did not grow their market shares as quickly as they had hoped or anticipated.

Also, online stores underestimated their own dependence on companies with a physical presence, such as warehouses and distribution centers. Amazon.com is a perfect example of a company that ultimately was reorganized when managers recognized they needed the physical world more than they originally imagined (Vigoroso, 2002).

Brick-and-mortar companies making e-business investments struggled less with e-business investments, as they already had the infrastructure support they needed and they also had a clearer understanding of their customer base. In fact, many brick-and-mortar companies learned very quickly how to adopt best practices from the efforts of virtual companies and had the capital to implement their ideas with much less trouble than the virtual firms. Yet it is also interesting to note that many of these brick-and-mortar ventures into e-business lacked the innovation and forethought that could have resulted in truly innovative business practices. For example, Barnes and Noble developed their Web presence completely separately from their physical presence. Barnesandnoble.com had a completely different staff and completely different databases. Once the managers of the brick-and-mortar establishment felt that the market had stabilized and that the threat of market share loss from such companies as Amazon.com had dissipated, the managers of the brick-and-mortar Barnes and Noble decided to keep some shares in barnesandnoble.com but sell off the rest of virtual Barnes and Noble. Imagine, however, what innovations might have developed if, for example, the online databases had been fully integrated with the databases of sales from physical inventories? A much more complete understanding of customer spending habits on books could have been obtained.

Organizing the Keys to Success

Many of the keys to success for e-business ventures are simply the keys to success for any new business. The business world has learned a great deal by doing postmortem analyses of failed e-business start-ups. We have learned that customers want Web options as opposed to Web exclusivity in their lives. We have relearned that revenues count, relationships with suppliers are important, and a host of other traditional business values are still relevant. Many core considerations for building a successful company did not change as a result of the high tech investment boom and have not changed since the investment bust. Yet there are also some unique issues to tackle for e-business start-ups. The next four sections of this paper provide a layered view of methods for building a successful e-business plan, starting with the most general success considerations and building to the most specific issues. In particular, keys to success are analyzed as follows: considerations for any new business venture, considerations for any new company, special concerns when planning a new e-business venture for an existing brick-and-mortar firm, and special considerations when starting a new business that is primarily an e-business.

CONSIDERATION FOR ANY NEW BUSINESS VENTURE

A business venture may be anything, from an investment in a major new project by an existing company, to the start-up of a new company. Although new and established companies have some unique challenges and opportunities, there are also numerous issues common to both types of companies. Regardless of the size and sophistication of any given company, it is imperative to begin with three basic questions: what, who, and how much. More specifically, what is the venture goal or strategy, and how is the proposed business plan different from competitors' plans? Who will be designated as the key leaders for the venture, and approximately how much capital is needed to start the project or company? This section takes a closer look at each of these issues.

Identification of a Competitive Mission

The first thing angel investors or VCs will look at in a business plan is the executive summary. Specifically, they will be looking to see how the mission of a company is different from others they have seen. Investors will be looking for evidence that the company is proposing products or services that are in demand and that the organizational leaders in some way demonstrate innovation in their thinking about running the business. They will also be looking for evidence that the key managers have given adequate thought and consideration to the competitive environment. Investors want assurance that thorough analysis of the customers, competitors, and suppliers has been completed. Since the failure of so many e-business start-ups, investors have started scrutinizing mission statements very carefully and asking organizational leaders numerous difficult questions prior to making an investment. In a sense, this is an advantage to the proposed organizational leaders, as they should be forced to consider many possible business scenarios prior to actually starting their business.

Established brick-and-mortar companies investing in e-business operations, either B2B or B2C, should ask themselves the same difficult questions that VCs and bankers will ask entrepreneurs, to ensure that the proposed business plan fits well with the organization's existing missions and goals. However, brick-and-mortar companies often find themselves in a position of investing in e-business out of competitive necessity rather than out of competitive strategy. As a result, the e-business investments of the brick-and-mortar companies are often not leveraged to the extent they could be if they were more strategically linked to organizational goals and missions. Barnes and Noble is an example of lost opportunity when a major investment in e-business is never strategically linked to other core services offered by the company.

Key Employees

It is important to identify project leaders and key personnel as early as possible. These individuals need to provide strong leadership to the organization and to shape the company's future. Yet aspiring entrepreneurs often learn that finding a good business partner is about as difficult as finding a good marriage partner. First and foremost, entrepreneurs should find someone whose skills complement their skills. For example, a software engineer needs someone to be responsible for designing a marketing and sales plan. Also, entrepreneurs need partners who share their vision and, perhaps most important, are capable of helping fulfill that vision. Many would-be entrepreneurs are enthusiastic at the beginning of a start-up venture but do not know how, or do not have the wherewithal, to see the vision through to fruition. It is generally not a good idea to jump into a business venture with a relative stranger. A possible exception is if the partner candidate has a proven track record and enough time is spent with him or her to know that a good rapport exists. A proven track record for follow-through is of equal importance to rapport, however, and should not be overlooked simply because the person is likable. Anyone who can't execute your business plan effectively will quickly become less likable!

Ronald Grzywinski and Mary Houghton, cofounders of Shorebank Corp (http://www.sbk.com) note that effective management also requires a commitment to developing and creating opportunities for others to move through the ranks of the organization. They find that it is most difficult to find personnel with strong general management skills. Accordingly, they invest a great deal in building these skills in their existing personnel.

Identifying key personnel for e-business ventures of brick-and-mortar companies has its own challenges. Identifying whom to designate as the new managers for the e-business venture of a brick-and-mortar company involves deciding whether to move proven managers from the existing organization over to the e-business, or whether to hire new personnel from outside the company. Existing employees can ensure that an understanding of the current customer base is considered as decisions are made to develop the new venture. On the other hand, it may be possible to attract e-business veterans who can help the traditional management team with the e-business learning curve. It seems like an attractive option to hire a combination of insiders and outsiders to run new e-business ventures, but care must be taken to ensure that a culture clash does not get in the way of effective management.

In any event, it is most important that the strategic goals and missions of the e-business be clearly thought out and articulated at the very beginning, and that every subsequent decision be measured against these goals.

This will ensure that the scope of projects considered by the company stays reasonable and that the company does not take off in directions that cannot be subsequently supported by the core capabilities of the organization. Although this sounds like common sense, managers often get so caught up in either making a sale—any sale under any circumstances—that they forget to focus on fulfilling the strategic missions of the company. A clearly articulated and carefully considered mission that is continuously referenced by the management team can significantly reduce the likelihood of miscommunication within the organization and will help keep all personnel on the same strategic page.

Budgeting

Budgeting for any new business venture is not easy. E-business ventures, however, are particularly difficult to budget for, as the majority of capital used in start-up is for Web and other software development, network infrastructure, personnel, marketing, and other intangible items. Budgeting for intangibles is difficult because costs are difficult to estimate and the resulting financial benefits are difficult to calculate. Yet without adequate effort to capture estimated costs and benefits, financial control of a company is quickly lost. Oracle financial managers note that traditional business planning relies heavily on return on investment (ROI) as the key metric for measuring project effectiveness. However, to accurately measure e-business effectiveness, organizations are looking at multiple additional metrics, including changes in productivity, changes in cost of sales, and changes in the costs of customer acquisition and the gains in customer retention (Oracle, 2001). In any event, perhaps it is most important to remember that numbers associated with intangible assets are invariably based on numerous assumptions. Wherever financial calculations and projections are made pertaining to e-business, the assumptions should be readily available as well. Typical financial information that should be incorporated into the business plan include the following: sales projections, product demand, cost of sales/services, breakdown of fixed and variable costs, projected months to break even, projected months to positive cash flow, estimated capital burn rate, and a full set of pro forma financial statements.

While developing financial projections, it is also worthwhile to consider outsourcing some e-business activities. Even if managers ultimately decide to develop and manage everything in-house, consideration of outsourcing can help clarify cost and management issues. Common e-business activities that many companies have decided to outsource today include hosting of Web services, customer support applications, information security management, and advertising.

It is worthwhile mentioning that there are numerous budgeting tools available for e-business entrepreneurs on the Web. For example, at Entrepreneur.com, many forms are available for downloading, including forms to help managers estimate business start-up cash needs, business insurance planning worksheets, personal cash flow management statements, and development budget worksheets. There are also many stories in the online business periodicals documenting financial mistakes made in e-business start-ups. An article by Benoliel (2002) cites five of the most common financial mistakes made by new e-businesses.

Overstating Projections. Benoliel notes that like Enron, some companies may overstate expected revenues to deceive, but many companies overestimate earnings simply by being overly enthusiastic. In either case, realistic budgets and projections are the best choice for the long-term success of relationships between managers and investors.

Ignoring Immediate Budgetary Needs. Although some managers err by being overly optimistic, others will not ask for enough upfront capital to get started because they don’t want to scare off potential investors. Since the failure of so many e-businesses, managers have created more conservative budgets, believing that capital will be much more difficult to come by. Ultimately, however, there is still a lot of investment capital out there and investors are looking for good ideas to fund adequately for success. Again, best-estimate budgets are better than overly ambitious or overly conservative budgets.

Revenues = Positive Cash Flow. This is a simple accounting principle that many entrepreneurs without a business background can get into trouble over. Where possible, a conservative policy of delaying new purchases until after revenues are collected and existing bills are paid is a good business practice for young companies with minimal cash inflow.

Forgetting Taxes. Sales tax and employee withholdings are paid periodically instead of perpetually and accordingly may be temporarily forgotten as genuine expenses until it is time to pay them.

Mismanaging the Advertising Timeline

Advertising costs are often recorded as a percentage of sales in the same period. Yet advertising costs are actually incurred in the hope that they will lead to future sales. Failure to budget the appropriate items in a strategic time frame will underutilize finances needed to achieve sales goals and can lead to overspending in later months.

Security of Transactions

Eighty percent of the brick-and-mortar companies still not engaged in electronic commerce claim the primary reason for their trepidation is the inherent insecurity of the Internet medium. Thus, full consideration must be given to all security issues involved in the use of the Internet for e-business. Specifically, considerable thought should be given to security of information as it resides in company databases and as it is transmitted from point A to point B. Also, the confidentiality and privacy of customer information needs to be carefully considered. General security plans should be explained in business plans to the extent possible.

Many entrepreneurs consider the use of third-party Web site security providers as a means of ensuring transaction security and thus attracting new customers.

Specifically, some of the most frequently used companies for assuring information security, information privacy, or both include TRUSTe (http://www.truste.org), the Better Business Bureau (http://www.bbbonline.com), the AICPA (http://www.aicpa.org), and Verisign (http://www.versign.com). Major differences in offerings from these four organizations are briefly summarized here. For an in-depth analysis of the differences, the reader should consult the corresponding Web sites. Essentially, the Better Business Bureau is, and always has been, a consumer-oriented organization. As such, they focus primarily on assuring consumers that online vendors will respond appropriately to consumer complaints. Although this is the lowest level of assurance, it is the oldest company, so an entrepreneur may actually attract more average consumers with this seal than with lesser known seals that indicate stronger security. The TRUSTe seal assures consumers that an online company provides certain levels of protection of personal information in addition to promising to respond to customer complaints. Verisign, on the other hand, focuses on authentication of online merchants to assure that they are who they say they are, as well as on assurance that actual transactions are safely transmitted in an encrypted form to protect against data theft. Finally, the AICPA focuses on providing comprehensive transaction integrity assurance as well as on informing customers about specific business policies. AICPA services are far more comprehensive, and far more expensive, than other organizational offerings.

NEW START-UP CONSIDERATIONS

Anyone thinking about starting a new company needs to consider at least two issues, in addition to those discussed in the previous section. Specifically, would-be entrepreneurs of new companies need to consider how they will go about building brand recognition and customer loyalty, and how they will go about financing the start-up of their company. These are concerns for any new company, high tech or otherwise.

Building Brand and Customer Loyalty

It costs a company five times as much to acquire a new customer as it does to keep an existing one. This is good news for existing companies building e-businesses but rather daunting news for a start-up company. The fact that acquiring new customers is difficult has lured many e-business entrepreneurs into spectacular spending on advertising campaigns. As mentioned in the introductory section of this chapter, there was a brief period during the late 1990s when e-business managers focused on establishing brand recognition at the expense of all other business considerations. The fact that it worked for companies like monster.com fueled overspending by many e-business managers, who followed their lead. Another example is Drkooop.com. Prior to their demise, they spent very heavily on advertising. Specifically, they had deals with Creative Artists Agency, ABCNews.com, and three of Disney's GO Network sites to be their exclusive health content provider. In July 1999, drkoop.com signed a four-year, $89 million contract to feature its logo on AOL's portals—an amount that represented nearly 181% of the company's total available cash at the time. Although traffic increased dramatically, the price paid by Drkoop.com proved too high, just as it did for Pets.com. In December 2001, Drkoop.com filed for bankruptcy. Although we now have proof that focusing only on brand recognition is more often than not a fatal business concept, establishing brand recognition is still a critical success factor for start-ups. Balancing spending to establish brand with all other start-up costs when budgets for new companies are becoming quite lean is particularly challenging.

A good starting point for spending on brand is to identify a target market and build advertising campaigns specifically matched to interests of individuals in that target market. Media choices should be carefully selected based on target market habits. Even if a generous budget is set for advertising and marketing, a well thought out plan should drive spending on brand. Otherwise it is very easy for this expense to spin out of control. Sales and marketing personnel should be given liberal freedom to spend, but expenses should also be reconciled against plans, and personnel should be expected to justify expenditures on a periodic basis. Perhaps the most infamous example of why justification and reconciliation are so important is the story of the six Barclay bankers who ran up a $62,700 dinner tab (mostly for drinks) at a fine restaurant in London and then tried to pass it off as a client expense. Reconciliation and justification efforts resulted in five of the six bankers getting fired. Thankfully, most entrepreneurs do not need to worry about their sales personnel spending $62,000 on one dinner, but if management makes it clear early on that all employees are accountable for the money they spend, they will think twice before treating themselves to airline upgrades, expensive hotel rooms, valet parking, and other unnecessary luxuries commonly expensed when no one is watching.

Building customer loyalty is related to building brand recognition in that having loyal customers is one of the most effective means of establishing brand. Yet customers are usually loyal to companies that provide unique products and services, or that provide products and services in a consistently reliable fashion or at consistently lower prices. Accordingly, building customer loyalty is particularly challenging for B2C start-up companies that aim to sell commodity-type goods over the Internet. A broad definition of commodity is used here: It means that products manufactured with the same specifications are not different from each other. In other words, two items that are configured in exactly the same way are, for all intents and purposes, interchangeable. Books, CDs, computers, and automobiles are examples.

Financing Options

As with many other aspects of business, favored financing options for start-up companies have in a sense come full circle. Before the e-business boom, many new entrepreneurs built their businesses slowly, by starting with one or two clients, and then applying revenues from those sales either directly to investments in a new company or as collateral for a traditional bank loan.

The dream of early e-business entrepreneurs, however, was to grow their company quickly to a substantial size. What we have learned from the growing pains experienced by many of those firms is that slow and steady has definite merits over fast and fatal! For example, Donna LaVoie, entrepreneur, launched her corporate communications company in the fall of 2001 (Hendricks, 2002). She took a one-third prepayment of services to be rendered for her first client and used that to hire her first employee.

This return to old-fashioned values may not be entirely by choice for many entrepreneurs, however. Results from a recent survey by the National Association of Manufacturers show that more than a third of respondents find it harder to get loans from their banks now than it was in early 2001, whereas results from another survey, by the National Venture Capital Association, reveal that the number of companies receiving venture money fell from 6,245 in 2000 to 3,736 in 2001 (Henricks, 2002).

Yet there is also evidence that capital is still readily available for well-presented business plans. Enter the term venture capital into any good search engine, such as Google, and a very large number of venture capital firm sites will be returned. A few especially good sites to begin with include http://www.Start-upjournal.com, http://www.businessplans.org, and http://www.garage.com. Before approaching VCs, however, entrepreneurs interested in external funding should understand a little bit about the basic categories of financing options. New start-ups with no initial capital and no customers will usually start by looking for "angel" investors. Angel investors are individuals or companies willing to take bigger risks with their capital than VCs are, but they will also expect bigger company percentages than traditional VCs, generally in the form of a larger share of the start-up company. Angels generally expect to contribute anywhere from $100,000 to $1,000,000,000 to help get a company started. VCs today will come in a bit later and large venture capital companies will often want a seat on the company's board of directors to help protect their investments. Another investment option is to approach companies that specialize in providing management services in addition to financial backing. These companies are called incubators.

This chapter has described the numerous advantages and disadvantages both to self-financing and to external financing of operations, with particular emphasis on the pros and cons of using venture capital. These issues need to be carefully considered before financing options are pursued in earnest.

SPECIAL CONSIDERATIONS FOR E-VENTURES OF BRICK-AND-MORTAR FIRMS

Brick-and-mortar firms need to consider the issues discussed in sections one and two of this chapter, as well as the issues unique to their environment, which are described in this section. Specifically, brick-and-mortar companies have unique customer and operational management issues to sort out.

Potential for Channel Conflict/Channel Complement

Channel conflict occurs when a company cannibalizes its own sales with other operations. For example, eSchwab cannibalizes some of Schwab's traditional services and fees, but other online brokerage services were capturing part of their market share, so they felt they did not have a choice. At the same time, Schwab did a good job of building synergies between their online and offline service offerings, ultimately resulting in channel complements that helped build customer loyalty.

In retail, many companies have developed an online presence, believing it is a competitive necessity. This often leads to a situation where little is truly gained by the online presence, as little strategic intellectual capital is invested. One company that has done a great job of building channel complements between its online and offline business is Talbots. Talbots was one of the first retail companies to embrace the idea that customers want the convenience of being one customer to the entire company. Accordingly, you can buy a product at Talbots.com and return it to a brick-and-mortar Talbots store with no hassle. This has done a great deal to boost their sales overall.

Most businesses lose about 25% of their customers annually. If brick-and-mortar companies viewed e-business investments as a means of keeping their existing customer base happy, they would likely be more profitable overall, by reducing the number of customers lost.

Operational Management Issues

The first major management decision that brick-and-mortar companies need to make is whether to manage the online operations completely separately from the offline business. The temptation is great to manage them separately because it is far simpler and more familiar. Yet separate management increases the likelihood that the two different channels will end up competing for the same customers. Separation also increases the risk that the online operations will not stay aligned with the corporate business missions and goals. There are tremendous opportunities for creative thinking about channel management and building customer loyalty if a company decides to operate the online and offline operations synergistically. Yet commitment to building synergies is likely to be very expensive, as team management issues and data architecture issues may require significant upfront capital outlays.

In any event, strong management leadership and a commitment from top management is a major key to the success of e-ventures made by brick-and-mortar companies.

One advantage that brick-and-mortar companies have over virtual companies is that they are more likely to have good business policies and practices in place for measuring success of investments and for evaluating management performance. Constant feedback on performance is key for a new venture. Another advantage brick-and-mortar companies have is that they start with an existing customer base. Identifying creative means for leveraging this base can be the difference between success and failure.

SPECIAL CONSIDERATIONS FOR NEW E-BUSINESSES

Finally, there are a couple of special considerations for new e-business entrepreneurs. Specifically, new e-businesses must give special consideration to bandwidth and security, in addition to the issues discussed in the first three sections of this chapter.

Bandwidth

A company that is completely dependent on the Internet for sales must ensure that customers have minimal wait time for pages and images to appear on screen. This is a life and death issue for start-up companies. It is important to select top-quality Internet service providers and to have highly scalable software solutions. The user interface should be attractive and helpful but should not be unnecessarily bandwidth intensive.

Additional Security Issues for New E-businesses

It is fairly well known by now that companies with an online presence attract computer criminals. The latest annual security survey from the Computer Security Institute revealed a number of shocking statistics, including the following findings (http://www.gocsi.com):

Ninety percent of respondents detected computer security breaches within the past 12 months.

Eighty percent acknowledged financial losses due to computer breaches.

For the fifth year in a row, more respondents (74%) cited their Internet connection instead of their internal systems as a frequent point of attack.

Forty percent detected system penetration from the outside.

Forty percent detected denial of service attacks.

Although all companies with an online presence need to ensure the best security possible for online transactions, for a company that is completely dependent on online customers, one security breach is potentially fatal to the entire company. Thus, new e-business entrepreneurs need to ensure that they budget adequately for security of financial and personal customer data, security of financial and personal employee data, appropriate internal and remote access controls, control over portable and handheld computing devices, and transaction security mechanisms and policies.

PREPARING THE BUSINESS PLAN

In this final section, all the elements described in previous sections are pulled together. The key elements of a modern business plan are described and an outline of essential e-business plan elements is provided. Writing a business plan for an e-business is not much different from writing one for any other business now. If anything, what has changed since the investment in, and subsequent failure of, so many Internet companies is that investors have become a lot more savvy about their investments and scrutinize business plans greater than ever. Investors in new companies like to take calculated risks and are usually looking for new and exciting ideas to invest in. In the business plan, the entrepreneur must communicate effectively yet simply the innovation in his or her business ideas. It is critical that the business plan include a reasonable explanation of the value of the company's ideas.

Business plans are generally shorter than they used to be, because investors expect either to be involved in company decision making or to keep close contact with the start-up company's management. First and foremost, a business plan should begin with a good executive summary. If the executive summary doesn't hook potential investors, they will not read the rest of the business plan. Following the executive summary, a business plan should have at least four major sections: a detailed description of the business, a marketing plan, a financial plan, and a general management plan. There are a multitude of Web-based resources for writing a business plan (Table 2) and there are a number of possible additions to a business plan beyond the basic four elements described above. The model in the Appendix provides a reasonably comprehensive description of the business plan sections most commonly found in an e-business plan.

Ultimately, whether a business plan is read depends on whether it sparks interest with the reader. Accordingly, entrepreneurs should get to the point of uniqueness quickly, emphasize why their team can fulfill the concept better than any other company, and put forth reasonable financial goals for getting the job done. If these key elements are in place, the end result will likely be successful funding of the business proposal.

APPENDIX

The following is an excerpt from Professor Dennis Galletta's Web site on Business Plans (http://www.pitt.edu/~galletta/iplan.html). It lists the sections of an e-commerce business plan.

Executive Summary: This section must concisely communicate the basics of an entire business plan. Keep in mind that your reader may be unfamiliar with the Internet and its tremendous potential.

Business Description: In this section, discuss your firm's product or service, along with information about the industry. Describe how your product and the Internet fit together or complement each other.

Marketing Plan: Discuss your target market, identify competitors, describe product advertising, explain product pricing, and discuss delivery and payment mechanisms.

Customers: Define who your customers are and how many of them exist on the Internet. An analysis of the customer base should not be a casual guess.

Competitors: Use Internet search engines to look for known competitors or products similar to yours. Be sure to use several search engines, because each uses different search techniques. All major direct competitors should be found and analyzed in your plan.

Remember, readers of your business plan will be very interested in knowing how you are going to beat the competition.

Advertising: Describe how you are going to tell the Internet community about your product or service. Designing beautiful Web pages is only a first step. You must also get the word out about your Web site. Some tips: Detail a plan to add your Web address to the databases of search engines, add it to the bottom of all of your e-mail messages, and perhaps create physical novelties for local customers.

Pricing: How are you setting prices for your products or services? If your product is intangible information delivered over the Internet, you should try to create some sort of pricing model to justify your prices. You could start by researching what others are charging for similar products.

Delivery and Payment: How are you going to deliver your product and get paid? E-mail alone is not secure. Consider encryption techniques and online payment services.

Research and Development: The technical aspects of your company, this addresses where the company is now andd the R&D efforts that will be required to bring it to completion; it will also forecast how much the company will cost. Since the Internet is continually developing, you should also address continuing plans for R&D.

Operations and Manufacturing: Discuss the major aspects of the business, including daily operations and physical location. Also, what equipment will your business require? Will you be using your own Web server, or will you be contracting with another company? Who will be your employees—will you hire staff with knowledge of the Internet or will you train them in-house? Be sure to include cost information.

Management: Address who will be running the business and their expertise. Because the business centers around the Internet, be sure to discuss the management team's level of Internet expertise and where they gained it. Also, describe your role in the business.

Risks: Define the major risks facing the proposed business. In addition to such regular business risks as downward industry trends, cost overruns, and the unexpected entry of new competitors, also include risks specific to the Internet. For example, be sure to address the issues of computer viruses, hacker intrusions, and unfavorable new policies or legislation.

Financial: Include all pertinent financial statements. Potential investors will pay close attention to this area, because it is a forecast of profitability. Remember to highlight the low expenses associated with operating on the Internet compared to those of other business.

Timeline: Lay out the steps it will take to make your proposal a reality. When developing this schedule, it might be helpful to talk to other Internet businesses to get an idea of how long it took to establish their Internet presence.

GLOSSARY

Angel investor Early investors in new Start-up companies who usually are willing to accept even higher risks than venture capitalist but in exchange for anticipated larger returns, generally in the form of a larger share of the Start-up company for their investment than later venture capitalists would expect to receive.

Brick-and-click companies Companies with both traditional operations and e-business operations. Originally, brick-and-click was used to describe brick-and-mortar companies that built an e-business presence. Now many e-businesses are also building traditional operations.

Brick-and-mortar companies Companies without any e-business presence or to traditional companies whose operations are completely dependent on physical buildings and other assets and physical business infrastructures.

Business-to-business (B2B) Internet age term referring to the online exchange of products, services or information between two or more business entities.

Business-to-consumer (B2C) Internet age term referring to the online sale of products, services or information to consumers by businesses.

Channel conflict When a company cannibalizes their own sales with other operations.

Dot bomb A failed dot-com company.

Dot-com A dot-com is any Web site intended for business use and, in some usages, it's a term for any kind of Web site. The term is popular in news stories about how the business world is transforming itself to meet the opportunities and competitive challenges posed by the Internet and the World Wide Web (definition taken from www.whatis.com).

E-business venture Any major investment in an e-business initiative ranging from investment in a new Web-enabled transaction processing system for a brick-and-mortar company to a new virtual company built around a set of e-business missions and goals.

Incubators Companies that specialize in providing management services in addition to financial backing

Venture capitalist (VC) Investors, usually in smaller private companies, who are looking for larger than average returns on their investments. VCs may be in private independent firms, in subsidiaries or affiliates of corporations, or government supported agencies.

Venture funding Investment funds received from a venture capitalist.

Virtual company A company with primary operations that are independent of other brick and mortar companies.

Business-to-Business (B2B) Electronic Commerce

Julian J. Ray, *Western New England College*

INTRODUCTION

The focus of business-to-business e-commerce (e-B2B) is on the coordination and automation of interorganizational processes via electronic means. E-B2B is conducted between business organizations and is a subset of all e-commerce activity, which includes, among others, business-to-consumer (B2C), business-to-government (B2G), and consumer-to-consumer (C2C) activities.

Before an in-depth analysis of e-B2B, it is worthwhile to note that many authors today identify e-commerce as one component of a more general form of electronic business termed e-business. E-business is generally used to identify the wider context of process automation that can occur between businesses and includes automating the provision and exchange of services, support, knowledge transfer, and other aspects of business interaction that do not necessarily result in a buy or sell transaction being executed. Within this document the terms e-commerce and e-business are used interchangeably and refer in either case to the wider context defined above.

E-B2B is a major driving force for the Internet economy. According to research from the Gartner Group (http://www.gartner.com), B2B is growing at a rate of 100–200% per year. With an estimated $430 billion in 2000, the total value of e-B2B activity was initially expected to exceed $7 trillion by 2004 with the largest shares in North America ($2.8 trillion), Europe ($2.3 trillion), and Asia ($900 billion), and 24% of all e-B2B transactions are expected to be performed electronically by 2003 (SBA, 2000). However, the recent slowdown in the global economy has caused a revision of these initial predictions to reflect changing economic conditions. Current estimates for 2004 global B2B revenues have been reduced to $5.9 trillion with a growth rate of 50–100% per year (Gartner Group, 2001). Even with the slowdown, the rates of adoption are significant and on track to exceed $8.5 trillion in 2005.

FOUNDATIONS OF B2B E-COMMERCE

Sustaining a high rate of adoption and growth in e-B2B activity requires several key components: the innovative application of technology, a ubiquitous communication medium well suited for the transmission of e-B2B-related documents and information, a business and regulatory environment suitable for sustaining the process, and last but not least a set of motivating forces prompting organizations to adopt interbusiness automation as part of their day-to-day operations.

Innovations in Technology

The technological foundations of e-B2B have been developing over the past 30 years and reflect innovations in telecommunications, computer communications protocols and methods, and intraorganizational business process management. During the 1970s, electronic funds transfer (EFT) and electronic data interchange (EDI) were nascent communication standards developed for business exchanges over expensive private computer networks. The costs of participating in these initial systems were high. EDI systems, for example, require specialized data processing equipment and dedicated telecommunications facilities, prohibiting all but the largest businesses to participate. However, the potential benefits realized from implementing these early electronic B2B systems included greatly reduced labor costs and processing time as well as vast increases in accuracy.

Private communications networks requiring dedicated telecommunications facilities, initially the only option for e-business, are still in use today and provide a secure medium for exchanging electronic data. A value-added network (VAN) is a type of semiprivate communications network usually managed by a third-party provider that allows groups of companies to share business information using commonly agreed-upon standards for transmitting and formatting the data. VANs have traditionally been associated with EDI and provide an alternative to more costly private communications facilities.

More recently e-business has adopted the public Internet as its basic communication medium. The Internet provides the ubiquitous connectivity and high data rates necessary to support modern e-business. The significantly reduced costs of operation and costs of entry of the Internet with respect to other communication systems such as traditional VANs or private lines makes the adoption of an e-business model more attractive and sustainable to smaller organizations.

One of the key technologies allowing the Internet to support e-business is the virtual private network (VPN). VPNs are a form of protected communication using a combination of encryption methods and specialized data transmission that allows companies to use the public Internet as if it were a private system. VPNs also enable development of extended private networks (extranets), which are shared with business partners. Today VPNs largely replace the role played by early value-added networks with a cost-effective alternative allowing companies to freely share private business information over the public Internet.

Processing transactions electronically can significantly reduce the cost and time taken to manage business information. Computer servers today can handle thousands of transactions per second and significantly help reduce the costs and risks associated with sending and recording a business transaction. One of the greatest current interoperability challenges is the development of common methods and protocols to enable semantic translation. To date there are hundreds of protocols and standards that govern almost every aspect of using the Internet to transmit and translate business data. Extensible markup language (XML) is an example of a data-format technology that can be understood and processed by a wide variety of computer languages and systems.

These new and emerging standards build on earlier protocols such as EFT and EDI. When coupled with system-independent data communication protocols such as the Internet's TCP/IP, these initial data translation protocols enable business data to literally transcend organizational and technological boundaries. For example, while EDI documents can still be sent over private lines, today it is also possible to complete the same transactions using the Internet and XML at a fraction of the cost of traditional EDI. Companies who invested heavily in the early technologies can maintain their original investment and still participate in modern e-business initiatives while companies who could not afford technologies such as EDI are now able to engage in intraorganizational data exchange.

Innovations in Business Processes

Greenstein, O'Leary, Ray, and Vasarhelyi (in press), in a discussion on the electronization of business, identify the surge of e-B2B activity as a progression of an evolving process that has been evident throughout the industrial revolution. The authors attribute the rise of e-business activity as a response to dramatic improvements in both information processing and telecommunications systems, which have facilitated revolutionary change in organizational business processes. This most recent of technological revolutions centered around the Internet provides businesses with the ability to automatically place orders, send quotes, share product designs, communicate sales projections, and collect payment using electronic means, providing the potential to reduce operating costs, shorten time-to-market for new products, and receive payment faster than ever before. Moreover, businesses willing to commit to transitioning to the new digital economy have the potential to partner with other similarly minded businesses creating tightly integrated supply chains, remove intermediaries, and develop networks of loyal customers and trading partners who, research shows, collectively outperform their competitors.

Recent changes in the banking industry provide an example for understanding the potential improvements in business processes that can be achieved using electronic automation. The U.S. Federal Reserve along with 6 other central banks and 66 major financial firms recently implemented a system called the Continuous Link Settlement System. This system is designed to automate the trading and settlement of foreign currency exchanges. Traditionally, when performing a trade, two banks agree on an exchange rate and wire the money to each other. This is a process that can take two to three days during which time events can change the value of a country's currency, ultimately affecting the exchange rate. In extreme cases banks have gone bankrupt in this period of time (Colkin, 2002). Banks trade on the order of $300 trillion each day, so the ability to perform trades in real time can reduce the amount of lost interest. Accordingly, the risk associated with transaction latency justifies the $300 million investment in technology that the Continuous Link Settlement costs.

MOTIVATION FOR B2B E-COMMERCE

There are a number of reasons why a company might decide to invest in developing and implementing an e-B2B strategy. Established companies, faced with rising costs and increased competition, often have a set of motivating factors and goals different than that of newer companies. Newer companies are often more technologically agile and can readily take advantage of newer e-business strategies and products.

Benefits for Established Companies

E-B2B strategies have been proven to cut operations cost for companies and to reduce cycle time during product development. We provide examples from Federal Express and General Motors later in this text to illustrate how different e-B2B strategies can lead to cost reduction and an increased ability to compete by reducing the time required to design and develop new products. The ability of a company to automate its supply chain is another significant advantage of e-B2B. Reducing costs and production times are only a few of the types of benefits that can be realized by e-B2B companies. Other benefits are associated with increased visibility over the supply chain allowing for better planning and inventory management, strengthened relationships with business partners, and the ability to integrate with new business partners in a variety of interesting and innovative ways using mechanisms such as online exchanges and auctions.

Norris, Hurley, Hartley, Dunleavy, and Balls (2000) identify three stages in the adoption of an e-B2B business model by established companies. The early focus of a company's e-B2B activity are on increasing the efficiency of the sales and/or purchasing processes while minimizing the disruption to organizational culture and business processes. The second stage of adoption is usually on improving business processes by using electronic information technologies to integrate the supply chain and streamline the process of conducting business. This stage is often aimed at reducing costs and increasing the effectiveness of operations beyond sales and purchasing. The last stage in the conversion of a company to a mature e-business model is the development of strategic, tightly coupled relationships between companies to realize the mutual benefits and joint rewards of an optimized supply chain. General Motors (http://www.generalmotors.com) is an example of a traditional company that is rapidly evolving into an e-B2B company. General Motors has adopted a multipronged approach in its transition to an e-business using small pilot projects to test different e-B2B strategies in a drive to increase its competitive edge and reduce costs. Among GM's e-B2B initiatives are joint product design, dealer portals, and online auctions (Slater, 2002).

E-B2B can be used to reduce a company's risk such as the financial risks associated with completing monetary transactions in a timely manner as demonstrated by the Continuous Link Settlement System. E-business can also be an effective tool in reducing the risk associated with performing business under changing economic conditions. Such risk can be mitigated by developing economic as well as digital ties to existing business partners and providing a framework wherein new business partners can be introduced and incorporated into the supply chain.

New Products, New Services, and New Companies

E-business strategies may involve creating and introducing new products and services within existing companies as well as providing the basis for the creation of entirely new e-business. Online exchanges, for example, have emerged as a multibillion dollar industry virtually overnight as a result of the desire for increased speed and expediency of interorganizational electronic business transactions.

Proprietary supply-chain integration is another area with significant e-B2B activity. However, even with these proprietary efforts, companies acting as intermediaries may provide a large part of the technology and services involved in supply-chain operations. Examples of such companies include Manugistics (http://www.manugistics.com), which has successfully adapted its more traditional technologies and services to operate within the emerging e-business environment across a broad array of industries, as well as brand new technology-savvy companies such as Elogex (http://www.elogex.com) with niche strategies of developing technology and services specifically for a narrow industry focus: consumer goods, food and grocery in this case.

For small to mid-sized organizations, the barriers to participating in the e-business arena have been removed. The financial overhead associated with implementing early e-business systems such as EDI is significant and out of reach of all but the largest corporations. The rapid adoption of the Internet as a ubiquitous communication medium along with the reduced cost of computer systems and software over the last decade has allowed all types of companies to develop e-business strategies providing increasing levels of competition, innovation, and access to a global pool of potential business partners. In fact, the inverse relationship between size and agility gives small to mid-size firms some competitive advantages.

The dot-com boom of the late 1990s, which was so visible in the B2C sector with companies such as Pets.Com and WebVan, carried over into the B2B sector. During this time large numbers of highly innovative, technology-savvy Internet-focused companies became immersed in all areas of online business-to-business activity. By 2000 there were an estimated 2,500 online B2B exchanges serving industries such as electronics, health care, chemicals, machinery, food, agriculture, construction, metals, printing, and medical lab equipment (Wichmann, 2002). Like their B2C counterparts, however, many of the B2B dot-com companies have failed as a result of weak business models and misguided, overzealous venture capital. Now less than 150 of these exchanges are left.

CLASSIFICATION OF B2B STRATEGIES

E-business strategies are usually classified based on the nature of the interaction taking place between the business partners. Four strategies that may be classified using this approach are e-selling, e-procurement, e-markets, and e-collaboration. Within each of these strategies we can further identify the vertical or horizontal industry focus of the participation and whether the participation involves the use of intermediaries.

Companies with a vertical focus usually operate within a single industry such as the automotive, chemical, energy, or food-retailing industries. Alternatively, companies with horizontal focus provide products and/or services across a wide range of industries. Office supplies and computers are examples of products horizontally focused.

Intermediaries in e-B2B are most often associated with e-markets and electronic auctions where one company, the intermediary, acts as a broker allowing other companies to buy and sell products and services by collaborating using the infrastructure provided by the intermediary.

E-selling

E-selling is concerned with the direct sale of products and services to other businesses using automated means. The business model is similar to the B2C direct-sale model but differs in that B2B interaction requires prenegotiation of prices, catalog items, and authorized users. Turban, King, Lee, Warkentin, and Chung (2002) identify two major methods for e-selling: electronic catalogs and electronic auctions. Electronic catalogs can be customized in both content and price for specific businesses and can be coupled with customer relationship management software such as SAP's Internet sales solution (http://www.sap.com) to provide personalized content delivery. There are many examples where companies provide a direct sales channel to other businesses using the Internet: Dell Computers (http://www.dell.com) and Staples (http://www.staples.com) are examples of companies that allow businesses to set up accounts through the Web and customize the content available for online purchase. Cisco is another example of a company that has a very successful direct-sale approach using the Internet (http://www.cisco.com). Using Internet based pricing and configuration tools, Cisco receives 98% of their orders online, reducing operating costs by 17.5% and lead-times by at least 50% down to 2–3 days (Turban et al., 2002).

Electronic auctions are sites on the World Wide Web where surplus inventory is auctioned by a business for quick disposal. Auctions allow companies to save time and reduce the cost of disposing of surplus inventory, allowing the company to obtain a better price. Ingram Micro, for example, receives on average 60% of an item's retail cost by selling surplus inventory through an online auction. Prior to using the auction Ingram Micro recovered 10–25% of the price using traditional liquidation brokers (Schneider, 2002). Some companies create and manage their own auction sites such as CompUSA. CompUSA's Auction Site (http://www.compusaauctions.com) is designed to allow small and mid-sized companies to bid on its inventory. Alternatively, companies can use existing general purpose or industry-specialized auction sites such as eBay (http://www.ebay.com) or ChemConnect (http://www.chemconnect.com). Both Sun Microsystems and IBM have successfully adopted eBay as an auction site for surplus computer hardware, software, training courses, and refurbished equipment. eBay in this case is operating as a horizontally aligned intermediary between Sun Microsystems and the companies or individuals bidding on Sun's products. ChemConnect is an example of a specialized third-party auction site designed to manage the selling and buying of chemical and plastic products using an auction format. Unlike eBay, which is horizontally focused, ChemConnect has a vertical focus and concentrates on selling specifically to the chemical industry.

E-procurement

E-procurement is concerned with the automated purchasing of goods and services from suppliers. These applications are designed to facilitate the exchange of electronic information between trading partners by integrating a buyer's purchasing process with a seller's order entry process (Davis & Benamati, 2002). E-procurement systems can be either buy- or sell-side applications. Buy-side applications reside on the buyer's systems and control access to the ordering process, the authorization of the order, and possibly the list of trading partners allowed to receive the order. Sell-side applications reside on supplier's systems and allow authorized buyers to access and place orders directly on the system. Sell-side systems are often implemented as extranets where access to the electronic catalogs and pricing information is carefully controlled.

According to the Aberdeen Group, e-procurement is one of the main areas of e-B2B that is "delivering rapid and quantifiable results." They estimate that 80–90% of companies plan to use online procurement systems by 2003 (Aberdeen Group, 2001b). The sorts of products purchased by e-procurement systems are generally limited and of relatively low value. Strategis (http://www.strategis.gc.ca), an online branch of Industry Canada, report that 42% of e-procurement purchases by businesses in Canada in 2001 were for office supplies, furniture, and office equipment, followed by IT hardware and software (29% of total) and travel services (15% of total) (Strategis, 2002). Similarly, Microsoft reports that 70% of their annual 400,000 procurement purchases are for requisitions less than $1,000 (Microsoft, 2000).

Early e-procurement implementations relied on fax, e-mail delivery, EDI, or real-time system processing to transfer data among trading partners. Newer e-procurement systems use Internet technologies to manage the ordering process. Recent surveys indicate that most commercial solutions now use XML and the Internet to share procurement data and provide access to online market places as part of the offering (Aberdeen Group, 2001b).

E-procurement systems can significantly benefit companies in a variety of ways. In 1999 Federal Express identified e-procurement as a key strategy in reducing costs and saving time in the purchase order process. FedEx purchased a B2B commerce platform from Ariba Inc. (http://www.ariba.com), which was implemented within a month and reportedly returned a positive ROI within three months. The new system manages about 20% of FedEx's 25,000 annual requisitions and has reduced purchasing cycle times from 20 to 70%, depending on the type of items purchased. The purchase of new PCs now takes 2 days rather than the 17–19 days it took using a traditional paper-based approach. FedEx also managed to reduce the purchasing department staff by half, allowing these extraneous staff to be reassigned (Aberdeen Group, 2001a). Microsoft reports similar success with MS Market, a desktop procurement system designed to run from a Web browser over the company's corporate intranet. MS Market is deployed to 55 Microsoft locations in 48 countries and saves the company an estimated $7.5m annually (Microsoft, 2000). In the United States, Microsoft use MS Market to order almost 100% of the company's requisitions at an average cost of $5 per requisition.

E-collaboration

E-collaboration is a term broadly used to describe any form of shared e-business activity in which companies collaborate together with the goal of providing a mutually more efficient business environment. E-collaboration can take many forms such as supply-chain integration, the joint design and development of products, joint demand forecasting, and joint planning. General Motors, for example, shares specialized engineering software and data files with its suppliers in a drive to reduce product development time. As part of this joint-product design strategy, General Motors partially or fully underwrites the cost of the software licenses for some of its suppliers in order to standardize the design platform across the supply chain. By standardizing and sharing design tools, General Motors reduced the design-to-production cycle for new products by 50% to just 18 months (Slater, 2002).

Collaborative Planning Forecasting and Replenishment (CPFR) is a collaborative approach that allows suppliers and sellers to jointly forecast demand for products in an attempt to better coordinate value chain processes such as restocking, managing exceptions, and monitoring effectiveness. The major idea underlying CPFR is that better forecasting between trading partners will lead to improved business processes, which in turn will reduce costs and improve customer service and inventories. Wal-Mart's RetailLink is an example of a CPFR system that operates over the Internet using EDI documents to share information. RetailLink allows Wal-Mart's suppliers to receive detailed information about store sales, inventory, effects of markdowns on sales, and other operational information that allows the suppliers to effectively manage their inventory at the individual Wal-Mart stores.

CPFR and similar types of supply-chain integration can result in numerous benefits for companies interested in collaborating with business partners. After interviewing 81 companies, Deloitte & Touche concluded that companies that "collaborate extensively" with their supply-chain partners while focusing heavily on customer loyalty and retention are almost twice as profitable as companies that are "below average" in the areas of supply-chain collaboration. Deloitte & Touche also found that companies who understand customer loyalty are much more likely to exceed their goals on shareholder returns, return on assets, and sales growth, and 12% of the companies studied were in this group (Rich, 2001).

E-markets

E-markets provide third-party integration services by supplying online applications that allow organizations to exchange goods and services using a common technology platform. In essence, these electronic marketplaces are designed to bring suppliers and buyers together in a common forum with a common technology platform. E-markets are usually vertically aligned for industries such as energy or automotive but there are also horizontally aligned e-markets that service industries such as office supplies and information technology. Many e-markets are independent exchanges managed by a company that is neither a buyer nor a seller in the marketplace but provides third-party services that allow other businesses to collaborate through them. Alternatively, e-markets can be created and managed by a company or consortia of companies who are leaders in the industry being served. In the late 1990s third-party e-markets were the focus of a lot of new dot-com activity. Berlecon Research identified 2,500 independent exchanges on the Internet by 2000. Due to competition and the downturn in the economy, by late 2001 fewer than 150 of these exchanges were still in operation (Wichmann, 2002).

Covisint (http://www.covisint.com) is an example of a global marketplace sponsored by a consortium of industry leaders rather than an independent third party. In this case the industry leaders are DailmerChrysler, Ford, and General Motors among others. Covisint was jointly funded in 2000 to provide a global solution for the automotive industry with the goal to "improve the effectiveness of mission critical processes such as collaborative product development, procurement and supply chain management . . . through implementation and use of a secure and comprehensive online marketplace" (Covisint, 2002). Covisint's mission is to "connect the automotive industry in a virtual environment to bring speed to decision making, eliminate waste and reduce costs while supporting common business processes between manufactures and their supply chain."

Covisint provides three products: Covisint Auctions, Covisint AQP (Advanced Quality Planner), and Covisint Catalog. Covisint Auctions are online bidding events that provide rapid, real-time, Web-based negotiations in a secure environment for the purpose of supporting the sourcing of parts and components. Covisint AQP is an Internet-enabled application that provides an environment for collaboration, reporting, routing, and visibility of information important to developing high-quality standards for components being designed for vehicle production. Lastly, Covisint Catalogs are electronic purchasing environments for indirect and Maintenance, Repair, and Operations (MRO) material. This application allows users to shop online and provides a system to automate approvals and the creation of necessary supporting documentation such as purchase orders.

The total value of transactions managed by Covisint in 2001 was more than $129 billion. During the year, General Motors used Covisint to buy $96 billion worth of raw materials and parts for future vehicle models. In a single four-day period in May, DaimlerChrysler used the exchange to procure $3 billion worth of parts—the single largest online bidding event to date. Ford reported that it used the exchange to save $70 million, which is more than its initial investment in the exchange and expects to save approximately $350 million in 2002 (Konicki, 2001). Recent research has questioned the validity of the savings claims made by exchanges in general as they reflect the maximum theoretical savings that could be achieved at the close of the auction while the amount of actual savings is likely to be less (Emiliani & Stec, 2002).

METHODS FOR IMPLEMENTING B2B

Integrating a business process in one company with a business process in another requires that both companies provide the necessary technology that allows the information systems to be integrated over a computer network such as the Internet. Depending on the type of activity, this could include interfacing with other companies' supply-chain management, procurement, or sourcing systems, or involve something less complex such as simply establishing an e-mail system or sharing electronic files on tape or other digital media. Newer businesses are more likely to have modern information systems specifically designed for integration and collaboration; older companies are more likely to have legacy systems, which were never designed to be used for data sharing and pose significant challenges for B2B. A variety of methods that allow companies to overcome issues with legacy and incompatible business systems and allow them to effectively share business information have been developed.

Point-to-Point Transfer Methods

The point-to-point transfer of business information using computer data files dates back to the earliest B2B integration efforts. By the 1950s companies had already started to use computers to manage business transactions. Business information moving between companies at this time used paper forms, which had to be re-entered into the recipient computer systems using manual methods: a process that was unreliable, expensive, and redundant (Schneider, 2002). By the 1960s companies had started to use magnetic tape and punch cards as a medium to record business information for transfer. The encoded tapes or card decks would be transferred to a recipient computer system and automatically processed using card or tape readers. The advantages of these automated methods were in the removal of the expensive and error-prone process of redigitizing the business information as the data could be entered directly from the transfer medium.

Tape and card decks were replaced by automated file-transfer methods such as Tymnet, UUCP, Kermit, and later by the ubiquitous file transfer protocol (FTP) for use on the Internet. Using these applications, one computer system exports business data from an application to a data file; the file is then transferred to the recipient computer system over a phone line, computer network, or the Internet. At the recipient end the file is imported into the application using specialized software. FTP is part of a suite of protocols specifically designed for the Internet and is implemented today by most computer systems, allowing for a seamless transfer of binary or text data from one computer system to another. This “built-in” ease of use has largely replaced other file transfer applications for the business-to-business transfer of information.

The point-to-point business integration model using file transfer methods is simple to design and implement and works well in situations where there is little change in the applications sharing information and a high-degree of collaboration between the business entities. Yee & Apte (2001) identify several disadvantages of this approach. With respect to the format of the data being shared: the sending and receiving applications must agree on a fixed file format, export and import logic is often restricted by the applications, and lastly, the overall system is brittle and can fail if either system changes the data format. From a data management perspective, data transfer is conducted in batch mode rather than real time, which introduces latency into the system; there are no methods for recovery or guaranteed delivery of the data. Sharing data with multiple business partners becomes difficult to manage as the impact of these disadvantages becomes multiplied with each additional business partner.

Database Integration Methods

Point-to-point file transfer methods are perhaps the simplest integration approaches where the only factors in common between the collaborating systems are a prenegotiated file format and data content and a common communication method. Accessing data directly in the databases is another data integration method that can be relatively straightforward to implement given the correct set of preconditions.

Database software such as Oracle’s Enterprise Database, Microsoft’s SQL Server, and IBM’s DB2 software can be thought of as layered applications. At the lowest layer is the data itself and a set of procedures designed to efficiently manage the organization of the data on the host computer system. At the top level is a user interface, which allows users to connect to the database, manage the data, and format reports. Between the data and the user interface layers exists a suite of applications that implement the data management and query capabilities of the database. This application layer typically uses a specialized computer language called structured query language (SQL) to manage all aspects of a database and to interface between the users and the data itself. Database connectivity middleware such as JDBC, ODBC, and ADO allow direct programmatic access to the application layer of remote databases using a variety of programming languages and environments and replaces the user-interface layer of the database by generating SQL commands directly from the programming environment. This direct access allows systems designers to create points of direct integration between an application and a database over a telecommunications system such as the Internet. These database connectivity technologies also tend to shield the collaborating applications from the specifics of the data storage, overcoming differences in storage formats between disparate databases and computer systems. For example, a business transaction could be extracted by a remote application from an Oracle database instance on a Windows Server and inserted into an IBM DB2 database instance on an OS/400 server without difficulty, only relying on the understanding of the organization of the recipient database and permission to access the requisite database resources.

Newer business systems tend to decouple the application logic from the storage of the business data and store the data in a commercial database. This design makes the process of integration relatively simple as the database can be accessed directly. Older business systems, however, tend to tightly couple the business logic to the data and are less “open” in systems terms. These types of systems may use proprietary data stores and/or data storage formats, which makes integration at the database level problematic. Linthicum (2001) suggests that integration with these older “closed” systems is best managed at the application level as it is often impossible to deal with the database without dealing with the application logic as well.

A recent trend among database vendors is to facilitate interapplication data integration by allowing database software to send and receive data using XML syntax. XML data can be processed by the databases and either stored and queried in native (XML) form or converted to more traditional database storage types. This approach further serves to open up information systems for integration and often provides a way in which legacy systems with closed database platforms can integrate with newer systems.

Many companies use multiple databases for storing and maintaining their business data. Each database could be associated with a single application or be a point of integration for two or more applications in use within the company. Integrating data from multiple data sources provides a complication for normal direct database integration approaches as these typically require a single data source to connect with. To overcome the issue of integrating a business system with multiple target data sources database gateways can be used. Database gateways are middleware technologies that provide a query facility, often using SQL, against multiple target data sources. The middleware acts as a proxy and accepts requests for data from client systems, which it then translates into a form that can be executed against one or more connected databases. The database gateway middleware merges the underlying databases to form a "composite" or "virtual" database, which is a conjoining of all or selected parts of the underlying (managed) database schemas. IBM's Distributed Relational Database Architecture (DRDA) is an example of a database gateway built into IBM's DB2 enterprise database systems to facilitate interoperation of multiple databases within heterogeneous computing environments.

While proficient at providing read-only access to business data for remote applications, Yee & Apte (2001) maintain that database gateways systems have limitations for e-commerce systems. In particular, database gateways are inefficient when integrating multiple disparate systems as queries against the virtual database must be recast to query the underlying data sources and the results merged by the middleware to form a set of results that can be returned to the client. Further, Yee & Apte argue that the database approach to integration bypasses the business rules implemented in the application code and may result in redundant business logic, which must be both developed and maintained at some cost.

API Integration

As an alternative to integration through direct access to the data, applications can often share information via a set of interfaces "built in" to the application and designed to be accessed using other programs. These application programming interfaces (APIs), as they are called, allow external applications (clients) to share data and business logic with a host application (server) often via the Internet or other connection media. Depending on the type of technology used, the applications, and the form of the APIs, the two independent programs can share simple computer data composed of text strings and numbers and even complex structured data objects that represent an atomic information component such as a customer or purchase order. Some APIs allow the client system to execute business logic functions on the server such as removing an element of data or performing some action.

Integration via APIs is often more difficult in a heterogeneous computing environment as differences in how systems can be accessed and the representation of data components such as strings, numbers, dates, and complex higher-order objects can vary enough to render data generated on one system intelligible on another. These well-known system compatibility issues often require middleware applications, which can broker between the data representations on the different systems. Remote procedure calls (RPCs) are a middleware technology that provides a framework for translating system-specific data to and from a common data format, which can then be transferred without loss of representation between client and server systems over a computer network. RPC frameworks, initially developed to network UNIX applications together, are available on most computer systems used by businesses today and rely on a common computer language called interface definition language (IDL), which all data must be translated to before it can be sent over the network. Other API technologies are in common use. Microsoft (http://www.microsoft.com) has extended its Component Object Model (COM) to allow computers to share data and methods between systems running different versions of Windows software over a network. This Distributed COM, also known as COM+, is available on all second-generation Microsoft Server products. The Common Object Request Broker Architecture (CORBA) is a system similar to Microsoft's DCOM that was developed as an open specification by the Object Management Group (http://www.omg.org), a consortium consisting of over 800 independent software developers. The initial CORBA specification was developed in 1991 and, although it has been overshadowed in recent years by Java and XML, is still in use especially in the banking industry, who has adopted it as a standard method of integration.

Message-oriented middleware (MOM) was developed to address some of the issues associated with tightly coupled solutions such as RPC and COM. MOM applications transfer data between applications in the form of messages: an application-defined unit of data that could be in binary format or text-based. Most message-driven applications use an asynchronous processing model rather than the synchronous model used by most tightly coupled systems. In an asynchronous message-driven system one application sends messages to another application. Unlike RPCs, which deliver the data immediately, the messages sent from one application to another using MOM are typically placed into a specialized piece of software that allows the messages to be stored and queued. When the recipient application is ready to process messages it accesses the queue and extracts the messages from the queue that are for the application. This model allows the sending system to send messages to possibly several systems at the same time without having to wait for the recipient applications to process the data. This "fire-and-forget" model allows all systems to work independently and at different speeds. IBM's WebSphere MQ software—formally MQSeries—is an example of a widely deployed MOM system.

Java is a computer language developed by Sun Microsystems (http://java.sun.com) in the 1990s specifically for use on the Internet. Unlike most other computer languages Java uses a data format that is common to all Java applications, is independent of the hardware/software environment, and negates the need for an intermediate language such as IDL to represent data that will be transmitted between applications over a network. This "one-size-fits-all" approach greatly decreases the cost of developing and maintaining networked applications although Java critics maintain that Java is slow compared to other programming languages due to its device-independent run-time architecture. Since its inception the Java language has been rapidly growing to accommodate the evolving needs of the business community. Versions of the Java language are now available specifically to meet the needs of enterprise applications and mobile users. Java 2 Enterprise Edition (J2EE) provides a framework for developing robust distributed applications using specialized software platforms called application servers. J2EE application servers such as BEA Systems WebLogic (http://www.bea.com/framework.jsp?CNT = index.htm&FP = /content/products/platform), IBM's WebSphere (http://www-3.ibm.com/software/info1/websphere/index.jsp), and Oracle's 9iAS (http://www.oracle.com/ip/deploy/ias/) provide frameworks for efficiently accessing databases, managing transactions, creating message-driven applications, and developing Web-based interfaces. Java 2 Mobile Edition (J2ME) is a version of the Java language specifically designed for mobile devices such as Personal Digital Assistants (PDAs) or in-vehicle systems.

The recent adoption and proliferation of XML and XML-oriented middleware has provided an alternative means for sharing data between systems and is the basis of the new generation of interapplication methods called Web services. Web services are similar to RPCs in that middleware exists on both the client and the server that communicate and act as proxies for the client and server applications. Web services use a common XML document format based on the simple object access protocol (SOAP) specification developed jointly by Microsoft, IBM, and others to share data and can utilize commonly available Internet network connections and protocols such as HTTP and TCP/IP to communicate. Web services further benefit system developers because they can implement dynamic discovery mechanisms and centralized service registries that allow client applications to locate services and "discover" the interfaces and data formats available from the services and automatically integrate with them, thereby reducing the amount of time and the complexity required to build integration components.

Process-Oriented Integration

Process-oriented integration focuses on the logical sequencing of events and the processing of information as it moves within and between business organizations and relies on a business process rather than a technological foundation. The goal of process-oriented integration is for trading partners to share relevant business data with the intention of increasing competitive advantage through cooperation. This approach tends to be more strategic than tactical as the results are often hard to measure in terms of traditional investments as they involve developing trust relationships with suppliers and sharing private and often confidential information to realize more intangible benefits such as better products, increased customer satisfaction, and better supply-chain operation. Sharing production forecasts and schedules with suppliers, for example, allows business partners to better plan their own production activities, which in turn can lead to lower costs overall as the guesswork involved in anticipating demand can be removed and the likelihood of stock-outs diminished. Changes in production schedules can similarly be communicated, allowing suppliers to automatically adjust their production schedules to match, thereby reducing waste and uncertainty.

In its simplest form process-oriented integration might simply be a group of companies agreeing on a common suite of products to use for their internal systems such as SAP/R3 (http://www.sap.com) or Oracle's e-business applications suite (http://www.oracle.com/applications) and then deciding which processes they are willing to externalize as integration points. Establishing a common technology platform for the business systems also establishes a framework for sharing information as the data moving between businesses are guaranteed to be compatible and interchangeable as most enterprise-scale systems have built-in APIs or messaging systems to facilitate the sharing of data within and across organizations.

Evaluating and Selecting Integration Approaches

The wide variety of methods available for B2B system integration provides companies in the planning phase of a B2B initiative a number of alternatives they can choose among. Key design characteristics that must be evaluated for new systems are open vs closed implementations, integration at a data level using databases and/or middleware APIs or at a systemic level by adopting common business processes and systems, whether to use the public Internet as the data transport medium or to invest in private or semiprivate networks, and lastly, the ease of integration with existing and planned internal systems.

One of the key decisions is to determine the level of effort necessary for trading partners to couple and decouple from the trading environment. Systems such as SAP/R3, which use proprietary technology and require specialized hardware and connectivity environments, can be expensive and difficult to implement. Hershey Foods, for example, spent three years and $115 million implementing a software system from SAP. The new system was designed to replace a number of older systems and tie into supply-chain-management software from Manugistics and customer relationship management products from Siebel. Glitches in the ordering and shipping systems, however, resulted in a 12.4% drop in sales during the company's busiest quarter (Osterland, 2000).

ERP II is a new generation of Internet-centric enterprise resource planning (ERP) software designed specifically to address the types of implementation issues associated with sharing information across a supply chain experienced by Hershey Foods. For companies who have already invested in ERP systems, ERP II will allow them to leverage their investments and move toward a collaborative planning system by upgrading their existing ERP systems over time (Bond et al., 2002). Companies without an existing investment in ERP will be able to adopt a system that provides both internal and external business process integration.

In contrast to ERP II, light-weight technologies like XML/SOAP can provide points of integration between business systems and facilitate relatively low costs of entry into a trading consortium. A possible disadvantage of this relatively low cost of entry and ease-of-implementation is that trading partners could move to a competitor system with relative ease, thereby undermining the trust relationship between companies.

Other key decisions will center on the robustness, security, and scalability of the technology being selected. Last but not least, companies should examine the record of systems vendors and critically examine the vendors' record with respect to implementation success, after-sale support, and case studies proving the advertised ROI.

B2B E-COMMERCE CHALLENGES

There are several challenges to companies planning an e-B2B strategy, including managing and valuing e-B2B projects and getting up to speed on the regulatory environment surrounding e-B2B and the technical challenges associated with selecting and implementing e-B2B technologies.

Management Challenges

One significant management challenge associated with developing and sustaining a viable e-B2B initiative is measuring the true tangible and intangible benefits of the investment. Intangible benefits are hard to isolate and quantify and can accordingly effect how an investment is perceived by the company and shareholders. Other challenges for management include developing and maintaining an information technology strategy in an environment that is rapidly changing and evolving and managing the trust and expectations of business partners.

Measuring Intangible Benefits

Businesses choose to develop an e-B2B strategy for a variety of reasons, such as increasing process efficiency, reducing costs, and integrating new suppliers and customers. Tangible benefits such as increased sales, decreased production time, and reduced waste can be estimated fairly accurately. However, the intangible benefits of e-B2B are hard to evaluate using purely economic measures. For example, intangible benefits such as increased customer satisfaction and stronger relationships with business partners are two benefits that are highly sought but difficult to measure. The potential benefits from increased global visibility through an electronic presence on the Internet might include better hiring opportunities or more favorable investment opportunities. Again, such benefits are extremely difficult to quantify.

Managing Trust Relationships

Coupling business processes through technological frameworks requires that participants trust each other with valuable and often confidential business information such as new product specifications, purchasing patterns, and production forecasts. As businesses increasingly move toward a pattern of sharing information in real time a bond of trust must be established and proactively managed to ensure continued and mutual benefits for all companies involved. This trust relationship involves not only guaranteeing the security and confidentiality of the data being shared but also guaranteeing the accessibility and reliability of the systems being integrated. Managing trust relationships involves determining and maintaining predefined levels of system performance such as the speed and volume of transactions that can be processed, the stability of the information systems, and how systems should respond to erroneous or unprocessable data. Also important are agreements to establish responsibility and availability of the systems for routine maintenance and upgrade cycles.

Managing Information Technology Infrastructure

In an e-business, the information technology infrastructure of a company is the foundation for business success. The information technology infrastructure must be carefully managed to support the business goals of the company and should be perceived internally as a strategic asset. The Hurwitz Report (Hurwitz Group, 2001) identifies several ways in which the management and perception of the role of a company's IT organization is critical to success. In traditional companies, the IT group is responsible for managing internal processes and is used to support or maintain business functions. While IT groups are often treated as overhead and run as cost centers in traditional businesses, the IT organization in successful e-businesses is viewed as a revenue generator and treated as a competitive asset allowing innovation within the organization to drive competitive advantage and help reduce costs.

The reliability of the infrastructure is also paramount and must be carefully managed. As companies become more reliant on online processes, the potential consequences to a company and its business partners of even a temporary loss of service can be devastating. For example, a survey of companies in 2001 showed that for 46% of the companies surveyed, system downtime would cost them up to $50k per hour, 28% of the respondents would incur a loss of up to $250k per hour, and 26% would loose up to or over $1m per hour (Contingency Planning Research, 2001).

Managing Expectations

Simply developing the e-business technology is just the start of the electronic collaboration process. A key challenge to successfully implementing an e-business strategy is managing the expectations of the e-business and effectively communicating the benefits to business partners. At the request of the Boards of Grocery Manufacturers of America and Food Marketing Institute Trading Partners Alliance (TPA), A. T. Kerney developed an action plan to accelerate the degree of cooperation between TPA members after over $1 billion had already been invested in a variety of exchanges and electronic collaboration platforms within the industry. Central to the recommendations made by A. T. Kerney was the need for better communication among the partners to address common concerns over data synchronization, education about the benefits of collaboration and implementation best practices, and regular feedback through surveys and progress tracking initiatives. Also identified was the need for individual companies to proactively encourage trading partners to join through training and sharing of best-practices (Kerney, 2002).

Monitoring and Regulation Challenges

There are many challenges associated with monitoring and regulating online businesses. These challenges are exacerbated by the increasing internationalization of business. Issues with taxation, security, and privacy are more difficult to manage when applied in a global environment where the laws and ethics governing business are often conflicting rather than complementary. Issues also exist with standardizing the accounting mechanisms for digital businesses and processes as traditional accounting principles must adapt to the new business environment. Lastly, due to the global nature of the Internet, issues with managing the security of the digital systems and prosecuting those who attempt to disrupt the flow of digital information provides significant challenges for international legal organizations.

Internet Business

As a global phenomenon, e-B2B poses a complicated series of issues for those organizations charged with monitoring and regulating international business. The Internet compresses the natural geographic separation of businesses and the related movement of products and money between these businesses and allows business operations to span political borders literally at the speed of light. To date, the Internet is largely uncontrolled and business on the Internet follows suit. It is the responsibility of individual countries to decide how to regulate, how much to regulate, and who should regulate the Internet and Internet-related business operations within their boundaries, as well as the degree to which they should accommodate the rules and regulations set up by other countries.

Within any country there are opposing forces at work. Governments are trying to regulate the Internet in a way that stimulates their economies and encourages use. At the same time governments must protect the rights of citizens and existing businesses. It is not surprising that few Internet regulatory laws have been passed even though e-B2B has been in place for many years. To further complicate the regulatory issue, the ubiquity of the Internet has resulted in the rapid expansion of businesses interoperating across international borders. Traditionally only large, well-financed companies could perform international commerce; now there are no limits to how small a multinational company can be.

Confidentiality and Privacy

As businesses and industries in general move toward higher degrees of collaboration at a digital level, issues about the security of the digital information being collected, stored, and transmitted as part of normal business operations becomes more important. Many of the regulatory laws that do exist pertain to protection of personal, confidential, or legally sensitive business data. For example, in the United States personal finances and healthcare records now must be protected from accidental or malicious exposure. The Health Insurance Portability and Accountability Act (HIPAA, 1996) is an attempt to regulate the movement, storage, and access to healthcare-related personal information through enforcement of privacy standards. HIPAA is a direct regulatory response within the United States to several well-publicized breaches of doctor–patient trust including the errant transfer of prescription records on a computer disk sold to an individual in Nevada, medical records posted on the Internet in Michigan, and digital media containing medical records stolen from a hospital in Florida. These are just a few of the better-publicized cases. The HIPAA regulation is scheduled to go into effect in 2003.

Accounting for Digital Transactions and Digital Assets

The Federal Accounting Standards Board (FASB, 2001) identifies several challenges to the accounting industry associated with the transition from a traditional paper-driven economy to one where business is transacted using digital documents. From an accounting perspective, there is no standard measure for determining the short-term or long-term value of technology, knowledge capital, and intellectual property associated with implementing and managing an e-business infrastructure. Yet companies are investing huge amounts of capital in these activities that must be accounted for fairly. Valuing these intangible assets would require that the accounting profession extend its province to nonfinancial areas of business operations and generate standard frameworks and metrics for reporting and tracking nonfinancial information.

Computer Crimes

There are many types of criminal activity associated with the Internet, ranging from petty acts of vandalism and copyright violations to organized systematic attacks with malicious intent to cause damage, financial loss, or in extreme cases, wholesale disruption of critical infrastructure. Each week it seems that there are reports on new attacks, break-ins, viruses, or stolen data made public. Different countries, however, treat different types of computer attacks in different ways with little consensus as to the degree of criminality and severity of punishment. Turban et al. (2001) provide a comparison of computer crime legislation in several countries and note that an activity such as attempting to hack (to gain access to an unauthorized system), while legal in the United States, is illegal in the United Kingdom. However, successful hacking, which causes loss, is criminal in both countries but punished far more severely in the United States, carrying a maximum penalty of 20 years.

Security breaches and malicious attacks such as vandalizing Web sites and disabling computer servers using viruses, denial-of-service (DoS) attacks, and buffer-overflow techniques can prove costly to e-business by making the systems unavailable for normal operation, often resulting in incomplete transactions or lost business while the systems are incapacitated. A recent survey based on 503 computer security practitioners in the United States reported that 90% of respondents detected security breaches in their systems within the 12-month reporting period. Eighty percent of the respondents attributed financial loss to these security breaches, amounting to approximately $500 million from the 44% who were able to quantify their loss (Computer Security Institute, 2000).

The global nature of the Internet makes regulating this so-called cybercrime a significant issue as attacks against systems can be launched from countries with less-stringent regulations and lower rates of enforcement. The United States has recently caused international concern by successfully detaining and convicting foreign nationals accused of crimes against systems in the United States even thought the attacks were launched from non-U.S.-based systems (U.S. Department of Justice, 2002). However, not all attacks are malicious and are often perpetrated to expose security holes in business systems as a means to draw public attention to issues of vulnerability with the intent of eliciting a general hardening of the systems by the systems developers (Hulme, 2002).

Technological Challenges

Some of the most extreme information technology requirements found in the commercial business world are associated with designing and implementing large-scale e-business systems. Issues with the design and deployment of such systems include localizing the applications for international users, managing the quality of service, and protecting access to the data and applications.

Localization and Globalization

Like other forms of e-commerce, e-B2B is increasingly multinational and differences in language and culture can affect the usability of systems. One technological challenge is the process of designing and developing software that functions in multiple cultures/locales, otherwise known as globalization. Localization is the process of adapting a globalized application to a particular culture/locale.

A culture/locale is a set of rules and a set of data specific to a given language and geographic area. These rules and data include information on character classification, date and time formatting, numeric, currency, weight, and measure conventions, and sorting rules. Globalizing an application involves identifying the cultures/locales that must be supported by the application, designing features that support those cultures/locales, and developing the application so that it functions equally well in any of the supported cultures/locales.

If business systems are to share information across national and cultural borders, the information they are sharing must be both syntactically correct and unambiguous for all the systems involved. Of particular importance to cross-cultural systems are the design and development of data storage and data processing systems that can accommodate the differences in data and translate the data between supported locales. Consider three companies operating in the United States, U.K., and Japan respectively, and sharing data about a shipment date that will occur on the date specified by the string "07/08/02." In the United States this date string is interpreted as July 8, 2002. In the U.K. the date and month field are transposed, resulting in a local/culture-specific interpretation of August 7, 2002. In Japan the year and month field are transposed resulting in an interpreted shipment date of August 2, 2007. This is a simple example but the cost associated with developing new or re-engineering existing systems to translate culture/locale-specific values such as simple date strings across a variety of culture/locales is high. There are similar issues associated with sharing data that contains time information, addresses, telephone numbers, and currency.

Scalability, Reliability, and Quality of Service

The general planning considerations for engineering a service such as a B2B marketplace are to provide sufficient system functionality, capacity, and availability to meet the planned demand for use of the systems, which translates loosely into the number of transactions that can be processed in a given time period. The difficulty lies in estimating and planning the processing requirements for a system and engineering a system that can respond to periodic increases in use. In particular, system designers need to understand the demand on the system during "normal" operations and how the demand on the system might vary over a period such as a single day, a week, a month, or the course of a year. Further, system designers need to plan for the effects of "special events," which might cause a short-term increase in the use of the system. Lastly, the system designers need to understand how the B2B interactions translate to workload against the internal systems such as an ERP and plan for matching the capacity of the internal systems with that of the external-facing systems being designed so that the internal systems do not become the weak link in the processing chain.

From a trading-partner perspective, the primary concerns will pertain to the quality of service (QOS) provisions for the system they are going to integrate against. The QOS concerns can be broken down into four key areas: system reliability, system security, system capacity, and system scalability. E-business companies need to set design goals for these key QOS requirements and plan the level of investment and predicted ROI accordingly.

Protection of Business Data and Functions

One result of growth in e-business activity is the associated increase in the transmission and storage of digital information and the corresponding increase in reliance on information systems to support business activities. This poses two major problems to information technology management: how to maintain the integrity and confidentiality of business information and, secondly, how to protect the information systems themselves from security breaches, malicious attacks, or other external factors that can cause them to fail.

Potentially sensitive information shared between businesses is at risk not only during the transmission of the information from one system to another but also as it is stored on file servers and in databases accessible over the computer network infrastructure. The general trend toward open systems poses transmission security issues because open systems rely on text-based data formats such as EDI and XML. If intercepted, these documents can be read and understood by a variety of software publicly available on the Internet. Standards for encrypting XML documents are being developed but have yet to make the mainstream. Encryption technologies for securing data moving over the Internet between business partners, such as VPNs, have been available for a decade or more but rely on coordinating privacy schemes among businesses, sharing encryption keys, and above all developing effective implementation policies that must be constantly revised and tuned to adapt to changing events. Even using encryption systems is often not enough as systems using 40- or 56-bit keys can now be broken using brute-force methods in a few minutes using a personal computer. On the other hand, strong encryption systems that protect data from these brute-force attacks can often not be shared with partners outside of the United States.

Maintaining the integrity and confidentiality of business data and computer systems is important. An often overlooked part of the e-business process, however, is the protection of access to the business systems themselves. The tragic events of September 11, 2001, in New York City have served to underline the fragility of electronic business systems and have provided new priorities for e-business companies. Rather than just simply protecting business data stored in corporate databases by backing it up on tape, companies are now considering holistic approaches to protecting business operations, including protecting access to critical applications such as e-mail as well as protecting lines of communication to those businesses upon which they are dependent (Garvy & McGee, 2002).

B2B E-COMMERCE IN PERSPECTIVE

Whether or not the actual global value of e-B2B activity meets the predictions for 2005 mentioned in the Introduction, the current rates of adoption and continuing pervasiveness of e-B2B activity across all types of business and all types of industry are indicators that e-B2B is going to remain a major driving force within the global economy. At the same time, e-B2B should be regarded as a nascent activity that is rapidly emerging and consequently exhibiting growing pains. Based on a survey of 134 companies around the world, the Cutter Consortium provides some interesting insight into the e-B2B implementation experience (Cutter Consortium, 2000):

Asked to rank the obstacles to e-business, respondents chose “benefits not demonstrated” as the number-one obstacle, followed by financial cost and technological immaturity.

Success with electronic supply-chain management is mixed, with half of those using it enjoying success rates of 76–100% and about a third experiencing success rates of 0–10%.

Similarly, Deloitte & Touche examined data from 300 U.S.- and U.K.-based companies in a wide variety of industries and identified a highly conservative trend to e-business. Less than half of the companies examined expected their e-business strategy to involve transforming business processes while the majority expected to engage in simple Internet-based buying and selling. More telling is that only 28% of the companies had actually developed a formal e-business strategy, the majority being in some stage of investigation (Rich, 2001).

Undemonstrated returns on investment, unsuccessful implementations, and lack of knowledge about the technology, the risks, and the rewards associated with e-B2B all combine to make businesses cautious as they plan ahead for a connected future. The Deloitte & Touche study reports that approximately 50% of respondents indicated that the major barriers to e-B2B lie in the lack of skills and training, or existing business culture compared to approximately 20% of respondents who perceive technological or security issues as the major barrier. These are issues that can be overcome with time as the global corporate knowledge base grows, as more case studies illustrating successful and profitable implementations are available, and as the technology framework becomes more robust, secure, and prevalent.

The success stories available are highly compelling: General Motors, Federal Express, and Cisco are examples that clearly demonstrate the returns possible when e-business is implemented successfully. The bottom line that drives most organizations to evaluate and adopt e-B2B is that performing business electronically is both cheaper to execute and more efficient in terms of time than traditional means. An electronic transaction is also more accurate, which often draws trading partners into supply-chain integration efforts. Indeed, recent evidence indicates that businesses are still investing in e-B2B infrastructure, particularly for electronic supply-chain integration including e-procurement as well as for e-markets. Berlecon Research estimate that the number of B2B exchanges worldwide will grow 10-fold over the next two years particularly in Europe where there are several underserved industries that lack online B2B marketplaces (Wichmann, 2002).

Clearly, implementing an e-business strategy is highly technical and involves many facets of information technology that are new to most companies and indeed new to the information technology industry as well. In essence, everyone is learning how to perform e-business and the technical solutions are adapting to meet the evolving requirements of e-B2B. However, as one author puts it, “Business comes before the e” (Horne, 2002), reinforcing the idea that e-business is not a means to an end but should be regarded as an extension of a sound and well-constructed business plan.

GLOSSARY

ActiveX Data Objects (ADO) Middleware developed by Microsoft for accessing local and remote databases from computers running a Windows-based operating system.

Application programming interface (API) Components of an application that allow other applications to connect to and interact with the data and services of the application; usually published by the application developer as a formal library of functions.

Dot-com Companies that emerged during the Internet boom of the late 1990s with a focus on building applications for or selling products on the World Wide Web; usually funded by large amounts of venture and private equity capital.

E-business All types of business activity performed using electronic means; has a wider context than e-commerce and includes business exchanges that involve interorganizational support, knowledge sharing, and collaboration at all levels.

E-commerce A form of e-business that results in a business transaction being performed using electronic means such as a buy or sell event.

Electronic data interchange (EDI) One of the first forms of e-business used to pass electronic documents between computer systems often over private telecommunication lines or value-added networks; still used by many businesses today.

Electronic funds transfer (EFT) An early form of e-commerce used to transfer money electronically between banks.

Enterprise resource planning (ERP) A collection of applications designed to manage all aspects of a business. ERP systems are designed to integrate sales, manufacturing, human resources, logistics, accounting, and other enterprise functions within an organization.

Intermediary A company that adds value or assists other companies in performing supply-chain activities such as connecting suppliers with buyers.

Java Database Connectivity (JDBC) Middleware used for accessing remote databases from an application written using the Java programming language.

Message oriented middleware (MOM) Middleware used to integrate applications using a system of messages and message queues; allows systems to share data using an asynchronous processing model.

Middleware Software that enables the access and transport of business data between different information systems often over a computer network.

Open Database Connectivity (ODBC) Middleware specification originally designed by Microsoft to access databases from Windows platforms using a standard API. ODBC has since been ported to UNIX and Linux platforms.

Protocol A standard for the format and content of data passed between computers over a computer network; often maintained by independent organizations such as the World Wide Web Consortium.

Remote procedure call (RPC) Middleware technology originally developed for UNIX systems for sharing data and methods between applications over a network.

Structured query language (SQL) A computer language developed by IBM in the 1970s for manipulating data stored in relational database systems; became the standard language of databases in the 1980s.

Supply chain The end-to-end movement of goods and services from one company to another during a manufacturing process.

Transmission control protocol/Internet protocol (TCP/IP) Communication protocols originally developed as part of ARPANET that today form the basic communication protocols of the Internet.

Transaction A record of a business exchange such as a sell or a buy event.

Tymnet An early value-added network developed by Tymshare Inc. and used by companies for transferring computer files between computer systems; the largest commercial computer network in the United States and was later sold to MCI.

UNIX-to-UNIX-Copy (UUCP) A utility and protocol available on UNIX systems that allows two computers to share files over a serial connection or over a telephone network using modems.

Value-added network (VAN) A form of computer network connection often between two companies to perform e-business that is managed by a third party; initially used to transfer EDI documents; modern ones can operate over the Internet.

Virtual private network (VPN) A form of network connection between two sites over the public Internet that uses encrypted data transmission to provide a private exchange of data.

Business-to-Business (B2B) Internet Business Models

Dat-Dao Nguyen, *California State University, Northridge*

NATURE OF B2B E-COMMERCE

In general, B2B e-commerce can be classified according to the nature of the goods/services in transaction, the procurement policy, and the nature of the supply chain.

Businesses conduct B2B e-commerce to sell or buy goods and services for production and/or nonproduction. *Production materials,* or direct materials, go directly to the production of goods or services. Usually they are not shelf items that could be readily purchased at anytime in the marketplace. Their use is scheduled according to a production plan. They are purchased in large volume after negotiation and contracting with the sources to guarantee a continuous stream of input materials for the production process. *Nonproduction materials,* or indirect materials, are used in maintenance, repairs, and operations. They are also called MROs, containing low-value items. Although constituting 20% of purchase value, they amount to approximately 80% of an organization's purchased items.

Depending on the strategic nature of the materials in the production, a procurement policy may involve a long-term contract or an instant purchase/rush order. S*trategic sourcing* for a long-term contract results from negotiations between suppliers and buyers. *Spot buying* for an instant purchase/rush order concludes at a market price resulting from the matching of current supply and demand. Due to the strategic role of direct materials in the production, a manufacturer wishes to secure a consistent long-term transaction at an agreed upon price with its suppliers. Most organizations spend a great deal of time and effort for upstream procurement of direct materials, usually high-value items, and overlook low-value items, including MROs. Consequently, there are potential inefficiencies in the procurement process, such as delays in production due to insufficient MROs and/or overpayment for rush orders to acquire these MROs.

From a value chain and supply chain perspective, B2B e-commerce can take place in a vertical market or a horizontal market. A *vertical market* involves transactions between and among businesses in the same industry or industry segment. Usually this market deals with the production process or direct materials necessary for the production of goods and services of firms in the same industry. A *horizontal market* involves transactions related to services or products of various industries. These materials are diversified and related to the maintenance, repair, and operation of a specific firm. Most of these materials do not contribute directly to the production of goods and/or services offered by the firms.

Before the advent of B2B e-commerce, companies used the following tendering process. A department in a company submits a requisition for the goods/services it needs. The purchasing agent prepares a description of the project, giving its specification, quality standards, delivery date, and required payment method. Then the purchasing department announces the project and requests proposals via newspaper/trade magazine ads, direct mail, fax, or telephone. Interested vendors/suppliers may ask for and receive detailed information by mail. Then these suppliers prepare and submit proposals. Proposals are evaluated by several departments/agents at the buying company. Negotiation may take place and the contract is awarded to the supplier who offers the lowest price. In this process, communication mostly takes place via letter or fax/phone.

Similarly on the selling side, a supplier announces in newspapers or trade magazines the inventory to be disposed of and invites interested parties to inquire and bid. A sales force may be set up to identify and make direct contact with potential buyers. The interested parties may request additional information about the goods to be delivered by mail or fax. Then they decide to submit a sealed bid by mail. At the closing date, the bids are examined and the highest bid wins the auction.

This manual and paper-based process takes a long time and is prone to error. Electronic processes conducted via telecommunication systems are faster but require an investment in a dedicated private network. Recently, Web-based technologies have made business communication much less expensive and easier to administer. Transactions over the Internet also make it possible to reach a larger pool of business partners and to locate the best deal for the project.

There are many classification schemes for B2B e-commerce business models (Laudon & Traver, 2001; Turban et al., 2002; Pavlou & El Sawy, 2002). The classifications provide details on the context and constraints of the various business models so that an interested business may select an appropriate strategic choice to gain a competitive advantage.

In the following, B2B e-commerce business models are classified on the basis of business ownership and transaction methods.

B2B BUSINESS MODELS BY OWNERSHIP

Depending on who is controlling the marketplace and initiating the transactions, B2B e-commerce can be classified as company-centric or an exchange model. A *company-centric model,* representing a one-to-many business relationship, involves one business party initiating transactions and deals with many other parties interested in buying or selling its goods and services. In a *direct-selling* model, a company does all the selling to many buyers, whereas in a *direct-buying* model a company does all the buying from many suppliers.

In these models, the initiative company has complete control over the supportive information systems. However, a third party may serve as an *intermediary* to introduce buyers to sellers and vice versa, and to provide them with a platform and other added-value services for transaction. In many cases, buyers and suppliers having idle capacity in their Internet host sites for B2B e-commerce have served as intermediaries for other smaller businesses.

An *exchange or trading model,* representing a many-to-many business relationship, involves many buyers and many suppliers who meet simultaneously over the Internet to trade with one another. Usually there is a market maker who provides a platform for transactions, aggregates the buyers and sellers, and then provides the framework for the negotiation of prices and terms.

A variation of the exchange model is a *consortium trading exchange,* which constitutes a group of major companies that provide industry-wide services that support the buying and selling activities of its members. The activities can be vertical/horizontal purchasing/selling.

Direct Selling

This is a company-centric B2B model focusing on selling, in which a supplier displays goods and services in a catalog at its host site for disposal. The seller could be a manufacturer or a distributor selling to many wholesalers, retailers, and businesses.

In this model, a large selling company transacts over a Web-based, private-trading sales channel, usually over an extranet, to its business customers. A smaller business may use its own secured Web site. The company could use some transaction models, such as direct selling from electronic catalogs, requests for proposal (RFP), and selling via forward auctions, and/or one-to-one dealing under a long-term contract. The classification of these transaction methods in B2B e-commerce is discussed in detail in the next section.

In the B2B direct selling, the involved parties may benefit from speeding up the ordering cycle and reducing errors processing. They also benefit from reducing order processing costs, logistics costs, and paperwork, especially the reduction of buyers' search costs in finding sellers and competitive prices and the reduction of sellers' search costs in advertising to interested buyers.

Most major manufacturers have conducted B2B e-commerce with their business partners. For example, *Dell.com, Cisco.com, IBM.com, Intel.com,* and *Staples.com,* among others, have special secured sites for registered partners to provide them with information on products, pricing, and terms. At this site, business customers can browse the whole catalog, customize it, and create and save a shopping list/shopping cart for internal approval before placing orders. The sites have the tracking facility for customers to follow up on the status of their orders. These sites also have links to shipper's Web site (UPS, FedEx, Airborne Express, etc.) to help customers keep track of delivery.

In this model, depending on whether a manufacturer/distributor that hosts its own Web site and support provides complete transaction or not, the company may have to pay fees and commissions to intermediaries for hosting and value-added services. Usually, corporate buyers have free access to the e-marketplace after a free registration to the site.

Direct Buying

This is a company-centric B2B model focusing on buying, in which a company posts project specifications/requirements for goods and services in need and invites interested suppliers to bid on the project.

In this model, a buyer provides a directory of open requests for quotes (RFQs) accessible to a large group of suppliers on a secured site. The buying company doesn't have to prepare requests and specifications for each of these potential tenders. Suppliers could be notified automatically with an announcement of available RFQs, or even the RFQs sent directly from the buyer site. Independent suppliers can also use search-and-match agent software to find the tendering sites and automate the bidding process. Then suppliers can download the project information from the Web and submit electronic bids for projects. The reverse auction could be in real time or last until a predetermined closing date. Buyers evaluate the bids and negotiate electronically and then award a contract to the bidder that best meets their requirements. A large buying company can also aggregate suppliers' catalogs at its central site for the ease of access from its own branch offices. These affiliations will purchase from the most competitive supplier. In this case, the suppliers will be notified directly with the invitation for tender or purchase orders.

This model streamlines and automates the traditional manual processes of requisition, RFQ, invitation to tender, issue of purchase orders, receipt of goods, and payment. The model makes the procurement process simple and fast. In some cases, it increases productivity by authorizing purchases from the units/departments where the goods/services are needed and therefore bypassing some paperwork at the procurement departments. The model helps in reducing the administrative processing costs per order and lowering purchase prices through product standardization and consolidation of orders.

The model also contributes to improving supply chain management by providing information on suppliers and pricing. It helps to discover new suppliers and vendors who can provide goods and services at lower cost and on a reliable delivery schedule. It also minimizes purchases from noncontract vendors at higher prices for uncontrollable quality goods/services.

An example for this model is GE's *Trading Process Network* (TPN), where a company's sourcing department receives internal material requests and sends off RFQs to external suppliers. Currently GE opens this network to other business partners, at *gxs.com* site.

In this model, a buying company may set up its own Web site and may engage other services from intermediaries with licenses. Suppliers have to register at the host site and may have to pay an access fee.

Exchange/Trading Mall

The exchange model involves many suppliers and buyers meeting at the marketplace for transactions. The marketplace could be a dedicated site or a trading mall open to the public. Transactions in this marketplace involve spot buying as well as negotiation for a long-term buying/selling contract. In spot buying, a deal is concluded at a price based on supply and demand at any given time at the marketplace. In systematic sourcing, the exchange aggregates the buyers and sellers and provides them with a platform for the negotiation of prices and terms.

In the exchange, a company lists a bid to buy or an offer to sell goods/services. Other sellers and buyers in the exchange can view the bids and offers, although the identity of the tenderer or the bidder is kept anonymous. Buyers and sellers can interact in real time, as in a stock exchange, with their own bids and offers to reach an exact match between a buyer and a seller on price, quantity, quality, and delivery term. Third parties outside the exchange may provide supporting services, such as credit verification, quality assurance, insurance, and order fulfillment.

The exchange provides an open marketplace so that buyer and seller can conclude/negotiate the transaction at a competitive price resulting from the supply/demand mechanism. It has the characteristics and benefits of a competitive market in terms of classic economics. A buyer may benefit from lower costs due to a large volume of goods/services being transacted. A supplier may benefit from reaching a larger pool of new buyers than is possible when conducting business in a traditional market.

In this business model, some exchanges act purely as information portals by transferring the order/inquiry to the other party via hyperlinks so that the transactions will take place at the seller/buyer sites. Others aggregate suppliers and/or buyers for the convenience of the trading parties. In supplier aggregation, the exchange standardizes, indexes, and aggregates suppliers' catalogs and then makes them available to buyers at a centralized host site. Or requests for proposals (RFPs) from participant suppliers are aggregated and matched with demand from participant buyers. In buyer aggregation, RFQs of buyers, usually the small ones, are aggregated and linked to a pool of suppliers that are automatically notified of the existence of current RFQs. Then the trading parties can make bids.

Another type of exchange is called a *consortium trading exchange,* formed by a group of buyers or sellers. In *buying consortia,* a group of companies joins together to streamline the purchasing process and to pressure the suppliers to cut prices and provide quality, standardized goods/services in vertical as well horizontal supply chain transactions. An example of a buying consortium is *Covisint.com,* an automotive industry joint venture by GM Motors, Ford, DaimlerChrysler, Renault, Peugeot Citroen, and Nissan. In *selling consortia,* suppliers in the same industry deal with other downstream businesses to maintain reasonable prices and controllable production schedules for goods/services in vertical trading. An example of a selling consortium is the *Star Alliance,* an alliance of major domestic and international airlines, consisting of Air Canada, Lufthansa, SAS, United Airway, and others. These companies sell or exchange seats in their airplanes to one another to assure full booking for their fleets.

The use of exchange would especially benefit smaller businesses, which don't have large customer bases or supplier sources. Transactions via exchange and intermediary sites don't require additional resources for information technology infrastructure, staffing, and other related costs. If the exchange is controlled by an intermediary, this third party often assumes the responsibility for credit verification, payment, quality assurance, and prompt delivery of the goods.

There are intermediary exchanges, such as *eBay.com* and the Trading Information Exchange of GE Global eXchange Services (*gxs.com*), that provide an open marketplace for many suppliers/vendors and buyers. In other cases, manufacturers provide upstream and downstream partners with a service enabling them to do business with one another.

One prominent example is Boeing's secured site *MyBoeingFleet.com,* at which Boeing's airline customers can access the PART page to order maintenance parts directly from Boeing's suppliers. This service significantly streamlines time and labor in the procurement process for all business partners. One no longer needs to go through archives to look for blueprints, specifications, and sources of thousands parts of an aircraft for the requisition of a specific item.

On the revenue models of exchanges, if a major partner of the supply chain owns the site, access to an exchange marketplace could be free of charge. In other cases, participants pay an annual registration fee and/or a transaction fee that is either a fixed amount or a percentage

Table 1 B2B E-commerce Business Models

Order aggregation		•	•
Auction	•	•	•
Bartering			•

of the transaction volume. The participants may also pay for added-value services, such as credit verification, insurance, logistics, and collection, provided by the exchange. Some exchanges generate extra revenue from online advertisements on the site.

B2B BUSINESS MODELS BY TRANSACTION METHODS

B2B business models could be classified by the transaction methods a buying/selling company uses to conduct business with its partners in the e-marketplace. A company may use one or many transaction models suitable for its transactions.

Electronic Catalogs

Using this model, a supplier posts an electronic version of its catalog in a Web site for free access from interested parties. The company benefits from exposure to a large pool of potential buyers over the Internet without the costly creation and distribution of voluminous catalogs. The electronic catalog can be updated in a timely manner. Most companies have this model as a supplement ary to their paper-based catalogs to reach more customers outside their physical facilities. The transactions incurred may be handled with a traditional procurement process.

In this passive and low-cost business model, a supplier could inform potential buyers of the existence of the catalogs via regular mail or e-mail. The supplier may also register the Web site in the directories of some exchanges or intermediaries. Using a search engine, interested buyers may discover the competitive offer and then contact the supplier directly for further information about products and services.

Automated RFQs

In this model, requests for quotes (RFQ) are automatically distributed from the buying company to its business partners via a private communication network. An example of this model is GE's Trading Process Network (TPN). At GE, the sourcing department receives the requisitions electronically from other departments. It sends off RFQs containing specifications for the requisitions to a pool of approved suppliers via the Internet. Within a few hours, potential suppliers around the world are notified of incoming RFQs by e-mail or fax, instead of within days and weeks, as in the traditional paper-based system. Suppliers have a few days to prepare bids and to send them back over the extranet to GE. The bids are then routed over the intranet to the appropriate purchasing agents and a contract could be awarded on the same day. GE reports that, using TPN, labor involved in the procurement process was reduced by 30% and material cost was reduced from 5% to 50% due to reaching a wider base of supplier online. Procurement departments of GE's branches around the world can share information about their best suppliers. With TPN, it takes a few days for the whole procurement process instead of weeks, as before. Because the transactions are handled electronically, invoices are automatically reconciled with purchase orders and human errors in data entries/processing are minimized accordingly.

In this business model, sourcing cycle time in the acquisition process is reduced significantly, with the distribution of information and specifications to many business partners simultaneously. It allows purchasing agents to spend more time negotiating for the best deal and less time on administrative procedures. A company also consolidates a partnership with suppliers by buying only from approved sources and awarding business based on performance. Consequently, it allows the company to acquire quality goods and services from a large pool of competitive suppliers around the world.

With the advent of Web-based technology, networking becomes affordable and cost effective for interested businesses. A smaller company can engage an intermediary, or Web-service provider, to alleviate the cost of building and maintaining a sophisticated transaction network.

Digital Loyalty Networks

As in traditional business, highly valued business partners in B2B e-commerce may get special treatment. In this model, a B2B e-commerce Web site differentiates visitors by directing the valued ones to a special site, instead of trading in a public area opened for other regular business partners. The system may also direct special requests/offers to a preferred group of business partners.

Using this business model, different RFQs will be sent to different groups of potential suppliers from the approved supplying source for the company. A business may differentiate between its suppliers based on past performance in terms of product quality, pricing, delivery, and after-sales services. Similarly, a selling company may reward its preferred buyers with special discounts and conditions on transactions.

Metacatalogs

In this model, catalogs of approved suppliers are aggregated, indexed so that buyers will have the opportunity to deal with a large pool of suppliers of goods/services. These metacatalogs are usually kept in a central site for ease of access to potential buyers. Using this model, a global company may maintain a metacatalog of suppliers for the internal use of its branches. Or a trading mall can keep a metacatalog for the wide public access.

For the internal use of a global company, the model aggregates items of all approved suppliers from their catalogs into one source. Buyers from affiliated firms or branches can find the items in need, check their availability and delivery time, and complete an electronic requisition form and forward it to the selected supplier. In this transaction, prices could be negotiated in advance. Potential suppliers tend to offer competitive prices, as they would be exposed to a larger pool of buyers, in this case the world-wide affiliations/branches of the buying company. In addition, suppliers may become involved in a long-term relationship with a global company and its affiliations/branches. The listing in the metacatalog is free to the suppliers as a result of the negotiation of terms and prices for the goods/services to be provided to the buying company.

For wide public access, an intermediary or a distributor will create metacatalogs and make them available for its clients. Because buyers have an opportunity to deal with a large source of suppliers, these suppliers are under pressure to compete with one another in terms of price, quality, and services to win business. In this model, the supplier may have to pay a fee for listing on the catalog and/or a commission as a percentage of the transaction value. The buyer may have a free access or may pay a membership fee to the host/distributor.

Order Aggregation

In this model, RFQs from buyers are aggregated and sent to a pool of suppliers as invitations to tender. The order aggregation could be internal or external. In an internal aggregation, company-wide orders are aggregated to gain volume discounts and save administrative costs. In an external aggregation, a third party aggregates orders from small businesses and then negotiates with suppliers or conducts reverse auctions to reach a deal for the group. Usually, an intermediary will aggregate RFQs of participant buyers and match then with requests for proposals (RFPs) from participant suppliers.

In order aggregation, small buyers benefit from the volume discount through aggregation that could not be realized otherwise. Similarly, suppliers benefit from providing a large volume of goods/services to a pool of buyers and save the transaction costs incurred from dealing with many, fragmented buyers. Order aggregation works well, with defined indirect production materials and services having relative stable prices. In this model, if the order aggregation is undertaken by an intermediary, then involved business parties may have to pay a flat fee and/or a commission on the transaction value.

Auction

To reach a deal, business partners involved in B2B could use auction and/or matching mechanisms. A *forward auction* involves one seller and many potential buyers. A *reverse auction* involves one buyer and many potential sellers. In *double auction,* buyers and sellers bid and offer simultaneously. In *matching,* related price, quantity, quality, and delivery terms from the bid and ask are matched.

In a buying-side marketplace, a buyer opens an electronic market on its own server, lists items in need, and invites potential suppliers to bid. The trading mechanism is a *reverse auction,* in which suppliers compete with one another to offer the lowest price. The bidder who offers the lowest price wins the order from the buyer. Other issues, such as delivery, schedule, and related costs, are also taken into account when awarding contracts to bidders.

In a selling-side marketplace, a seller posts the information for the goods/services to be disposed and invites potential buyers to bid. The trading mechanism is a *forward auction,* in which participating buyers compete to offer the highest price to acquire goods/services in need.

The transaction can also take place at an intermediary site, at which buyers post their RFQs and suppliers post their RFPs. Depending on the regulations of the auction site, bidders can bid either only once or many times. In the latter case, bidders can view current supply and demand for the goods/services and change their bids accordingly. The transaction concludes when bidding prices and asking prices are matched.

The advantage of this model is that it attracts many buyers to a forward auction and many suppliers to a reverse auction.

The auction can be conducted at the seller/buyer private trading site or at an intermediary site. The auction can be in real time or last for a predetermined period.

If the auction is conducted at an intermediary site, the involved business parties may have to pay an access fee. In addition, sellers may have to pay a commission on transaction value.

Bartering

In this model, a company barters its inventory for goods/services in need by announcing its intention in a classified advertisement. Actually, a company rarely finds an exact match by itself. The company will have a better chance if it joins an e-commerce trading mall, as it could reach a larger pool of interested parties over the Internet.

An intermediary can create a bartering exchange, at which a company submit its surplus to the exchange and receives credits. Then it can use these credits to buy the items in need from the stock of goods/services listed for bartering at the exchange. An example is the bartering site of *Intagio.com* (formerly *Bartertrust.com*), where the owner claims to be the market leader in facilitating corporate trading in which goods and services are exchanged between businesses without using cash. Business parties using an intermediary site may have to pay for a membership fee and/or a commission on the transaction volume.

MERITS AND LIMITATIONS OF B2B E-COMMERCE

Along with other business models in the e-marketplace, B2B e-commerce has been welcomed as an innovative means of conducting transactions over the Internet. These business models promise not only effective and efficient business operations/transactions, but also competitive advantages to early adopters. Companies have adopted B2B e-commerce more slowly than predicted, but even conservative projections estimate that B2B transactions will top $3 trillion by 2004 (mro.com, 2002). It has been predicted that 66% of bids for MRO goods will be solicited over the Internet and 42% of MRO orders will be electronic (Fein & Pembroke Consulting, 2001).

An example of cost savings in B2B e-commerce is the story of Suncor Energy Inc. of Canada. In 2000, the company was working with 1,000 suppliers, with a total MRO budget of $192 million. About 70% of its expenditures went to 40 suppliers, yet its purchasing staff spent 80% of their time manually processing transactions with the 900 smallest suppliers. The switching to e-Procurement was predicted to generate a savings of $32 million directly from e-Procurement, $64 million from the redeployment of the purchasing workforce, and $10 million in inventory reductions (mro.com, 2002). It is noteworthy that these savings come from process automation, not from forcing price concessions from distributors.

Although having certain merits, these business models encounter some limitations that hinder the effective and efficient implementation and operation of a sustainable business. However, there are many possible solutions for overcoming these limitations.

Merits of B2B E-commerce

B2B e-commerce in general exposes a selling/buying company to a larger pool of suppliers and corporate buyers. Transactions over the Internet help overcome the geographical barrier, bringing business partners from all over the world to the e-marketplace. A company may benefit from transactions with business partners beyond the local market.

The Web-based technology of e-commerce helps minimize the human error found in the paper-based activities and supports timely, if not real-time, communication between and among partners. Different from traditional, costly telecommunications networks, Web-based technology makes transactions over the Internet affordable to most businesses involved in the e-marketplace. Also, the existence of many intermediaries also provides interested businesses with low-cost solutions for implementing a B2B e-commerce model.

B2B e-commerce models address the concerns about the effectiveness and efficiency of the supply chain management of business partners—suppliers as well as company buyers. Supply chain management coordinates business activities from order generation, order taking to order distribution of goods/services for individual as well as corporate customers (Kalakota & Whinston, 1997). Interdependencies in the supply chain create an extended boundary that goes far beyond an individual firm, so that individual firms can no longer maximize their own competitive advantage and therefore profit from cutting costs/prices. Material suppliers and distribution-channel partners, such as wholesalers, distributors, and retailers, all play important roles in supply chain management. B2B e-commerce models address the creation of partnerships with other parties along the supply chain, upstream as well as downstream, to share information of mutual benefit about the need of final customers. The key issue is that all upstream and downstream business activities should be coordinated to meet effectively the demand of final customers. Each partner in the stream should coordinate its own production/business plans (order fulfillment, procurement, production, and distribution) with those of the other partners so that sufficient streams of goods/services will reach customers in the right place at the right time.

B2B business models also address issues of customer relationship management (Kalakota & Whinston, 1997), the front-end function of a supply chain. An effective business model helps in creating more loyal customers who are not inclined to shop for lower prices but rather who pay for quality and service, in retaining valued customers, and in developing new customers by providing them with new quality products and services. The customer base could be segmented on history of performance in sales/purchases. This information will serve as a basis for promotion and discount, promoting the loyalty of current customers.

Limitations of B2B E-commerce and Possible Solutions

Some limitations of B2B e-commerce have been identified, such as conflicts with the existing distributing channel, cost/benefit justification for the venture, integration with business partners, and trust among business partners (Laudon & Traver, 2001; Turban et al., 2002)

Most suppliers have existing distributing networks of wholesalers, distributors, and dealers. If a company decides to do business over the Internet directly with interested partners, it may cause conflict in terms of territory agreement and pricing policies on product lines. A possible solution could be redirecting these potential customers to the appropriate distributors and having the company handle only new customers outside the current sales territories of these distributors. Another alternative could be the company handling specific products/services not available within the traditional distribution channel. Or orders could be taken at the central site, with a distributor providing downstream added-value services (delivery, maintenance, support) to the new customers of the company.

Another limitation is the number of potential business partners, and sales volume must be large enough to justify the implementation of a Web-based B2B system. Selling-side marketplaces for B2B e-commerce is promising if the supplier has a sufficient number of loyal business customers, if the product is well known, and if the price is not the critical purchasing criteria. For the buying side, the volume of transactions should be large enough to cover the investments and costs in the B2B e-commerce venture. In many cases, the interested business could participate in an exchange by paying a fixed fee or a commission on the volume of transactions. Using an intermediary could be feasible, as the company would not need to invest and maintain the expensive and sophisticated infrastructure of B2B e-commerce systems.

On a technical perspective, unless a B2B e-commerce site has implemented a comprehensive network/system architecture, integration with a variety of business partners systems (Oracle, IBM, or other ERP systems) may cause an operational problem. These business partners should be able to transact on compatible network platforms and protocols of communication. Sometimes the conversion implies additional investments and requires an extra cost/benefit analysis for the project. Also the technology should handle global transactions, such as multiple currencies and multiple languages from multiple countries, multiple terms of contract, and multiple product quality standards. *Commerce One* has been offering a "Global Trading Web" solution to address these issues.

Because transactions over Internet are not face-to-face, most business partners are unknown to each other. Consequently, the issue of trust in B2B is the same as in B2C e-commerce transactions. Many B2B exchanges have failed because they did not assure the creditability of the involved business partners. Trust in e-commerce could be enhanced with some quality assurance services and warranty seal programs, such as *WebTrust* and *SysTrust* of the American Institute of Certified Public Accountants (AICPA) (Nagel & Gray, 2001). In these programs, a third party (such as a CPA) audits the e-commerce transactions and infrastructure of a company to assure that it implements and follows some procedures and policies to guarantee the security of the online transactions and integrity in terms of fulfilling its obligation toward and honoring the privacy of its business partners. Once the company meets some prescribed criteria, it is awarded with a warranty seal to post on its Web site to inform the potential business partners on the security and quality of its online transactions.

CRITICAL SUCCESS FACTORS FOR B2B E-COMMERCE

From the performances of current B2B e-commerce entities, one can highlight some critical success factors having an impact on sustainable business and competitive advantages (Laudon & Traver, 2001; Turban et al., 2002).

A company has pressure to cut costs and expenses in the traditional paper-based procurement process related to vendor and product searches, vendor performance and cost comparison, opportunity costs, and errors of manual system. B2B e-commerce would provide ample opportunities and alternatives to optimize the procurement process. In this circumstance, the company has an incentive be involved in an effective and efficient cost-saving venture using Web-based technology. In addition, the top management will be interested in sponsoring and advocating the project.

Another success factor would be for a company to have experience with EDI or other non-Web-based business-to-business electronic transactions and be willing to integrate its current systems with new technologies in B2B. This would create a favorable climate supporting technology innovation. This factor is important in evaluating the technical feasibility of the B2B e-commerce project. It helps assess the readiness of the company, in terms of its technological maturity, to nurture an innovative system, and the availability of technical expertise needed to develop, operate, and maintain the system.

The industry concentrates on selling and buying with fragmented supplier and seller, and experiences difficulties in bringing both parties together. The larger source of buyers and sellers offered by B2B e-commerce would provide a company with opportunities to optimize its supply chain management. In this context, the potential economic and operational benefits would justify involvement in a B2B e-commerce venture.

Large initial liquidity is needed in terms of the number of buyers and sellers in the market and the volume and value of transaction to attract early business venture. In any economic feasibility analysis of a new venture, one needs to assess the cost of development and the payback period of the system. A large initial liquidity would justify the initial investment in a sustainable business.

A full range of services, such as credit verification, insurance, payment, and delivery, is needed to attract small and medium businesses. The market maker also needs available domain expertise for these services. The added-value services would facilitate the transactions of smaller businesses. These business partners, without a sophisticated infrastructure and expertise, will need a one-point access to the e-marketplace to conduct a one-stop transaction in B2B e-commerce.

Business ethics should be respected, to nurture trust among business partners, fairness to all business parties, especially in non-face-to-face transactions over the Internet. Security issues should be implemented to protect privacy and trade secrets of involved business entities in an open networked marketplace. To address the issue of trust, the company may include some quality assurance services and seal programs, such as WebTrust and SysTrust of AICPA.

Another factor is being able to successfully manage the channel conflict, to avoid any impact on the short-term revenue of supply chain partners. This conflict of interest is one of the limitations of B2B e-commerce and possible solutions to it were discussed in the previous section.

B2B E-COMMERCE ENABLE TECHNOLOGIES AND SERVICES

The hands-off nature of such Internet technologies as the communication protocols TCP/IP and HTTP and the programming languages HTML and XML enables the progress of e-commerce. These technologies assure interoperability across businesses using various platforms, which is necessary for global communications and transactions. XML, as a widely distributed standard, is compact and easy to program and permits businesses to more completely describe documents and transactions over the Internet.

Involvement in B2B e-commerce does not necessarily require intensive investment in hardware, software, or staffing for a sophisticated telecommunications network and database. There are many application and service providers that offer cost-efficient solutions for business interested in participation in this innovative marketplace. These services may support the complete value chain processes/activities of a business from its upstream suppliers to its final customers. Below are reviews of some service providers in B2B e-commerce.

GE's Global eXchange Services (GXS) (*gxs.com*) offers many services to B2B business. Its Trading Information Exchange (TIE) is a global extranet service with features such as online information publishing, dynamic delivery of supply chain data, and promotions–management workflow applications, enabling partners to share detailed operational information and to jointly manage key business processes. Its Source-to-Pay Services suite includes facilities for posting and responding to RFQs, online auctions, catalog purchases, invoice tracking, and payment. This provider has served more than 100,000 trading partners conducting about 1 billion transactions worth $1 trillion annually. GE itself has used these services internally since 1999 to connect with about 36,000 of its suppliers and has conducted about 27,000 auctions worth close to $10 billion (isourceonline.com, 2002).

Commerce One promotes the Global Trading Web to link buyers, suppliers, service providers, and e-marketplaces in a single, global community. This network is based on an open architecture—without closed and proprietary applications—and widely disseminated standards to assure technical and operational interoperability. The standards on data, content, and document format are established across the community. The technical interoperability assures that files, data, and applications can be transferred across platforms. The operational interoperability assures that e-marketplace processes and procedures can operate in unison. There are about 10,000 buyers and suppliers participating in the Global Trading Web. In addition nearly 100 e-marketplaces in all sizes and industries make up the membership that forms the backbone of the trading community (commerceone.com, 2000).

Ariba (*ariba.com*) products and services have enabled B2B e-commerce processes for more than 100 leading companies around the world, including over 40 of the Fortune 100, in diverse industries. Ariba products have been implemented on more than 3,750,000 desktops around the world (ariba.com, 2002). Web-based marketplaces powered by Ariba unite fragmented value chains operated by interdependent trading partners, bringing together buyers, suppliers, and service providers in Internet-speed trading communities. Ariba provides solutions for the rapid deployment and configuration of online procurement portals and automates end-to-end commerce processes, including catalog searches, requisitioning, purchasing, and invoicing. Integration with Ariba Supplier Network provides the infrastructure and third-party services companies need to transact, manage, and route orders in real time. It connects companies to e-procurement on-ramps, supplier-hosted catalogs, and other marketplaces. Ariba Marketplace integrates seamlessly and comprehensively with dynamic sourcing and RFQ capabilities, providing market makers with cost-efficient trading models, such as auctions, reverse auctions, bid/ask exchanges, and negotiations features. It can also handle real-time multicurrency translation for increased payment capabilities.

i2 (*i2.com*) has over $1 billion in revenues with more than 1000 customers. It has delivered about $30 billion in audited value to customers (i2.com, 2002). i2 Global Network is an Internet collaboration space that enables buyers, suppliers, and marketplaces to rapidly connect to each other and use i2 Network Services for content, collaboration, and commerce. These services allow the enterprise to extend its e-procurement and collaboration initiatives beyond tier 1 suppliers. i2 industry solutions include preconfigured industry templates, packaged role-based workflows, integration capabilities, product configurations, and example models and scenarios built specifically for an industry. From this starting point, companies can easily modify the template to meet their unique needs. i2 Supplier Relationship Management (SRM) supports the partnership with suppliers by coordinating processes across product development, sourcing, supply planning, and purchasing within a company and across companies. i2 Supply Chain Management (SCM) manages the supply chain within a company and across companies in the value chain as well. It provides multienterprise visibility, intelligent-decision support, and execution capability utilizing open, real-time collaboration with trading partners. i2 Demand Chain Management (DCM) synchronizes customer front-end processes with operations, enhancing responsiveness of the supply chain to maximize customer profitably and loyalty.

MRO Software Inc. (mro.com) provides fully hosted, off-the-shelf online services for Web storefront, security, catalog management, supplier administration, customer relationship management, order management, transaction processing, and integration with other online B2B services in the e-marketplace. This provider has served more than 8,000 customers (mro.com, 2002).

BEYOND SELLING AND BUYING B2B MODELS

B2B e-commerce extends to activities other than just selling and buying. For example, partners in a value chain could be involved in *collaborative commerce* (c-commerce) in a Web-based system to meet final consumer demand by sharing information on product design, production planning, and marketing coordination. Once consumer demand is identified, the quantity on hand of the raw material and semifinished and finished products of one partner will be made visible to others, avoiding bottlenecks along the value chain and supply chain (Laudon & Travers, 2001). In this type of business, some partners act as value chain integrators while others are value chain service providers. This business model assures the production of goods/services that effectively meet consumer demand with the collaboration between manufacturers and retailers. Then the product design and production cycle will be efficiently shortened with the collaboration between manufacturers and upstream suppliers.

GLOSSARY

Aggregation of orders and/or RFQs A compilation of small orders and RFQs of many businesses into a larger package to gain volume discount and economic of scale.

Bartering A trading method in which business partners exchange their surplus to one another without using cash.

Company-centric B2B e-commerce A business model represents a one-to-many business relationship in B2B e-commerce. In this model, a company involves in direct selling or direct buying of goods and services with many business partners.

Digital loyalty network A business model to offer special treatment to valued/preferred business parties in the value chain or supply chain in terms of priority, pricing and contract conditions.

Exchange/trading mall A business model represents a many-to-many business relationship in B2B e-commerce. In this marketplace, many buyers transact with many suppliers for goods and services.

Meta-catalog A compilation and index of goods and services offered by many small businesses into one source for easy of access to the public or interested parties.

MRO Non-production or indirect materials in maintenance, repairs, and operations.

Request for proposal (RFP) A tendering system in which a seller lists the materials for disposal and asks potential buyers bid on the contract. Buyer offers highest bid (forward auction) will win the contract.

Request for quote (RFQ) A tendering system in which the buyer lists the materials in need and asks the potential suppliers bid on the contract. Supplier offers lowest bid (reverse auction) will win the contract.

Business-to-Consumer (B2C) Internet Business Models

Diane M. Hamilton, *Rowan University*

INTRODUCTION

For as long as commerce has existed, there have been diverse business models. A business model, very simply stated, is the method by which a firm manages to remain a going concern, that is, the way in which a company earns sufficient revenue to remain in business. By far the most often encountered business model is one in which an organization sells a product or provides a service in exchange for currency. Consider the *manufacturing* business model and, as an example, Dell Computer. Dell is in the business of building personal computers and selling them either to other businesses or to the general public. With the *retailing* business model companies also sell products in exchange for cash payment—for example Zales Jewelers. Zales does not manufacture the jewelry it sells; it provides a retail outlet, that is, a physical location, where potential customers can engage in the purchase of the goods that Zales has to offer. A variant on the retail model is the *catalog* business model. Catalog companies often don't have physical facilities (although some do); rather, they offer their goods for sale via their catalog and then ship the goods to the purchaser. An example of a catalog retailer is Figis, which sells gourmet snacks and gifts. The *service* business model has been growing significantly over the past several decades. Service-type businesses are quite varied, including, for example, beauty salons, attorneys, plumbers, and physicians. What they all have in common is that a service is rendered in exchange for a cash payment. Not all business models involve providing a product or service in exchange for cash. Consider, for example, the way some health clubs provide child care to their members. In some cases, the health club provides a room where children can remain happily occupied while their parent exercises. In order to avail themselves of the facilities for their children, health club members must be willing to personally provide the supervision for a fixed number of hours. That is, health club members who take advantage of the room by leaving their children there when they exercise pay for this benefit by working a few hours themselves in the child-care room. This service is paid for, then, not by cash but by a corresponding service. For any business model to be successful, it must generate some type of revenue or "value" that will enable the organization to continue in operation.

The arrival of the Internet's World Wide Web has brought about myriad new business models as well as a variation on the business models that had already existed, most notably the retailing model. These new business models take advantage of the Internet in many ways: to change a delivery system (e.g., digital delivery of software instead of physical shipment of the product); to improve customer service (e.g., online tracking of orders through the United Parcel Service); or to reach a wider audience (all geographical and time constraints are removed). Regardless of the model, however, the principle remains the same. A successful business model is one in which an exchange occurs between entities (companies or individuals) such that the organization can be self-sustaining through the receipt of revenue or something else of value, and it is worth noting that no level of sophisticated technology can make up for the lack of a good business model.

The next section is devoted to the definition and illustration of the most popular business-to-consumer (B2C) Internet business models. Later, some important tenets for Internet strategy are presented, along with lessons learned as a result of the quick rise and fall of many dot-coms.

INTERNET BUSINESS MODELS (B2C)

Some businesses have migrated to the Internet without changing their business model at all. These companies built Web sites, aptly called *brochureware,* which simply provide information about the company—as it exists in the physical world. They don't attempt to provide another sales channel, that is, to engage in virtual commerce. Other businesses, called brick-and-clicks, moved to the

Internet by offering their current products for sale online. Still others didn't exist prior to the advent of the World Wide Web and couldn't operate without it. There are clear advantages to electronic commerce from the perspective of both the business and the consumer. For example, an online business is available to a much larger set of customers than would be possible if the customer had to physically visit the business establishment. Also, this larger potential market allows a business to sell its product with lower marketing costs. Further, online businesses can actually improve customer service, for example through online help desks. Finally, an online business can better utilize human resources and warehouse/retail space.

Benefits also accrue to consumers who shop online. Customers can now shop at their convenience—any day and any time of day. They have a much larger selection to choose from; that is, it is possible to visit many more online retailers than would be feasible if they had to get in their car and drive from store to store. Price comparisons are more easily made online, especially with the aid of shopping bots, as is described later.

It is rare, however, to find a business environment that provides advantages without also having potential problems. Electronic commerce is no different. Problems are possible for both the online business and the online consumer. For example, online businesses suffer from a much higher rate of credit card fraud than their real-world counterparts, according to Visa—24% for online transactions compared with 6% overall for all transactions (Mearian, 2001).

In the following sections, the most popular business-to-consumer (B2C) business models are described and illustrated. It should be noted that although there are many ways to classify business models, no generally accepted categorization scheme for Internet business models currently exists.

The breakdown provided in this paper attempts to show the diversity of business models operating on the Web according to the type of transaction (or activity) engaged in, coupled with the way revenue is earned. Revenue can be earned, for example, through traditional sales purchases, as a commission on auction purchases, or through advertising that supports free information. Some of these business models, for example auctions and reverse auctions, existed in the physical world prior to the advent of the World Wide Web. However, the Web has allowed these business models to be redefined in virtual space, taking advantage of the huge Internet community. There are other business models that only came into existence after the advent of the World Wide Web, for example shopping bots. The way each of these unique models operates on the Internet is described in the following sections.

The Retail Model

Businesses adopting the *retail* model sell a product in exchange for cash. These retailers can be further differentiated according to whether the company exists solely online (online-only storefronts) or whether the Internet serves as just one of multiple sales channels (brick-and-click retailers). *Online-only storefronts* are more popularly called *dot-coms;* these businesses did not exist prior to the advent of the World Wide Web. As a matter of fact, it was the World Wide Web that provided the conditions allowing for the emergence of the dot-coms—companies that exist only on the Internet. Perhaps the most well-known dot-com company is Amazon.com, which started as a bookseller and migrated into a marketplace that now sells many diverse product lines, such as electronics, toys and games, music, cars, and magazine subscriptions. Amazon titles their home page "Amazon.com—Earth's Biggest Selection." They have clearly ascribed to the "reach" strategy as espoused by Evans and Wurster (1999) as they have grown their company. (This strategy, along with several others, is explained in the final section of this chapter.) Somewhat less well know than Amazon is Pets.com, one of the more famous "failures" in the sea of dot-coms, going out of business late in 2000. Amazon owned a large share in Pets.com. Unfortunately for Amazon, this was the second company they backed that went out of business (Living.com was the first).

Organizations conducting business in the physical as well as the virtual world are often referred to as *brick-and-click* companies (and sometimes *click-and-mortar*). In contrast to dot-coms, these firms had an established business before the advent of the World Wide Web, and after the Web was created, an online presence was added. More recently, firms in this category have found that the most successful strategy is to use the Internet as a way of supporting their primary channel—in most cases, the retail store. Although some companies may have created a Web site that's simply brochureware (information without any transaction ability), brick-and-clicks are capable of conducting retail business over the Web. Consider two extremely well-known, yet very different, brick-and click-companies, Lands' End and Wal-Mart.

Lands' End appeared on the Internet very early, in 1995, and today boasts the world's largest apparel Web site. Well known as a catalog retailer, Lands' End also sells through outlet stores and the Internet. One reason for their Internet success is likely their initial catalog experience. Catalog stores have much in common with electronic commerce and have, therefore, proved to be successful when the Internet channel is added. Another reason for Lands' End's success is the way in which they have utilized the Web to add value for their customers. For example, "My Virtual Model" allows customers to "try on" clothes after creating a virtual model of themselves by entering their critical measurements. Lands' End also provides a feature they call "My Personal Shopper," wherein customers answer a series of questions about themselves, thus allowing a virtual personal shopper to make various recommendations. Another one of their features, "Lands' End Custom," provides custom tailored apparel on request, and they also provide online chat facilities with customer service.

WalMart became the nation's number one retailer in the early 1990s and the nation's largest employer in 1997. It is famous for its huge superstores, where a consumer can find just about anything at an everyday low price. Walmart.com, a wholly owned subsidiary of Wal-Mart Stores, Inc., came into existence in January 2000, making it a somewhat late entry in the e-commerce market.

Wal-Mart has been successful on the Web because they have exploited their channels, rather than keeping them separate. For example, a consumer can make a purchase on the Web and return it to a store, if desired. Consumers can see the current Wal-Mart circular or the current advertised sales by visiting the Web site, and they can request e-mail notice of special values.

The Auction Model

The *auction* business model has existed for a very long time; consider, for example, Sotheby's, who auctions valuable items to the public in large halls where many prospective buyers can assemble. Although Sotheby's has now added online auctioning to their services, eBay has clearly revolutionized the auction business model. eBay calls itself "The World's Online Marketplace." Their mission is to "help practically anyone trade practically anything on earth" (http://www.ebay.com). eBay has reinvented the auction by including every conceivable type of item—from the most expensive (e.g., automobiles and rare collectibles) to the least expensive (e.g., junk souvenirs) to professional services (e.g., Web design or accounting). eBay is one of the very few dot-coms that managed to make a profit almost immediately after it appeared on the Internet. It earns revenue in several ways: from "posting" fees, from "special feature posting" fees, and from commissions on item sales. That is, sellers who wish to join the auction pay a very nominal posting fee (ranging from a few cents to a few dollars) in return for eBay providing space to show their item. If the seller wishes to use a special feature that might catch the attention of prospective buyers (e.g., highlighting an entry or listing an item at the "top" of a search), he or she pays another small fee. These two types of fees are paid by the seller whether or not the product eventually sells. However, because they are such nominal fees, there is very little at risk to the seller when the item is placed for bid. The final type of fee is collected by eBay if anyone bids on the item and it eventually sells. This fee is based on the amount of the sale; that is, the seller would pay more for a car that is auctioned than for a used book or CD that sells. What eBay provides is the *mechanism* for completing a transaction between a buyer and a seller. It provides the complete software interface for the transaction, and it does so splendidly. Its proven dependability and accuracy has attracted almost 40 million registered users and made it the leading online marketplace for the sale of goods and services—almost $15 billion was transacted on eBay in the year 2002. Many reasons exist for eBay's success, not the least of which is the flawless operation of its Web site, or the low cost for putting items up for bid. In addition to these basic items, however, eBay has provided added value in several other ways. For example, "Buy it Now" is a feature that allows a buyer to purchase an item immediately, at a stated price, if no one has yet placed a bid on the item, without waiting for the full auction time (typically a week) to expire. eBay even has a feature that allows bidders to participate (real time) in auctions that are currently being conducted in the world's leading auction houses. Other Web sites offer auctions (e.g., Yahoo and Amazon), but their volume and success is far less than that achieved by eBay since it came into existence, in 1995.

The Reverse Auction Model

Like the auction model, the *reverse auction* business model was not born on the Internet; businesses have utilized this approach for many years through requests for proposals (RFPs). Whereas an auction offers a good or service for sale and invites interested parties to bid higher and higher to obtain it, a reverse auction specifies the demand for some good or service and invites sellers to offer the item for sale at lower and lower prices. Although there are many reverse auction sites available on the Net, no individual Web site in the B2C market has become a household name. Examples of reverse auction sites include Respond and PillBid. Respond offers consumers the opportunity to request either a product or a service in widely diverse categories, such as automobiles, computers, legal services, travel, and home improvement. As a matter of fact, about 60% of all online requests are actually for services, rather than for hard goods, according to Respond. The most often requested service categories are hotels/motels, auto insurance, apartment/house rentals, DSL service providers, and day spas (Greenspan, 2002). Respond earns their revenue from two basic sources: affiliates and product/service providers. Any site can become an affiliate by adding a link to Respond's site, and affiliates are paid $1 every time a visitor clicks through and makes a request at Respond. Product/service providers can choose from one of two payment options: a subscription plan or a straight fee schedule. Under the subscription plan, providers are given access to all leads along with lead management and scheduling tools. Under the fee schedule, providers pay a small amount for each lead to which they choose to respond.

A niche-oriented reverse auction occurs at PillBid, where consumers post an interest in filling a prescription. PillBid serves as the intermediary between the consumer and pharmacies and offers an additional, value-added service: a search of the PillBot database. PillBot searches online pharmacies and advises the consumer about the lowest prices available on the Net.

What the Internet provides for any Web site utilizing this type of business model is the potential for a huge community of participants, which is important for the ultimate success of a reverse auction. The ability to facilitate auctions without human intervention and the potential for a very large number of participants are the factors provided by the Internet that allow for the sale of low-price items and the ability of a company to achieve profitability by charging very low commissions. This would not be possible in the physical world.

The "Name-Your-Price" Model

Many people consider Priceline to be a reverse auction, and it is often referred to as such in the literature. However, Priceline claims that it is not a reverse auction because sellers do not bid lower and lower for the ability to fill the demand for an item (www.priceline.com). Instead Priceline has patented a technology that they call *"Name Your Own Price."* Their system works as follows. Consumers make purchase offers with a fixed price for such things as airline tickets and hotel rooms. Additionally, they agree to some level of flexibility with respect to vendor, travel date, number of connecting flights, and so forth. Finally, they agree in advance to make the purchase (by supplying credit card information) if their price and flexibility levels can be matched by a vendor. Priceline then takes these offers and attempts to find a vendor that will provide the product or service for the terms specified. This business model exploits the Internet by improving information about supply to buyers and information about demand to sellers. That is, Priceline provides added value by serving as an information intermediary. Like other market makers, Priceline obtains its revenue as the difference between the price of acquiring the product or service and the price at which it turns the product or service over to the consumer (Mahadevan, 2000). Priceline, now a household name, has seen its share of success and failure. Its stock has traded at as high as $158 and as low as just a few dollars. It has found tremendous success in the sale of airline tickets; as a matter of fact, Priceline has claimed to be the largest seller of leisure air tickets in the United States (Anonymous, 2000). On the other hand, it lost so much money attempting to sell groceries and gasoline that it had to exit these markets soon after entry. This would lead one to conclude that some categories are far better suited to the name-your-price business model than others.

The Flea Market Model

Each of the three previous models (auction, reverse auction, and name your price) belong to the broad category of models categorized as the "broker" model by Rappa (2001). In its simplest form, a broker is a site that brings buyers and sellers together, and that facilitates buying transactions by providing a location and a system where the buying can take place. Like the previous models, the *flea market* model acts as a broker. However, it differs from the other models because the purchase transaction more clearly takes place between the buyer and the seller, rather than through some type of auctioning system. The interaction "feels" more like a typical flea market purchase. This type of model is employed at Half, which is a subsidiary of eBay. Sellers can post items for sale at Half, and when buyers search for them, they see the selling price and data about the current "condition" of all items available. Once the buyer selects an item, the sale is enacted immediately at the posted selling price. Half, acting as a broker, accepts payment from the buyer, deducts its net commission (based on selling price and shipping costs), and gives the proceeds to the seller. Half also earns revenue by inviting other Web sites to become affiliates (similar to the affiliate program explained earlier for Respond.)

An even more typical flea market transaction takes place at iOffer. iOffer has an interface that closely resembles eBay, but it is not an auction. At iOffer, a prospective buyer can search for an item and see a listing of items that match the search criteria. (If nothing matches the buyer's criteria, the buyer can post a free "want ad." These want ads are then used to provide relevant sellers with potential sales leads.) Once the buyer finds an interesting item, he/she can either buy the item at the selling price or make an offer. This second choice allows the buyer and seller to interact directly, making offers and counteroffers, until either the sale is transacted or the buyer "walks away." As with other broker sites, the seller pays a fee based upon the selling price of the item.

The Group-Buying Model

Manufacturers and distributors have always provided price breaks to buyers as the number of units ordered increased. That is, a company would expect to pay less per unit for an order of 1,000 units than for an order of one unit. The *group-buying* business model attempts to provide individual consumers with this same advantage. Operationally, items for sale appear on the group-buying Web site for a period of time, generally several days to a week. As time passes and more buyers join the "group" (i.e., place an order at the current price), the price goes down, reflecting the large volume discount. At the end of the buy cycle, all group members are billed for the final price. Group members who have placed an order are likely motivated to attempt to get others to join the group, causing the ultimate price to go down even further. This sounds like a good idea; however, in practice, this business model has failed in the B2C market. In January 2001, both of the well-known consumer group-buying sites, Mercata and MobShop, closed their doors to consumers. Mercata had performed well since their opening, in May 1999, and was the top-ranked online buying service in Spring 2000, according to Gomez Advisors. MobShop, which opened in October 1998, had been attempting to shift to the business-to-business (B2B) and government markets when it discontinued consumer service. MobShop's software is now used by the U.S. General Services Administration and some B2B marketplaces (Totty, 2001).

The Shopping Bot (Buyer Advocate) Model

A "bot" (short for robot) is a software tool that can search through tons of data on the Internet, return the found information, and store it in a database. Shopping bot programs crawl from Web site to Web site and provide the information that will ultimately populate the databases of search engines and shopping sites. Shopping bots can provide prices, shipping data, product availability, and other information about products available for sale online. This data is then aggregated into a database and is provided to a consumer when he or she is interested in making a purchase online. Most shopping bots were started by small, independent organizations and quickly sold to large companies for proprietary use on their site. For example, Amazon bought the technology supporting Junglee in 1998 and MySimon was purchased by Cnet in 2000. Shopping bot technology is incorporated into many sites; for example, DealTime, is incorporated into AOL's shopping section and that of other portals, such as Lycos and iWon. Initially, bots were often blocked by retail sites for fear of uncompetitive prices. However, bots are now considered advantageous because they drive consumer traffic to the site (buyers can "click through" to the desired retailer from the bot site.) As a matter of fact, bots now partner with shopping sites for revenue enhancement. Multiple revenue streams exist in this business model. For example, merchants can pay for advertising space on the bot site to promote special incentives and sales. Some bot sites, such as mySimon and DealTime, allow merchants to pay for a higher position in the retailer listing, and mySimon also obtains revenue for placing some products in a list of so-called "recommended" items (White, 2000). Other bot sites, rather than accept revenue for a higher place in the listing, charge all retailers simply to list on the site (Borzo, 2001). It will be interesting to watch the success of this business model, which earned quick popularity by exploiting a strategy of affiliation with the consumer, but which has systematically moved away from affiliation with the customer and closer to affiliation with the retailers.

The Full-Service Market-Making Model

Market makers don't sell products they personally produce. Rather, they bring together potential buyers and sellers and provide a virtual marketplace where all parties can discuss and engage in transactions. When the products and services are all related, a full-service site emerges. Revenue generally comes from two areas—program fees and advertising.

Autobytel, for example, improves the vehicle purchasing process by providing data for the initial research and comparison of models, the actual auto purchase, and the ultimate auto resale. It also supports car ownership by listing data about recommended service schedules and vehicle recalls, and it gives users the ability to schedule service and maintenance appointments online. Finally, the site provides featured articles and links to myriad auto parts and accessories retailers. Autobytel describes itself as an "Internet automotive marketing services company that helps retailers sell cars and manufacturers build brands through efficient marketing and customer relationship management tools and programs." Autobytel is the largest syndicated car buying content network, and its four branded Web sites received nine million unique visitors in just the fourth quarter of 2001 (http://www.autobytel.com). Like a good many other Internet business models, Autobytel earns revenue from a combination of sources, including dealer program fees, advertising, enterprise sales, and other products and services.

The Online Currency Model

Initially, *online currency* was designed to fill a desire for consumer privacy. That is, many thought that consumers might want to make online purchases where the detail wouldn't show up on a credit card statement. In other cases, e-cash was designed to enable payment of micropurchases. Qpass online currency, for example, can be used to make micropurchases (e.g., data on mutual funds) at Morningstar online. Currently, there are very few opportunities for micropurchases on the Net; however, as revenues from online advertising continue to decline, micropurchases may yet emerge successful for the purchase of small information items, such as news and medical information. Online currency has also been used to encourage surfers to visit particular sites, and their visits were rewarded with small amounts of online currency. This has not proved to be a successful business model, however. Cybergold, for example, paid consumers for various actions, such as reading ads, answering surveys, and registering at Web sites. Beenz acted similarly and attempted to fill a niche by providing e-cash in various international currencies. Cybergold and Beenz have both gone out of business. Flooz, another failed brand, was marketed as a gift certificate for Internet shopping. The model used for all these online currencies was to take a small percentage from transactions at their participating retailers, that is, the same as the credit card model. Paypal, a successful brand, with an initial public offering in early 2002, mainly facilitates eBay transactions and processes payments via major charge cards or direct checking account access. It now offers multiple currencies to facilitate global transactions. In some ways it appears that generic online currency is a solution still waiting for a problem.

The Free-Information Model

Free information of all types is ubiquitous on the Internet. For example, virtually all major news organizations maintain Web sites with regularly updated news items. When people don't have access to a newspaper or a television set (and even when they do), they can visit their favorite news site to find out what's happening in the world, what the weather is expected to be, and how their favorite sports team is faring. CNN, USA Today, and others use these sites to strengthen their brand and earn revenue through advertising.

News isn't the only type of information available on the Web, however. Diverse types of free information can be found, for example, at MapQuest, Nolo, and Encarta. MapQuest allows users to get driving directions between any two addresses in the United States—at no charge whatsoever. Nolo provides free advice about various legal issues, for example as related to creating a will or obtaining a divorce, and Encarta, provided by the Microsoft Network (MSN), is an online encyclopedia. These sites collect revenue in various ways. For example, MapQuest licenses its technology to thousands of business partners and provides advertising opportunities using banner ads and electronic coupons for hotels, restaurants, and the like, which target consumers as they travel. Nolo sells legal software and books on its site, and the free information that drives users to the site could also entice a user to make a purchase there. The Encarta site provides a great deal of information for free, but the full Encarta Reference Library is available for sale on the site, as are many other products. (This is the MSN, after all.) Just how long so much free information will remain free is unknown. In the future, these types of sites might be excellent candidates for micropurchases, should that concept ever become popular.

Search Engines

Search engines provide free information. However, they are unique enough and important enough to be discussed as a subcategory of the free-information model. Search engines serve as indexes to the World Wide Web. At a search engine site, people use keywords to indicate the type of information they are looking for, and the site returns matches considered relevant to the user's request. The data provided by a search engine comes from their database, which is continually updated. These databases are populated and updated through a continual search of the Web by programs called spiders. A number of search engines exist, for example Google, Lycos, and AltaVista. Because the spider code differs from search engine to search engine, as does the capacity of the database, the results one gets will also differ. Portals (discussed below) sometimes partner with a search engine in order to provide search facilities; for example, Comcast utilizes Google on its home page and Yahoo uses Google as its back-end search engine (Notess, 2002).

Directories

Directories are different from search engines in that a user typically selects from among a choice of categories, which have multiple levels of subcategories, to find the desired data. Yahoo was the first directory on the Web, and in addition to grabbing territory early, it has continually grown and reinvented itself. Yahoo now provides both directory and search engine facilities. It provides a tremendous amount of content, as well as services (e.g., e-mail), and shopping. As a result of the immense capability of its site, users spend increasingly large amounts of time there, and this, in turn, provides a great deal of information to Yahoo. This information is used to target advertising, which yields significant revenue, because targeted ads can sell for up to 60 times more than untargeted ones (Anonymous, 2001).

Portals

Although *portals* don't necessarily have to provide free information, in reality they generally do, so they are best discussed as a subcategory of the free-information model. A portal is a place of entry into the virtual world, that is, the site that a user chooses as his or her "home" in a browser, and most portals are, in fact, search engines or have search engine capabilities built in. Yahoo, for example, is one of the most popular sites used as a Web portal. Many other sites serve as the portal of choice for Web users, most notably those provided by Internet service providers, such as AOL or MSN. Because these general-purpose portals appear by default on the desktop when a browser is launched, they have a distinct competitive advantage. News sites such as USA Today or CNN are also popular portals. General-purpose portals typically provide current news items, shopping, and the ability to configure the page according to personal interest. Many also provide e-mail capabilities, online calendars, and Web-based storage. Some Web users prefer a portal targeted to their specific interests, such as Healtheon/WebMD, funtrivia.com, or MavenSearch (a portal to the Jewish world). Regardless of the type, portals derive their revenue from site advertising and partnership agreements, or in the case of Internet service providers (discussed below), subscription fees help to defray the costs of maintaining their portal.

The Service-for-a-Fee Model

Although products can and are purchased on the Web, services are available for online purchase as well. The *service-for-a-fee* model operates in the same fashion as the retail model in that consumers pay for services rendered, and these fees account for the great majority of earned revenue. At Resume.com, for example, professionals will write, revise, or critique a resume. They will also prepare cover letters and thank you letters or even serve as a "personal career agent." The price for these services ranges from $50 for a cover letter, to $99 for a "classic" resume, to $1,499 to act as a personal career agent.

In the same basic industry, Monster provides services to both job seekers and employers. Monster's slogan is "Work. Life. Possibilities." They accept job postings from both employers and potential employees and allow either group to browse the available listings. The price for a job posting starts at $120, which is much less than many large, urban newspapers will charge, yet the audience reach is significantly broader. They also provide a number of job-related services, such as the "Personal Salary Report," which gives job seekers an idea of their potential worth in the current job market, and the "Inside Scoop," which purports to tell job seekers what interviewers "really want to know." Monster is the largest employment site on the Internet, operating in at least 21 countries, thus providing a huge marketplace for employers and employees to meet. They are a real success story among the dot-coms, having about 30 million unique visits and over 12 million resumes. Yet they continue to seek avenues for new growth. For example, Monster recently joined with AOL, providing it with the largest consumer base on the Net, over 30 million members (www.tmpw.com), and it began providing online training and employee development services in August 2001 (Moore, 2001). This site is especially useful for employees who are willing to relocate or for employers who want the broadest possible geographical exposure for their positions. A search function using keywords is available for both employers and employees, to simplify the search process.

E*Trade, an online brokerage and banking firm, was launched in 1983 as a service bureau before the World Wide Web came into existence. It linked with AOL and CompuServe in 1992, becoming Etrade.com, one of the first all-electronic brokerage firms. It is now a global leader in personal financial services, providing portfolio tracking, free real-time stock quotes, market news, and research. E*Trade Bank, now the largest purely online bank, was added to its portfolio in 2000 to offer a variety of financial services, including checking, saving and money market accounts, online bill paying, mortgage and auto loans, and credit cards. In 2001, E*Trade announced its first proprietary mutual fund, which is to be solely managed by E*Trade Asset Management (www.etrade.com).

Internet Service Providers (ISPs)

Internet service providers are a little different from other types of services available on the Web, because they are not generally thought of as a "destination" on the Internet. Rather, ISPs provide consumers with the ability to access the Internet, and to send and receive electronic mail. Some of the most well known of these ISPs are AOL, CompuServe, and MSN. More recently, cable providers (e.g., Comcast and Cox) and DSL providers (e.g., Verizon) have earned and continue to increase market share by providing a high-speed alternative to modem access. As of early 2002, 7% of U.S. households were using one of these broadband alternatives for Internet access and the percentage is growing (Associated Press, 2002). ISPs charge a monthly fee for their service, which accounts for the vast majority of their revenue.

NetZero is the most well-known *free* ISP, but in return for being "free," it requires users to allow their surfing and buying behavior to be snooped. Thus, although the user is not paying for this service with cash, he or she is paying for it by providing a large amount of personal information. This information is worth a great deal to NetZero, who can turn it into cash by selling the information to other businesses. NetZero also fills the user's screen with more than the usual amount of advertising banners. Some believe that the free ISP model is not sustainable in the long run (Addison, 2001), and it should be noted that even NetZero has two types of service—free and "platinum." Platinum costs less than most well-known ISPs (currently $9.95/month), but it offers better service than the free subscription does, and it removes the plethora of banner ads from the screen. Other examples of the free-service model are mentioned below. NetZero is an example of both the service-for-a-fee model and the free-service model. It is included here because it is an ISP.

The Free-Service Model

It is often difficult to distinguish between free information and free services. For example, are the driving directions Mapquest provides a service or information? For purposes of categorization in this chapter, a *service* that actually provides *information* is considered as belonging to the free-information model. Only services providing something distinctly different from information are categorized as service models. One type of *free service* is the provision of games, such as games of chance. At Freelotto, for example, visitors can play an online lottery, which is supported by online advertisements. Napster provided a much publicized example of an extremely popular, free-service site. At Napster, users could trade music files; however, in reality, no trading was actually required. Members provided music files free to anyone who wanted to download them, and they could download as many files as they desired. Napster was shut down as a result of a lawsuit brought by music providers. There are similar sites still operating (e.g., www.imesh.com), but none of these sites is anywhere as successful as Napster. It is worth noting that the music industry has attempted to replace the popular Napster service by offering "fee-for-download" sites, such as RealOne and Pressplay. However, these sites are relatively expensive (about $10/month) and have alliances with only a subset of the large record companies, resulting in members being able to download only music sold by alliance companies. Most sites that offer a free service earn their revenue through site advertising and/or reselling of consumer information.

INTERNET STRATEGY

Creation of a successful Internet business model must also include the clarification of a firm's strategy, including the consideration of how to best exploit the features of the Internet. It should be noted that Internet strategy is not the same as a business model. The strategy outlines the specifics of how a company will implement a given model, and any business model can be implemented by an almost unlimited variety of strategies. The fact that some companies succeed when using a particular business model (e.g., auction) while others fail clearly attests to this fact. During the process of delineating an Internet strategy, one must clearly define how the day-to-day operations of the organization will allow the firm to become self-sustaining within a reasonable period of time. The amazing proliferation of dot-coms, and the incredible losses that accrued to some, provide us with many "lessons learned," which are also briefly discussed in this section.

Competitive Advantage Through the Internet

Evans and Wurster (1999) suggest that success on the Internet will accrue to those organizations that exploit one of the following: reach, affiliation, or richness. *Reach* is defined along two dimensions: (a) how many customers a firm can reach and/or (b) how many products/services can be provided to a customer. The advantage of reaching a large potential customer base is obvious, and that's one of the main reasons why many businesses set up shop on the Internet. Customers from virtually anywhere in the world can shop online 24 hours a day, 7 days a week. On the Internet a business can also provide a huge number of products, significantly more than can be provided in a finite physical space. For example, Amazon, one of the Internet's pioneers, offers 25 times more books for sale than the largest bookstore anywhere in the world.

Competitive advantage can also be achieved through *affiliation*—specifically, through affiliation with the consumer. Consumers will have more trust in an organization that appears to be on "their side." For example, if someone is going to buy an automobile, whose opinion will carry more weight with the buyer, the auto manufacturer (e.g., Ford or Totota) or an unbiased third-party (e.g., Edmunds.com or *Consumer Reports*)? The Internet has seen the rise of new types of business models that affiliate themselves with the consumer, for example search engines such as Yahoo or Google. Consumers can visit these sites, request data, have their requests honored, and pay nothing for the service.

The final dimension suggested by Evans and Wurster is *richness*. They define richness as (a) how much detail the organization provides to the consumer or (b) how much information about the consumer is collected by the organization. In the first case, firms can achieve competitive advantage by providing significant detail to the consumer—more than the amount provided by their competition. This strategy will be most effective when the product is technical and/or changes frequently. Examples of the types of products that might benefit from a strategy of richness are computers, wireless phones, and digital cameras. A firm can also achieve competitive advantage if it holds a significant amount of information about its customers, because information is an asset when used effectively. Many online companies use information about their customers' buying habits to customize the site for each visitor and also to provide suggestions about additional products the visitor might be interested in.

Lessons Learned

The advent of the World Wide Web brought with it a rush of businesses hoping to be first to achieve market share online. During this frenzy of the mid-1990s, venture capitalists were willing to invest in almost any type of online organization. The belief seemed to be that just about any idea could bring a fortune online. Nothing appeared to be too extreme. However, by the late 1990s, many of the companies that, years later were still losing money, started to appear less elegant, and much of the venture capital funding that was so easily obtained earlier was drying up. One phenomenon worth considering is the reliance on Web advertising for revenue. In the early days of Internet surfing, the banner ad was something new and intriguing, and many people were motivated to click through, hoping to discover a "terrific deal" or to find out what they "won." However, this initial curiosity was followed by consumer disinterest, as a result of both previous disappointments and the sheer numbers of ads popping up everywhere. Business models that relied solely on advertising revenue were among those fighting for their virtual life. Considering history and the current environment, a variety of recipes for online success have been espoused. Patton (2001) suggests several rules for online success. One is *be diverse*. Travelocity, for example, has found success by moving from its initial business model, which was to sell airline tickets and collect revenue from online advertising, to its revised model, which no longer depends so much on advertising, relying instead on its extensive customer database to sell things other than airline tickets (e.g., hotel rooms, membership in travel clubs, and suitcases) This is also an example of using "richness" to achieve competitive advantage. A second rule is *exploit channels*. Retailers have historically used multiple channels—such as retail stores and catalogs (e.g., Victoria's Secret or L.L. Bean)—for selling their merchandise. The mistake made by some retailers was to consider the Web as a separate, competing channel, so that what a person bought in one channel, for example online, could not be returned to a different channel, such as the retail store. This practice was met with consumer frustration and dissatisfaction. On the other hand, the more successful enterprises exploited their channels, using one channel to promote another and treating all channels equally. This practice strengthened their brands and increased customer loyalty.

Hamel (2001) suggests that there are three ways to imminent online failure, which he labels "dumb," "dumber," and "dumbest." He claims that it is a *dumb* idea to miscalculate timing. That is, there are circumstances that require speed, such as where customer benefits are substantial and competitors are likely to appear quickly. On the other hand, there are circumstances that call for a slower approach, that is, where complementary products or new customer behaviors are required in order to take advantage of the product. Even *dumber* is to overpay for market share. For example, Pets.com paid $180 for every customer it ultimately acquired. This huge cost, plus its inability to differentiate itself, led to its speedy failure (Patton, 2001). In order to be effective, a company must acquire customers at a discount, not at a premium. The *dumbest* idea, according to Hamel, is to come to market without a good business model, and he claims that there are two fundamental flaws that will kill a business model. They are (a) misreading the customer (are there really customers who actually want what you are going to sell?) and (b) unsound economics (are there really enough customers available to render your business profitable?).

CONCLUSION

A business model is the method by which a firm manages to remain a going concern, and a business strategy helps to define the goals of the particular business model chosen. With the advent of the Internet, some existing business models were revised and other new models were invented. Many of the revised business models simply incorporated the addition of a new sales channel—the World Wide Web. Companies utilizing these models are called brick-and-clicks. However, simply adding this new sales channel has provided no guarantee of success. Rather, companies who added this channel successfully did so through their specific implementation strategy. For example, Lands' End added value to their Internet channel by incorporating special features and services that would entice people to shop on their Web site, and Wal-Mart utilized their Web site to strengthen their primary channel—the Wal-Mart store. These Internet strategies (i.e., value-added features or services and channel exploitation), along with others described above, helped aspiring brick-and-click companies achieve Internet success.

Some companies revised an existing business model by adding value that could only be provided by the Internet. For example, eBay reinvented the auction model by providing an efficient and effective online marketplace, where sellers could market their goods with very little risk and for a very reasonable expenditure level. This has resulted in a volume so large as to exploit both the reach and affiliation strategies as espoused by Evans and Wurster (1999). Another example, the free-information model, is sometimes a variation on the traditional broadcast (television or radio) model. Companies such as CNN and USA Today provide free information to the public, and they earn their revenue through advertising. In other cases, the free-information model more closely resembles an ongoing "promotion" using free samples. Consider, for example, the information provided on the Nolo site, which might entice the user to purchase the related software package.

Finally, the Internet has provided the catalyst for some completely new models, and these models would not exist without the Internet. Examples in this category are search engines, Internet service providers, and portals. These brand new business models exist for the purpose of helping people effectively access the World Wide Web. That is, ISPs provide the technology necessary to connect to the Web, portals provide a place to start activity once access to the Web is gained, and search engines help users find the right path to Web sites of interest. Portals and search engines exploit an affiliation strategy, and the most successful ones provide the quality and quantity of information and services desired by the consumer, thereby exploiting richness.

Regardless of whether a business model merely includes the Internet as a separate sales channel or adds value to an existing model in order to exploit the unique features of the Internet, or whether a model was invented specifically for the Internet, it has been shown that no firm can be successful without a good business model coupled with sound strategy, resulting in sufficient revenue to allow the firm to remain a going concern. It is also clear that technology alone, no matter how sophisticated it is, cannot overcome the problems inherent in a business model that, for example, misreads the customer or for which insufficient customers actually exist. The days of unlimited venture capital are over; future funding will require sensible models united with a profitable strategy.

GLOSSARY

Bot Programs that can autonomously search through data on the Internet and return the data for storage in a database (short for robot; also called *spider*).

Brick-and-Click Companies conducting business in both the physical and the virtual world.

Business Model Method by which a firm manages to remain a going concern.

Click-and-Mortar Companies conducting business in both the physical and the virtual world.

Dot-com Companies that exist solely on the Internet.

Ecash Special-purpose currency that can be spent when shopping online.

Internet Service Provider (ISP) Provides Internet services such as access to the World Wide Web and e-mail.

Micropurchase An online purchase having a cost of from just a few cents to a dollar or two.

Portal A place of entry into the virtual world; the site a user selects as "home" in a browser.

Search Engine An index to the World Wide Web; allows users to enter keywords that help to find desired information.

Spider Programs that can crawl from Web site to Web site and retrieve data that is stored in the database of a search engine.

C

Capacity Planning for Web Services

Robert Oshana, *Southern Methodist University*

INTRODUCTION

The Internet is continuing to grow rapidly throughout most of the world. The most popular Internet applications continue to be the World Wide Web (Web), electronic mail, and news. These applications use a client–server paradigm: Systems called servers provide services to clients. Client–server describes the relationship between two computer programs in which one program, the client, makes a service request from another program, the server, which fulfills the request. Although the client–server idea can be used by programs within a single computer, it is a more important idea in a network. In a network, the client–server model provides a convenient way to interconnect programs that are distributed efficiently across different locations. The client–server model has become one of the central ideas of network computing. Most business applications written today use the client–server model. So does the Internet's main program, TCP/IP (transmission control protocol/Internet protocol). It is critical that these servers are able to deliver high performance in terms of throughput (requests per second) and response time (time taken for one request). As new capabilities and services make their way to the Web, the ability for forecast the performance of integrated information technology networks will be critical to the future success of businesses that provide and rely on these capabilities and services.

The explosive growth of Internet sites and e-commerce has presented new challenges in managing performance and capacity. Also, the ability to estimate the future performance of a large and complex distributed software system at design time can significantly reduce overall software cost and risk. These challenges have led to the development of a discipline of managing system resources called capacity planning, which Menasce and Almeida (2000, p. 186) described as "the process of predicting when future load levels will saturate the system and of determining the most cost-effective way of delaying system saturation as much as possible."

Performance management is an important part of the capacity planning process. The goal of performance management is to proactively manage current system performance parameters such as throughput and latency to provide the user adequate response time as well as minimal downtime.

Planning Considerations

Determining future load levels can be difficult if a disciplined process is not used. There have been many examples of systems that suffered economic and reputation damage as a result of not planning correctly and adequately for growth and capacity. Building systems "on Internet time" appears to have been a way to get around disciplined system development processes in some cases.

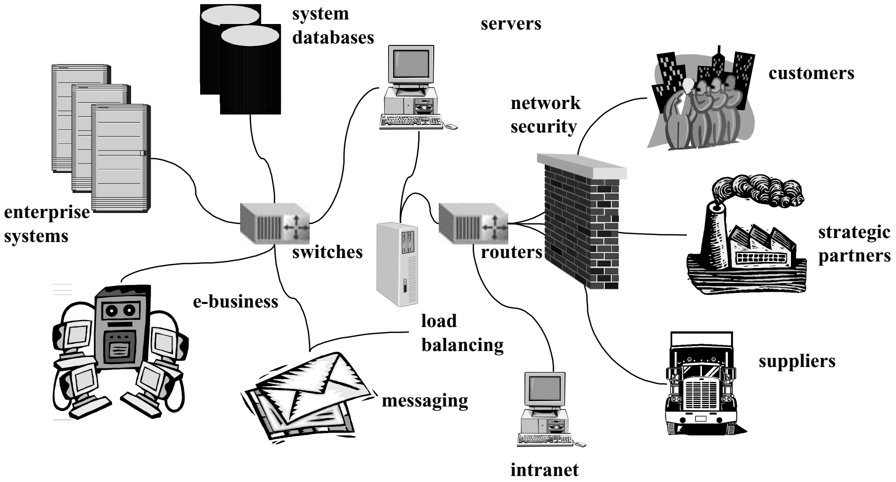

Figure 1: Modern information technology systems are complex networks with many stakeholders and performance requirements.

Modern information technology systems are complicated and involve a number of stakeholders and users (Figure 1). New capabilities are continuously being added to further complicate these already taxed systems. Planning the growth and evolution of these systems and managing them effectively cannot be a part-time job. There are too many interrelated factors that prevent it from being such, and businesses have come to be extremely dependent on these systems for their livelihoods.

Nevertheless, the determination of future load levels should consider how the workload for the system will evolve over time. If a Web system is just coming online, supplemented by an increasing advertising campaign, developers should expect an increasing workload due to an increasing number of visits to the site. If there are plans to deploy a system in increments, adding new capabilities periodically during a phased deployment schedule, this should be considered in the planning of future load levels. Finally, changes in customer behavior should be considered. Whether this is due to a sale, a world event, or seasonal functions being added to the site, the estimation should be predicted and managed accordingly. Regardless of the driver for future load level changes, the goal should be to head toward a predictive pattern and not based solely on experimentation.

Service Level Agreements

Service level agreements (SLAs; Figure 2) should be put in place with the customer (internal or external) to establish the upper and lower bounds of performance and availability metrics. For example, the customer may need to have the site availability greater than 99.95% for security reasons. This should be stated in the SLA. If the server side response time to information requests must be less than 5 seconds per request, this should also be stated in the SLA.

SLAs vary by organization. The creation of an SLA is a management function with feedback from the user as well as the information technology developers. If any of the IT functions are outsourced, the SLA becomes more important and should be the basis for subcontractor management.

Determining Future Load Levels

Determining future load levels of a system requires careful consideration of three major factors. The first is the expected growth of the existing system workload. Consideration should be given to how the company or business will evolve over time.

The second is the plan for deploying new system services and new or upgraded applications. These new capabilities will require more memory, processing power, and I/O (input/output). These capabilities must also be measured against how often they will be used in order to determine the overall system impact when they are deployed. For example, for a new semiconductor design workbench capability added to its Web site, an estimate of the processing resources required to run the new application as well as the number of new users drawn to the site that will be using the new capability must all be considered.

Finally, the third factor to consider is changes in customer behavior. This includes surges in site traffic due to world events, news stories, sales and advertisements, and other events that draw people to a specific site. The site must be able to sustain these temporal changes to load levels. If the semiconductor design workbench capability is accompanied by a large advertising campaign, the system should be built to handle the surge in new users registering for this capability, each of which will need system resources to operate their virtual design workbench.

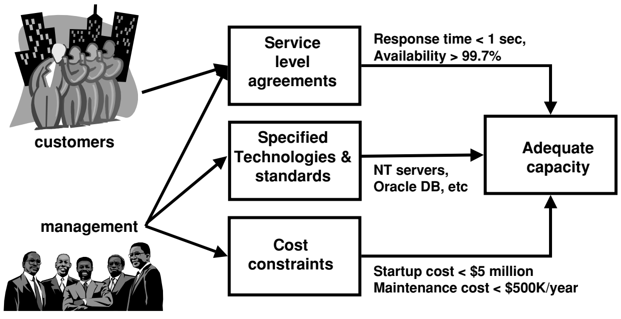

Figure 2: Capacity planning is driven by several system parameters.

In determining adequate capacity for a site, there are several factors that must be considered (Figure 2; Menasce & Almeida, 2000, p. 187):

- **System performance.** This includes factors such as performance and availability metrics for the system. Examples of performance metrics to be considered are server-side response time and session throughput. (A session in this context will normally consist of several Hypertext Transfer Protocol [HTTP] requests performed by a user during the period the user is browsing, shopping, etc.) Examples of availability metrics include site availability. Site availability is driven by many other factors including backup time, time to install new hardware and software, reboot time for failed applications, system maintenance time, and so on.
- **System technologies.** Internet solutions can draw from a number of technologies in the industry. Servers are available from many vendors that have provided certain advantages for specific types of applications (for example, transaction-based applications). There are many database solutions available as well. The choice of these technologies and the decisions of how to integrate these technologies has a significant effect on the overall site performance.
- **System cost.** System performance and system technologies are ultimately affected by the cost constraints for the system. Cost drives many of the decisions with respect to the type of servers, the number of servers, the technology used, training on the new technology, and so on.

CAPACITY PLANNING METHODOLOGY

Menasce and Almeida (2000) described a capacity planning methodology as consisting of four core planning processes: business, functional, resource, and customer behavior planning.

Business Planning

The main goal of this process is to generate a business model that describes the type of business conducted. Web-based businesses can be business to business (B2B), which is a business that sells products or services to another business; business to consumer (B2C), which is a business that sells products or services to a targeted set of end user consumers; and consumer to consumer (C2C), in which untrusted parties sell products and services to one another. Business planning also considers the type of delivery associated with the business model. For example, selling books requires a fulfillment model that is different from distributing an upgrade to a software application that may be a digital delivery directly over the Internet. Business planning must also consider the use of third-party services that can vary from such functions as fulfillment and delivery, to site maintenance, to customer support. Other quantitative measures are also considered, such as the number of registered users, which may be important for an online subscription product to consumer buying patterns, which may be important to the advertisers sponsoring some or all of the site development.

Functional Planning

A functional model of the system can be created that includes important information about the functions provided by the system including how the user interacts with the system, the Web technology used, the type of authentication used for e-business sites, and so on. The functional model is required before resource allocation can be estimated. The functional model can vary by business type and needs and will have a considerable impact on the overall resource allocation. The selection of the search engine, for example, will have a direct impact on the processing resources required to execute the particular search algorithms (which vary from search engine to search engine). The type of database model will dictate the type and form of query required, which will also drive resource demands. An online workbench for designers will require a certain amount of processing resources and memory to support this type of activity.

Resource Planning

Resource planning is used to map resources based on customer behavior models the functional and business planning. Resource planning requires the development staff to characterize the current information technology (IT) environment and model it for performance analysis. This model is then analyzed and calibrated, if necessary, iteratively until the model is validated against the requirements of the system and SLA. Because few organizations have infinite cost resources to accommodate all wishes, the performance model must be consistent with the cost model for the project. The iterative nature of this phase attempts to develop a system, as closely as possible, that matches both the performance model as well as the cost model of the system. Because of this goal, a lot of "what if" analysis is usually performed in this phase to achieve the most optimal solution.

Customer Behavior Planning

Customer behavior models are also required to perform adequate capacity planning. These models are used to determine the possible navigation patterns by the user. This information is then used to determine required or needed site layout adjustments as well as new services. For example, if the navigation pattern data showed users spending a majority of time performing information queries, the database server will need to be designed to accommodate this pattern. If the navigation patterns showed customers navigating to a function that displayed various product images, this information can be used to provide adequate performance in image presentation. The customer behavior characterization leads to workload characterization and forecasting. Based on the navigation patterns of the user and where the user spends most of the time when navigating a Web site, the workload can be estimated to provide a goal for resource allocation.

A well-thought-out and planned methodology for capacity planning will lead to more effective systems integration and execution. Effective capacity planning also depends on accurate predictive performance models.

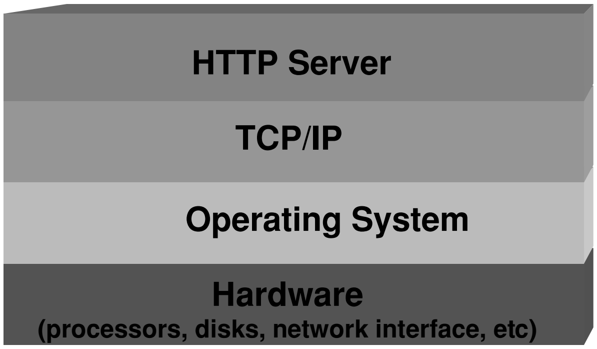

Figure 3: Layered infrastructure for Web-based systems.

UNDERSTANDING THE SYSTEM AND MEASURING PERFORMANCE

A complex infrastructure supports the delivery of Web services. The main components of any Web-based architecture are the hardware (central processing units [CPUs], disks, network interface cards, etc.), the operating system, the communication protocol (TCP/IP, UDP [uniform datagram protocol], etc.), and the HTTP server (Figure 3).

The bottleneck in performance can be anywhere along the chain of delivery through this infrastructure. It is therefore important to understand what to measure and how to measure to model and predict future needs accurately.

Web services infrastructure consists of not only servers that crunch user requests, but also local area networks (LANs), wireless area networks (WANs), load balancers, routers, storage systems, and security systems. To make matters worse, many of these resources are shared between many other Web services, groups, companies, and individuals.

Determining Response Time

The overall response time can then be broken down into two major components: the network time, which is the time spent traveling through the network, and the Web site time, which is the time the request spends being processed at the Web site. The network time consists of the transmission time of the request. This is the time it takes for the required information to be sent from the browser of the user to the Web site. This can vary depending on the technology the user has (modem, digital subscriber line [DSL], cable, etc.) as well as how much data is being sent (which dictates how many packets of information will be sent). Even the TCP/IP stack on the user side has an impact on the overall performance. There are many commercial and customer implementations of TCP/IP stacks. Benchmarking must be performed to get the true performance. The other component of network time is the latency, which is a measure of how many round-trip messages are required to be sent from the user to the Web site. Again, this varies and is dependent on many factors. For example, if the Web site requires the use of a cookie to be placed on the user machine, then each time the Web site is visited, the cookie exchange will take additional overhead to complete and must be added to the overall response time.

The main components of the Web site time include the service time and the queuing time. Each of these components is dependent on the hardware available to handle these functions—the CPU, the storage disks, and the LAN network. The service time is the time spent getting service from the CPU, storage device, and so on. Modern programming models protect these resources using mechanisms such as semaphores to prevent problems such as the shared data problem in which more than one task can corrupt data structures based on their calling sequence. Mechanisms such as semaphores inherently imply that while one task is using a resource like a CPU, other tasks that also want to use that resource must wait until the resource is free. This leads to a queuing model, which must be considered and modeled because it can add a substantial amount to the overall Web site time. Engineers must understand what the specific queuing model is (operating system, ping-pong buffer, etc.) and consider the impact in the overall performance numbers. In some network devices such as routers, the queuing mechanism may simply be a hardware buffer where all requests get stored and processed.

Configuration of network resources has a significant impact on the overall performance estimate. For example, adding fast memory (random access memory, or RAM) to a server will improve performance by some amount (which must be measured). Access time to RAM is much better (by orders of magnitude in some cases) than access time to magnetic media like a hard disk. The trade-off is usually cost and the cost-versus-performance analysis must be a variable that is known in advance (usually described in the SLA). Even the configuration of the user browser can have an impact on overall performance. Cache size settings in the browser, for example, can have an impact. Because this is a parameter set by the user, the model should consider either default values in the browser or be set to some average industry setting.

Web page download time must also be considered because this varies considerably based on the application. Modern Web pages contain markup language as well as embedded images and other embedded objects. To estimate the average download time for a Web page (independent of network traffic and other factors not associated with the Web page itself, although these factors must be considered in the final analysis), analysis must be performed on various computer configurations and settings. Models must be developed that take into consideration the number of embedded objects, the size of the embedded objects, HTTP header size, and the number segments per object. The more elaborate the Web page, the more processing is required to get the page to the user and provide the response time called for in the SLA. Keep in mind that the response time for a Web page with complicated embedded objects will vary considerably depending on the connection type. If many users will be working or accessing the site from home, dial-up modems' performance should be considered, not only the performance assuming a T1 line or other high-performance connection.

Interaction Performance

As with most user interface systems, it is not just the performance of the system itself that must be considered, but also the performance of the person interacting with the Web site. When analyzing any user interface

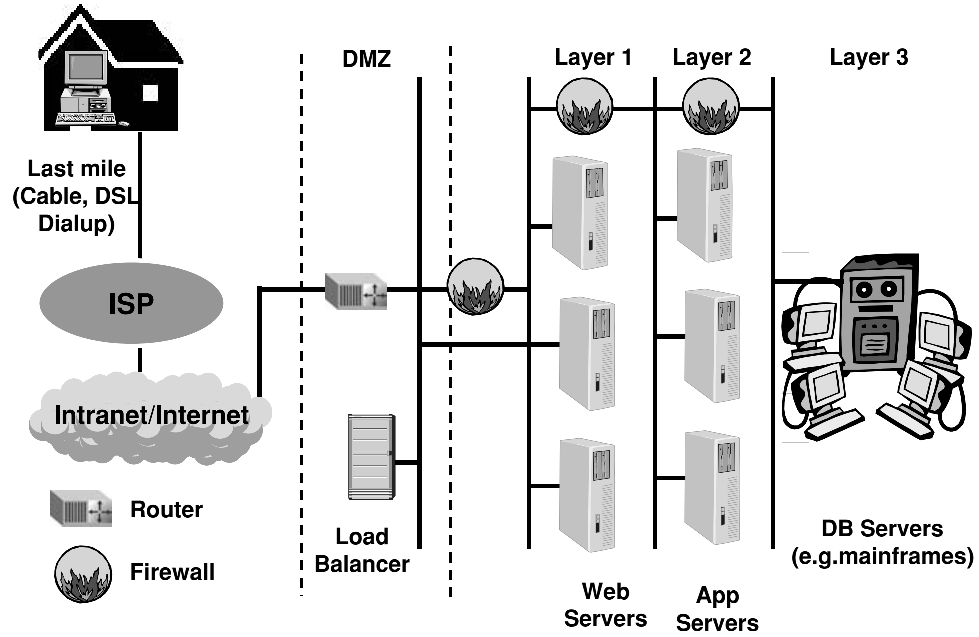

Figure 4: The Web infrastructure consists of many components, all of which must be considered for accurate capacity planning.

for performance-related issues, there is a delay associated with the interaction associated with the user think time. This is the period of time in which the user is perceiving the information and deciding what to so next. If the Web page is complicated and difficult to navigate, this "think" time will increase. Easy to understand and navigate Web sites reduce the think time. Designers of Web sites need to be careful when using the latest Web development technology to create fancy animated images, using multiple colors, and so on because these cause the user to become distracted from the task and lead to unnecessary delays in the overall interaction.

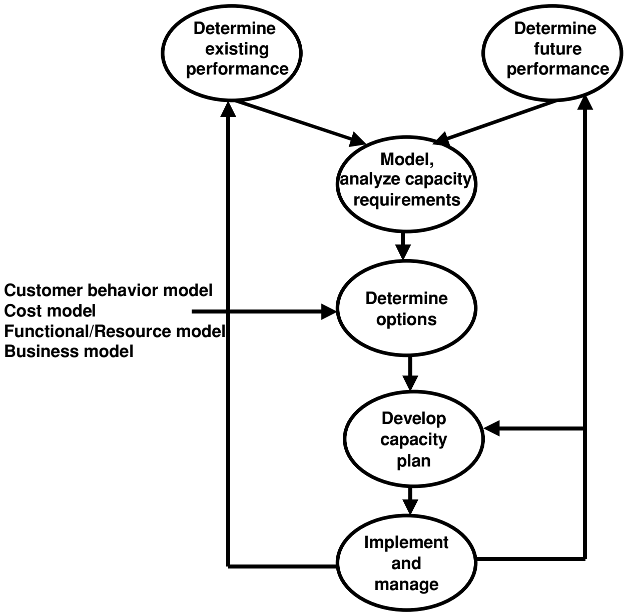
A Web infrastructure contains many interacting components (Figure 4). Servers, Internet service providers, firewalls, several levels of servers, load balancers, and so on combine in different ways to achieve a certain performance level. There can be a significant performance difference depending on whether the user is accessing information from inside or outside a firewall, for example. With the growing popularity of wireless technology and the Wireless Application Protocol (WAP), the complexity will continue to grow. This presents significant challenges with respect to performance analysis and capacity planning. The randomness with which the thousands or millions if users interact with a company intranet or extranet or the Internet, in general, makes the forecasting and capacity planning job extremely difficult. The first step is to understand the various components involved in the deployment of a system and model the current and predicted workloads as accurately as possible.

THE PERFORMANCE AND CAPACITY PROCESS

Menasce and Almeida (2002, p. 178) defined adequate Web capacity as having been achieved "if the Service Level Agreements (SLAs) are continuously met for a specified technology and standards, and if the services are provided within cost constraints." This assumes that the organization has an SLA. If not, adequate capacity will normally be defined by users who complain or stop using the service if they do not consider the performance adequate.

Model for Capacity Planning

There are many models for capacity planning. Figure 5 is one simple model that describes the major factors involved in capacity planning. Regardless of the model, before improvements can be made and plans for the future can be drawn up, there needs to be a way to assess current



Determine existing performance
Determine future performance
Model, analyze capacity requirements
Customer behavior model
Cost model
Functional/Resource model
Business model
Determine options
Develop capacity plan
Implement and manage

Figure 5: The performance and capacity planning process.

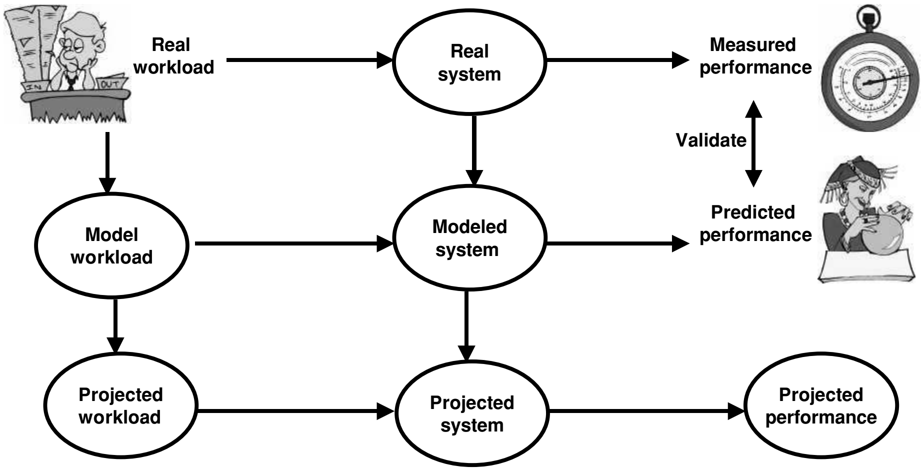


Figure 6: Modeling a Web system produces a platform by which to estimate future performance

performance. This requires understanding the system and environment and estimating its use. To understand the environment adequately requires an understanding of the client and server technology, the applications running on the servers and clients, the network connectivity used, the access protocols in the system, and the usage patterns of various types of customers and clients (e.g., when do they shop, when do they log on, what pages are frequented most often, etc.).

Usage Patterns

Once the main components of the system are understood, the usage patterns should be mapped onto the system model to determine the overall workload characterization. This provides the capacity planner an estimate as the workload intensity allocated to each of the main components in the system. This is useful for determining bottlenecks and knowing where to focus the effort in terms of overall system performance. Each of the components of the system can be measured in terms of the following parameters:

- Number of client visits,
- Average message size,
- Total CPU use,
- Number of transactions per unit time,
- Number of e-mails sent and received per day, and
- Number of downloads requested.

The actual parameters depend on the component being measured, and other components in addition to these can come into play as well. They are different depending on whether the component is an e-mail system, a search engine, an interactive training module, and son on. The capacity planner must determine what makes sense to measure for each of these components.

Once the components have been selected and the important parameters have been chosen for each component, the capacity planner must collect the appropriate data and perform a series of benchmarks to measure the performance on the actual physical machine. The main benchmarking technique is to run a set of known programs or applications in the target system and measure the actual performance of the system in relation to the parameters chosen in the analysis phase. It is not important to run a truly representative application, as long as the workload is well defined on a given system so an accurate comparison can be made. For Web-based systems the major benchmarking measures are time and rate. Time is from the users point of view; how long it takes to perform a specific task is important to this user group. From a management perspective, the main measure is the rate that drives how many users can be processed per unit time, which relates to overall productivity, revenue, or cost, depending on the application.

The process of benchmarking and measuring true performance on a real system is an important step and one that must be completed before proceeding to the step of modeling and predicting future performance. As shown in Figure 6, real workload should first be run on real system and the performance measured. The next step is to model the workload so that an accurate projection can be made about the future. This modeled workload must be run on the "system of the future," which is unknown at this time. To perform the required "what if" analysis, the system must also be modeled. This allows the modeled workload to be run on a modeled system. Measurements are made to ensure that the modeled system is an accurate representation of the real system. These measurements are made directly between the real system and the modeled system (of the real system). Any differences in the modeled measurements and the real measurements must be explained and understood. The modeled workload should be run through the modeled system to get the predicted performance. As a final validation step, the predicted performance produced by the modeled system should be compared with the measured performance of the actual system. Again, any differences should be understood.

Only after the model of the system has been validated can the effort of developing a projected workload and a projected system model be made. The projected workload should come from a variety of sources, including the SLA.

Figure 7: Deciding how to model the Web system depends on the questions that are needed to be answered. From *Scaling for E-Business* (p. 289), by D. A. Menasce and V. Almeida, 2000, Upper Saddle River, NJ: Prentice Hall, 2000.

Modeling Parameters for Web-Based Systems

The key parameters associated with modeling a Web-based system are workload, performance and configuration. These parameters can be used in various ways to answer different questions. For example, analyzing workload plus configuration gives a measure of performance, which helps in predicting the future system requirements. Likewise, configuration and performance give a measure of workload, which helps to determine saturation points of the system. Finally, performance and workload help determine system configuration, which helps determine the sizing required in the future system.

Modeling Approaches for Capacity Management

Capacity planning can be simplified substantially by creating representative models of the real world using a simplified capacity model. This model should be based on critical or bottleneck resource availability as well as by interpreting the demand on that resource alone to determine the overall likely output. This technique can provide a rough order of magnitude verification that demand and capacity are in balance.

The phrase "all models are wrong but some are useful" is accurate in the sense that models, by definition, are abstractions of reality and therefore not 100% reflective and accurate with respect to reality. As the level of abstraction increases, the accuracy of the model decreases. System level models are higher levels of abstraction but can nevertheless be useful for modeling complex systems like Web-based systems. They can provide meaningful information to the capacity planner when making decisions about how to build and deploy future systems. Depending on the data needed for analysis, the question that needs to be answered is in what detail does the system (exiting and proposed) need to be modeled (Figure 7).

Of the many modeling approaches available, I focus here on several proposed by Menasce and Almeida (chapter 4), which are applicable to Web-based systems. The client–server interaction model is one approach that helps one to understand the interaction between the clients and servers in the system. In a multitiered system, this model can be useful in showing the important interactions at each tier. This can be used for future workload estimates. As shown in Figure 8, each e-business function of importance can be modeled in this way to show all possible interactions with that function. In Figure 8a, the interactions at the different computing tiers over time in a model that resembles a UML (unified modeling language) sequence diagram (where time increases from top to bottom) can be represented. This provides a time-based model of the interactions over time. Figure 8b shows the interactions between the different servers (application server, database server, and Web server) in a Markovian model. The Markovian model can be thought of as consisting of states (server nodes), arcs (arrows connecting the nodes showing interaction between the servers), and probabilities that represent the navigation patterns for the specific e-business function. This information effectively represents the customer behavior when interacting with the e-business function. Web sites can be optimized by applying modeling approaches such as the Markov model to the analysis of Web logs (Venkatachalam & Syed, n.d.).

Finally, the message sizes can also be represented and are shown in the diagram as well. With this information, a mathematical model can be developed that estimates the workload, message traffic, and other meaningful information about the system. Keep in mind that, like all other Markovian models, the model is only as accurate as the probability data assigned to the arcs. Relatively accurate

[Image not available in this electronic edition.]

Figure 8: A client…serverinteraction diagram showing all possible interactions for an e-business function: (a) the interactions over time; (b) the interactions showing navigation patterns and message sizes. From *Scaling for E-Business* (pp. 74…75)by D. A. Menasce and V. Almeida, 2000, Upper Saddle River, NJ: Prentice Hall, 2000.

data can be obtained from analyzing current systems, the logs on these systems for existing applications, estimates from other sources such as prototypes, and other products in the field. These models are also hierarchical, which allows them to be decomposed into lower level, more detailed models when necessary.

At the next lower level of detail (the component level), additional detail can be added. For example, queuing affects can be analyzed as service requests pass through the various levels of a multitiered application. Figure 7 can be represented from a queuing perspective as shown in Figure 9, in which each symbol represented a queuing function. Combination of these queuing functions form a queuing network in which each queue represents a system resource, such as a CPU or a disk drive, and the request waiting to use that resource. Average response times can be applied to each queue. Each of the system resources may have a different queue characteristic; use of the resource may be load independent which means the service time is not dependent on the queue length (e.g., a disk access), it may be load dependent where the service time is a function of the queue length (e.g., a CPU), or the queue may be a simple finite delay element (e.g., a network).

Regardless of the modeling approach used and which parts of the system are modeled, the result should be answers to the important questions raised during the planning process and used to drive the decisions on what and where to improve to meet future demands.

[Image not available in this electronic edition.]

SOFTWARE PERFORMANCE ENGINEERING—MANAGING THE PROCESS

Many Web-based systems must meet a set of performance objectives. In general, performance is an indicator of how well a software-intensive system or component meets a set of requirements for timeliness. Timeliness can be measured in terms of response time, the time required to respond to some request, and throughput, which is an indicator of the number of requests that can be processed by the system in some specified time interval. Scalability is another important dimension of an embedded real-time system. Scalability is a measure of the systemís ability to continue to meet response time or throughput requirements as the demand for the system increases.

Choosing the right server, network, software, and so on for the job means nothing without proper performance management through the development life cycle. The consequences of performance failures can be significant, from damaged customer relations, to lost income, to overall project failure and even loss of life. Therefore, it is important to address performance issues throughout the life cycle. Managing performance can be done reactively or proactively. The reactive approach addresses performance issues by using a bigger server, dealing with performance only after the system has been architected, designed, and implemented and waiting until there is actually something to measure before addressing the problems. Proactive approaches to managing performance include tracking and communicating performance issues throughout the life cycle, developing a process for identifying performance jeopardy, and training team members in performance processes.

Definition of Software Performance Engineering

Software performanceengineering (SPE) is a proactive approach to managing performance. SPE is a systematic, quantitative approach to constructing software intensive systems that meet performance objectives (Smith & Williams, 2002). SPE is an engineering approach to performance, which avoids the “fix it later” mentality in designing real-time systems. The essence of SPE is using models to predict and evaluate system tradeoffs in software functions, size of hardware resources, and other resource requirements.

The Software Performance Engineering Process

The SPE process consists of the following steps (Smith & Williams, 2002):

- **Assess performance risk.** What is the performance risk of the project? The answer to this question helps determine the amount of effort to put into the SPE process.
- **Identify critical "use cases."** Use cases are an informal, user-friendly approach for gathering functional requirements for a system (Booch, Rumbaugh, & Jacobsen, 1999). Critical use cases are those use cases that are important from a responsiveness point of view to the user.
- **Select key performance scenarios.** These represent those functions that will be executed frequently or are critical to the overall performance of the system.
- **Establish performance objectives.** In this step, the system performance objectives and workload estimates are developed for the critical use cases.
- **Construct performance models**. A relevant model is developed for the system to measure performance. This can be an execution graph, a rate monotonic resource model (Rate Monotonic Analysis, 1997) or other relevant model to measure performance.
- **Determine software resource requirements.** This step captures the computational needs from a software perspective (e.g., number of messages processed or sent).
- **Add computer resource requirements.** This step maps the software resource requirements onto the amount of service required from key system devices in the execution environment (e.g., a server processor, fast memory, hard drive, router).
- **Evaluate the models.** If there is a problem a decision must be made to modify the product concept or revise the performance objectives.
- **Verify and validate the models.** Periodically take steps to make sure the models accurately reflect what the system is really doing.

SPE Assessment Requirements

The information generally required for a SPE assessment for network systems is as follows:

- **Workload—** the expected use of the system and applicable performance scenarios. It is important to choose performance scenarios that provide the system with the worst case data rates. These worst case scenarios can be developed by interfacing with the users and system engineers.
- **Performance objectives.** This represents the quantitative criteria for evaluating performance. Examples include server CPU utilization, memory utilization, and I/O bandwidth. The choice, in part, depends on the customer requirements.
- **Software characteristics.** This describes the processing steps for each of the performance scenarios and the order of the processing steps. One must have accurate software characteristics for this to be meaningful. This data can come from various sources such as early prototype systems using similar algorithm streams. Algorithms description documents, if available, also detail the algorithmic requirements for each of the functions in the system. From this, a discrete event simulation can be developed to model the execution of the algorithms.
- **Execution environment.** This describes the platform on which the proposed system will execute. An accurate representation of the hardware platform can come from a simulator that models the I/O peripherals of the embedded device as well as some of the core features. The other hardware components can be simulated as necessary.
- **Resource requirements.** This provides an estimate of the amount of service required for the key components of the system. Key components can include CPU, memory, and I/O bandwidth for each of the software functions.
- **Processing overhead.** This allows the mapping of software resources onto hardware or other device resources. The processing overhead is usually obtained by benchmarking typical functions (search engine, order processing, etc.) for each of the main performance scenarios. One example of a flow used to develop this data is shown in Figure 10.

The model is only as accurate as the data used to develop the model. For example, key factors that influence the processor throughput metric are as follows:

- The quantity of algorithms to implement
- Elemental operation costs (measured in processor cycles)
- Sustained throughput to peak throughput efficiency
- Processor family speed-up

The quantity of algorithms to perform is derived from a straightforward measurement of the number of mathematical operations required by the functions in the algorithm stream. The number of data points to be processed is also included in this measurement. The elemental operation costs measures the number of processor cycles required to perform typical functions. The sustained throughput to peak throughput efficiency factor derates the "marketing" processor throughput number to

Algorithm Metrics
Real-time Adjustment Factors
Final Performance Metrics

Figure 10: Performance metric calculation flow.

something achievable over the sustained period of time a real world code stream requires. This factor allows for processor stalls and resource conflicts encountered in operation. The processor family speed-up factor can be used to adjust data gained from benchmarking on a previous generation processor.

Key factors that influence the memory utilization metric are as follows:

- Size and quantity of intermediate data products to be stored,
- Dynamic nature of memory usage,
- Bytes/data product,
- Bytes/instruction, and
- Size and quantity of input and output buffers based on worst case system scenarios (workloads).

SPE for Web-Based Applications

For Web-based applications, the SPE calls for using deliberately simple models of software processing. These should be easy to build and solve (like the ones discussed in the previous section) and provide the right feedback on whether the proposed software architecture will be sufficient to meet the performance goals. The SPE approach relies on execution models which then get mapped to system resources. The goal is to provide enough data to make the capacity planner comfortable with the following (Smith & Williams, 2002, p. 132):

- Placement of objects on the right processor and processes,
- Understand the frequency of communication among the objects,
- Understand which forms of synchronization primitives are required for each communication between the software objects,
- The amount of data passed during each communication, and
- The amount of processing performed by each software object.

AVAILABILITY MODELING AND PLANNING

When online systems are down, productivity and revenue is lost. The magnitude of the loss varies, depending on the type of system and how it is used. But the numbers can be in the hundreds of thousands per hour and even per minute. Online systems operating 24 hours a day, seven days a week, 365 days per year for international business opportunities have become a key mechanism for delivering services and products to customers. Downtime is just as important as a store being closed in the middle of a business week. Customers unable to access online systems are likely to take their business elsewhere, resulting in long-term revenue loss as well.

Although all downtime (also referred to as outage) is a potential loss of productivity or revenue (or both), some downtime is unavoidable. There must be "planned" downtime for system and application upgrades, new hardware and software, and backups. It is the "unplanned" downtime which must be minimized. Unplanned downtime occurs because of hardware failures, software crashes, computer viruses, and hacker attacks.

The solution to online system availability is not adding more hardware and other system resources. The system platform accounts for about 20% of the total system availability. The other 80% comes from a combination of people, process, and product (McDougall, 1999, p. 2).

Process

The industry has developed many processes over the last couple of decades to increase overall system availability. Some of the well-proven processes include system installation standards, change control, release upgrade processes, and backup and recovery testing. Just as standard software development processes are in place to allow quicker development of quality software, so are good processes and techniques important for maintaining online systems.

People

Availability should be considered an attitude instead of a priority. The staff responsible for maintaining the system should be trained properly to deal with backup and recovery techniques, as well as the standard processes for conducting business.

Product

The system platform itself contributes to overall downtime but not as much as the system process and people techniques described earlier. The system includes the hardware, the network infrastructure, and network operating system, and other required software, and hardware support. The investments made in the product (hardware and software) will add to the overall availability, but the right system configurations must be tested to ensure reliability of all the system parts working together. Given the large combination of different configurations, proper planning for this form of system testing is paramount to prevent unanticipated system surprises.

Availability Specification

Before beginning to address system availability, there must exist a set of requirements that define the key system goals for availability. An example availability specification may have the following statements:

- "During the peak hours of the system, 90% of queries will be completed in less than 1 second on average, with up to 100 users online. No queries will exceed three seconds" (modified from Cockroft & Walker, 1999, p. 31).
- "The order processing system for the XYZ online bookstore will be capable of sustaining 3,000 transactions per second during normal business hours."

Measuring Availability

As with any kind of process improvement effort, there must be a way of knowing whether the investment in process or product improvement is working. The cost of achieving additional availability can be extremely expensive, so knowing when to stop investing is important. Most measurements of availability are measured in percentage terms. Typically "five nines" availability, 99.999% is a often cited goal, but can be difficult to achieve.

Before beginning to address system availability, there must exist a set of requirements that define the key system attributes:

- Coverage—the normal business hours of the system. If the system is reporting stock exchange transactions, for example, the normal business hours will be a certain part of the business day and week. Availability should always be measured in terms of the coverage time only.
- Outage—This represents the number of minutes per month that the system can be down.

Availability is then measured as (coverage–outage)/ coverage × 100.

Availability can also be measured in terms of mean time between failures (MTBF—how long the system is up) and mean time to repair (MTTR—how long the system is down).

$$\text{Availability} = \text{MTBF}/\text{MTBF} + \text{MTTR}$$

As can be seen from this availability equation, as the MTTR approaches zero, the availability approaches 100%. As the MTBF gets larger, the MTTR begins to have lesser impact on availability.

Availability must be measured at several levels including the hardware platform level, the network level, and the application level—there can be failures in any one of these layers that can bring down the entire system.

Design Principles for System Availability

There are several general design principles that should be used when designing system to meet availability goals. These include but are not limited to the following (Zuberi & Mudarris, 2001):

- Select reliable hardware,
- Use mature and robust software,
- Invest in failure isolation,
- Test everything,
- Establish service level agreements,
- Maintain tight security,
- Eliminate single points of failure, and
- Availability modeling techniques.

There are approaches to modeling systems to produce availability estimates, but this is a difficult process because many system components that must be modeled are interrelated which makes accurate modeling more difficult. The common modeling approaches used to determine system availability include Markov models and Monte Carlo simulation techniques (Gilks, Richardson, & Spiegelhalter). These approaches model the system as a series of known system states and state transitions. Additional information such as time taken to go between system states and the probability of moving between system states are included in the model to improve accuracy.

TOOLS TO SUPPORT CAPACITY PLANNING

Capacity-planning software was created to help network executives and capacity planners plan for long-term growth and implement new initiatives. These same planning tools can also be used to help companies make their existing assets stretch further. A common thought with capacity planning is "I want to buy more," but this is actually a flawed understanding. Capacity planning is oftentimes not about buying more.

It is no surprise that as the importance of capacity planning has grown, commercial tools have become available to help manage the process, collect data, and visualize it in useful ways. When deciding on a capacity planning tool, it is important to understand how the tool will be used in the capacity planning process. Selecting the right tool for the job remains just as important as it always has.

Examples of Capacity Planning Tools

Sun Microsystems Resource Management Suite focuses on the capacity planning for storage systems. Some of the common storage-related problems are as follows:

- The inability for companies to keep pace with increasing storage demands;
- Storage is too expensive and complex to manage effectively;
- The inability to accurately plan, budget, and justify future storage needs; and
- The lack of data to support new storage architectures.

When planning for storage capacity, the common questions to answer are as follows:

- How much storage do I have today?
- How can I prevent storage related crashes?
- How can I predict future capacity needs accurately?

The tool provides the necessary infrastructure to forecast storage growth, manage heterogeneous storage, create and enforce storage policies, track usage, and create plans for future upgrades. Trend graphs are available to characterize usage patterns over selected time intervals.

Compaq's Enterprise Capacity and Performance Planner is a modeling tool used to predict the performance of both stand-alone and clustered systems. The tool is used to determine system performance levels for various workloads and system configurations. The tool also collects and analyzes data collected on the various platforms. Performance predictions are made with the tool using analytic queuing network models. A graphical component allows for "what if" analysis. A baseline model is developed from the data collected from the existing system and becomes the starting point for assessing the impact of changes to the system configuration of user estimated workloads.

The "what if" analysis forms the foundation for the overall capacity planning effort. Performance statistics are provided in detailed reports that encompass the main capacity planning performance statistics:

- Resource utilization,
- Response time,
- Throughput,
- Queue length, and
- Service time.

CAPACITY MANAGEMENT—PERFORMANCE AND STRESS TESTING OF WEB-BASED SYSTEMS

The only true way to assess the performance of a product is to try it out. The same holds true for a Web-based system. Performance testing is done to gain an understanding of the specific services being offered under specific and actual workload conditions. The capacity planning team should work in cooperation with other groups—development, production, and management staff—to plan, execute, and follow up on the results of this process.

Types of Performance Testing

There are several types of performance testing, including load testing which measures the performance of the system under load conditions called out in the SLA. The load can be actual or simulated depending on the system and process used. Spike testing is another useful performance test that tests a Web service under specific circumstances, and, just like the name implies, subjects the system to a heavy spike of traffic to determine how the system will react under this specific load condition.

Probably the most important type of performance testing is stress testing. Stress testing attempts to expose and help address the following important concerns:

- Stability issues—unexpected downtime and poorly written Web objects,
- Performance problems—locate bottlenecks and whether the application will handle peak loads, and
- Capacity planning—how many machines are needed to support usage.

Stress testing, if performed correctly, can help find and fix problems to avoid financial losses as well as ensure customer satisfaction. Stress testing is effective at locating the following bottlenecks:

- Memory,
- Processor,
- Network,
- Hard disk, and
- COM (Common Object Model) component.

Stress Testing Model for Web-Based Systems

A traditional stress test model is shown in Figure 11. The Web server is the system under test and is connected to a number of stress clients that simulate the workload by performing certain tasks, requests, operations, and so on from the Web server. The test is controlled by a controller stress client that directs the other stress clients as to the workload patterns while the test runs as well as collects the information needed to analyze the results of the testing process.

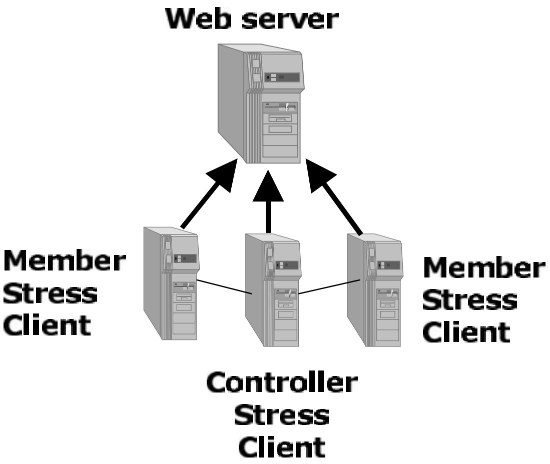

Figure 11: A traditional stress test model for Web-based systems.

The basic approach to stress testing involves the following steps:

- Confirm that the application functions under load,
- Find the maximum requests per second any application can handle,
- Determine the maximum number of concurrent connections the application can handle, and
- Test the application with a predefined number of unique users.

Based on the information obtained from the testing process, certain types of performance can be calculated. For example the following formula can be used to measure performance to aid in future capacity planning:

$$\text{MHz Cost} = N * S * \text{avg (PT)/avg(Rps)},$$

where N = number of processors, S = speed of processors, PT = % total processor time (this is a measure from the actual system servers), and Rps = requests per second, reports view (this comes from an analysis of the results of a test and is an application service provides (ASP) based measurement).

As an example, consider a test using a four processor Web server that achieved 750 requests per second, with the processors 80% utilized. This works out to

$$4 \text{ processors} * 500 \text{ MHz} \Longrightarrow 2 \text{ GHz}$$
$$80\% \text{ processor utilization} \Longrightarrow (2 \text{ Gig}) * (0.80) \Longrightarrow 1.6 \text{ GHz used}$$
$$750 \text{ ASP (Active Server Page) requests per second}$$
$$1.6/750 \Longrightarrow 2.1 \text{ million cycles per ASP request}$$

There are commercial tools available to aid the capacity planner in performing different types of performance testing, including stress testing. One such tool from Microsoft called Application Center Test (ACT) automates the process of executing and analyzing stress tests for Web-based systems.

The explosive growth of Internet sites and e-commerce has presented new challenges in managing performance and capacity. Also, the ability to estimate the future performance of a large and complex distributed software system at design time can significantly reduce overall software cost and risk. Capacity planning is the disciplined approach of managing system resources and defines the process of predicting when future load levels will saturate the system and of determining the most cost-effective way of delaying system saturation as much as possible.

GLOSSARY

Capacity planning The process of predicting when future load levels of an Internet-based system will saturate the system and the steps required to determine a cost-effective way of delaying system saturation as much as possible.

Client–Server A communication model between computer systems in which one system or program acts as the client and makes requests for service from another system or program called the server that fulfills the request.

E-commerce The buying and selling of goods and services on the Internet.

Markov Model A model consisting of a finite number of states and a probability distribution relating to those states, which governs the transitions among those states.

Network time The time spent for a packet of information to travel through a network.

Performance management An integral part of the capacity planning process in which system performance is managed proactively to ensure optimum efficiency of all computer system components so that users receive adequate response time.

Service level agreement An agreement between the customer and the system developer that outline the acceptable levels of performance and capacity requirements for the system.

Service time The time spent getting service from the central processing unit, storage device, and so on.

Software performance engineering A proactive, systematic and quantitative approach to constructing software intensive systems that meet performance objectives.

Stress testing The attempt to create a testing environment that is more demanding of the application than it would experience under normal operating conditions.

Unified modeling language (UML) A general purpose notational language used to specify and visualize software-based systems.

Web site time The time that a request for information spends being processed at a Web site.

Cascading Style Sheets (CSS)

Fred Condo, *California State University, Chico*

INTRODUCTION

Structure and Presentation in HTML

Hypertext markup language (HTML) provides for embedding structural information into text files. User agents (Web browsers) contain a default style sheet that controls the display of HTML. In the mid-1990s, the makers of Web browsers, principally Netscape and Microsoft, introduced presentational extensions into HTML, without regard to the wisdom of such extensions. These extensions gave Web page producers the ability to override the default browser styles. Examples of these extensions include the *font* element for specifying type styles and colors, and the *center* element for centering text and graphics horizontally. The result of using these presentational extensions is a commingling of presentation information with the structural markup and content of Web pages, or, worse, a substitution of presentational markup for structural markup.

Such a result may not be intuitively disadvantageous, but there are several problems that arise from the practice of mixing content with presentational directives. For example, there is no way to express the idea that all level-one headings (h1) throughout a Web site should be centered, set in a sans serif font, in red. Instead, the same directives must be specified along with every instance of an h1 tag. The result is that every page in the site carries redundant presentational information, which the server must transmit over the network each time. Maintaining the site becomes error prone and inefficient. If the designer decides to change the presentation of h1 elements to a serif typeface, for example, then someone must edit every page of the Web site. A person editing many pages is likely to miss a few pages or a few instances of the h1 tag; hence, the appearance and consistency of the site will degrade. Because a real site will have many more style rules than just this one example, the complexity and risk of error in maintenance are compounded. In the worst case, a naïve Web page producer may omit the h1 tags entirely. Such a practice makes it impossible for user agents to detect headlines, which has its most serious impact on vision-impaired users, who depend on user agents to list headlines by voice.

Consider an HTML page that uses *font* and *b* tags for headings: `<font size="4" face="Arial" color="#FF0000"><b>Text of heading</b></font>`. This code devotes more text to presentation than to content, and the text concerning presentation has to appear with every instance of a heading. With style sheets, the HTML code becomes much simpler: `<h1>Text of heading</h1>`. The HTML code is easier to understand, and it carries with it the important information that the text is a major heading. In the corresponding style sheet, this code appears (but only once for the entire Web site): `h1 {font-weight: bold; font-size: 125%; font-family: Arial, sans-serif; color:#F00;}`.

Cascading style sheets enable HTML authors to change the default specifications in a style sheet rather than in HTML code, so that new style rules may be applied to all instances of a specified HTML context throughout a site. In addition, cascading style sheets help preserve the structural context of HTML that indicates how pieces of content relate to one another. For instance, it is possible to grasp the structural difference between content within level-one heading tags and content within level-two heading tags. Level-one headers take precedence over level-two headers. It is not possible to grasp with certainty the structural differences between content wrapped in one set of presentation tags and content wrapped in another set of presentation tags by evaluating the HTML code. For instance, HTML authors will often forgo the list and list item elements in order to control the spacing of list items and the images used as bullets. This usually results in HTML code that cannot be recognized as describing a list. As well as helping authors maintain a separation of structure and presentation, CSS affords other benefits that were never available under HTML extensions.

Benefits of CSS

Separation of Presentational Information From Structure and Content

Much of the trouble associated with the embedded presentational directives of HTML is attributable to the commingling of content with presentational information. Because the only way to associate presentational HTML tags and attributes with their targets is to place them in close proximity in the same file, there is no way to disentangle them. CSS provides a mechanism whereby the association of content and presentation can exist without physical proximity. Designers can, as a result, physically and logically separate the content from its associated presentational styles. The most important benefits of CSS arise from this partition of content and style.

Centralization of Presentational Information

Because Web page producers no longer need to reduplicate style information for every page, they can collect general style rules into a single file or small group of files. HTML 4.01 and XHTML 1.0 provide mechanisms for associating a page with one or more style sheets. Once that link exists, it is no longer necessary to edit each Web page to effect style changes. Instead, the designer edits the central style sheet, and the change immediately takes effect throughout all pages that are linked to the style sheet. The process of changing a central style sheet is vastly simpler and less error prone than performing a complex set of edits on every page in a Web site.

Adaptability to Multiple Media

It is no longer safe to presume that users access the Web solely by means of a graphical Web browser such as Mozilla, Opera, or Internet Explorer. Web-access devices, like human users of the Web, are more diverse than ever. The Web needs to adapt to presentation via handheld computers, cell phones, computer-generated speech, and printers.

Designer Control Superior to Presentational HTML Extensions

Designers, too, need control of Web presentation. Their demands motivated early browser makers to pollute (as it turned out) HTML with presentational controls. For example, the *font* element enables Web producers to influence the face, size, and color of type. The drawback is that such presentation control is intermingled with the rest of the Web page such that changing the presentation requires tedious and error-prone editing. Moreover, presentation controls embedded in the page increase disk space requirements and network transmission times and obscure the structural relationships between the HTML elements of a page.

User Control of Display

Users of the Web, too, need control of presentation. This idea makes no sense in traditional print media, which are permanent, rigid, and fixed at the time of printing. Users need to adjust the Web's presentation to accommodate their special needs. For example, some users need to use large print or accommodate a deficiency in color perception. Such users benefit if they can override the designer's presentation styles; they would be excluded from the Web without such a capability.

Goes Beyond HTML

Throughout this chapter, reference is made to HTML elements and attributes, because HTML styling is the principal application for CSS. CSS, however, is not limited to HTML. With the appropriate software and hardware, CSS can style any markup language. For an example of a non-HTML style sheet, see the style sheet for RDF at W3C, http://www.w3.org/2000/08/w3c-synd/style.css.

CSS Standards

The World Wide Web Consortium has promulgated two recommendations for CSS. These are cascading style sheets level 1 (CSS1; Lie & Bos, 1999a), and cascading style sheets level 2 (CSS2; World Wide Web Consortium, 1998). CSS2 adds to CSS1 support for different media types, element positioning, and tables and for a richer set of selectors.

DOCUMENT VALIDATION

For a browser such as Mozilla or Internet Explorer to apply styles to the appropriate part of an HTML document, it must be able to analyze unambiguously both the HTML document and the style sheet. This requirement imposes a modest burden on authors of Web pages: Their pages must follow the actual rules of the HTML specification, and the style sheets must conform to the CSS specifications. Fortunately, the computer can test pages and style sheets for conformance to the standards, and it can even correct some HTML errors automatically. Using a code generator rather than coding "by hand" in a general text editor also helps prevent errors.

Both the World Wide Web Consortium (2001) and Quinn (2002) provide online HTML validators. The latter will recursively or batch validate up to 100 pages at a time. Both validators are Web front ends for Clark's (n.d.) *nsgmls* software, which runs on the Unix or Windows command line. The World Wide Web Consortium (2002a) provides a CSS validator for CSS levels 1 and 2. Finally, HTML Tidy (n.d.), software for many platforms, automatically cleans up common errors in HTML and can convert presentational HTML into embedded styles. Using such tools helps ensure that standards-conformant browsers will render pages as expected.

MEDIA TYPES

Media types apply styles according to the kind of display device on which a user is viewing (or hearing) your page. Media types are part of CSS2. There are four dimensions that characterize media types. Although many style capabilities work across media, some styles are specific to a particular medium. For example, there are no font styles for audio media, nor is there stereo separation for print, but both print and screen media support background colors.

Each of the discrete points on the four dimensions labels a media group. The four dimensions that characterize media types are as follows: continuous or paged; visual, aural, or tactile; grid or bitmap; interactive or static. Continuous media consist of uninterrupted streams, such as a scrolling window. Paged media have discrete segments, such as paper sheets for print, or stepped screens on a handheld system. Visual, aural, and tactile media are, respectively, seen, heard, and felt. Grid media consist of a grid or array of discrete character positions. Examples include traditional computer terminals and character printers. Bitmap media can freely represent graphics, letterforms, and glyphs, like the screen of a modern personal computer. Interactive media permit the user to interact with the display, as in traditional screen-based Web browsing. Static media do not allow interaction. Printed pages are an example of a static medium.

To associate a media type with a group of styles, you can create a separate style sheet file for each media type, or you can group them in a construct such as the following: `@screen {...}`. All the styles between the braces would apply to the screen medium. When creating separate style sheet files, specify the media type in the link or style tag in the HTML document with a media attribute, such as `media="screen"`.

There are nine media types in CSS2, plus a tenth type, *all,* which makes no distinction based on medium. Many style sheets comprise a base sheet associated with all media types, with media-specific style sheets that override styles or provide additional styles. The nine media types are, alphabetically, as follows: aural, braille, emboss, handheld, print, projection, screen, tty, and tv. CSS2.1 (World Wide Web Consortium, 2002b) will drop the aural media type and add speech and will split the aural media group into speech and audio.

In the sections below, each media type is briefly described and is characterized according to media group on the four dimensions mentioned above (using the CSS2.1 designations). If a dimension is not listed for a particular media type, the media type belongs to no group on that dimension. Some media types may occupy more than one group on a dimension, depending on the context or particular display device.

Speech. *Speech* styles apply to speech synthesis. Users of speech synthesizers include the visually impaired, those who must not divert their visual attention, such as the drivers of automobiles, and those who cannot use written words. In terms of the four dimensions, aural media are *continuous, speech,* and *interactive* or *static*.

Braille. *Braille* is for dynamic braille tactile devices, not for braille embossed in a fixed medium. Braille is *continuous, tactile, grid,* and *interactive* or *static*.

Emboss. *Emboss* is for braille printers. Emboss is *paged, tactile, grid,* and *static*.

Handheld. *Handheld* is for handheld devices. The CSS2 specification characterizes such devices as having small, monochrome screens and limited bandwidth. Already, the emergence of color handheld devices has overtaken the standard. No doubt some future revision of the standard will catch up with technological changes. Handheld is *continuous* or *paged, visual, audio,* or *speech, grid* or *bitmap,* and *interactive* or *static*.

Print. *Print* is for printing on traditional opaque media, most commonly paper. Print is *paged, visual, bitmap,* and *static*.

Projection. *Projection* is for paged presentations, whether on a computer projector or printed onto transparencies. It is not for the general case where a standard computer screen is enlarged via a projector (*screen* is the media type in that case). Projection is *paged, visual, bitmap,* and *interactive*.

Screen. *Screen* is for common computer screens. Screen is *continuous, visual* or *audio, bitmap,* and *interactive* or *static*.

Tty. *Tty* is for devices, such as teletypes, terminals, or some handheld displays, that use a fixed-width character grid. The pixel unit is not allowed for this media type, as such displays are not pixel addressable. Tty is *continuous, visual, grid,* and *interactive* or *static*.

Tv. *Tv* is for low-resolution displays with sound available, but with weak or clumsy scrolling controls. Tv is *continuous* or *paged, visual* or *audio, bitmap,* and *interactive* or *static*.

CSS BOX MODEL

Every element displayed on a visual medium has an associated box with various parts that influence the display. A diagram of the box model appears in Figure 1. The box model defines the following regions: content, padding, border, and margin. Only the content region is not optional. Each region defines a set of properties. Each region is described below, working from the center outward.

The *content* is the region where the element is displayed. Its dimensions correspond to the width and height properties of the element. This means that the box may be larger than the *content-width* and *content-height* dimensions. The overall height or width of the box is the sum of the height or width property and the adjacent padding, border, and margin.

The *padding* is the region surrounding the content. No foreground text or graphic appears in the padding, but background properties of the element, such as color, do appear in the padding region.

The *border* is the region where border properties are drawn. Some browsers may incorrectly continue the background into the background of the border, so beware. The specification says that the border's appearance shall depend solely on the element's border properties. Even though you might think of a border as a line of zero width, in the box model, it may have any arbitrary width.

The *margin* is a transparent region outside the border region. It separates the visible parts of an element's box

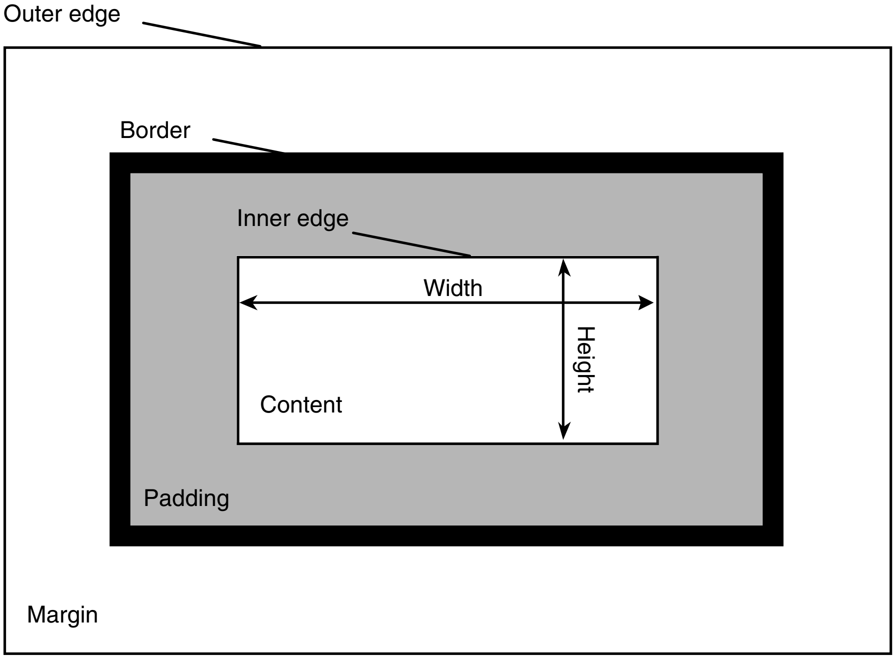

Figure 1: CSS box model.

from those of any adjoining boxes. Because the margin is transparent, the background of any enclosing element shows through.

Because HTML elements may contain other elements (as the *body* element contains a sequence of *p* elements), each box is nested within the box of its parent element. The entire box, including the padding, border, and margin, of the inner box, is inside the content region of the outer box. Thus, CSS boxes resemble nested Russian dolls.

Boxes do not overlap, with two exceptions. First, a box whose position has been altered through positioning properties may overlap other boxes on the page. Second, adjacent vertical margins, such as those of two paragraphs in sequence, collapse. You see only the larger of the two margins. Without the latter exception, the space between blocks of text would be excessive and tedious to control.

INHERITANCE AND THE CASCADE

In any given instance, several style rules may be "competing" to apply to a particular element of a Web page. This situation may seem chaotic, but allowing multiple style sheets to participate in styling Web pages is a major feature of CSS. It enables designers to create modular style sheets that are easy to maintain. It enables designers to override general styles for special cases. And it enables users to override designers so that the Web may accommodate special needs (for large type, for example).

A typical use of the cascade is to have two site-wide style sheets to which each HTML page has links in its *head* section. The first link refers to the style sheet for all media, and the second link refers to the style sheet for print. The print style sheet contains only *overrides* of the all-media style sheet. The remaining styles "flow" into the print style sheet (the term "cascading" is meant in analogy to a series of waterfalls). A page in the site that needs unique styles may have a *style* element in its head section. That style tag must appear *after* the *link* tags that refer to the overall style sheets for the site. By appearing last, the style rules in the style element can override the site-wide styles. Finally, a context requiring unique treatment may have a tag with a style *attribute*. The style attribute (not tag) is the most specific context of all and provides a local override of all other styles. Figure 2 shows a (contrived) HTML page that contains links to style sheets for multiple media, a style tag, and a style attribute.

When a browser assigns a value to a property for an element it is rendering, it goes through a process that, in principle, is quite simple. First, if the cascade (see below) yields a value, use that. Next, if the property in question is one that is inherited (see below), use the inherited value. Otherwise, use the initial, or default, value defined in the CSS specification.

Inheritance

Inheritance is based on an analogy to a family tree. Each HTML element that appears within some other element is said to be a *child* of the enclosing element. For example, in the HTML fragment of Figure 3, the emphasis element is a child of the paragraph element, and the paragraph is the child of the body. For properties that the specification says are inherited, descendents to any arbitrary level of descent (child, grandchild, great-grandchild . . .) inherit the property, unless the cascade overrides it. Elements that are children of the same parent element are called *siblings*.

Some properties are not inherited. This is for the convenience of the style sheet author. For example, it would be inconvenient in most cases if border properties were inherited, so they are not. Consider how tedious it would

```
<!DOCTYPE html PUBLIC  "-//W3C//DTD XHTML 1.0 Transitional//EN"
    "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head>
<link rel="stylesheet" type="text/css" href="all-media.css" media="all"/>
<link rel="stylesheet" type="text/css" href="print-overrides.css" media="print"/>
<style type="text/css">
    h1
    {
          font-family: "Times New Roman", Times, serif;
          color: yellow;
    }
</style>
<title>How Cascading Works</title>
</head>
<body bgcolor="#C0C0C0">
    <h1 style="font-family: Arial; color: blue">THIS HEADING1 TEXT
    IS BLUE ARIAL</h1>
</body>
</html>
```

Figure 2: Link, style-tag, and style-attribute contexts in the cascade.

be to have to turn off the inherited borders on each element within a paragraph with a border!

Because descent and inheritance are ambiguous when elements overlap, overlapping elements are not permitted in HTML. This is one of the reasons you need to validate your HTML code.

Cascade

Style Sheet Origin

Each style sheet has one of three origins: the style sheet's author, the user (who may have a personal style sheet), or the browser. Except when the *!important* weight is in play, the author's styles take precedence over the user's styles, which take precedence over the default styles of the browser. Browsers may not have !important rules.

Cascading Order

The cascade determines which style rule applies to a given situation by means of a four-step procedure.

1. Find all matching declarations from all style sheets involved. If there is but one matching declaration, use it and stop.
2. Otherwise, sort the matching declarations by origin and weight. Author styles override user styles, and user styles override browser styles. Any !important declaration overrides a normal declaration regardless of origin. If both author and user have an !important style, the user wins in CSS2 (the author won in CSS1, but this was an impediment to accessibility). If only one declaration is a clear winner, use it and stop.
3. Otherwise, sort by how specific the selector (see CSS Selectors, below) is. The more specific selectors override the less specific ones. If one style rule has the most specific selector, use it and stop.
4. Otherwise, if there is still a tie, the last rule wins. Apply it.

```
<body>
    <p>
      This is
      <em>very</em>
      important.
    </p>
    <p>
      I am a sibling of the
      paragraph above.
    </p>
</body>
```

Figure 3: Containment.

CSS SELECTORS

Every style rule consists of a *selector* and a set of *declarations,* each consisting of a *property* and a *value,* in this format: `selector { property: value; }`. There may be any number of declarations between the braces. The selector determines the context to which the declarations apply.

Selectors are patterns that match particular contexts in HTML documents. When a selector matches a context and makes it through the cascade, its style declarations apply to the whole context. For example, a selector "body" would match the context of the *body* element of an HTML document. For this reason, it is common practice to assign default values for the style sheet to the body selector. Through inheritance, those properties propagate to all the descendants of the body element, unless the cascading rules override them.

In addition to element names such as body, selectors may use the values of *id* or *class* attributes. Further, the specifications define a set of pseudoclass and pseudoelement selectors that behave like class and element selectors. They differ from real classes and elements in that they arise from a variable context or from user-generated events. For example, the *:first-line* pseudoelement depends on the width of the browser's display, and the *:visited* pseudoclass depends on the user's browsing history.

In addition, selectors may be grouped to apply a given style to several disjoint contexts. Finally, selectors may be arranged in various ways to match very specific contexts.

CSS1 defines a basic selector model that supports element, class, id, and descent contexts, including some pseudoelements and pseudoclasses. To this model CSS2 adds additional pseudoelements and pseudoclasses, as well as more precise contexts based on sibling and descent relationships between elements.

CSS1 Selectors

CSS1 defines the following kinds of selector: type selectors, descendant selectors, class selectors, ID selectors, link pseudoclasses, and typographical pseudoelements.

Type Selectors

Type selectors are so designated because they match all elements (tags) of a single type. A more intuitive way to regard such selectors is as redefiners of the appearance of HTML tags. Any HTML element, such as *body,* may act as a type selector.

```
body { background-color: #FFFFFF; }
```

Descendant Selectors

A space-separated list of selectors matches if the context named on the left contains the context named on the right. The sample code below sets emphasized text in red, but only if the emphasized text is in a level-two outline heading.

```
h2 em { color: #FF0000; }
```

Class Selectors

A class selector is introduced with a dot and matches the value of an HTML tag's class attribute. Example 1 below applies a border to any element whose class is "note"; example 2 does the same, but only if the element is a paragraph. Example 1:

```
.note { border-width: thin; border-style:
  solid; }
```

Example 2:

```
p.note { border-width: thin; border-style:
  solid; }
```

ID Selectors

ID selectors work the same way class selectors do, but they match the id attribute. In the style sheet, they are introduced with the # sign rather than a dot. Bear in mind that IDs must be unique in the HTML document; often a class is more convenient. Example 1:

```
#note1 { border-width: thin; border-style:
  solid; }
```

Example 2:

```
p#note1 { border-width: thin; border-style:
  solid; }
```

Link Pseudoclasses

The link pseudoclasses are *:visited* and *:link*. They correspond to links that the user has or has not followed. These pseudoclasses replace the link and vlink attributes of the HTML body element.

```
a:link { color: #0000FF; }
a:visited { color: #FF00FF; }
```

Typographical Pseudoelements

The typographical pseudoelements in CSS1 are *:first-letter* and *:first-line*. They apply styles to the corresponding parts of an element. In the case of :first-line, it dynamically adapts to changes in the window size or font. The example below creates a drop-cap on a paragraph designated with the id "initial".

```
p#initial:first-letter { float: left;
  font-size: 3em; }
```

CSS2 Selectors

CSS2 adds to CSS1 the following kinds of selectors: child selectors, the universal selector, adjacent-sibling selectors, dynamic pseudoclasses, the language pseudoclass, text-generating pseudoelements, and attribute selectors.

Child Selectors

Child selectors are pairs of element names separated by >, in which the right-hand element must be a child of the left-hand element. The first example sets the line height of paragraphs that are children of the body (child paragraphs of div would be unaffected). The second example sets ordered lists to have uppercase Roman numerals as markers, and ordered lists nested one level deep in other ordered lists to have uppercase alphabetic markers. Example 1:

```
body > p { line-height: 1.5; }
```

Example 2:

```
ol { list-style-type: upper-roman; }
ol > li > ol { list-style-type:
  upper-alpha; }
```

Universal Selector

The universal selector ∗ is a wild-card selector. It matches any HTML element name. The example below sets in red any emphasized text that is exactly a grandchild of the body element, regardless of what the parent of *em* is.

```
body > * > em { color: #FF0000; }
```

Adjacent-Sibling Selectors

Adjacent siblings are elements that have the same parent and no other elements between them. The general form of an adjacent-sibling selector is $x + y$, where x and y are elements. The style applies to y. The example applies a drop-cap to a paragraph if and only if it immediately follows a level-one heading.

```
h1 + p:first-letter { float: left;
  font-size: 3em; }
```

Dynamic Pseudoclasses

The dynamic pseudoclasses are *:hover, :active,* and *:focus*. Hovering occurs when the user points at but does not activate an element, as when pointing but not clicking on a link. An item is active while the user is activating it, such as during the time between clicking and releasing the mouse button on a link. Focus occurs when an element is able to receive input from the keyboard (or other text input device). In the example below, links are blue when unvisited, red when visited, yellow when pointed at, and green during the mouse click. Note that the order of the style rules is significant, because some of the selectors are equally specific. This cluster of style rules should appear in the order shown or some of the styles will never show up.

```
a:link    { color: blue; }
a:visited { color: red; }
a:hover   { color: yellow; }
a:active  { color: green; }
```

Language Pseudoclass

The language pseudoclass is *:lang(C),* where C is a language code as specified in the HTML 4 standard (Raggett, Le Hors, & Jacobs, 1999), or RFC 3066 (Alvestrand, 1995). (The CSS specification actually refers to the obsolete RFC 1766, but implementations should use the current definition of language tags.) Some instances of language codes are *en* for English, *en-us* for United States English, and *fr-ch* for Swiss French. The pseudoclass selector matches according to a liberal algorithm such that :lang(en) would match either of the English codes shown above, just as :lang(fr) would match the Swiss French code. The language of an element may be determined from any of three sources in HTML: a lang attribute on the element, a *meta* tag, or HTTP headers. Other markup languages may have other methods of specifying the human language of a document or element.

The example below is quoted from the CSS specification section 5.11.4 (Bos, Lie, Lilley, & Jacobs, 1998). It sets the appropriate quotation marks for a document that is either in German or French and that contains quotations in the other language. The quotation marks are set according to the language of the parent element, not the language of the quotation, which is the correct typographic convention.

```
HTML:lang(fr) { quotes: '« ' ' »' }
HTML:lang(de) { quotes: '»' '«' '\2039'
  '\203A' }
:lang(fr) > Q { quotes: '« ' '»' }
:lang(de) > Q { quotes: '»' '«' '\2039'
  '\203A' }
```

Text-Generating Pseudoelements

The *:before* and *:after* pseudoelements inject text before and after the content of the selected element. The sample code below inserts the bold label "Summary:" at the beginning of every paragraph whose class is "summary." Note the space between the colon and the closing quotation mark.

```
p.summary:before
{
      content: "Summary: ";
      font-weight: bold
}
```

Attribute Selectors

Attribute selectors match according to an element's attributes in one of four ways: *[attribute]* matches when the element has the specified attribute, regardless of value; *[attribute = value]* matches when the element's attribute has the exact value specified; *[attribute ~ = value]* matches when the attribute can be a space-separated list and one of the members of the actual list is the specified value; *[attribute | = value]* matches the value according to the rules for matching language codes, as specified in RFC 3066 (Alvestrand, 2001).

The example below applies a dotted border below any abbreviation or acronym element that has a *title* attribute. In addition, it asks the browser to change the mouse pointer to the help cursor when hovering over the element. Few browsers successfully render all these styles, however.

```
abbr[title], acronym[title]
{
    border-bottom: black;
    border-width: 0 0 1px 0;
    border-style: none none dotted none;
}
abbr[title]:hover, acronym[title]:hover
{
    cursor: help;
}
```

Grouping

To apply the same style to a set of distinct selectors, separate the selectors with commas. The example below applies a green text color to all six levels of heading.

```
h1, h2, h3, h4, h5, h6
{
      color: #006666;
      background-color: transparent;
}
```

CSS PROPERTIES

Every style rule comprises a selector and one or more declarations. Each declaration has a property and a value. The values permitted for each property depend on the domain of that property. For example, the *margin* property accepts only length values, and the *font-family* property accepts only a list of font names as its value.

Many properties have two forms, a specific form and a combined, or shorthand, form. For example, the *border* property sets the width, style, and color on all four sides, so it is much more compact to write than it is to write all the individual properties pertaining to borders. The shorthand form, however, has a subtle yet important impact on the cascading rules. Any properties that you do not set in the shorthand form act as though you had explicitly set the initial, or default, value in the style rule. Recall that although the cascading rules give low priority to default values, explicit rules (even implicitly explicit ones) take on the priority of the associated selector. You need to be aware of this subtle difference when you choose to use shorthand properties.

The CSS specifications define over 100 properties, and space does not permit them to be listed here. The property definitions are readily available online (Lie & Bos, 1999b; Bos et al., 1998) and in exhaustive references, such as Meyer (2000) and Lie & Bos (1999a). If you do refer to the specifications themselves, be sure to refer to the associated errata as well.

Value Types, Units, and Representations

Color

Color has four representations in style sheets: color names as defined in HTML 4; hexadecimal color codes (long and short forms); percentage RGB codes; numeric RGB codes. The following examples all represent the same color.

```
yellow
#FFFF00
#FF0
rgb(100%, 100, 0%)
rgb(255, 255, 0)
```

URL

Any URL (uniform resource locator) may appear in the following notation: `url()`. Between the parentheses, either absolute or relative URLs may appear. If document relative, they are relative to the style sheet itself.

Length

You may express absolute lengths in terms of inches (in), centimeters (cm), millimeters (mm), points (pt), or picas (pc). When writing a length, put no space between the number and the unit, as in this example: `3mm`.

You may express relative lengths in terms of ems (em), exes (ex), or pixels (px). The em unit is equal to the current font size. The ex unit is equal to the height of the lowercase letter *x* in the current font, although browsers often set it equal to 0.5 em. The pixel unit is usually a screen pixel, but for printing, the specification calls for the pixel unit to be rescaled so that it has the same approximate viewing size as it does on the screen.

Percentage

Percentages appear as a number followed by the percent sign, as in this example: `150%`. Percentage values for lengths are relative to some other length, usually some dimension of a parent element.

Key Words

All other values discussed in this chapter take key words or lists of key words as their values. For example, this style rule asks the browser to set the type of a page in a serif font, preferably Palatino or Times: `body { font-family: Palatino, Times, serif; }`.

PRACTICAL CSS IN ACTION

Linking Styles to Web Pages

There are two basic ways to associate a style sheet with a Web page. The first uses the HTML link element; the second uses the style element. Every page in a Web site needs to be associated with the site's style sheet, but once the association exists, maintaining the styles is easy.

Whether you use the link or the style element, it must be a child of the head element of your HTML page. The first example below uses link; the second uses style. Both examples are in HTML 4. Example 1:

```
<link rel="stylesheet" href="css/screen.css"
  type="text/css" media="screen">
```

Example 2:

```
<style type="text/css" media="all">
   @import url(css/screen.css);
</style>
```

W3C Core Styles

The W3C core styles are eight prewritten style sheets that are available for anyone to use with their HTML documents (Bos, 1999). They are called *Chocolate, Midnight, Modernist, Oldstyle, Steely, Swiss, Traditional,* and *Ultramarine*. You can interactively preview the eight style sheets at http://www.w3.org/StyleSheets/Core/preview. To use one of these style sheets, use a link element like the one in the example, which specifies the Modernist style sheet.

```
<link rel="stylesheet" href="http://www.
  w3.org/StyleSheets/Core/Modernist"
  type="text/css">
```

Alternate Style Sheets

Every Web page that uses style sheets has up to three different kinds of style sheet: persistent, preferred, and alternate, none of which is mandatory (Raggett, Le Hors, & Jacobs, 1999). The alternate style sheets are mutually exclusive, and modern browsers such as Mozilla afford the user a way to choose which alternate style sheet to use. The preferred style sheet is the one that the browser loads initially. The browser always combines the currently selected preferred or alternate style sheet with the persistent style sheet, if any. The persistent style sheet is a good place to put basic styles that the designer wishes to appear at all times. Then only the variant parts of the style sheet need to appear in the preferred and alternate style sheets. There may be any number of alternate style sheets but no more than one persistent style sheet and no more than one preferred style sheet.

The designation of a style sheet as persistent, preferred, or alternate depends on the particular combination of *rel* and *title* attributes on the link tag that associates a Web page with the style sheets: The link to a persistent style sheet has `rel="stylesheet"` and no title attribute at all. The link to the preferred style sheet has `rel="stylesheet"` and a title attribute of your choosing. The link to an alternate style sheet has `rel="alternate stylesheet"` and a distinct title of your choosing. Not all Web browsers provide a user interface for switching style sheets. To provide a switching facility to users of such browsers, you may use HTML form elements, such as buttons or pop-up menus, and some JavaScript code (Sowden, 2001; Ludwin, 2002).

Examples

The following examples are conservative. They are intended to show that interesting results can issue from quite simple CSS code. For more elaborate and cutting-edge examples, see the bibliography for items by Meyer (2001a; 2001b; 2002a; 2002b).

Logo Fixed to the Top Left Corner

The example in Figure 4 assumes that you have a 72-pixel-wide logo in a file *logo.png* that you wish to affix to the top, left corner of your page. The left margin is set in pixel units to move text to the right so that it does not overlap the logo. The margin is set somewhat larger than the width of the graphic so that there is some space between the logo and the text.

Two-Column Layout Without Tables

The examples in Figures 5 and 6 constitute a simplified version of the technique of Zeldman (2001). The goal here is to create a two-column layout with a list of links on the left and the page's principal content on the right. To achieve this layout, the HTML code in Figure 6 uses two div tags to organize the menu links and the content. The division with the content has an id of "content," to which the CSS code in Figure 5 refers. That code primarily employs the underutilized *float* property to float the content to the right side of the page. Margins and padding are adjusted for esthetics, and a border helps the eye distinguish the content from the menu links.

```
body
{
      margin-left: 82px;
      background-position: left top;
      background-attachment: fixed;
      background-repeat: no-repeat;
      background-image: url(logo.png);
      color: #000000;
      background-color: #ffffff;
}
```

Figure 4: Code for a fixed background image.

```
div#content
{
      float: right;
      border-left: 1px solid #000;
      border-bottom: 1px solid #000;
      width: 70%;
      padding-top: 0;
      padding-right: 0;
      padding-left: 3em;
      padding-bottom: 3em;
      margin: 0;
}
```

Figure 5: CSS for two-column layout.

BEST PRACTICES

Modern Web browsers are fairly good implementations of CSS (Web Standards Project, n.d.), and the CSS specifications offer a broad range of perhaps alluring stylistic capabilities. Nonetheless, adhering to certain best practices will minimize the risk that one or another of the standards-compliant browsers will fail to render a page as the designer expected. In addition, many of these practices result in fluid documents that adapt well to different window or screen sizes and user preferences for font size. Some of the practices avoid programming errors that exist in popular Web authoring agents. We examine best practices in two groups: (a) a list of practices by the inventors of CSS (Lie & Bos, 1999), and (b) some new practices that I recommend.

Recommendations of Lie & Bos (1999a)

Use Ems to Specify Lengths

Designs that use ems are scalable, fluid, and adaptive. The em unit, traditionally the width of the glyph M, in CSS is equal to whatever the height of the current font is. Because

```
<body>
<div id="content">
  <p>Content goes here.</p>
</div>
<div id="links">
  <ul>
    <li>link a</li>
    <li>link b</li>
    <li>link c</li>
    <li>link d</li>
  </ul>
</div>
</body>
```

Figure 6: HTML code fragment for two-column layout.

the font height is the basis of this unit, it is a relative unit that scales proportionally as the font size changes. When you set margins and padding in terms of ems, the margins and padding grow or shrink in proportion to the changes in the font on the display device. This preserves the balance and overall appearance of the design while accommodating a variety of display devices and user needs and preferences for font size.

Use Ems to Specify Font Sizes

This recommendation may seem oddly circular at first glance. What does it mean to specify font sizes in terms of font sizes? The em unit for font size is relative to the default font size of the Web browser or other user agent. For example, 2em is equal to twice the default font size. Using ems, rather than traditional type units such as points or picas, results in pages whose font size adapts to the needs and preferences of the end user, or to the limitations of the display medium. Using absolute units for font size is a common reason that type on Web pages appears too big or, worse, too small to read.

Use % When You Wish Not to Use Ems

There are elements for which em is not the appropriate unit. For example, the margins of the page as a whole (the body element) are usually more pleasing if they are based on the size of the display window, rather than on the font size. The % (percent) unit is the appropriate unit for such cases.

Use Absolute Units Only When You Know the Size of the Output Medium

First, a caveat: It is rare to know the dimensions of Web-related output media. Even in print, there are regional variations in the dimensions of the paper. The United States generally uses paper that is 8.5 by 11 or 17 inches for office productivity applications. In Europe, the A4 metric size is common. Bear in mind as well that even in print, some users may need larger than usual type, and others may prefer very small type. If, however, you do know the dimensions of the medium, and if your design has very tight tolerances, CSS provides a menagerie of absolute units: points, picas, centimeters, millimeters, inches.

Float Objects Rather Than Using Layout Tables

In presentational HTML, it is possible to float images or tables to the left or right margin; other content wraps around the floated elements. Designers often resort to a table to move other, nonfloatable elements to one side of the page, creating a multicolumn layout.

With CSS, any element can float if you assign the float property to it, so it is not necessary to use tables for layout. The two principal advantages of CSS floating over layout tables are faster rendering and better accessibility. Tables, especially complex layout tables, often take much time for the browser to render. In addition, the World Wide Web Consortium (1999) recommends against using tables for layout.

Arrange Content in Logical Order

Another way of stating this guideline is don't rely on CSS to position your content in the order you wish users to read it. Arranging the content of a page in its logical sequence ensures that the page continues to make sense even in browsers that cannot render the styles.

Test Pages in the Absence of CSS

Even in a modern CSS-compliant browser, the style sheet may become temporarily unavailable due to a network failure or other cause. For this reason, you should test your pages for legibility with style sheets off. Failure of pages to degrade gracefully in the absence of style sheets causes serious problems of accessibility as well.

Test Pages in Relevant Browsers

Despite the emergence of browsers that adhere to the HTML and CSS standards, it is still necessary to test designs in several relevant browsers. This is due to ambiguities in the standards, differences in interpretation of the standards, or outright errors in implementations. If a significant proportion of your site's visitors uses older browsers, testing is imperative.

Use a Generic Font Family

In print, designers can choose from a multitude of typefaces and can specify the font that best solves a communication problem. On the Web, only the typefaces installed on the end user's computer are available. Typically, these are the fonts installed by default in the computer's operating system. Nonetheless, you may wish to specify fonts for various contexts in your Web pages. When you do, always list the appropriate generic font family as the last item in the list of font families for your style rule. For example: `body { font-family: Palatino, "Times New Roman", serif }`.

There are five generic font families: *Serif* fonts have small extensions (serifs) on the ends of strokes; *sans-serif* fonts lack serifs (from the French sans, meaning "without"); *monospace* fonts have glyphs that are all the same width; *cursive* fonts look like handwriting; *fantasy* fonts are miscellaneous display fonts for special uses. Many computers lack cursive or fantasy fonts, in which case the browser will substitute another font.

Use Numeric Color Codes

The CSS standard defines only 16 color names (aqua, black, blue, fuchsia, gray, green, lime, maroon, navy, olive, purple, red, silver, teal, yellow, and white). Even though browsers may recognize other names, such names are nonstandard and may produce unexpected results, particularly in older browsers. Therefore, it is best always to specify colors as hexadecimal or percentage codes.

Know When to Stop

Listen to your graphic designer and your usability expert. CSS gives you broad power to control the formatting of Web pages. Such power calls for a trained eye and great restraint. You can create a page with 10 fonts and every word in a different color, but such a page would be unreadable. Usually two or three fonts suffice to distinguish the various kinds of text. Using color sparingly makes the color you do use stand out with great emphasis (but be sure that color is not the only way your page conveys information).

Other Best Practices

Use External Style Sheets

Create style sheets as discrete text files that you link to your Web pages. This practice eliminates unnecessary redundancy in the Web site and enables you to establish alternate style sheets. Use embedded styles only when you need to override your external style sheet for a single, exceptional page. If you find that you are often overriding the external style sheets, it is time to redesign the external style sheets. Finally, reserve inline styles with the style attribute only for situations where it is absolutely necessary to accomplish an effect, such as dynamically moving layers around on the page.

This practice is particularly important because it minimizes maintenance tasks. The less style information is dispersed throughout a site's pages, the less effort needs to go into maintaining the site's style sheets. By keeping as much style information as possible in centralized external style sheets, you will reduce the likelihood that a style you want to change is neglected.

Use @import to Hide Styles from Netscape 4

Version 4 of the Netscape browser is now badly obsolete, yet it still has many users. Its CSS implementation is both nonstandard and erroneous. It is possible to create valid HTML and CSS code that is completely unusable in Netscape 4, such that links become inactive. To avoid having to work around the problems in Netscape 4, eliminate styles for that browser by taking advantage of Netscape 4's ignorance of the *@import* directive.

Zeldman (2001) recommends code like the example below for screening style sheets from Netscape 4.

```
<style type="text/css" media="all">
    @import "/styles.css";
</style>
```

For XHTML, use code like the example below, which permits the page to validate under the XHTML document type definitions.

```
<style type="text/css" media="all">
    /*<![CDATA[*/
    @import url(/styles.css);
    /*]]>*/
</style>
```

You may need to decline this practice if your audience has a high proportion of Netscape 4 users. The trade-off is that you will be limited in what aspects of CSS you can use and you will suffer exposure to the risk that trivial changes in your CSS will break your site for Netscape 4. Rigorous testing is required under such circumstances. Because of the severity of the trade-offs, you may decide to politely encourage your users to move to browsers that support standards. The Web Standards Project (n.d.b) provides techniques for doing so.

Use a W3C Core Style

If you are not a graphic designer or do not wish to take the time to develop your own style sheets, use one of the W3C core styles mentioned above. They provide a variety of basic style sheets appropriate for general use, they have already been written and tested for you, and they work (as much as possible) in Netscape 4. If you use a core style, you may omit the preceding practice.

Judiciously Use and Name Classes

Use HTML classes to distinguish elements, such as paragraphs, that serve different purposes in your documents. Name the classes according to their function, not according to their appearance. You may change your mind as to the appearance, and it would make no sense for a class called "blue" to appear in green. But a class called "summary" will make sense regardless of the styles you apply to it.

Avoid Workarounds

One of the benefits of Web standards is that Web page creators can avoid working around quirks and bugs in browsers. Nonetheless, there are bugs and quirks even in modern browsers. Searching the Web for "CSS workaround" will confirm this. Many of the workarounds have to do with layouts that require pixel accuracy, and whose designers consider a browser's misinterpretation of the box model to "ruin" the design. To avoid such bugs, many examples on the Web use bizarre syntax that risks failure when repaired versions of browsers emerge.

Rather than work around the bugs, it is best not to insist on control down to the pixel. Heed the practices above that encourage fluid, adaptive documents, and heed the next practice, as well.

Be Flexible to Keep It Simple

CSS does not offer the precision of presentation control that exists in print. It would be counterproductive for the Web to have such a rigid level of control, because of the diversity of users who, and output devices that, access the Web. The best design practice is to create flexible presentation styles. Simplicity is best. It is not necessary to exercise every nuance of the box model or work around every bug in Internet Explorer. If you are willing to accept some deviation from your ideal design, your style sheets will be simple and easy to maintain.

EVOLUTION OF CSS

The World Wide Web Consortium (2002b) continues to develop the CSS standards. Most recently, it released a draft specification for CSS2.1. This update corrects several errors in the published standard for CSS2. More important, it amends the standard to conform with practice in the following ways: (a) maintains compatibility with widely implemented and accepted parts of CSS2; (b) modifies the specification where implementations have overwhelmingly contradicted CSS2; (c) omits features of CSS2 that have never (or almost never) been implemented; and (d) omits CSS2 features that are to be superseded in CSS3.

CSS3 is still under development. A key feature of CSS3 is that it is being developed in modules. This method of developing the latest CSS specifications will enable implementers and users to accept or reject parts of CSS3 without necessitating revisions to the entire specification. It would not be surprising if only small portions of CSS3 ever see widespread implementation. Nonetheless, it does address the needs of linguistic and other communities whose ways of communicating were ignored in CSS1 and CSS2.

GLOSSARY

Border The region of the box model immediately outside the padding.

Box Model A part of the CSS specification that defines where the content and other parts of an HTML element will appear on the display medium.

Cascade The rules or logic by which multiple style sheets participate in an orderly manner to affect the appearance of a document.

Child An HTML element that is part of the content of an enclosing HTML element.

Content The region of the box model where an HTML element's text or graphic appears.

Declaration The assignment of a value to a property.

Inheritance The propagation of a style from a parent to a child or other descendant.

Margin The transparent region of the box model surrounding the border.

Padding The region of the box model between the content and the border; background properties appear within it.

Parent An HTML element that contains another HTML element.

Property An aspect of style that CSS can control.

Selector The part of a style rule that expresses the context to which the style should apply.

Style Rule A complete expression in CSS that specifies styles and the context to which they should apply; consists of a selector and declarations.

User Agent Software or a device that acts on behalf of a user. The most common user agents are graphical Web browsers.

Validator Software that tests code for syntactical conformity to a standard.

Value A specific setting chosen from a range of possibilities.

C/C++

Mario Giannini, *Code Fighter, Inc., and Columbia University*

WHAT IS C/C++?

C and C++ are closely related programming languages used to create computer programs. Using these languages, programmers write documents called *source files* and then use a program called a *compiler* to convert the source files into program files that can be executed by a computer.

According to CareerInfo.net (http://www.acinet.org), computer software engineers are projected to be the fastest growing occupation, rising from 380,000 jobs in 2000 to an estimated 760,100 by 2010. The growing demand for technologically skilled software developers makes it a popular field.

The programs developed using C and C++ can cover a wide range types. Games, office products, utilities, server programs—just about anything can be developed using the C and C++ languages. C and C++ are not considered "high-level" programming languages, and unlike other languages such as COBOL or Visual Basic, they are designed to apply to a number of varied tasks, rather than specific ones.

A History of C and C++

The C language was originally designed by Dennis Ritchie for the DEC PDP-11 computer system and the UNIX operating system, between 1969 and 1973. It was directly influenced by the BCPL and B programming languages.

In 1969, Bell Telephone Laboratories was in the process of abandoning its Multics operating system, believing that its strategy would prove too expensive to completely implement. Ken Thompson led a group to investigate the creation of a new operating system, which would eventually evolve into the UNIX operating system.

Thompson wrote the original version of UNIX using assembly language, a complex and low-level language. He decided that UNIX would need a "system language," a programming language that would serve as the primary language for developing applications. Initially, he created his own language, named B. Thompson used BCPL (created in the mid 1960s by Martin Richards) as his inspiration for creating B.

B underwent several changes to improve several short comings and was renamed to the NB language (for, "New B"). As more changes were added, however, the language started to change considerably from its B predecessor. By 1973, the language was essentially completed and had been named C.

At the time, there was no "official" definition of C. The language had not undergone any standardization approval and was therefore open to interpretation by any company that wished to produce a C compiler. In 1978, Brian Kernighan and Dennis Ritchie wrote *The C Programming Language*. This was the most detailed description of the language and would soon be used to describe a version of the language named K&R C, for the author's names.

In 1983, the documentation from Kernighan and Ritchie's book was submitted to the American National Standards Institute (ANSI), to get their approval for an exact and standard definition of exactly what C was. Once approved, then the C language would carry with it the extra clout of having an official standard, to which compiler producers would need to meet in order to sell their products as an official C compiler. By 1989, after several changes, the ANSI XJ311 committee approved what is now called ANSI C. This is the language still in use today.

While C was undergoing its many changes for standardization, C++ was appeared around 1980 and continued to grow in popularity. C++ was originally termed "C With Classes" and was created by Bjarne Stroustrup at AT&T Bell Labs. Stroustrup was using Simula67, which followed an object-oriented approach to software development. Unpleased with Simula67's performance, Stroustrup decided to enhance the C language, to implement classes and objects.

Since its introduction, C++ has been considered a superset of C; everything in C is pretty much still in C++. C++ adds a number of features, primarily in the area of object-oriented programming. It is still possible to compile a C program using a C++ compiler, but not vice versa. The name C++ is a take on the ++ operator of C, which means "add one." So, C++ can be considered as "C + 1," or the next evolution of C.

Stroustrup created C++ in an informal fashion. There was no formal committee or project dedicated to its creation. It more or less promoted itself into development, offering the performance of C++, but with object-oriented enhancements and patterns to improve development. Because of this informal process, there is not a great deal of information about the evolution of its specification. Despite this fact, and as with the early years of C with no standard definition, C++ grew quickly in popularity. By 1987, it was decided that C++ should be submitted to the ANSI body for official standardization. By 1989, Stroustrup had completed the documentation required for standardization, and Hewlett Packard had initiated the process for ANSI submission.

In 1989, ANSI created the X3J16 committee, which was to serve as the review body for standardization approval. During the review process, C++ underwent a number of changes. An official standard stream (or Input–Output) class hierarchy was defined, as was a set of standard "template" classes. By 1995, a proposal was made that would eventually be approved. By 1998, ANSI had approved and published a C++ standardization, which is the language still in use today.

Programming Languages

Everything a computer does is the result of a program that runs on it. Even when a computer seems to be idle, waiting or a user to press a key, it is in fact doing many things. A program is defined as a set of instructions that the computer executes. A computer follows an ordered pattern of instructions, just as a person reads a recipe to bake a cake and executes the recipe's instructions in order.

Each computer (or central processing unit [CPU] inside the computer) understands a specific set of instructions. The Intel CPUs found inside Windows computers executes a different instruction set then Motorola CPUs found inside an Apple Macintosh computer. The instructions the CPU knows how to handle are called its *instruction set*. Even thought the Intel and Motorola CPUs have a different instruction set, many of the instructions are similar. For example, both provide instructions to do simple math such as addition and subtraction, as well as to move data from one memory location to another or compare the results of some mathematical operation. The instructions executed by the CPU are also called *Machine Code,* because the machine can execute it directly.

A CPU's instruction set represents everything it understands and can execute. Unfortunately, the instruction set is defined as a set of numbers, and each number tells it to perform a certain operation. This makes creating a program using the exact instructions quite complex. For example, the following numbers (in hexadecimal) on an Intel CPU would tell it to add "1" to memory address "100":

```
C6 06 64 00 01
```

Using this format can become complicated, given that each instruction performs only a small part of a program's function (even a very small program, such as Windows' Notepad program, contains about 50,000 bytes of instructions). To simplify the creation of a program, machine code instructions need to be made less complex. The first step in achieving this is to introduce a set of mnemonics for the instructions. These mnemonics are a representation of the machine code that is more readily understood by humans, called *Assembly* or *Assembly Language*. An example of the same set of instructions, written in assembly, would look like this:

```
ADD BYTEPTR[100],1
```

Now, by just looking at the mnemonics, one can begin to understand that the program is attempting to add 1 to a memory address (memory address 100). The computer doesn't understand mnemonics, however; it understands the numbers in its instruction set. Therefore, an *Assembler* program is used to convert Assembly Language into actual CPU instructions.

Assembly is defined as a low-level language. This means that it offers programmers complete control over the programming process, but they must take responsibility for every operation, no matter how minor. Higher level languages were developed, like C and C++, to simplify the task of creating programs.

A single statement or instruction in C or C++ may translate into several machine code instructions. For example, the following code adds "1" to a variable in C or C++:

```
Count = Count + 1;
```

This is much easier to read and understand than the assembler mnemonics.

Compilers and Linkers

A compiler is a program that translates instructions and statements from one language, such as Fortran or C, into machine code (code that the computer can directly execute). The output of the compilation process is called an object module and is made up of the translated machine code. A linker takes one or more of these object modules and links them together into a single file called an executable. The idea behind linking is that if a program has a set of instructions to do something useful, such as printing a string, the programmer will want to be able to reuse that set of instructions in this and other programs. If the programmer compiled these instructions into an object module, then he or she simply needs to link it into a new program to reuse it.

All programming languages are defined as either *interpreted* or *compiled.* Interpreted means that the program is not directly executed by the computer, but by a program on the computer. Compiled languages are ones that are compiled (or translated) directly into machine code, which can run directly on the computer. They are typically faster than interpreted programs, but interpreted programs are generally easier to create and debug. PERL, Java (with the JVM), and PHP are all examples of interpreted languages. C and C++ are examples of compiled languages.

To simplify programming, developers can write their programs using C language, following its rules and syntax. They then compile the program and link it to whichever object modules they need to create an executable program file. The computer is then able to execute that file directly.

To create an executable program using the C and C++ languages, programmers need the following items:

- A text editor, to type in the C or C++ statements
- A compiler, to convert the C or C++ statements into machine code (object modules)
- A linker, to join one or more object modules into an executable file

Most operating systems come with some form of text editor, such as *vi* or *Emacs* in Unix or *Notepad* in Windows. Unix and Linux operating systems also come with a built-in C and C++ compiler and linker, but Windows and MacOS do not. When developing programs, however, most programmers will use an integrated development environment (IDE). These are programs are actually a suite of programs that combine text editor, compiler, linker, and other helpful tools such as a debugger into a single application. For Windows, common IDEs include Visual C++ from Microsoft and C++ Builder from Borland. For the Macintosh, CodeWarrior from Metrowerks sells a C an C++ IDE.

C Versus C++

As noted earlier, C++ is often considered a superset of C; everything C can do, C++ can do as well, but not vice versa. With a C++ IDE, one can still create "pure C" programs (programs that do not take advantage of the benefits of C++), but C++ adds several useful attributes to C, including the following:

- C++ introduces classes and a syntax to create and use them. Classes are a syntactical method by which the programmer can group data and functions into a simple package or container.
- C++ introduces a set of predefined classes and functions called the standard template library (STL) to reduce development time. STL increases functionality, for example, by offering a means to manage data collections and sort or search those collections.
- C++ introduces function overloading (the ability to write several functions with the same name). This permits a more intuitive means for naming functions to manipulate different types of data for similar tasks (e.g., three "clear" functions that clear three different entities—a string, a file, or a list of data).

C++ provides developers a way to make smaller, more manageable "objects" to work with data in their programs, rather that trying to string together a set of similar but unrelated functions. This, combined with a string library of classes such as STL, permits faster program development, a key benefit of C++.

The remainder of this chapter provides examples in C++. Some of these will work in a "Pure C" program, but others will not. In certain cases, such as printing a string to a console, each language has its own way of performing a task, but only the C++ version is given here (except where noted).

GETTING STARTED WITH C/C++

I begin by demonstrating a simple C and C++ program that will display the text "Hello World" on the console (screen) and then terminate. Although relatively simple, upon completion you will have written a small program and compiled, linked, and executed it.

First, create a *source file* to contain the program and its C++ statements. Depending on the compiler, a programmer would normally add a .cpp extension to the file name, although some compilers prefer .cxx or some other variation. Here, assume that the source file can be called helloworld.cpp. Place following code in the source file:

```
//Include header file so we can use the
  cout object
#include <iostream>

//This next line simplifies using the std
  STL library classes and
//objects, like cout:
using namespace std;

/* main is where the program starts */
int main()
{
        //Use the cout object to display a
          string to the console.
        cout << "Hello World" << endl;
        return 0;
}
```

Now that this text has been added to your helloworld.cpp file, you will compile, link, and execute it (the exact steps depend on the compiler and linker you are using, as well as your operating system). The program demonstrates several issues, discussed below.

Comments

Comments in C/C++ are pieces of text that the compiler ignores. They are used to permit the programmer to make notes and comments about the source code. C permits developers to put comments (as many lines as he or she desires) between the /* and */ characters. C++ adds a // comment sequence, where anything following these two characters, to the end of the line, is treated as a comment.

Functions

A function is a group of C/C++ statements that can be called on from various places within a program. A function is defined as a return type, then the function name, and a list of parameters within parenthesis, and finally the actual set of C or C++ statements enclosed in curly braces {and}. In the previous example, *main* is a function that returns an int data type and accepts no parameters. It also has special significance, because this is where a C or C++ program begins execution. Sometimes main is written to take two parameters, commonly named argc and argv. In

Table 1 Primitive Data Types for C and C++

TYPE	DESCRIPTION	EXAMPLE
char	Represents a single character	char Ch = "A"
short	Represents a small integer, usually 16 bits in size, that can contain a value from –32768 to 32767 (or 0 to 65536)	short S = 0;
long	Represents a large integer, usually 32 bits in size, that can contain a value between –2 billion and 2 billion (or 0 and 4 billion)	long l = 0
int	Represents an integer that typically defaults to a *long,* but can also be a short	int i = 0
float	Represents a floating point (non–whole number) value, typically with seven digits of precision	float f = 3.142857
double	A floating point (non–whole number) value, typically with 15 digits of precision	double d = 3.14285714285714

this version, argc will contain the count of command-line arguments passed to the program, and argv will be a string array of those arguments.

Let's say I decide a useful function would be to ask the user to input a number. Rather than repeating code to perform this task, I place it inside a function and simply call or invoke the function as needed. For example:

```
int PromptInt( const char* Prompt )
{
      /* This function prompts the user for
         input, and returns the input */
      int Ret;
      cout << Prompt << endl;
      cin >> Ret;
      return Ret;
      /* The return statement permits a
         function to return a value to its
         caller (main, in this example) */
}
int main()
{
      //Use the cout object to display a
         string to the console.
      cout << "Hello World" << endl;

      int Age = PromptInt
         ( "Enter your Age: " );
      int Weight = PromptInt
         ( "Enter your weight: " );
      return 0;
}
```

Note how the actual number of steps to output a prompt (e.g., "Enter your Age:") and accept an input from the user takes four lines of code. I have placed those 4 lines of code into the *PromptInt* function, however, so that when I need to do this task I only have to write one line of code to call the *promptInt* function, such as in the line:

```
      int Age = PromptInt
         ( "Enter your Age: " );
```

Creating functions allows programmers to reuse code easily and therefore simplifies the task of programming. Some other languages refer to a function with a return value as a "function" and one without a return value as a "subroutine"; C and C++ do not. The term "method" is often used to describe a function that exists within a class.

Simple Data Types

A program is made up not only of coded instructions but of data as well. For example, when people use a word-processing program, the text they type is stored as data in memory while the program is running. This data is typically stored to a disk, so that when the user shuts down the program, the data (i.e., the document) is retained for future use. When the word processor is run again, it simply reloads the file into memory.

C and C++ provide several basic data types to do various things. These are all called fundamental or primitive data types because they are relatively simple. They can be used to construct more complex data types, however, such as structures or classes. The core list of primitive data types for C/C++ is shown in Table 1. These data types can be used in a variety of ways. For example, a short might be used to count from 1 to 100, to execute something 100 times, or a float might be used to hold a person's hourly pay rate or a foreign currency exchange rate.

Pointers

Pointers are often viewed as the most complex part of learning C and C++, but they are actually simple. A pointer is a variable that contains the memory address of some other variable or function. Pointers, like all variable types, require proper initialization. C and C++ are sufficiently high level that developers need not worry about the exact address.

Pointer variables are declared similarly to other variables, bt they use the * operator in their declaration. For example:

```
int i; /* i is an integer variable */
int * ip; /* ip is a pointer to an
  integer */
```

Initializing a pointer can be done a number of ways, but a fairly good example is to use the "address of" operator &, with an existing variable:

```
ip = &i; /* Initialize ip with the
  'address of' i */
```

Now, I again use the * operator to dereference the data to which ip points (i.e., of which ip contains the memory address). For example:

```
*ip = 3; /* Puts 3 into the i variable */
```

Note the difference between `ip = &i;`, which initializes ip itself, and `*ip = 3;`, which initializes the integer to which ip points.

Arrays

An array is a set of variables in contiguous or continuous order. Although declaring a single integer data type to hold a value like a counter is important, practical programming often requires an array of integers to hold several things, such as students' IDs. An array is declared by placing brackets ([]) and the number of desired elements after the variable name. For example:

```
int StudentIDs[30];
```

This example creates an array named StudentIDs that contains 30 integers. In C and C++, access to an individual element of an array starts at zero, so the first integer in the array is named StudentIDs[0] and the last is StudentIDs[29]. Once an array has been declared, an individual element can be treated like any other variable of that same type (integers, in our example). For example:

```
int Index = 0;
cout << "Enter student ID: " << endl;
cin >> StudentIDs[Index];
```

Arrays can be multidimensional. For example, consider the following:

```
int Month[5][7];
```

Here, month is a two-dimensional array, for which one can imagine 5 rows of 7 days (one wouldn't use 4 rows, because that would only be 28 days).

Simple Input and Output

C++ has two objects to permit programmers to input (get input from the keyboard) and output (display something on the screen), named *cin* and *cout* respectively. These objects are actually global variables that are predefined. Both cin and cout can work with the various fundamental data types, meaning that cin knows how to get integers ('int') and strings (char arrays or *string* objects) from the keyboard, and cout knows how to format the same types for display.

To display or output a value, programmers use the cout class, and the << (insertion) operator. cout can work with variables or constants (as in the constant string example). cin can only work with variables, because it stores data into them. Using cin requires use of the >>>> (extraction) operator. For example:

```
#include <iostream>
#include <string>
using namespace std;//Simplifies usage of
  cin, cout, and string

int main()
{
       string Name;
       int Age;

       cout << "Enter your name:" << endl;
       /* endl is an End of Line character,
         and a buffer 'flush' */
       cin >> Name;
       cout << "Enter your age:" << endl;
       cin >> Age;
       cout << "Hello " << Name << ", you
         are " << Age << " years old."
         << endl;

       return 0;
}
```

In this code, the string *Enter your name:* is output by cout, and then the user types his or her name and presses ENTER, which cin takes and places into the Name variable. A similar process is performed for the *Age* variable. An example program run would look like this (users input are in **bold**):

```
Enter your name:
Mario
Enter your age:
38
Hello Mario, you are 38 years old.
```

C provides printf and scanf functions (among several others) for performing output and input, respectively. Additional details are beyond the scope of this chapter, but it is worth noting that the same routines will work in C++ programs as well.

Classes: An Introduction

As described in the previous section, C and C++ programs comprise functions or subroutines that operate on data or variables. It would be beneficial to take functions that operate on a certain type of variable and combine them with the variables on which they work. This is just one of the things that a *class* can do.

The definition of a class is covered in more detail later in the chapter and is closely related to object-oriented programming. For the purposes of this section, however, a class is a simple means of grouping functions and variables together. In other words, a class is used as a container that holds both data and functions that work on that data.

Imagine that I have a person's name and age in variables, and I have functions to input and output the person's data. By using a class, I can combine them into one object. Creating a class in C++ represents declaring a new data type using the *class* keyword. The following is an example of a class definition:

```
#include <iostream>
#include <string>
using namespace std; //Simplifies usage of
  cin, cout, and string

class Person {
public:
       string Name;
       int Age;
       void Input() {
              cout << "Enter person name:"
                << endl;
              cin >> Name;
              cout << "Enter person age:"
                << endl;
              cin >> Age;
       }

       void Output() {
              cout << "Name: " << Name
                << " Age: " << Age << endl;
       }
};

int main(int argc, char* argv[])
{
       Person p; //p is now a Person object,
         with a Name and Age inside it.

       p.Input();
       p.Output();

       return 0;
}
```

This program's output would look like this (user input in bold):

```
Enter person name:
Mario
Enter person age:
38
Name: Mario Age: 38
```

The *Person* class I created contains two variables: Name and Age. Each instance of a Person object I create, such as *p*, will contain its own Name and Age variable. Because functions never change, there is only one copy of each function in the class, no matter how many instances of a Person object we create.

FLOW CONTROL

Flow control refers to how a program executes or what path it takes through its lines of code as it executes. Flow normally goes sequentially from line to line, executing each line of a function in top-down order. There are times when programmers may want to repeat certain sections of code or to skip other sections altogether. To accommodate this, C and C++, like all other languages, use flow control.

Expressions

As mentioned earlier, programmers may want to execute a certain piece of code multiple times or bypass it all together. To determine if they should repeat the code of skip it, programmers rely on an *expression*. Expressions can be logical, which are either true or false or mathematical, which result in a number (zero is considered as false, and anything else is considered true). In C and C++, programmers can use any type of expression to determine flow control, although logical expressions are the most common. For example, when inputting a person's age, I may decide that if the user enters a bad Age (such as –6 or 1,000), that the program will prompt for the age to be reentered. My expression would be *Age < 1 || Age > 120*. This expression says "Age is less than 1 OR Age > 120" (The || means 'or' in C and C++). To apply this in an actual example, we might see something like the following:

```
     do {
            cout << "Enter person age:"
              << endl;
            cin >> Age;
     } while( Age < 1 || Age > 130 );
```

This code uses a looping flow control statement called a *do while*. It will "do" the code in between the {and} braces, while Age < 1 or Age > 130 (under the assumption that people don't live past 130 years).

For an OR expression to be true, at least one of its sides must evaluate to true on its own. There is also an "and" operation, which is written with the && symbols. For an AND expression to be true, both of its sides must evaluate to true. I can mix and match the || and && operators as needed. For example, the following code will tell me if the variable Ch contains a digit from 0 to 9 or a + or – character:

```
if( (Ch >='0' && Ch <='9') || Ch=='-' ||
  Ch == '+')
```

Note that in this example, > = means greater than or equal to, < = means less than or equal to, and = = means equal to. You can also use ! =, which means not equal to.

Looping and Nonlooping

Flow control statements are divided into two types: looping and nonlooping. As the names imply, looping statements can cause a block of code to be executed multiple times, and nonlooping statements will permit the programmer to selective execute a piece of code only once.

The nonlooping flow control statements are *if*, *switch*, and *goto*. Of these, the *goto* does not use an expression test to determine if it should go the specified point. *goto* statements are usually overused when a programmer doesn't comprehend the other flow control statements, so many new programmers are warned not to use them.

If Statement

The *if* statement has an optional *else* that permits programmers to execute alternate pieces of code. The following are three variations of using the if and else statements:

Version 1

```
if(Age >= 65)
      cout << "Eligible for Social
        Security" << endl;
```

Version 2

```
if(Age >= 65)
      cout << "Eligible for Social
        Security" << endl;
else
      cout << "Not eligible for Social
        Security" << endl;
```

Version 3

```
if(Age >= 65)
      cout << "Eligible for Social
        Security" << endl;
else
{
      if(Age < 18)
            cout << "Not eligible to work"
              << endl;
      else
            cout << "Eligible to work"
              << endl;
}
```

Switch Statement

The switch statement performs similarly to an if–else combination, although it has some differences. The switch optionally permits multiple code sections to execute, depending on the order and structure of the code. For example:

```
int Vowels=0, Letters=0, Spaces=0;
char Ch='a';

switch(Ch)
{
       case ' ':
              Spaces = Spaces + 1;
              break; //Take us out of this
                switch
       case 'a':
       case 'e':
       case 'i':
       case 'o':
       case 'u':
              Vowels = Vowels + 1;
              //No break, we fall through to
                the next line of code
       default:
              Letters = Letters + 1;
}
```

This code will add 1 to the Spaces count if Ch is a ‘ ‘ character, 1 to both the Vowels and Letters count (vowels are letters) if Ch is a vowel, or 1 to the Letters count if Ch is not a space or vowel.

For Statement

The for statement combines an initialization section and an operation section, along with the expression test to determine if it should repeat. The basic format is:
for(initialization; Expression Test; Operation)

A practical example of this is the following:

```
void PrintStars( int Count )
{
       int i;
       for( i=0; i < Count; i = i + 1 )
              cout << "*";
       cout << endl;
}
```

In this example, the *initialization* sets the variable *i* to zero. The *Expression Test* would be to see if *i* were less than Count (if it is, the body executes; if it isn’t, the body is skipped and the program continues). If the body was executed, then the *Operation* is performed, which in this case adds 1 to *i*. The *Expression Test* is then reevaluated, and the process repeats.

While and Do While Statements

The *while* statement works basically like the *for* statement, only it has no specific initializer or operation steps. More often than not however, they are found in or near the *while* statement. The format is as follows:
while(Expression Test)

An example would be:

```
void PrintStars( int Count )
{
       int i;
       i=0; //Similar to initializer in
         for loop
       while( i < 10 )
       {
             cout << "*";
             i = i + 1; //similar to
               operation in for loop
       }
       cout << endl;
}
```

The difference between the *while* and *do while* is that the expression test occurs at the end of the body, and the body is guaranteed to execute at least once. An example of a *do while* loop can be found at the start of this section.

Exceptions

C++ introduces the concept of an exception, which C does not support (there is a roughly similar technique in C++ using the *setjmp* and *longjmp* functions). An exception is a way to jump from the middle of a function back to the middle of another function that may have called it. Many programmers think of exceptions as useful only for undoing errors, but although this is their most common use, they can be used at any time to leave one section of code and return through several function calls. A lengthy description of exceptions is beyond the scope of this chapter, but the *try, catch,* and *throw* key words are used to implement exceptions.

ADVANCED DATA TYPES

C and C++ provide several more advanced and complex data types, as well as the ability for programmers to create their own. As noted earlier, the *class* key word can be used to create a simple container; following is a more detailed description of that process, as well as other advanced data types.

Structures and Unions

In C++, a structure works just like a class does, except that members are public by default, whereas in a class they are private by default. Like classes, a structure in C++ can also contain member functions. In C, structures can only contain data members, and no functions.

A typical structure definition uses the *struct* keyword, and can be demonstrated with the following:

```
struct MyDate {
       int Month, Day, Year;
}
```

Here, MyDate is a new type of data that contains three integers: Month, Day, and Year. In memory, each data member of the struct is laid out sequentially. This means that the size of the struct in memory would be the size of three integers.

A union has a similar syntax as a struct but has a significant difference: Each member of a union occupies the same memory address. As a result, the size of a union in memory is the size of its largest member. The following is an example:

```
union DateOrTime {
       struct { int Month, Day, Year;} Date;
       struct { int Hour, Minute, Second;}
         Time;
};
```

The DateOrTime union has a Date and a Time data member, but these members overlap each other. This means it can only contain a valid Date or a valid Time, but not both. The size of the union would be the size of three integers.

To access a data member of a struct or union, the programmer must first have a variable of that type and then use the operator (or the -> operator if you have a pointer to a struct or union). For example:

```
struct MyDate BirthDay;
cout << "Enter Month: " << endl;
cin >> MyDate.Month; /* Get integer from
  user, and store it in a data member */
```

Classes

Classes can be used for more than a simple container. There are a wide variety of topics to address in classes, but I cover only two issues: constructors and destructors and inheritance. Accessing the member variables or methods of a class, is similar to that of the struct or union, and uses the. operator (or the -> operator if you have a pointer to a struct, union, or class).

Constructors and Destructors

A class can provide two special functions, called a constructor and a destructor. These functions are automatically called when an object is created or destroyed, respectively (objects are typically created when they are declared as a variable and destroyed when the function that declared them is done running).

Both the constructor and destructor functions have no return value and must have the same name as the class they are in, but a destructor must have a tilde (~) prefix in its name as well. Constructors are used to initialize the data members of a class, whereas a destructor is used to clean up any resources (such as memory or an open file) that the object may hold. An example of a class with a constructor would be as follows:

```
class Person {
public:
       string Name;
       int Age;

       Person () // Constructor, to
         initialize data members
       {
              Age = 0;
              Name = " ";
       }

       void Input()
       {
              cout << "Enter person name:"
                << endl;
              cin >> Name;
              do {
                     cout << "Enter person
                       age:" << endl;
                     cin >> Age;
              } while( Age < 1 || Age > 130 );
       }

       void Output()
       {
              cout << "Name: " << Name <<
                " Age: " << Age << endl;
       }
};
```

Note that this class has no destructor. If the class had been designed so that it opened a file or perhaps allocated some other type of resource, then a destructor would have been written to ensure that the resource was closed when the object was being destroyed.

Inheritance

A class (and structure and unions as well) can be used as the base class, or starting point, for another class. When programmers do this, they create a new class that inherits all the data members and functions of the base class. This permits them to reuse classes and build on them without having to modify the original version.

The following example demonstrates a simple class derived from the Person class:

```
class Worker : public Person
{
public:
             int Salary;
             void Input()
             {
                  Person::Input();
                    //Get person Input
                  cout << "Enter Worker
                    Salary: " << endl;
                  cin >> Salary;
             }
             void Output()
             {
                  cout << "Name: " << Name
                    << " Age: " << Age;
                  cout << " Salary: "
                    << Salary << endl;
             }
};
```

If I were to declare a Worker object, such as `Worker w;`, the *w* variable would contain a Salary integer (from the Worker class) and an Age and Name variable that it inherited from the Person class. By simply adding "public Person" to the declaration of the Worker class, I am saying that it is derived from the Person class.

The Standard Template Library

The ANSI standard version of C++ provides an entire collection of classes and functions, referred to collectively as the standard template library. Inside the library are classes and methods required to do common programming tasks. They implement collection classes for collecting and sorting data in a variety of fashions such as arrays, lists, and maps. The STL also provides classes for string management, file and stream input–output, as well as support to legacy C functions.

C AND C++ AND THE INTERNET

As mentioned at the beginning of this chapter, C and C++ are very generic languages, suited to serve a wide range of purposes. They are used to create everything from games, to device controllers, to desktop and server applications. I also noted that C and C++ can be used to create operating systems such as Unix and Windows, on which all other programs are run. This puts C and C++ in a unique position. Many other languages such as Practical Extraction and Report Language (PERL), Java, PHP: Hypertext Preprocessor (PHP), JavaServer Pages (JSP), or Active Server Pages (ASP) share a well deserved popularity, the truth is that most, if not all of these languages were actually created with C and/or C++ to begin with.

As a typical example, the Unix environment and the Apache Web server application are used to run many of the Internet's Web sites. At the time of this writing, the Apache Web server accounted for 59% of all sites surveyed (http://www.netcraft.com), and it was written in C. In addition, the scripting language PERL is commonly used to create CGI programs; PERL (or, interpreter) also was written in C. Put simply, C truly is the building block of the Internet. Although other languages may be more popular for Web site scripting, they wouldn't exist without C.

CGI Programming

A common gateway interface (CGI) program is one that is run on a Web Server, the output of which usually goes back to a clients' browser programs. Just about any time users fill in a form on a Web page that has a "Submit" button, it is gathering data from the form and sending it to a CGI program on the remote Web site.

Any programming language that can display output to the console can be used to create a CGI program, and this includes C and C++. If the program can read data from the keyboard or from an environment variable, it can also support form-based input from a clients browser. Again, C and C++ fit this bill. Because C is a compiled language and not an interpreted language like Java, Perl, or ASP, CGI programs created in C or C++ typically perform tasks faster than similar programs written in other languages.

How a CGI Program Is Run

A Web page typically uses a Hypertext Markup Language (HTML) FORM tag (which defines a set of controls such as edit boxes and drop-down lists for user input) to define a CGI program on the Web Server to be called. An example of such an HTML tag is the following:

```
<FORM ACTION= ”CGIFavColor.exe”
  METHOD=POST>
```

Here, this form should run the CGIFavColor.exe CGI program, with a POST method. CGIFavColor.exe would be a compiled C program on the Web server. Note that running the CGI program successfully depends on specific needs of different servers; for example, a programmer might need to set certain permissions for the CGI file and require a certain extension. In the example, using the .exe file extension assumes that the CGI program resides on a Windows-based Web server, and the same extension would not be used for a Unix-based CGI program.

Most commonly, a "Submit" button is used to invoke the CGI. A submit button is a special HTML tag intended for just this purpose. The HTML code for this submit button would look like this:

```
<INPUT NAME="RunTheCGI" TYPE="submit"
  VALUE="Submit Color">
```

The submit button will ask the Web Server to invoke the CGI program specified by the FORM tags *action* property. It sends all the data from the form (entered via the client's browser) to the server.

There can also be a link on a page run by a CGI program. To do this, the programmer specifies the name of the CGI program as the link, for example (this example also shows how to pass a parameter to the CGI):

```
<A HREF="../cgi-bin/CGIFavColor.
  exe?FavColor=Black">Favorite Color is
  black</A>
```

The link method does not use (or need) the FORM tag to specify a CGI program to run.

A CGI program can also be run when a page is loaded (often used for Web counters) by specifying the name of the CGI as an element, like an image. For example:

```
<IMG SRC="../cgi-bin/CGIFavColor.exe">
```

This method would assume that the CGI program would output an image, like a GIF file. In this case, when the tag is encountered by the browser, the CGI program is run, and it can do whatever it wants (e.g., increment a counter in a file), and then it returns (outputs) a GIF image.

CGI Output

A CGI program outputs its result by sending the data to the standard output device (using stdout, or cout in C++). The programmer must format all output in a specific format, however. The most common format is HTML text, but a program can also output an image, sound, or any other file type that a browser will recognize. For the remainder of this section, I describe HTML format, because it is by far the most common (an exception being access counters, which often output an image).

A CGI program must begin its output (again, for HTML) with the string `Content-type: text/html`, followed by two carriage returns. In C, this would be accomplished with the following:

```
printf( "Content-type: text/html\n\n");
```

In C++, we could do the following:

```
cout << "Content-type: text/html\n\n";
```

Next, the CGI must output the entire Web page using HTML tags. The minimum required would be the start and end BODY and HTML codes. The programmer can insert anything he or she wants between the start and end codes. For example:

```
printf("Content-type: text/html\n\n");
printf("<HTML><BODY>\n"); /* \n isn't
  needed, but makes source more readable */
printf("Hey! This is my first CGI
  response!<P>\n");
/* <P> is an HTML paragraph tag */
printf("</HTML></BODY>\n");
```

The Web server that ran the CGI program gathers all the output from the *printf* function call, and then redirects it back the client's browser for display.

Note that even error messages from the program must appear in the format.

CGI Input

CGI input, typically the user's data entered in HTML, is presented to the CGI program in one of two methods, GET or POST. The HTML FORM tag defines the method to use. The difference between the GET and POST is how the information from the form is sent to the CGI program from the server, and how it must retrieve the data.

A GET method will provide the user's input to the CGI program as an environment variable called QUERY_STRING. The CGI program would read this environment variable (using the C getenv() function) and parse it to get the user's input. A GET method will also show the input data to the user in the URL area of the browser, showing a string such as http://www.somewhere.com/CGIFavColor.exe?FavColor = Black. The GET method is acceptable for small amounts of data. Also, GET is the default method when a CGI program is run via a link.

A POST will provide the user's input to the CGI program as if it were typed at the keyboard using a standard input device, or stdin. If POST is used, then an environment variable called CONTENT_LENGTH indicates how much data is being sent. The programmer can read this data into a buffer by doing something such as the following:

```
char Buffer[512];
int InputLength = atoi(getenv
  ("INPUT_LENGTH"));
fread(Buffer, InputLength, 1, stdin);
```

The CGI program should inspect the REQUEST_METHOD environment variable to determine if the form

Table 2 C and C++ Open Source Programs

PRODUCT	DESCRIPTION
Linux	Unix-style operating system
MySQL	Structured query language (SQL) database server
Apache	Web server
Mozilla	Web Browser
Doom Legacy	Original Doom arcade game
Tcl	An interpreted Tool Control Language
Firewall Builder	Graphical tool and compilers for various firewall platforms
Enlightenment	Window Manager for X11 windowing system
CDex	CD Burning software

was a GET or POST method and take the appropriate action to retrieve the data from the user's form.

Parsing CGI Input

Once the input is received, it must be parsed. All field values from the form will appear as one long string. Each value is separated by an & character. For example, a two-value string might look like this:

```
FavColor=Black&FavFood=Twinkies
```

Here, FavColor and FavFood would be the names of two input fields from the form, and Black and Twinkies would be what the user entered in those fields.

The server will also perform two conversions on the data the CGI program receives:

- All spaces are converted to a + character
- Special characters (such as \n) are converted to a %, followed by the ASCII code for the character

The programmer needs to undo these conversions in the CGI program. Once the FORM input data has been obtained, the programmer can then do whatever he or she wants with the data. Because C++ has the ability (with the proper code and functions) to send e-mails, manage databases, create files, and so on, programmers can combine any of these tasks in their CGI programs. For example, one could get the users e-mail address (if it was entered in an HTML form), add it to a database, and then send an e-mail confirming they were added.

CLIENT–SERVER PROGRAMMING

C and C++ are used more in client–server programming than as a CGI program. A typical example of a client server program would be Apache or Internet Information Server as a Web server and Netscape Navigator or Internet Explorer as a Web browser client.

C and C++ are often used to write programs for both the client and server. Programs that communicate with each other over the Internet do so using something called a *socket*. A socket isn't a physical thing but a description of how to exchange data with other computers and programs. Although C and C++ do not have built-in support for sockets, the operating system under which the programs run usually provide a set of functions to work with sockets, which can in turn be called by C and C++ programs.

Typically, a program that acts as a server is running constantly, waiting for a client program to connect via a socket. The client program establishes the connection to the server by calling the appropriate operating system function. Once connected, the programs can freely transfer data back and forth, such as HTML files, email messages, and files.

Open Source

The Open Source movement is the practice of developing software applications and then sharing the source code for those programs with others, free of charge. The basic license, called the GNU license (GNU is a recursive acronym for GNUs Not Unix), basically states that programmers are free to use the source code as long as they also distribute the source code of their programs under the GNU license.

One of the largest Web sites that functions as a server for Open Source codes is http://www.sourceforge.net. A quick glimpse at its top-10 downloads of all time (http://sourceforge.net/top/toplist.php?type = downloads) shows that 8 of the top-10 items were mostly written with C and C++ (Delphi and PHP are the remaining two).

Table 2 is a brief list of some of the more popular C and C++ Open Source programs. The list demonstrates that C and C++ are used for a wide range of applications.

GLOSSARY

American National Standards Institute (ANSI) An organization that defines recognized standards.

Common gateway interface (CGI) A program run on a Web Server, usually at the request of a client (browser).

Class A template that defines code and data to perform a particular task; a data type.

Client An application that connects to a server to use a service, such as sending or receiving e-mails, or displaying Web pages.

Compiler A program that converts a source file into computer instructions.

Executable program A program that may be executed directly by a computer.

Inheritance The ability to create a new class from a preexisting class and inherit its functionality.

Instruction set The instructions or directives that a particular computer can execute.

Interpreted language A programming language whose programs rely on a running application to be parsed and processed to execute; PERL and PHP are examples of interpreted languages.

Linker A program that joins compiled program modules into an executable file.

Server An application that waits for client programs to connect and provides them with a service, such as sending or receiving e-mails or sending Web pages to a browser client.

Socket A method by which two programs can exchange data on either the same or different computers; Client and server programs typically communicate with each other using a socket.

Source file A text file that contains program execution statements, as keyboarded by a programmer.

Standard template library (STL) A set of functions and classes in ANSI Standard C++ that provides various functionality.

UNIX An operating system developed by Bell Labs.

Circuit, Message, and Packet Switching

Robert H. Greenfield, *Computer Consulting*

INTRODUCTION

Circuit, message, and packet switching are techniques for transferring information. These concepts are not unique to electronic networking. They have common, everyday models and historical prototypes. A common example of circuit switching is a voice telephone conversation between two people. Message switching is seen every day in the postal, paper-based mail system. Visualizing packet switching takes more imagination. Let's move a complete business—staff, furniture, files, business machines, and whatever—from its old location to a new building. We assume that the business is sufficiently large that it needs several autos and buses to move the people and a number of trucks to move the nonhuman assets. All these vehicles, each containing a portion of the company, move over a system of roads. Together, as an aggregate, the company is the sum of the payloads of all the vehicles.

We can take this "company-moving" example a little further to illustrate datagrams and virtual circuits. If we allow all the cars, trucks, and buses to select their own routes from the source to the destination, we have a datagram example. Each vehicle arrives on its own schedule. However, if we dictate a specific route, mandate a convoy, or a parade, by assigning a placard (A, B, C, etc.) to each vehicle, and require the vehicles to stay in sequence behind their predecessor, we illustrate a virtual circuit. Note that pedestrians in crosswalks, red lights, and cross traffic can interrupt and delay portions of the convoy. However, all vehicles arrive at the destination in their scheduled sequence, albeit with varying delays.

We use the terms "switching" or "routing" because the circuits, messages, and/or packets traverse a mesh of links and nodes. Links connect nodes. Nodes are also called switches. We route or switch the entities from one node to another, using the links, from the source, ultimately to the destination. The entire mass of links and nodes is a point-to-point network. Typically, wide area networks (WANs) are point-to-point networks. Another kind of network is a broadcast network. Local area networks (LANs) are typically broadcast packet networks.

In Figure 1, several nodes are shown with links connecting them. Not all nodes are directly connected to every other node. There may or may not be any loops in the network. Some nodes may be connected to only one other node. However, there are sufficient links so that, directly or indirectly, all nodes are connected to each other and form one complete network.

In Figure 2, several nodes are shown. All nodes are contained within a cloud and share a common medium or ether. A pretty, puffy cloud artistically depicts the network's edges. What is important is that each node is inside the cloud. Each node can, via the common medium, communicate directly with every other node. There is no privacy. Everyone can listen to everything.

Layering allows us to look at only a portion of the communications process at any one time. This simplifies our examination of something very complex. For example, on the data link, MAC (medium access control), and/or network layers, we may use an assortment of protocols, one on each layer or sublayer, as appropriate to the specific network. On the internet layer, we use IP (Internet protocol), a datagram protocol. On the transport layer, we use TCP (transport control protocol), a virtual circuit protocol. On the application layer, we employ SMTP (simple mail transport protocol), a message-switching technique, to ultimately transport our electronic mail messages.

Just as a real network is constructed using several different layers, each layer has its own set of addresses (e.g., hardware addresses, IP addresses, and port addresses) to specify the location of devices and services. In the case of the Internet, addresses don't always neatly map into layers.

We start by looking at the OSI and the TCP/IP models because communications networks are built in layers. For a better foundation, we also quickly look at broadcast networks, frame relay, ATM, and addressing, especially those kinds of addresses used on the Internet. Next, we look at circuit switching, briefly at message switching, and finally at packet switching in more detail.

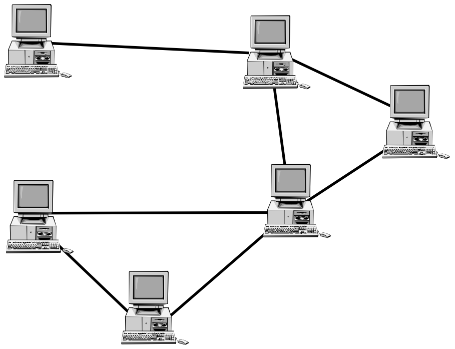

Figure 1: A point-to-point network.

CIRCUIT, MESSAGE, AND PACKET SWITCHING

Before tackling the prime topic of packet switching, it is worthwhile to discuss circuit and message switching. This provides a context for better understanding why packets were invented and remain useful.

OSI, TCP/IP, AND OTHER LAYERING MODELS

We build and discuss networks using layers, just as houses are built on foundations, usually resting on earth. A house's frame rests on the foundation, the interior and exterior walls hang on the frame, and the roof sits on top. Table 1 outlines the OSI reference model and shows a comparison to several versions of the TCP/IP model. Several TCP/IP model versions exist because it is an informal, loosely defined structure.

OSI Reference Model

The ubiquitous layering model is the seven-layer OSI reference model: physical, data link, network, transport, session, presentation, and application. This reference model, with its strictly separated and well-defined layers, was created to be a de jure blueprint for constructing point-to-point networks. However, the folks building systems that use this plan did not prevail and the TCP/IP Internet, built on its own plans, won the popularity contest. Today, the OSI reference model is used for its great pedagogic value. The realities of the world and expediency motivate us to depart from the OSI model for the construction of real networks.

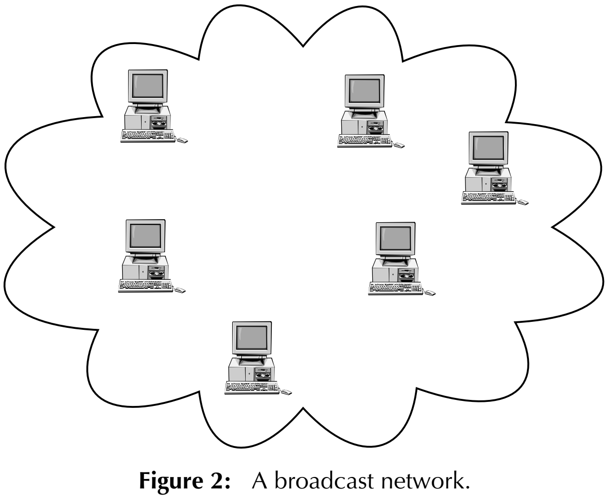

Figure 2: A broadcast network.

The OSI reference model was constructed with only point-to-point, homogeneous networks (wide area networks) in mind. It ignores the concept of a broadcast network and the idea of an internet (i.e., a network of networks constructed on top of networks). Because the OSI model is so specific and limited, we need to be especially careful when we discuss topics beyond its scope.

TCP/IP Model

The TCP/IP model is informal and is presented by different folks as a five- to three-layer model, including application, transport, and internet layers, with sometimes a data link layer and sometimes a physical layer (see Table 1). The Internet (an internet) has no network layer because it is a network, an internet, built on top of other (likely heterogenous) networks. The supporting networks might or might not have their own network layer. One supporting network could be a point-to-point WAN that likely has a network layer. Another supporting network could be a LAN, without a strictly defined network layer because it is a broadcast network (e.g., an ethernet).

The documents defining the Internet, the RFCs, standardize all sorts of things. They define techniques and protocols for the application, transport, and internet layers, and also some standards tying the internet layer to the layer supporting it (e.g., an ethernet). The definition of an ethernet is not made in the RFCs (requests for comments) but is specified elsewhere.

This chapter discusses the data link, network, internet, transport, and, briefly, application layers. The physical layer is of no interest to us here. In today's world, the presentation layer as its own entity is pretty much ignored. The session layer is almost always considered a part of the transport layer. This leaves us the data link, network, transport, and application layers from the original OSI reference model and the internet layer from the TCP/IP model to examine for circuit-, message-, and packet-switching techniques.

We examine the different layers before we get into the topics of circuit, message, and packet switching, because we most likely employ different kinds of switching on the different layers that build our network.

Broadcast Model

The OSI reference model was constructed with point-to-point (WANs) in mind. It ignores broadcast networks, which are not constructed with links joining nodes (Figure 1), but by a set of nodes all sharing the same medium (Figure 2). The OSI model can be made suitable for broadcast networks by splitting the data link layer into two sublayers, the MAC and the LLC (logical link control).

MAC sublayer protocols determine how a node or station gains access to the broadcast medium needed to transmit packets into the network. LLC sublayer protocols define a language that stations can use to decode the packets. It also provides a common layer, or glue, for

Table 1 The OSI Reference Model and Versions of the TCP/IP Model

OSI Layer	TCP/IP 5-layer	TCP/IP 4-layer A	TCP/IP 4-layer B	TCP/IP 3-layer
Application	Application	Application	Application	Application
Presentation				
Session	Transport			Transport
Transport		Transport	Transport	
	Internet	Internet	Internet	Internet
Network	Network access	Supporting networks		
Data link			Supporting networks	
Physical	Physical			

interfacing to upper layers. The LLC protocol defined by IEEE 802.2 defines a common protocol used by several different MAC schemes, such as Ethernet (IEEE 802.3), token ring (IEEE 802.5), and wireless (IEEE 802.11). There are many IEEE 802 standards. Some (e.g., 802.11) are today very rapidly evolving. A more detailed discussion is beyond the scope of this chapter.

Broadcast networks can do some things more easily than point-to-point networks can. One of these is to "broadcast" to all stations on the network. A special address designated as addressing all stations can exist. Packets with this destination address are copied by all stations in the network because all share the same medium, the same environment. In a point-to-point network, pains are taken to ensure that such broadcast packets are routed and repeated to all stations. This involves having many copies of the packet in the point-to-point network compared with needing only one in the broadcast network.

Multicasting extends the idea of broadcasting. Groups of stations are designated as sharers of a multicast address. Many such groups and many such addresses can be created. Packets sent to a multicast address are copied by all stations. Those stations recognizing the address as significant should copy the information. Other stations should ignore the message.

Packets directed to a designated destination are read by all stations. The addressed station acts on the information while other stations are expected to ignore it. Note the words "expected to ignore it." It is easy to spy and to copy everything. This is one of the motivations for using encryption on the higher layers: to keep private information private.

Frame Relay Model

Frame relay is an evolution of the X.25 networks developed using the OSI reference model. Changes in the world include the development of extensive digital switching and transmission equipment replacing older analog gear. Digital electronic switches replaced mechanical and analog electronic switches. Optical fibers replaced metallic cables. Speeds increased and errors decreased, both very significantly. The OSI reference model works by having data link frames (employing flow and error control) carrying network-layer packets (employing flow and error control), which, in turn, carry transport-/session-layer packets (employing flow and error control). Each layer has significant control overhead.

However, with digital circuits and optical cables, much faster transmission and many fewer errors exist. Why is all this repeated control work performed at each layer? Can we do it quickly enough using software computations? The frame relay solution is to collapse the data link and the network layers together and to just "switch" or "relay" the "frames" from link to link. This switching is done using hardware, not software, logic. It is performed quickly. Errors are so rare that the easiest solution to detecting an error is to discard whatever is wrong. The users (i.e., higher layer protocols such as TCP/IP) can retry when the omission is noticed.

What have we done? We've eliminated layers by merging them together. Also, we've replaced expensive, slow, software-based logic with cheaper, faster, hardware circuits.

ATM Model

If frame relay is an evolution, ATM is a revolution. In addition to the steps taken in evolving a traditional OSI-reference-model-based scheme into frame relay, we chop our data into very small, fixed-size cells (53 octets). There are two reasons for this. Hardware can manipulate the small, fixed-sized cells more easily (i.e., more quickly) than it can switch larger, varying-size frames (in the order of hundreds or thousands of octets).

Another reason for a small frame is that the transfer of CBR (constant bit rate, e.g., voice, video) traffic, in addition to bursty computer data, becomes feasible. CBR traffic is intolerant of delays that vary. Or rather it is more correct to say that it is we, human users, who are intolerant of varying delays. If a large frame of bursty computer data arrives at the switch just before a CBR frame does, the CBR data are delayed. If a small computer data cell arrives before an equally small CBR cell, there is little variability in the flow of the CBR traffic.

Table 2 lists the ATM AAL CS and the ATM AAL SAR. The AAL is the ATM adaptation layer or the application adaptation layer. It is the glue between the application and the ATM layers. The CS is the convergence sublayer. The SAR is the segmentation and reassembly sublayer

Table 2 Broadcast, Frame Relay, and ATM Models Compared to the OSI Reference Model

OSI Layer	Broadcast Model	Frame Relay	ATM
Network	DLC	Frame relay	ATM AAL CS
Data link			ATM AAL SAR
	MAC		ATM
Physical	Physical	Physical	Physical

(of the AAL layer). These two sublayers provide the glue to the layers above and below. A more complete description of ATM is beyond our scope. The ATM model changes the way data are switched on the lowest levels and provides standards to mate the ATM protocols with both CBR and computer data that utilize ATM.

TCP/IP and Other Addresses

A brief discussion of addresses gets dragged into our chapter for the purpose of clarifying where addresses fit into the scheme of packet switching. We restrict ourselves to brief peeks at Ethernet addresses, an example of hardware addresses, and IP addresses and port numbers because they are so pervasive. If we were to extend our discussion to AX.25, X.25, frame relay, ATM, or myriad other networks, we would have many other addressing schemes to examine. Even this limited discussion leaves many topics untouched.

First, let's not talk about DNS (domain naming system) addresses. An example of such a name is "gpfn.sk.ca." These mnemonic names are great for people to recognize and remember. They are not at all like the 32-bit IP addresses that they represent. IP addresses are hard to remember and to write—for human beings! IP addresses are great—for computers! The DNS is a very important scheme implemented by sophisticated Internet applications running on many computers. Additionally significant, the DNS allows us to easily change IP addresses and maintain permanence by retaining the DNS name. The computers are told about the new association and soon the change is complete.

Additionally, we will not discuss e-mail addresses, such as rhg@gpfn.sk.ca, which are composed from a character string, an @ sign, and a DNS name. Likewise, we will not discuss Web addresses (e.g., http://www.gpfn.sk.ca:80/%7Erhg/), which commonly specify a DNS name (sometimes an IP address instead), sometimes a port number, and commonly a file path designating a specific file on the computer.

Port addresses in the Internet model are 16-bit numbers that allow communications to a specific process on a host. The host is specified using an IP address (or more commonly a DNS name that is translated into an IP address). Applications bind themselves to specific ports when they want to request service in the case of client software, or when they wish to provide service in the case of server programs. (Some "well-known" ports have mnemonic names, e.g., ftp [port 21], http [port 80], smtp [port 23], on some computer systems.) The port addresses provide a glue between the Internet transport layer and application processes on the hosts.

Internet or IP addresses are 32-bit (IP version IV) numbers used to specify each host. A host can have several IP addresses, but no host can honestly exist without at least one unique IP address. IP addresses are commonly written using dotted decimal format, four decimal numbers in the range 0–255, separated with periods (e.g., 198.169.198.4). This IP address today belongs to "neale.gpfn.sk.ca," to "gpfn.sk.ca," and to "gpfn.ca." Tomorrow, the associations between the DNS names and the IP addresses may be completely different. Each device, host, computer, router, and switch on an internet has one or more IP addresses. These addresses are also used to route IP datagrams from source to destination.

00:05:02:d6:eb:7e, a 48-bit Ethernet address, written using 12 hexadecimal digits, is an example of a hardware address. This number is manufactured into each interface card. A computer has a unique Ethernet address for each interface card. Associations between IP addresses and Ethernet addresses are performed by Internet protocols that most of us, fortunately, never see. I say fortunately because usually, whenever we are interested in hardware addresses, it's because there is a problem to solve.

CIRCUIT SWITCHING

Circuit switching is easy to understand because its most common example, the voice telephone call, is so pervasive. Each call consists of three phases, establishment or setup, data transfer, the voice conversation, and termination. Establishment allocates resources to make a telephone call possible. Is the other telephone available? The called telephone could already be busy, or perhaps the line is cut or is otherwise unavailable. Is the desired person available? Are there sufficient resources within the telephone network to construct a route, or circuit, from the caller to the called station? Perhaps a natural disaster, such as a tornado or other usual weather, has caused many, many other folks to attempt phone calls, leaving the switches and trunks (the links between the switches) devoid of capacity because they are fully used by others.

The data transfer phase (i.e., the actual conversation) is the reason for making the call. The conversation usually has its own (application layer) protocol. Both folks say hello, engage in some kind of chitchat, and eventually say goodbye. The phones are replaced on their hooks. Bills may be prepared and the electronic facilities, switches, links, and so forth, are freed for other calls.

Phone calls are usually metered and billed by measuring their duration in time and sometimes the distance between the stations. The number of phonemes, words, sentences, and paragraphs transferred is not measured. Long periods of silence (i.e., no information transfer) is handled in the same way as intensive information transfer.

We can use the same voice telephone calls to transfer *computer data* (whatever that is) instead of analog voice information by using *modems*. The basic paradigm remains: establishment, data transfer, circuit termination, breakdown, and the dedication of facilities by time duration, not information transfer.

One special case needs mentioning, the "hot" or private line. Two (or sometimes more) telephones are permanently connected to each other. Facilities are always available to transfer information between the two locations. Costs for this kind of service are usually based on time (all the time) and on distance.

Why did we add the parenthetical comment "whatever that is" when talking about the transfer of computer data using "voice," analog telephone lines?

Today, telephone transmission and switching is almost universally digital, except in older facilities.

Our voice conversations are digitized, transferred, and switched as digital signals and then converted back to analog voice in time to deliver to the receiving party. Broadcast television is now (circa 2002) making the conversion to digital transmission. Broadcast radio is also slowly making this same transition.

MESSAGE SWITCHING

The great model for message switching is the paper-based postal system, which delivers cards, letters, and packages (which can contain files, books, and even electronic media). At any selected time, the information is in one location, in a carrier's vehicle or bag (moving or not), or in one of the postal stations (being sorted, waiting to be sorted, or waiting to be loaded into a vehicle for transportation). The application layer SMTP (simple mail transport protocol, e-mail) is an example of old electronic message switching that survives into the present.

Let's look at how mail delivery using SMTP works. In addition to the two folks sending and receiving the e-mail message, there are (at least) two kinds of software involved. Typically the sender employs a UA (user agent) program to compose and address the message and typically sends the message to a sender's local MTA (mail transfer agent) using SMTP. The MTA accepts the message from the UA and promises to try to deliver the message to its recipient. Usually the MTA searches for another MTA, on a distant host, willing to accept the message for the recipient. The two MTAs try to create a connection and negotiate message delivery using SMTP. This can fail for a number of reasons. The sending MTA, which still holds the message, either looks for an alternate, intermediate MTA willing to accept the message or holds onto it and tries again at a later time. The MTA holding the message is responsible for it until it is passed on to another MTA or until it returns it to the sender as being undeliverable. If the MTA passes a message on to another MTA, its responsibility for the message ends. Final delivery to the recipient's UA is done not by SMTP but by other techniques (including POP and IMAP, other e-mail protocols). This is why we added the parenthetical "at least" at the start of this paragraph.

What's important here? The message travels as a complete unit. At any one time, it exists completely in one place. Of course, we are only speaking about the application layer. What happens on the other layers is an entirely different tale!

Table 3 lists possible protocols used on each layer to transfer an e-mail message using SMTP, using TCP/IP, over a telephone connection. This same TCP/IP connection at another physical location might be supported by, say, an Ethernet LAN, because the Internet sits on top of heterogenous networks.

Table 3 Example of Different Techniques Used on Different Layers

Layer	Technique
Application	SMTP, message switching
Transport	TCP, virtual circuit
Internet	IP, datagram
Data link	PPP, virtual circuit Digitization of the analog signal within the telephone plant Modulation of an analog signal using digital data
Physical	Modem, telephone circuits, circuit switching

The application layer FTP (file transfer protocol) might be thought of as message switching because the entire file travels as a unit. However, FTP is not a good example because it is more involved with copying files than with moving them from one place to another. Also, only one FTP server is involved. In SMTP, one, two, three, or more MTAs are involved in message delivery.

The Bitnet, in the 1970s and into the 1980s, formed a worldwide network of (originally IBM) mainframes that transferred files from site to site. (An e-mail message can be regarded as a file.)

PACKET SWITCHING

We looked at circuit switching and at message switching. Why do we need to invent something new? One word: efficiency. Look at the model of the voice telephone conversation. It is always "on." Signals are always being transmitted even when both parties to the conversation are silent. What if we could reclaim those silent periods and insert other folks' conversations into the silence? With packet switching we do just that.

Think about phone conversations. There really are few silent periods. Humans insert some kind of noise (varying with the spoken human language used) to provide an indication to the other party that they are still there, still listening, and still (pretending to be) interested. Music, voice, and video information are traditionally known as CBR (constant bit rate) traffic because the smooth timing of delivery is very important to human recipients.

Think about computer online interactions, such as reading e-mail from a server using IMAP (or POP), obtaining files using FTP, or browsing the Web. A user creates a connection (without going into more detail about this) to the Internet. Using IMAP, the UA asks the mail server about received messages and gets a list. While the user stares at this list, what is happening on the computer link? Usually nothing. A particularly interesting message catches the user's eye and he asks to read it. Now the message is copied in a burst from the server to the UA and can be examined. Typically nothing happens while the recipient peruses the message, which may contain a huge

Table 4 Advantages and Disadvantages of Circuit-Switched and Packet-Switched Networks

Circuit-Switched Network	Packet-Switched Network
+ Dedicated, unshared	+ Shared
+ Constant delays	– Varying delays
+ No packet overhead	– Packet overhead

attachment. The reader decides that he wants the attachment, and then, all of a sudden, a long burst of line activity occurs to bring the attachment from the server to the client.

The previous paragraph demonstrates the bursty nature of computer communications: long periods lacking information transfer with more or less shorter or longer bursts of high-speed transfer. We want a fast link because we don't want to wait for information. However, most of the time, the (fast, expensive) line is idle because we are not using it. Packet switching was invented to cost effectively share the fast, expensive, high-speed lines with many users. In other words, packets provide something called *multiplexing*.

So what do we do? We chop our messages into units, cells, frames, packets, segments, and PDUs (protocol data units). All these words are pretty much interchangeable in general usage. Mostly our packets are of varying size (for several reasons). There are often minimum and maximum sizes (i.e., the packet is not allowed to be too small or too big). Sometimes packets are of fixed size (e.g., ATM [asynchronous transfer mode] cells are a small, fixed-size 53 octets). ATM is also called cell relay. (See Table 4.)

Datagram Networks

One thing we can do is chop our data into datagrams and spew them independently into the network. We must give each datagram two addresses: a destination address and a source address. Wherever the datagram roams in the network, the destination and the source are known because they are self-contained within the datagram. What are the advantages and the disadvantages of this scheme? On the minus side, each datagram is bigger because it contains two addresses. Also, frequently a *hop count* (or time-to-live) field is contained within the "overhead" of the datagram. The hop count is usually a positive number, which is decremented whenever a node sends the datagram onto a link toward another node. When the count is decremented to zero, the datagram is discarded. Here are two more disadvantages: Each datagram must find its own way through the network. The experience of previous datagrams (e.g., how they found a good route) is ignored. It is also possible for a datagram to wander about, to never reach its destination, and to be destroyed.

The advantages of datagrams are basically simplicity and robustness. We never perform the steps of establishing a circuit (or route) through the network. Likewise, because a circuit is never established, there is no circuit to break down and facilities to allocate. Datagrams are robust because each finds its own path through the network. If the network changes (e.g., nodes and/or links are destroyed, removed, or shut off), there is no effect on the datagrams other than it might take them longer to make the trip—as long as there is at least one possible route through the network from the source to the destination. (See Table 5.)

The IP (internet protocol) of the internet layer of the Internet employs datagrams. This makes it robust. One of its original design specifications in the late 1960s, by the U.S. Department of Defense, is nuclear survivability. Although the Internet has not been tested against a nuclear attack, destroying portions of the network, all sorts of other things have been tossed against it. It keeps on working. Recall that the internet layer is the layer that connects, sits on top of, the constituent networks. Resting on top of the internet layer is the transport layer. There are two Internet protocols on the transport layer, UDP (user datagram protocol), a datagram protocol, and TCP (transport connection protocol), a connection-oriented protocol.

Datagrams provide simplicity by avoiding the creation of a circuit. Often, we simply only want to send a small amount of information from the sender to the recipient and perhaps receive a reply. We gain by omitting the overhead of circuit establishment, maintenance, and breakdown for only a very short exchange. If we really do want a reply, when we don't get one, we just retry the whole exchange de novo.

Domain name service (DNS), the very important application that translates domain name addresses, such as gpfn.sk.ca, into IP addresses, such as 198.169,198.4, is performed using UDP/IP (i.e., datagrams on both the transport and the internet layers).

Note another characteristic of datagrams: If source A sends out a bunch of datagrams a, b, and c to destination B, there is no guarantee that any or all of the datagrams will arrive at their destination. Furthermore, we have no guarantee as to the sequence in which a, b, and/or c will arrive. This is like the Kentucky Derby. If the horses leave the starting gate at approximately the same time, we have no knowledge of the sequence in which they will arrive at the finish line. In fact, with a small probability, one or more of the horses may never cross the finish line. Sometimes this characteristic is just nice to know and is of no real consequence. At other times, it is a real concern and causes us to look toward connection-oriented services instead.

We see that datagrams have advantages and also disadvantages. There are times when it is better to use a connection-oriented protocol.

Table 5 Advantages and Disadvantages of Datagram and Virtual Circuit Networks

Datagram Network	Virtual Circuit Network
+ Efficient for short exchanges	+ Efficient for long transfers
+ Simple	– Circuit establishment and breakdown overhead
+ Robust	+ Sequenced delivery
−larger packets	+ Smaller packets

Table 6 Comparison of Datagram and Virtual Circuit Networks

Datagram Network	Virtual Circuit Network
Transfer data	Establish circuit Transfer data Breakdown circuit

Virtual Circuit Networks

TCP is the connection-oriented protocol on the Internet-transport layer, resting upon the (datagram) internet layer. Just as in circuit switching, we establish a circuit (calling it a virtual circuit), we transfer data through the circuit, back and forth, and then we disassemble the circuit and return the resources for reuse. (See Table 6.)

We do the work of allocating, maintaining, and disassembling resources with the expectation that the use we make of the virtual circuit will be sufficient to pay us back for our effort. What kind of payback can we expect? Because we have constructed a tube, like a garden hose, through the network, when the source sends segments (i.e., packets *a*, *b*, and *c*) into the pipe, we can expect them to arrive in order (i.e., *a* first, *b* second, and *c* third) at the destination. This guaranteed sequencing is an important property. These packets can also be smaller than datagrams because we no longer need the complete source and destination addresses in each packet. The virtual circuit that we initially constructed holds this information. We are saving something in the overhead in each individual packet. Each packet still needs identification, something that says which virtual circuit it belongs to and what its sequence is in the parade, in case it is destroyed in transit.

Packets in a virtual circuit scheme usually employ sequence numbers of some kind because they are part of a parade, with each packet having its own place. Packets are often numbered using three bits, 0, 1, 2, 3, 4, 5, 6; seven bits, 0, 1, 2, . . . , 125, 126; or even larger sequences, such as the 16-bit TCP sequence numbers. These sequence numbers are more overhead but are needed to identify damaged or missing packets that the receiver asks for again using a *negative* acknowledgement. The sequence numbers are also used for flow control, to moderate or slow the sender when the network and/or the receiver cannot handle the packets as quickly as they are being sent.

Virtual connections are useful in many situations (e.g., interactive telnet sessions allowing a user with a telnet client to log onto a remote computer, mail transfer using SMTP, delivery of Web content via HTTP [hypertext transfer protocol], and FTP, file transfers, are just a few examples of a small number of well-known services).

In telnet, HTTP, and SMTP, a client program opens a TCP/IP connection to a server and an application protocol (e.g., telnet, HTTP, SMTP) starts a structured conversation with the server using the “pipe.” For example, in HTTP, a browser opens a connection to a remote server and says, here is what kind of browser I am, send me this page. The server accepts the connection, parses the request, and sends the Web document (or perhaps an error) back, then closes the connection. This is the original HTTP version. However, a Web page can consist of several Web documents, graphics, frames, and/or client-side executable programs such as Java or JavaScript. The original HTTP requires a new TCP/IP connection for each document, with the overhead of establishing the connection, maintaining it, and breaking it down for each document. The newer HTTP version uses one connection and sends several documents through it, reducing the client–server overhead by using a more complicated application-layer protocol.

Permanent Virtual Circuit Networks

A permanent virtual circuit is just like a virtual circuit except that it is permanent. It is administratively constructed in the network. It is always there, whether or not it is being used. A few packets can be quickly sent down the pipe whenever needed with a minimum of fuss. The Internet does not have permanent virtual circuits. They do exist in X.25, frame relay, and ATM networks.

CONCLUSION

Let’s review what we’ve just seen.

Examples of and analogies to circuit and message switching exist in many everyday events.

Packet switching can also be illustrated with only a little more imagination.

Packet switching was invented to provide multiplexing, providing efficiency in digital networks by taking advantage of its traditionally bursty nature.

ATM was designed to accommodate CBR traffic in addition to traditional bursty computer traffic.

Packet switching can be divided into two techniques: datagrams, which provides simplicity and robustness, and virtual circuits, which offer efficiency in many common situations.

Networks, point-to-point, broadcast, and internets are naturally layered.

Each layer can be constructed using different techniques (e.g., circuit switching, datagrams, virtual circuits, and message switching).

Several different kinds of addresses are employed. Addresses may exist at particular layers or they may form a glue between layers.

Each kind of network has appropriate reference models that help us understand them.

GLOSSARY

Address Something that specifies a location or a unique instance. A person’s name, an apartment number, a house number and street name, and a telephone number are common examples.

Address, hardware An unchangeable address that is built into a device. An Ethernet address, manufactured into a network adapter, is an example. At one time, telephone numbers were hardware addresses, fixed to a specific location, albeit not to a specific telephone instrument. Today, telephone numbers are (within geographic limits) portable, not fixed.

Address, IP The Internet protocol address (version IV) is a 32-bit number assigned to a host computer on the Internet. (A host can have more than one address.) The address is used to specify a particular machine. An example is 198.169.198.4, using dotted decimal notation. Four decimal numbers, 0–255, written with dots separating them, is commonly used to write an IP address. IP addresses are used in selecting routes through the Internet from a source to a destination.

Address, port A 16-bit number. Each IP address has two complete pools of these numbers, one for TCP and one for UDP. Thus, at any one time, each IP address can sustain 4096 TCP connections and 4096 UDP transactions. The port addresses connect specific application instances, or processes, to the Internet. Each set of two IP addresses and two port addresses, at any specific time, are completely unique and specify one TCP connection.

Asynchronous transfer mode (ATM) A fast, modern networking scheme. Also called cell relay.

Bandwidth The range of frequencies, from lowest to highest, required to convey a signal. The frequency capacity of a channel. The capacity of a communications link (e.g., twisted pair, coaxial cable, optical fiber, etc.). Bandwidth is measured in units of Hertz. Increased bandwidth is strongly associated with increased data rate (measured in bits/second) and with increased signal rate (measured in Baud).

Baseband A communications link that has all of its bandwidth devoted to one communication. The link is not shared. All frequencies from the minimum (perhaps including direct current, which has a frequency of 0 Hz) to the maximum are devoted to one communication. Digital signals are often "baseband" in nature. An example is any kind of Ethernet (there are several kinds) with the notation "base" contained it its name. A more extensive definition is beyond the scope of this chapter.

Broadband A communications link that has its bandwidth shared between several communications, each having a specific frequency band. The link is shared. Frequencies from the lowest supported to the maximum are divided into bands. Analog signals can be broadband in nature. An example is television, both cable and broadcast. There is a (rarely used) version of Ethernet for cable TV with the notation "broad" contained it its name. A more extensive definition is beyond the scope of this chapter. Another, modern, use for this term is to specify fast communications. An explanation of how this usage evolved is beyond our scope.

Cell A packet, usually on one of the lower layers (e.g., data link) of the OSI reference model. Most often a cell is a small, fixed-size packet (e.g., an ATM cell).

Cell relay See ATM.

Circuit A route or path through a network. A circuit can exist in a circuit switching network or in a packet switching network. We habitually choose slightly different, and more specific, terms, such as virtual circuit or route, depending on what kind of network we are discussing.

Circuit switching The technique of establishing a route through a network that completely dedicates facilities of the links used to create the circuit entirely for one connection. The capacity of the circuit can be completely used, completely unused, or anything between. The circuit is dedicated (e.g., a telephone call).

Connected See Virtual Circuit.

Datagram An unconnected UDP packet on the transport layer of the TCP/IP model. An unconnected IP packet on the internet layer of the TCP/IP model. A generic term for a packet that travels through a network independently, from source to destination.

Frame A packet, usually on one of the lower layers (e.g., data link) of the OSI reference model. A generic term for a packet.

Frame relay A modern networking scheme.

Hardware address See Address, hardware.

Internet The worldwide network of networks employing TCP/IP. The underlying foundation networks are not homogeneous. Note the upper case "I."

internet A network of networks usually employing TCP/IP. The underlying foundation networks need not be homogeneous. Note the lower case "i."

IP Address See address, IP.

Intranet See internet.

LAN (local area network) A network in a limited geography (i.e., a room, a building, or a campus). Usually LANs are broadcast networks.

Layer Computer code, hardware, protocols (i.e., rules) that constitute an entity designed to perform a specific job. The layer is supported by lower level layers. In turn, it supports higher level layers. Ideally (OSI reference model), a layer is totally independent of its higher and lower neighbors (i.e., the layer can be entirely replaced without its peers being aware of the swap). Realistically (TCP/IP model), this is not true. TCP and UDP are useless without IP supporting it. IP has little use without TCP or UDP above it.

Layer, application The highest layer, associated with human beings and application programs.

Layer, data link The layer immediately above the physical layer, concerned with communications on links between nodes (hosts, routers, switches) of a network. This layer exists only between two nodes.

Layer, Internet The layer above supporting networks that creates a uniform internet on top of (likely heterogenous) networks. This is the IP layer.

Layer, network The layer above the data link layer. It encompasses the entire network.

Layer, physical The lowest layer, consisting of hardware and its mechanical, electrical, functional, and procedural specifications.

Layer, transport The layer above the network, or the internetwork layer, depending on context, concerned with the end-to-end delivery of packets. (UDP datagrams and TCP segments for an internet.)

MAN See metropolitan area network.

Message A complete entity. Examples include the contents of a book between its covers, the contents of an envelope in the paper-based postal system, a computer file, an e-mail (message).

Message switching The transport of a message through a network as a complete unit. The message is not broken into smaller units (i.e., packets; e.g., a letter in the postal system). The Bitnet operated as a message switching system.

Metropolitan area network (MAN) A network typically covering an area the size of a metropolis. The common example of a point-to-point MAN is the local cable TV distribution system. An example of a broadcast MAN is an FM transmitter sending information to the city. MANs are typically constructed as point-to-point networks but can be broadcast networks.

Multiplexing Various techniques for transparently sharing a transmission resource among disparate users. These include frequency and time division multiplexing for electronic signals and wave division multiplexing (WDM) for optical signals. Using packets is a form of multiplexing.

Network, broadcast A network employing a common medium or "ether." It consists of nodes and a medium accessible to all the nodes. An example is all CB radio operators tuned to a particular channel in a restricted geographic area.

Network, datagram A network organization that has packets traveling as independent units (i.e., uses datagrams). There are no circuits or connections.

Network, point-to-point A collection of nodes or switches, connected with links. The telephone system is a good example.

Network, unconnected See Network, datagram.

Network, virtual circuit A network organization that has the packets in a "connection" follow an established path through the network, in sequence, one after another.

Octet A grouping or unit of eight bits. Communications folks prefer this more specific term over the less specific "byte."

OSI reference model A seven-layer (physical, data link, network, transport, session, presentation, application) pedagogic model for networks. It is a old model that represents no modern network, but it is very useful in categorization.

Packet A "bunch" of data, usually with delimiting headers and trailers, typically tens to tens of thousands of octets, transmitted as a unit.

Packet switching The technique of breaking information into discrete "packets" and routing them through a network. The routing of the individual packets can be unconnected or connected.

Port address See address, port.

RFC, Request for Comments A constantly enlarging group of documents defining the Internet and its protocols. There are approximately 3,400 (circa August 2002) documents (http://www.ietf.org/rfc.html, retrieved August 2002).

Route See Circuit.

Routing The process of discovering and constructing a path, circuit, or route through the network from the source to the destination.

Segment A connected, TCP packet on the transport layer of the TCP/IP model.

TCP/IP model A three-layer (internet, transport, application) model for the Internet. This model sits on top of a foundation provided by other networks or LANs. Because there is no "true" standard for this model, it is variously a three-, four-, or five-layer model, which includes one or more lower layers upon which the TCP/IP layers rest.

WAN (wide area network) A network covering a large region. Usually larger than a metropolitan area. Typically it is a point-to-point network.

Click-and-Brick Electronic Commerce

Charles Steinfield, *Michigan State University*

INTRODUCTION

Despite the early fascination with dot-com companies, there is a growing recognition that the Internet is unlikely to displace traditional channels anytime soon, at least in the world of business-to-consumer (B2C) commerce. Rather, many traditional enterprises have moved to integrate e-commerce into their channel mix, using the Internet to supplement existing brick-and-mortar retail channels (Steinfield, Bouwman, & Adelaar, 2002). Electronic commerce researchers now consider the combination of physical and Web channels to be a distinct electronic commerce business model, most commonly referring to it as a "click-and-brick" or "click-and-mortar" approach (Timmer, 1998).

In this chapter, a broad overview of the click-and-brick approach to e-commerce is provided. The focus is on the use of the click-and-brick approach by firms selling consumer products and services via a combination of physical and Internet retail channels, given the relative prevalence of this situation in the e-commerce arena. Much of the discussion is also relevant to other types of companies that rely on both Internet and physical channels, such as those involved in education and health care. In the first section, a brief look at the current e-commerce situation highlights the overall importance of taking an integrated brick-and-click approach to e-commerce development. In the second section, a detailed examination of the sources of synergy between traditional and Internet-based channels is provided. The third section introduces the dangers of product and channel conflict and points out possible management strategies to improve channel integration. The fourth section highlights the potential benefits that firms may reap when pursuing a more integrated approach to e-commerce. Section five introduces four brief cases that give concrete examples of click-and-brick strategies. Section six discusses several critical factors that may inhibit firms' attempts to more tightly integrate physical and Internet sales channels. Finally, the chapter closes with several conclusions regarding the importance of the click-and-brick approach in electronic commerce research and practice.

CLICK-AND-BRICK E-COMMERCE OVERVIEW

Many types of companies can be considered click-and-brick firms, including retailers of tangible products, sellers of financial and other services, health care providers, and educational organizations extending learning services via the Internet. Even nonprofit organizations have employed a click-and-brick approach as they seek new ways of reaching and extending service to their constituents. Essentially, all click-and-brick firms have both Internet and physical outlets and seek synergies between them to reduce costs, differentiate products and services, and find new sources of revenue. In the B2C area, electronic commerce can be considered a marketing channel, which can be defined as a means to interact with end consumers. Many firms rely on a mix of different channels such as physical stores, catalog sales, and e-commerce. Firms pursuing channel integration attempt to tightly coordinate the use of channels, even within a single sales activity, to improve their profitability (Friedman & Furey, 1999). It is therefore helpful to distinguish the truly integrated click-and-brick approaches from those that treat electronic commerce more as a separate and parallel channel. The difference is illustrated in Figure 1. In the parallel case, customers are not able to move easily between electronic commerce and traditional channels. For example, many firms require that goods ordered online be returned directly to the e-commerce subsidiary, rather than through physical retail outlets.

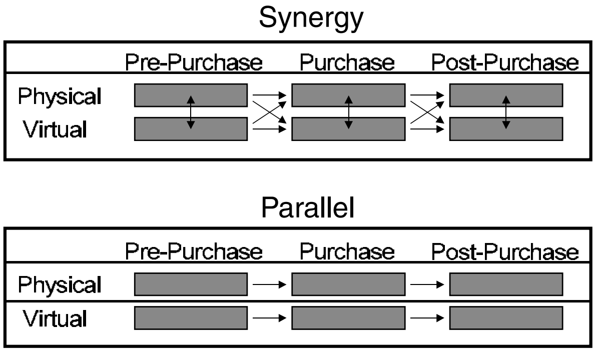

Figure 1: Contrasting synergy with parallel approaches to click-and-brick e-commerce.

In the integrated, or synergy approach, customers are able to move seamlessly between channels as they interact with a firm. For example, a customer may do product research and initiate an order online but pick up the merchandise and obtain after-sales service in a physical outlet.

In the early years of electronic commerce, many in the industry felt that pure Internet firms (the dot-coms) had significant economic advantages over traditional firms. As a result, many traditional firms chose a parallel approach to the Internet in an attempt to avoid saddling e-commerce divisions with the burdens of higher costs and reduced innovativeness that they felt characterized their traditional physical channels. The widespread failure of dot-com firms, however, forced traditional retailers to rethink this approach and seek out synergies. Laudon and Traver (2001) noted that traditional retailers are replacing all but the most established dot-coms (e.g. Amazon) on the lists of top e-commerce sites. The electronic commerce activities of traditional retailers have helped to maintain a steady growth in online sales during the period in which large numbers of dot-com enterprises have failed. The U.S. Commerce Department estimates that the number of people who have purchased a product or engaged in banking online more than doubled between 2000 and 2001, growing from 13.3% of the U.S. population in August 2000 to more than 29% in September 2001 (National Telecommunications and Information Administration [NTIA], 2002). Additionally, the NTIA (2002) reports that more than a third of Americans, and fully two thirds of the Internet users, now use the Internet to obtain product information. Not surprisingly, despite the economic slowdown in 2001 and 2002, this increased e-commerce activity has translated into growing online sales revenue. Fourth quarter 2001 e-commerce sales increased by 13.1% over fourth quarter 2000, reaching more than $10 billion. Total retail sales increased by only 5.3% during the same period. Statistics on online sales in 2002 continue to show year over year growth at a much higher rate than the overall retail sales sector (U.S. Census Bureau, 2002). (Note that this underestimates total consumer-oriented e-commerce activity, because the census does not include online travel, financial services, and ticket agencies in their retail sample.)

SOURCES OF SYNERGY BETWEEN TRADITIONAL AND E-COMMERCE CHANNELS

Click-and-mortar firms have a number of potential sources of synergy not necessarily available to pure Internet firms or traditional firms without an e-commerce channel. Borrowing from classic competitive advantage theory (see Porter, 1985), such sources of synergy include common infrastructures, common operations, common marketing, common customers, and other complementary assets that can be shared between e-commerce and physical outlets (see Figure 2).

Common Infrastructures

E-commerce channels can make use of a variety of existing infrastructures such as logistics or information technology (IT) systems to reduce costs or offer capabilities that would be difficult for dot-com firms to match. An example of the use of a common logistics infrastructure would be when a firm relies on the same warehouses and trucks for handling the distribution of goods for e-commerce activities as it does for delivery to its own retail outlets. Likewise, if a firm has a capable IT infrastructure, including product and customer databases, inventory systems, and a high-speed Internet protocol network with high bandwidth connections to the Internet, the adoption and use of Internet-based commerce can be enhanced. Firms can even use their Internet access to offer e-commerce services to customers who are actually in a store or branch, for example, via kiosks.

Common Operations

Existing retail operations can also be put to good use in support of e-commerce, permitting integrated applications to emerge. For example, an order processing system shared between e-commerce and physical channels may enable improved tracking of customers' movements between channels, in addition to potential cost savings.

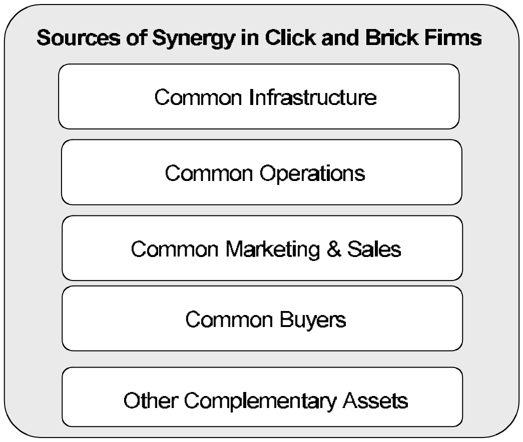

Figure 2: Sources of synergy in an integrated click-and-brick approach. Adapted from Steinfield, Adelaar, & Lai, 2002.

Common Marketing

E-commerce and physical channels may also share common marketing and sales assets, such as a common product catalog, a sales force that understands the products and customer needs and directs potential buyers to each channel, or advertisements and promotions that draw attention to both channels.

Common Buyers

Instead of competing with each other, or pursuing different target markets, e-commerce channels and physical outlets in click-and-mortar firms often target the same potential buyers. This enables a click-and-mortar firm to be able to meet customers' needs for both convenience and immediacy, enhancing customer service and improving retention.

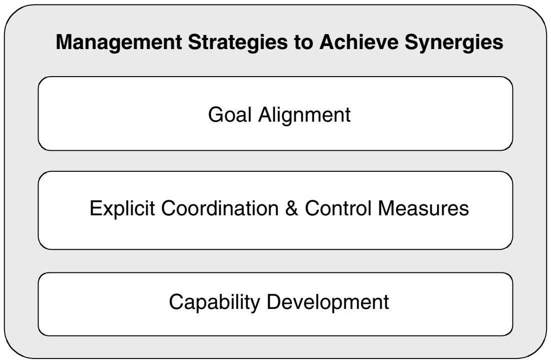
Other Complementary Assets

There are many other types of complementary assets that click and mortar firms possess that purely Internet firms may not. The management literature, for example, notes such additional complementary assets as existing supplier and distributor relationships and experience in the market. As with the other sources of synergy, to the extent firms are able to share these assets across channels, they will be better able them to take advantage of an innovation such as e-commerce (Afuah & Tucci, 2001; Teece, 1986).

Of course, click-and-brick firms also obtain many of the same benefits from the use of the Internet channel as other Internet companies. Certainly the Internet channel affords the possibility for 24-hours-a-day, seven-days-a-week customer access; lower cost access to many new markets; the opportunity to develop and maintain a community of customers; and an efficient communication channel for customer input.

MANAGING CHANNEL CONFLICT IN MULTICHANNEL FIRMS

The integration of e-commerce with existing physical channels is a challenging undertaking that can create problems for management. More specifically, firms with multiple channels may fall prey to channel conflict. Channel conflicts can occur when the alternative means of reaching customers (e.g., a Web-based store) implicitly or explicitly competes with or bypasses existing physical channels and are nothing new to e-commerce (Stern, El-Ansary, & Coughlan, 1996). One danger is that these conflicts result in one channel simply cannibalizing sales from the other. This is particularly a problem when there are clear cost, convenience, or other advantages for customers using e-commerce, causing them to substitute Internet channels for traditional ones. Such cannibalization of sales becomes a strong threat to company viability if it is difficult to capture equivalent revenues online. Media companies such as newspaper companies, although not exactly brick-and-mortar firms in a traditional sense, have experienced such product-channel conflicts. This is exacerbated by customers' unwillingness to pay for online information or entertainment, necessitating free online versions that steal subscriptions from physically distributed media products. Some of the loss is made up by increased advertising revenue from online channels, but it has become increasingly clear that such business models are not sustainable in the current environment (Laudon & Traver, 2001). Additional, and potentially even more damaging, problems for the content industries that sell music and other nonperishable content (i.e., not news) arise from piracy and the massive and unlawful distribution of copyrighted content among Internet users. Clearly, the product-channel conflicts experienced by companies in the content industry represent a significant challenge. The review in this chapter focuses on a narrower definition of click-and-brick firms, however, in which actual click-and-mortar outlets exist to support transactions with customers. Hence, I do not deal directly with issues of copyright and piracy.



Management Strategies to Achieve Synergies
Goal Alignment
Explicit Coordination & Control Measures
Capability Development

Figure 3: Categories of management strategies used to avoid channel conflicts and achieve synergy benefits. Adapted from Steinfield, Adelaar, & Lai, 2002.

Perceived threats caused by competition and conflict across channels can have other harmful effects, including limited cooperation across the channels, confusion when customers attempt to engage in transactions using the two uncoordinated channels, and even sabotage of one channel by the other (Friedman & Furey, 1999). Management must act to diffuse conflicts and ensure the necessary alignment of goals, coordination and control, and development of capabilities to achieve synergy benefits (Figure 3; Steinfield, Bouwman, & Adelaar, 2002).

Goal Alignment

One of the first tasks for managers of click-and-brick firms is to ensure that all employees agree that an e-commerce channel is needed and that they will support it. This represents a process of goal alignment. Aligning goals across physical and virtual channels implies that all employees involved realize that the parent firm benefits from sales originating in either channel. One problem faced by click-and-brick firms is that the contributions made by the Internet channel may be intangible and difficult to measure. Managers have to be open to such intangible benefits and not, for example, evaluate e-commerce divisions purely on the basis of online-only sales and profitability. For example, the improved communication with customers offered by Internet channels may enable firms to better understand customer satisfaction and needs, yielding better products and services and long-run customer retention. Such benefits may not show up in pure Internet sales figures, however. Moreover, there must be agreement as to what types of customers (e.g., existing vs. new) are to be targeted by the new e-commerce channel. In essence, to avoid channel conflict, management must be proactive in obtaining the support of all employees, building consensus about the goals, methods of evaluating success, and targets for e-commerce. If management simply puts an e-commerce division into place without this goal alignment step, existing employees may feel threatened and may be uncooperative.

Coordination and Control Measures

In addition to obtaining consensus on goals, explicit coordination and control mechanisms are needed to move a click-and-brick firm more in the direction of integrated, rather than parallel channels. First, it is important for click-and-brick firms to design for interoperability across channels, so that customers may move freely between online and physical retail outlets. For example, customers may want to search a particular store's inventory from their own home computer to see if a specific item is in stock or not. They may want the store to hold the item for them to pick up on their way home, rather than have it delivered. This implies that the online system connects and interoperates with the store system.

Another example of explicit coordination is the use of each channel to promote the other. For example, an online visitor may be informed about various in-store special sales, just as an in-store customer may be told about particular complementary services found on the click-and-brick firm's Web site. The use of kiosks in stores, for example, can directly enable customers on premises to access additional information, services, or promotions at precisely the moment they are considering a specific purchase. Cross-promotions enhance the perception that all the arms of the click-and-brick business are working together to add value for customers. They also create payoffs from e-commerce that can reduce resistance, such as when online promotions generate greater in-store traffic.

One of the most critical management issues for click-and-brick firms is to provide real incentives to employees to encourage cross-channel cooperation. Imagine a situation where store managers know that any time a customer buys something online instead of in the store, it represents lost revenue and lower compensation. Store personnel will invariably encourage customers to buy in the store, because this provides employees with real income. E-commerce sales may help improve customer relations, but no rational salesperson will knowingly direct customers to a sales channel that only ends up reducing his or her income. In many successful click-and-brick firms, efforts have been made to allocate online sales to particular establishments, so that e-commerce does not succeed at the expense of physical outlets. This often is possible when customers have accounts tied to a particular establishment, and online sales from specific accounts are credited to the home establishment. Another way of allocating online sales to a physical outlet is to use the address of the customer.

Finally, click-and-brick firms often find that they are able to capitalize on the unique strengths of each sales channel, affording the possibility for some degree of channel specialization (Steinfield, Bouwman, & Adelaar, 2002). For example, costs for certain types of transactions may indeed be less in an online environment, suggesting that companies should encourage customers to use more efficient channels when possible. Banks, for example, have long attempted to persuade customers to use ATMs for routine cash transactions, rather than coming to a branch and occupying the services of a teller. On the other hand, many financial transactions require expert advice and counseling and are best done in-person at a branch. Hence, click-and-brick banks following a channel specialization strategy might offer customers incentives such as better interest rates or lower fees in return for the use of more efficient online channels for routine transactions like money transfers or bill payments. When more "advice-sensitive" transactions are sought, customers would be directed to their local physical bank branch (Steinfield, Bouwman, & Adelaar, 2002).

When there is potential for severe product-channel conflicts, such as when customers decide to forego a newspaper or magazine subscription to read free content online, a channel specialization strategy may offer a viable alternative. For example, some newspaper and magazine companies derive additional revenue from their online versions using the unique search and archive advantages of the Web-based channel. A specific niche segment of their market may willingly pay for the ability to research back issues and articles on certain topics. This approach to adding value to an online version to encourage payment has been tried by such publications as the *Wall Street Journal* (Laudon & Traver, 2001).

Capability Development

In many situations, traditional firms may lack important competencies needed to achieve synergy benefits with e-commerce. For example, traditional firms may lack Web development skills or logistics skills needed to serve distant markets. Indeed, the ability to serve remote customers is an important prerequisite to successful Web-based commerce, which explains why catalog companies such as Lands' End have experienced so much success with e-commerce. It fits well with their existing capabilities and adds value in the form of enhanced transaction efficiencies and lower costs. When lacking such capabilities, alliances may be more useful than attempting to develop a virtual channel in-house. Managers must recognize whether the requisite competencies are present in the existing traditional company and, if a partner is needed, must carefully construct an alliance that ensures that their e-commerce partner is not simply siphoning business from physical retail outlets.

POTENTIAL BENEFITS OF AN INTEGRATED CHANNEL APPROACH

Once click-and-brick companies recognize the various sources of synergy across channels and develop management strategies to avoid conflicts and encourage

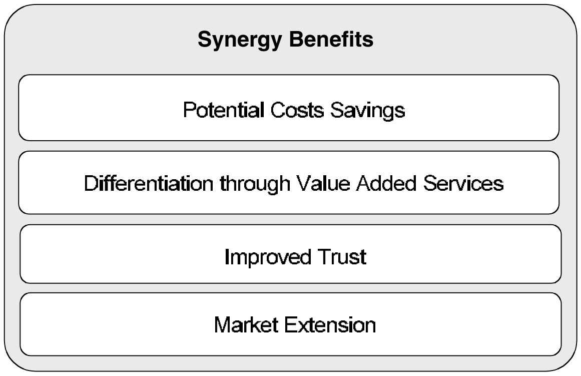


Figure 4: Categories of potential benefits from an integrated click-and-brick approach. Adapted from Steinfield, Adelaar, & Lai, 2002.

cooperation across channels, numerous benefits may result. Four broad areas of benefit include (a) lower costs, (b) increased differentiation through value-added services, (c) improved trust, and (d) geographic and product market extension. The potential benefits from physical and virtual integration are depicted in Figure 4 and discussed in this section.

Lower Costs

Cost savings may occur in a number of areas, including labor, inventory, marketing and promotion, and distribution. Labor savings result when costs are switched to consumers for such activities as looking up product information, filling out forms, and relying on online technical assistance for after-sales service. Inventory savings arise when firms find that they can avoid having to stock infrequently purchased goods at local outlets, while still offering the full range of choices to consumers via the Internet. Marketing and promotion efficiencies are garnered when each channel is used to inform consumers about services and products available in the other. Delivery savings may result from using the physical outlet as the pickup location for online purchases or as the initiation point for local deliveries.

Differentiation Through Value-Added Services

Physical and virtual channel synergies can be exploited at various stages in a transaction to help differentiate products and add value. Examples of prepurchase services include various online information aids to help assess needs and select appropriate targets, or, conversely, opportunities in the physical environment to test products. Examples of purchase services include ordering, customization, and reservation services, as well as easy access to complementary products and services. Postpurchase services include online account management, social community support, loyalty programs, and various after-sales activities that may be provided either online or in the physical store. Typical opportunities are in the areas of installation, repair, service reminders, and training. Although many of these value-added services are potentially available to single-channel vendors, combined deployment of such services (e.g., online purchase of computer with in-store repair or training) can enhance differentiation and lock-in effects (Shapiro & Varian, 1999).

Across all transaction stages, the improved communications from the Internet channel (assuming a well-developed and fully functional site) can yield better insights into customer needs and wants. Such customer relationship management can ultimately add value for both parties over the lifetime of a customer's interaction with a click-and-brick firm, offering benefits in excess of the actual online sales by enhancing loyalty and retention.

Improved Trust

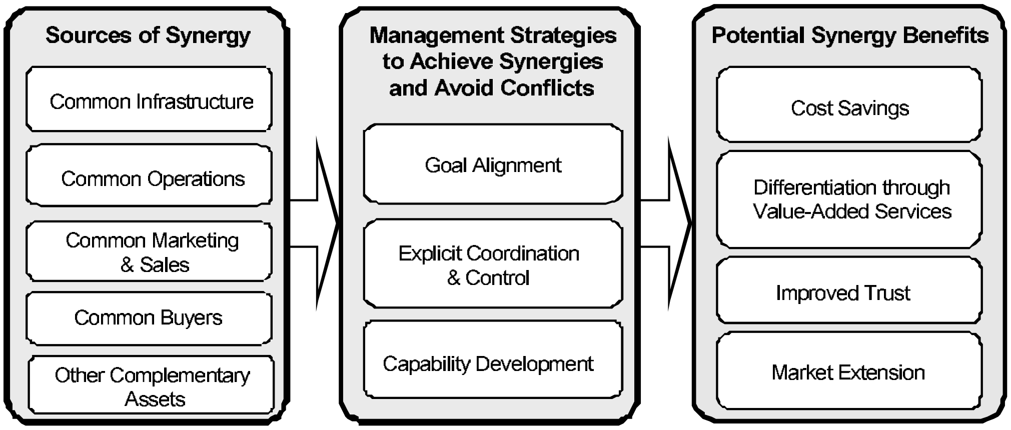
Three reasons for improved trust, relative to pure Internet firms, derive from the physical presence of click and mortar firms, including reduced consumer risk, affiliation with and embeddedness in recognized local social and business networks, and the ability to leverage brand awareness. Lower perceived risk results from the fact that there is an accessible location to which goods can be returned or complaints can be registered. Affiliation and embeddedness in a variety of social networks may facilitate the substitution of social and reputational governance for expensive contracts or legal fees (Granovetter, 1985). For example, an online customer may be more prone to trust the Web site of a business when the store manager is a member of his or her church or when the customer's business and the online vendor are both members of the same chamber of commerce. Such ties are more likely to exist between geographically proximate buyers and sellers, suggesting that there may indeed be a preference for doing business with firms that are already physically present in the local market. Finally, marketing theorists have long recognized the power of branding as a means of building consumer confidence and trust in a product (Kotler, 1999). Established firms are able to leverage their familiar name to make it easier for consumers to find and trust their affiliated online services.

Geographic and Product Market Extension

Adding a virtual channel can help extend the reach of a firm beyond its traditional physical outlets, addressing new geographic markets, new product markets, and new types of buyers. Those in other geographic markets may be new or former customers who have moved away. Virtual channels can also extend the product scope and product depth of physical channels by enabling firms to offer new products that they do not have to stock locally. Moreover, firms may add new revenue-generating information services online that would not be feasible to offer in physical outlets. Finally, the Internet may help reach customers within an existing market who may not have visited the physical outlet but are otherwise attracted to the virtual channel due to its special characteristics.

SUMMARY OF THE CLICK-AND-BRICK FRAMEWORK

The click-and-brick framework elements can be assembled into the summary framework portrayed in Figure 5.



Sources of Synergy
Common Infrastructure
Common Operations
Common Marketing & Sales
Common Buyers
Other Complementary Assets
Management Strategies to Achieve Synergies and Avoid Conflicts
Goal Alignment
Explicit Coordination & Control
Capability Development
Potential Synergy Benefits
Cost Savings
Differentiation through Value-Added Services
Improved Trust
Market Extension

Figure 5: A comprehensive click-and-brick model. Adapted from Steinfield, Adelaar, & Lai, 2002.

The framework directs our attention to the sources of synergy, the need for management strategies to capitalize on click-and-brick applications, and the potential benefits that can result.

EXPLORING THE FRAMEWORK WITH SEVERAL CLICK-AND-BRICK CASES

The framework is best illustrated by describing several cases of click-and-brick firms. These examples were selected and adapted from a series of click-and-brick cases developed by Steinfield, Adelaar, and Lai (2002). Among their cases (the actual firm names were not reported based on the wishes of the interviewed companies) were a specialty retailer, a business-to-business (B2B) building materials supplier, an automobile manufacturer selling through dealerships, and a financial services firm. Each represents a different basic business arrangement—a multichannel retailer operating in the B2C arena, a B2B wholesaler, a manufacturer promoting sales to consumers through an affiliated, but independently owned, network of dealerships, and a firm selling information and services rather than tangible products. They nicely illustrate the robustness of the click-and-brick approach.

An Electronics Retailer

This company is one of the largest specialty retailers of consumer electronics, personal computers, entertainment software and appliances with more than 400 stores. The firm recently rolled out a new e-commerce site that featured both a deeper selection of products and a tighter integration with its traditional physical stores. The click and mortar design strategy enables the firm to benefit from a range of synergies between its virtual and physical channels. The goal is to be “channel agnostic,” letting customers choose whichever channel or combination of channels best suits their needs.

A number of sources of synergy are available to the firm. One key source is the firm’s exploitation of a common IT infrastructure between its e-commerce and store channels. It accomplishes this by tightly integrating the Internet operations with existing databases and other legacy systems. The firm also consciously capitalizes on common operations, especially in terms of purchasing, inventory management, and order processing. That common marketing and common buyers were a source of synergy is evident in the emphasis on replicating and leveraging the store brand in its online services.

One of the services enabled by the tight IT integration allows online customers to check out the inventory of individual stores, so that they might order merchandise for immediate pickup in the nearest store. To achieve this value-added service and derive the differentiation benefit from it, the service had to be supported by a change in business processes that ensured interoperability across the two channels. For example, if only one or two items that an online purchaser desires are in stock, in-store customers might claim them by the time the Web customer arrives for pickup. To avoid this situation, store personnel must be notified that an online customer has requested an item for pickup. Then employees remove the item from the shelf and send an e-mail confirmation to the online customer. To ensure that stores cooperated with this new capability, management incentives were also considered to avoid or diffuse potential channel conflicts. In particular, the company included performance in fulfilling online orders as one of the parameters influencing store manager compensation.

This seemingly simple service thus reflects the main components of the framework. Several sources of synergy come into play. First, the firm built the service by tying the Internet to a common, integrated IT infrastructure. Second, it supports the service by using existing store inventory that was warehoused and delivered using common logistics infrastructure. Third, the shoppers can provide payment that is credited to the store, using existing operational systems such as credit card verification and approval systems already in place. Finally, the service targets common buyers, that is, people living near existing physical stores.

Management initiatives to achieve synergy and avoid conflict are also evident in this simple example. The online service depended on the cooperation of store personnel, reflecting a need for goal alignment. This was achieved by developing a service that brought traffic into the store, rather than simply bypassing it altogether. Moreover, management recognized that the Internet could assist in pre-purchase activities, even if the eventual sale was consummated in the store. It did not require the e-commerce channel to generate its own profits. Additionally, it attended to the need for explicit coordination and control by developing a business process that ensured cross-channel interoperability. Finally, it created an incentive system that rewarded store personnel for their cooperation with the e-commerce channel.

The benefits of this one service are also captured well by the framework. Consider the cost savings in labor that stores accrue when customers search for products online, conduct research, order the product, and even make payment ahead of time, all without needing the assistance of a single employee. In terms of differentiation, this is represents a prepurchase and purchase service that would be difficult for a non–click-and-mortar firm to offer. It caters to the different needs and wants of store and online customers, improving satisfaction. Because of the tie-in to the local store, which is also part of a well-known national chain, customers perceive much lower risk than they would if ordering from a less familiar, nonlocal Internet business.

The tight integration between the e-commerce and existing retail infrastructure offers this firm many other advantages that are derived from the same sources of synergy and enabled by many of the same management strategies. For example, because of the integrated approach, customers who order products online with home delivery are able to return products to their local store, enhancing trust and reducing perceived risk. Moreover, the integration of IT systems enabled store employees to access customer and order data to improve customer assistance, such as finding complementary goods.

Channel cooperation extends in both directions. In-store customers who are unable to find a product on the shelf can search the firm's online site through kiosks available in the store. Because of the integrated approach to marketing, the firm is also able to undertake promotional campaigns, such as sales and contests that customers can access in the store and on the Web. In addition, the Web channel also enables value added services geared toward improving customer relationship management. In particular, the Web site allowes customers to store items under consideration in a "Think About" folder. This provides useful marketing information to the firm, because it can provide more targeted promotions related to desired products.

A Building Material Supplier

The building materials supply company has a double-pronged approach to e-commerce. First, it maintain its own Web site, offering rich information services to its primary customer base—the professional builder. Second, it has an alliance with a building supply portal that allows it to offer e-commerce transactions to its existing client base as well as to new customer segments.

Professional builders are provided with an account that allows them to use the e-commerce site. They can log in directly from the builder supply firm's home page. A local lumberyard where the builder has an account fulfills the orders. Essentially, each lumberyard caters to the market located within a radius of 100 miles. Prices are individualized, encouraging builders to consolidate their purchases for volume discounts.

The building supply portal works with other suppliers but is tightly coupled with the case study firm because both firms have the same principle stockholder. In addition to providing online supply ordering services to builders, it also enables the firm to offer value-added services, extend into the consumer home improvement market, and provide customers goods that the local lumberyard does not carry. Among the value-added services are a variety of accounting and management options that builders can use. These include maintaining an online ledger for a project—for example, a house—that can be used as a template for the next project, saving builders time on order entry. Each builder can have his or her own personal Web page, including a personal product usage and construction plan folder. Builders can also check the status of their orders on a daily basis and order material outside the regular store hours. This is helpful because many builders do their administrative tasks at home in the evening. The personal pages include information on activities and promotions occurring at the local branch.

By outsourcing consumer e-commerce transactions to the online portal, the company now has a presence in the growing home-improvement market dominated by such superstores as Home Depot. Because of the other partners who participate in the portal, the company is able to offer their existing customers one-stop shopping services, even for goods that they do not carry.

Individual stores receive electronically all orders placed on the portal for their products and fulfill them through their normal supply chain and existing fleet of delivery trucks. New professional clients are first encouraged to set up an account at a local branch, where local employees negotiate individual pricing arrangements.

The Web-based service supports standard orders. The company still maintains outside sales representatives (OSRs), however, who visit with builders on job sites to maintain good customer relations. The increased use of online ordering by builders allows OSRs to pay less attention to administrative tasks and to focus on selling value-added services, giving advice, educating the client about the online channels, and strengthening customer relationships.

Through its online partner, the firm also completed a successful mobile service pilot using Palm Pilots. Builders were able to make on-site purchases for critical materials needed immediately. Materials were then brought out to the job by the local delivery truck. One interesting impact of this service is that it encouraged builders to wait until the last minute for some orders and to make orders in smaller quantities than they would through normal channels. This is, of course, less efficient for the supply firm, creating some challenges for their delivery system. It is, however, a new value-added service that strengthens their relationship with core clients.

An Automobile Manufacturer

All automobile manufacturers realize that car shoppers are able to conduct extensive research online before buying a car. Carmakers have well-developed Web sites providing rich information about their models, but for a variety of reasons they are not able to sell cars directly to end customers through the Web. Hence, they must work with traditional dealers to offer a click-and-brick experience. In one carmaker's e-commerce service, customers can configure their desired car online, obtain a fixed price quote, and choose a local dealer from whom they wish to take delivery. The application locates the matching car from dealer inventories, and if in stock at a different dealer from the one chosen by the customer, the dealers will swap cars with each other. The chosen dealer then gets full credit for the sale of the online-configured car, as well as the continuing service relationship to the customer. At the Web site, customers can also research cars and check the inventory of local dealers online. In addition, customers can apply online for credit and insurance, which is also submitted to local dealer.

This approach helps the manufacturer sell more cars without alienating its existing dealer network. The company realizes that in the car market, because of the logistics of delivery and the need for a physical presence for service and warranty work, bypassing dealers will not work. In fact, in many states, it is illegal for car manufacturers to sell directly to end consumers. To secure support from dealers for the initiative, an e-dealer advisory board was created. The manufacturer has also introduced features such as online scheduling for maintenance and repair and an ownership Web site where customers can find accessories that go with their car and receive maintenance service reminders.

Other electronic services initiatives include the introduction of mobile in-car services for safety, security, and information. They are combining the Global Positioning System with wireless technology to deliver emergency roadside assistance, stolen vehicle tracking, navigation aids, and other travel-related services. The selling dealer will activate these in-car wireless services and provide training to customers.

A Financial Services Provider

The final case described here is a large national bank offering a traditional range of banking and financial services. The company focuses on the consumer and small business segment and has more than 8 million households as customers. It took a somewhat different path from the other cases to arrive at a click-and-brick strategy. In fact, this bank, through acquisitions and mergers, had both a typical online banking service available to its account holders and an entirely separate Internet brand that solely targeted new customers over the Web. In the description of this case that follows, the former is referred to as the internal online banking service, whereas the latter is referred to as the Internet pureplay bank.

Their Internet pureplay bank was not successful, largely because of the high costs of customer acquisition and the lack of necessary synergies with the parent bank. One particularly troublesome problem faced by all Internet-only banks results from the difficulties and costs of transferring money into and out of the Internet bank. Because of customers' reluctance to deposit cash or checks in ATMs, Internet-only bank users first have to deposit funds in traditional banking account and then transfer money (e.g., via a check or bank transfer) to their Internet account. This implies that the Internet pureplay bank would always be a supplementary rather than a primary bank. Moreover, in this bank's earlier parallel approach, the Internet pureplay bank had to rely on other banks' ATM networks to allow customers to make cash withdrawals, resulting in relatively high surcharges.

On the other hand, the internal online banking channel service was closely tied to the brick-and-mortar branches, had much lower customer acquisition costs, and offered many customer retention services. Existing account holders were freely offered the opportunity to sign up for online access to their bank accounts and other banking services, allowing online customer acquisition at a fraction of the cost of finding entirely new bank account clients. Customer retention was enhanced by providing such services as online bill payment. Services such as this increase retention by raising switching costs, because customers need to reenter extensive billing information if they change to a new bank. Another synergy benefit the bank experienced with its internal online banking channel stemmed from cost savings at brick and mortar branches due to the ability to offload routine transactions to the cheaper and more convenient Web channel. In keeping with the channel specialization management strategy described earlier, price incentives were also introduced to stimulate the use the online services.

The parent bank took advantage of IT infrastructure synergies between its branches and its integrated online banking service by designing financial applications once and implementing them across the virtual and physical channels. For example, an application to speed up the approval of home equity loans was "mirrored" between the Web and the physical branches. The bank effectively developed coordination and control measures to be able to offer seamless customer support, so that customers would not have to repeat any transactions on multiple channels. For example, if customers changed their address using one channel, all systems would be updated at the same time. To achieve this, the bank had to integrate systems so that Web services were integrated into the day-to-day operations of branches.

As a result of these experiences, the formerly separate Internet pureplay bank was reintegrated into the parent bank, tying it more closely to the click-and-mortar branches. Networked kiosks in bank branch offices introduced the Internet brand more directly to existing bank clients. The parent bank now supplies many of the core services, including deposits and withdrawals, and its connection to the Internet brand creates the trust that had been lacking. The benefit for customers is that they have the choice of a more differentiated set of banking services, with more differentiated prices that reflect the costs of transactions.

CONCLUSION

This chapter has provided a broad overview of the click-and-brick business approach, noting both the potential benefits as well as the challenges that firms face because of channel conflicts. I introduced a framework to help understand the dynamics of managing a click-and-brick enterprise. The framework begins by identifying potential sources of synergy available to firms that choose to integrate e-commerce with traditional forms of business. It further emphasizes the many actions that firms can take to minimize channel conflicts and help achieve the benefits of synergy, and it describes four categories of synergy-related benefits from the integration of e-commerce with traditional businesses, including potential cost savings, gains due to enhanced differentiation, improved trust, and potential extensions into new markets. Four case studies were described to provide a concrete illustration of the approaches taken by click-and-brick firms.

ACKNOWLEDGMENT

I am grateful to the reviewers and editor for the thoughtful comments on an earlier version of this chapter.

GLOSSARY

Channel A means by which a seller interacts with end consumers. Many firms rely on a mix of different channels, such as physical stores, catalog sales, and e-commerce. Firms pursuing channel integration attempt to coordinate the use of channels tightly, even within a single sales activity, to improve their profitability.

Channel conflict Channel conflicts occur when an alternative means of reaching customers (e.g., a Web-based store) implicitly or explicitly competes with or bypasses existing physical channels. Perceived threats caused by competition and conflict across channels can have other harmful effects, including limited cooperation across the channels, confusion when customers attempt to engage in transactions using the two uncoordinated channels, and even sabotage of one channel by the other.

Channel specialization Click-and-brick firms that attempt to direct customers to the most appropriate channel (e.g., one that is the lowest cost or one that offers the requisite capabilities) are pursuing a channel specialization approach. It allows firms to capitalize on the unique strengths of each sales channel.

Complementary assets Assets possessed by a firm, such as existing supplier and distributor relationships and experience in the market, that help it take advantage of innovations such as e-commerce.

Differentiation A competitive approach used by companies to set themselves apart from competitors through higher quality products and better customer services. Click-and-brick firms hope that they can use their combined channels to differentiate themselves from competitors.

Kiosks Self-service computer stations, often with a touch-screen display, that are located in malls, stores, and other places where customers can use them to locate products or information and access services electronically. Click-and-brick firms may offer networked kiosks on store premises to allow in-store customers access to the firms' e-commerce channel.

Synergy When the combined effect of two actions is greater than the sum of the individual effects. Click-and-brick firms hope that by combining traditional and online services, they can offer an experience to customers that is greater than possible through each channel by itself.

Client/Server Computing

Daniel J. McFarland, *Rowan University*

INTRODUCTION

The name of an information system often describes the utility it provides. The functionality of a transaction processing system, a decision support system, and an executive information system are self-evident. However, client/server computing is broadly defined; rather than describing system utility, client/server describes the system's architectural configuration. As a result, a client/server system may incorporate a broad range of technologies and address a variety of business situations.

Client/server computing is a form of cooperative processing. Specifically, a client/server system includes at least two software processes working together to provide application functionality. At the most basic level, a client software process requests services from a server software process. In turn, the server process supplies services to the client process. The service request may provide access to an organizational resource, such as a database, a printer, or e-mail.

Client/server computing involves the coordination of assorted computing/networking devices and the coordination of various software processes. The client/server *system* architecture describes the physical configuration of the computing and networking devices and the client/server *software* architecture describes the partitioning of an application into software processes.

The system architecture focuses on the physical architecture of the system. In this context, clients and servers are seen as computers rather than software processes. Simple client/server system architectures include a client (e.g., a personal computer) that links to a server (e.g., a mid-range computer) using a network (e.g., a local area network). Each computer provides processing and memory resources to the client/server application. The system architectural perspective views a client/server application as a network of computers sharing resources to solve a problem.

The client/server *software* architecture describes the partitioning of an application into software processes. In this context, clients and servers are seen as software processes rather than computers. These processes may reside on the same computer or they may be distributed across a network of computers. The software architectural perspective views a client/server application as a set of programming modules sharing resources to solve a problem. This chapter focuses on the client/server *software* architectural perspective; consequently, a client shall refer to a software process that requests services from other software processes and a server shall refer to a software process that provides services to other software processes.

This chapter begins with a review of three common client/server classification methodologies. The first methodology classifies a client/server application based on the computational role of the constituent processes. In particular, how an application distributes its presentation, application processing, and data services determines how the application is classified. The second methodology classifies an application based on the number of constituent processes; this is known as the tier-based classification. Finally, a server-based classification methodology is presented; it describes a client/server application in terms of the server process utility.

The subsequent section describes three broad categories of enabling technologies. The first set of enabling technologies, middleware, provides a client/server application the ability to integrate client processes with server processes. The second set of enabling technologies, component software, provides self-contained, self-describing software modules that may be combined to form applications. The third set of enabling technologies, networking technologies, bridges the gap among the computing and networking devices.

The final part of this chapter reviews intranets, extranets, and the Internet, three popular client/server implementations.

CLIENT/SERVER CLASSIFICATION

A client/server classification provides information about the particular system architectural configuration. Three client/server classifications are reviewed below. The first classification employs the presentation–application–data (P–A–D) architecture, which describes the computational role of the client process. The second classification describes the number of separate processes in a client/server application, otherwise known as the number of tiers.

Table 1 P–A–D Architectural Classification of Client/Server Applications

Computational Service	Distributed Presentation	Local Presentation	Distributed Application Logic	Local Application Logic	Distributed Data
Data services	Server	Server	Server	Server	*Shared*
Application services	Server	Server	*Shared*	Client	Client
Presentation services	*Shared*	Client	Client	Client	Client

The final classification describes the functional role of the server process.

Presentation–Application–Data (P–A–D) Architecture

Client/server computing divides an application into two or more separate processes. The P–A–D architecture describes the computational role of both the client and server processes. In particular, the P–A–D architecture defines the computational requirements of an application in terms of presentation services, application services, and data services. The presentation services layer details the interaction between the user and the application. The application services layer includes the embedded programming and business logic. The data services layer describes the connectivity to organizational resources such as data, printers, and e-mail (Goldman, Rawles, & Mariga, 1999).

Presentation Services

Presentation services represent the interactions an application has with the external environment. At the most basic level, these interactions involve user input and application output. User input represents the portion of the user's knowledge submitted to an application. Input provides application boundaries, operating parameters, and/or data. Application output strives to provide the user/process/application with new knowledge. Output includes printed reports, audio signals, screen displays, and data. In many cases, a client/server application receives input from and provides output to multiple sources, such as users, other software processes, and/or other applications.

Presentation services can also influence the degree to which a person will use an application. A complex, synergistic relationship exists among the user, the business problem/context, and the application (Dix, Finlay, Abowd, & Beale, 1998). Several areas of study explore how people and technology interact, such as cybernetics, human–computer interaction, ergonomics, human factors analysis, technology acceptance, and industrial engineering.

Application Services

Application services describe how input is transformed into output. The application services layer represents the procedural knowledge (i.e., business logic) embedded in the application. These services include statistical, mathematical, graphical, and/or data transformations.

Data Services

Data services provide access to organizational resources including information-based resources (e.g., databases), hardware-based resources (e.g., printers), and communication-based resources (e.g., e-mail). The data services layer provides utility to the application services layer and/or the presentation services layer.

Organizational resources are often difficult to access as a result of security, budgetary, and/or technical constraints. Security rules restrict access to sensitive data such as payroll information. Budgetary constraints restrict accessibility to consumable resources such as printers. Additionally, technology-based resources, such as databases, often require special and/or proprietary interfaces. As a result, data services often attempt to hide the implementation difficulties associated with accessing and using organizational resources.

P–A–D Architecture-Based Client/Server Classification

The P–A–D architecture classifies client/server applications based on the distribution of computational services between the client process and the server process. As seen in Table 1, the P–A–D architectural framework includes five client/server classification levels. Each level is defined by the client-side P–A–D functionality.

In the first level, *distributed presentation,* the client shares the presentation processing with the server and the server handles all application and data services. In the second level, *local presentation,* the client handles the presentation services and the server handles the application and data services. In the third level, *distributed application logic,* the client addresses the presentation services and a portion of the application services; the server handles the data services and shares the application services with the client. In the fourth level, *local application logic,* the client handles the presentation and application services and the server handles the data services. In the last level, *distributed data services,* the client handles all presentation and application services and the data services are shared by the client and the server.

Tier-Based Client/Server Classification

Client/server computing partitions an application into two or more separate processes. The tier-based classification methodology views each software process as a computational component/layer/tier within the overall application.

A 2-tier system is the simplest and oldest client/server architecture. In a 2-tier system a client communicates with a server directly. This architecture often strives to provide reusable, robust links to organizational resources, such as printers and data.

In a 3-tier system, a client communicates to a server through an intermediary process. This intermediary process provides functionality as well as connectivity.

Middle tier functionality may include message queuing, application execution, and database staging. The middle tier also provides encapsulation for the data source and abstraction for the presentation services. As a result, changes to the data structure and/or user interface are less disruptive and more transparent. Furthermore, data encapsulation improves connectivity with legacy and/or mainframe systems. A 3-tier system may support a large number of concurrent users and is able to handle very complex processing (Carnegie Mellon Software Engineering Institute, 1997d).

The *n*-tier client/server architecture is a natural extension of the 3-tier architecture. An *n*-tier system has an undetermined number of intermediary processes and server processes. A client process might call upon a middle tier process, which in turn might call upon another middle tier process. In combining narrowly focused processes together, the *n*-tier architecture strives to provide application flexibility and software reusability.

Server Functionality Client/Server Classification

Many client/server applications strive to reuse server process functionality. Since a server process often embeds and hides complicated implementation details, reusing a process significantly reduces system development time and effort. Furthermore, reusing successful, robust server processes improves overall system reliability (Weiss, 2001).

To promote reusability and clarity, the functional role of a server process often describes the server. The following list describes a few server types. Table 2 provides a summary of the servers listed below.

Web Server

A Web server creates a standardized way for objects to communicate with each other over the Internet. A Web server provides session connectivity to clients running Web browsers. Early Web servers fetched files for clients without processing or interpreting the content. However, technologies such as common gateway interface (CGI), Active Server Pages (ASP), JavaServer Pages (JSP), Java Applets, ColdFusion, extensible markup language (XML), and Web services have dramatically expanded the processing and interactivity capabilities of Web servers.

Application Server

Application servers provide interactivity and processing functionality to clients. An application server may execute programming logic, store and process information, and/or manage user interactivity. Centrally storing programming logic allows developers to reuse existing, proven application functionality as well as simplifying software version control and software deployment.

Wireless Server

A wireless server provides network and Internet connectivity for wireless devices. Two popular wireless servers are *wireless enablers* and *wireless gateways*. A *wireless enabling* server stores information specifically designed for wireless devices, such as wireless markup language (WML). WML is a wireless-friendly version of hypertext markup language (HTML). A wireless client accessing a wireless enabling server would be provided with a WML file rather than an HTML file. Unlike a wireless enabler, a *wireless gateway* typically does not store content. It accepts requests from wireless and traditional devices and routes each request to an appropriate server based upon the request and device type. Some wireless gateway servers also translate wireless and traditionally formatted messages to/from WML and HTML. These translations allow wireless devices to access both traditional and wireless content.

Transaction Processing (TP) Monitoring Server

A transaction processing (TP) monitoring server introduces performance efficiencies when serving a large number of users. These servers accept client requests, merge

Table 2 Functional Descriptions for Several Server Types

Server Type	Functional Description
Web server	Connectivity and interactivity to clients running Web browsers
Application server	Interactivity and processing functionality
Wireless server	Wireless content locating services and/or wireless-friendly content
Transaction processing (TP) server	User responsiveness, processing prioritization, scheduling, and balancing
Message server	Message routing and delivery
E-mail server	Electronic-mail storage, routing, and delivery
Fax server	Fax storage, routing, and delivery
Proxy server	Intermediary content and processing functionality
Firewall	Access restriction based on a predetermined set of security criteria
Dynamic host configuration protocol (DHCP) server	Dynamic reuse of network addresses
File transfer protocol (FTP) server	File transfer capabilities

requests together by type, then transmit the resulting consolidated messages to appropriate servers. In addition, a TP monitor might monitor, prioritize, schedule, process, balance, and/or rollback service requests.

Message Server

A message server accepts and routes messages. A message is a service request that is packaged with destination information. An e-mail request is a message; it has embedded intelligence regarding the specific message destination. As a result, an e-mail server is a message server.

E-mail Server

An e-mail server accepts, routes, stores, and delivers electronic mail (e-mail) messages; it handles incoming and outgoing e-mail messages. Several e-mail standards exist such as messaging application programming interface (MAPI), X.400, and the Internet e-mail standard. Any compliant software product, regardless of the authoring product, may read standardized messages.

Fax Server

A fax server is similar to an e-mail server. It accepts, routes, stores, and delivers faxes; it handles incoming and outgoing faxes. Most fax servers provide additional features such as a direct-to-print option (i.e., allowing a fax to be sent to a printer rather than an electronic inbox).

Proxy Server

A proxy server is an intermediary process. It intercepts client requests and attempts to satisfy each request itself. If a request cannot be satisfied, the proxy server routes the request to an appropriate server.

A proxy server may control and manage Internet usage. Since all client requests go through the proxy server, an organization is able to monitor and/or limit Internet usage. A proxy server that filters Internet requests and/or logs Internet usage is acting as a firewall.

Firewall

A firewall reduces the risks associated with unauthorized access to a network and inappropriate use of networking resources. All requests entering or leaving a network must pass through a firewall. The firewall rejects those requests failing to satisfy the predetermined security criteria. A firewall might also record request and network activities. Firewalls are highly configurable based upon organizational security and auditing concerns.

Dynamic Host Configuration Protocol (DHCP) Server

Like a postal address for a brick-and-mortar building, each computer on a network must possess a unique address. Traditionally, these addresses were fixed, meaning (1) each computer required individual configuration, (2) potential conflicts were inevitable, and (3) organizations were required to manage large blocks of addresses.

A dynamic host configuration protocol (DHCP) server dynamically assigns Internet addresses to computers on the network. This permits an organization to standardize computer configurations, to reduce network address contention, and to continually recycle a smaller number of network addresses.

File Transfer Protocol (FTP) Server

A file transfer protocol (FTP) server transfers files from one computer to another using a network. An FTP server accepts file uploads (i.e., copying files to a server) and file downloads (i.e., copying files from a server). While many FTP servers provide unrestricted access, others provide access to authorized users only.

ENABLING TECHNOLOGIES

Enabling technologies allow heterogeneous software processes, computing devices, and networking devices to interoperate. Enabling technologies include technological standards, organizing frameworks, and product implementations. Three enabling technologies are discussed below: middleware, component software, and networking technologies.

Middleware

Middleware is a primary enabler of client/server computing. Middleware acts like glue holding together the separate software processes. Middleware products simplify the design, development, and implementation of complex applications by hiding server location issues, networking protocol details, and operating system differences (Carnegie Mellon Software Engineering Institute, 1997a). Middleware is broadly defined; it may be a type of program-to-program interface, a set of standards, or a product. Table 3 provides a summary of the middleware categories listed below.

Transactional Middleware

Transactional middleware supports transaction-processing functionality; it strives to provide responsiveness and data integrity while supporting a large number of users. It often includes load-balancing, replication, and/or two-phase commits. The Customer Information Control System (CICS) from IBM is a transactional middleware product. CICS is common on IBM mainframes and on several other IBM-platforms including OS/2, AS/400, and RS/6000. The distribute transaction processing (DTP) protocol from the Open Group is another transactional middleware standard. Many relational and object-oriented database management systems support DTP. BEA Tuxedo, from BEA Systems, is another a popular transactional middleware product.

Table 3 Middleware Categories and Implementation Examples

Middleware Category	Implementation Examples
Transactional middleware	CICS—IBM DTP—Open Group BEA Tuxedo—BEA Systems
Procedural middleware	ONC RPC—IETF DCE RPC—Open Group
Message-oriented middleware	WebSphere MQ—IBM JMQ—Sun Microsystems

Message-Oriented Middleware

Message-oriented middleware (MOM) supports client/server processes using asynchronous, peer-to-peer messages. A MOM does not require continuous, active communication between the client and the server. A client sends a message and does not wait for a response. If a server is busy or unavailable, received messages wait in a queue until they are satisfied. MOM solutions are well suited for event-driven and object-oriented applications. However, many MOM implementations are proprietary. As a result, they tend to be inflexible, difficult to maintain, and they lack interoperability and portability (Carnegie Mellon Software Engineering Institute, 1997b). MOM middleware products include WebSphere MQ (formerly MQSeries) from IBM and Java Message Queue (JMQ) from Sun Microsystems. WebSphere MQ is a mature product supporting over 35 platforms (http://www.ibm.com). JMQ is based on Java Message Service (JMS), which is a Java application programming interface (API) included in the Java 2 Platform, Enterprise Edition (J2EE). JMS is one of the many standards included in J2EE, which is a platform for developing distributed applications using the Java programming language. J2EE, using the CORBA/IIOP communications infrastructure, specifies many services including asynchronous communications using JMS, naming services using Java Naming, Directory Interface (JNDI), transaction services using Java Transaction API (JTA), and database access services using Java Database Connectivity (JDBC). J2EE implementations are developed and provided by a variety of vendors (Sun, J2EE, n.d.; Alur, Crupi, & Malks, 2001).

Procedural Middleware

A remote procedure call (RPC) supports synchronous, call/wait process-to-process communications. When using an RPC, a client requests a service then waits for a response. As a result, an RPC requires continuous, active participation from the client and the server. Each RPC request is a synchronous interaction between exactly one client and one server (Carnegie Mellon Software Engineering Institute, 1997c). Open Network Computing Remote Procedure Call (ONC RPC), developed by Sun Microsystems now supported by the Internet Engineering Task Force (IETF), was one of the first RPC protocols and is widely deployed to a variety of platforms. The Distributed Computing Environment (DCE), developed and maintained by the Open Group (formerly known as the Open Systems Foundation), is a set of integrated services supporting the development of distributed computing environments. DCE provides distributed services and data-sharing services including RPC, directory services (i.e., the ability to identify and locate system resources), time services, security services, and thread services (i.e., the ability to build concurrent applications). DCE data-sharing services include diskless support and distributed file system services (Open Group, 1996). DCE RPC is the protocol used by several object and component middleware solutions, such as Microsoft's Distributed COM (DCOM) and COM+ and it is also an optional protocol in the Object Management Group's Common Object Request Broker Architecture (CORBA).

Component Software

Component software strives to improve software development productivity through the reuse of self-describing, self-contained software modules called components. Each component provides specific functionality. An application calls upon components at run-time.

Component software exists within a component model, which defines the way components are constructed and the environment in which a component will run. The component model consists of an interface definition language, a component environment, services, utilities, and specifications. An interface definition language (IDL) defines how a component interacts with other components to form applications. The components exist within a component environment. A component environment is a computing environment providing the ability to locate and communicate with components. Popular component models include Microsoft's Component Object Model (COM), the Object Management Group's CORBA, Sun Microsystems's Enterprise Java Beans (EJB), and Web services.

Component Object Model (COM)

Microsoft's COM is a way for multivendor software components to communicate with each other. It provides a software architecture that allows applications to be built from binary components supplied by different software vendors. COM provides the foundation for many technologies including object linking and embedding (OLE), ActiveX, and Microsoft transaction server (MTS). Distributed COM extends COM by allowing remote component interactions. COM+ further expands the COM by encapsulating DCOM, MTS, and a host of other services including a dynamic load-balancing service, an in-memory database, a publish-and-subscribe events service, and a queued-components service. COM components require the COM application server, available on the Windows operating system platforms (Microsoft, 1998).

Common Object Request Broker Architecture (CORBA)

CORBA is an open, vendor-independent architecture describing object-oriented process interactions over a network. CORBA, supported by the Object Management Group (OMG), utilizes a standard communication protocol IIOP (Internet inter-ORB protocol). IIOP allows a CORBA process running on one computer to interact with a CORBA process running on another computer without regard to network, vendor, programming language, or platform heterogeneity. CORBA supports a variety of services including asynchronous and synchronous, stateless and persistent, and flat and nested transactions (OMG, n.d.).

Enterprise Java Beans (EJB)

Similar to CORBA, Sun Microsystems's EJB is a specification. An EJB must be programmed using Java and must be hosted on a J2EE application server. EJBs interact with each other using Java remote method invocation (RMI). An RMI is a set of APIs used to create distributed applications using Java; it is also an implementation that operates in a homogeneous environment using Java Virtual Machine (JVM). RMI allows Java objects to communicate remotely with other Java objects. Alternatively, an EJB built with EJB 2.0 specification, or higher, may communicate using the message-oriented-middleware, JMS (Marinescu & Roman, 2002).

An EJB system consists of three parts, the EJB component, the EJB container, and the EJB object. An EJB component exists within an EJB container running on an EJB server. The EJB object provides access to the EJB components. An EJB component is a software module that provides specific functionality; it may be discovered and manipulated dynamically at run-time. The EJB container provides the execution environment for the EJB components; it handles the communication and interface details. An EJB container may support more than one EJB component. While an EJB component runs on a server, an EJB object runs on a client. An EJB object remotely controls the EJB component (Sun, RMI).

Web Services

Web services are an extremely promising set of technologies; they may represent the first successful cross-platform component architecture. A Web service is a self-contained program providing a specific function that is packaged in such a way that it may be called upon remotely. A Web service is a platform-independent module that utilizes existing Internet standards, primarily XML, to provide, validate, and interpret data; hypertext transfer protocol (HTTP) to provide synchronous communications; and simple mail transfer protocol (SMTP) to provide asynchronous communications.

Web services provide Internet-accessible, building block functionality to developers; they allow for incremental development and deployment. Web services support new application development and promise to provide access to existing applications. By wrapping traditional processes in Web service protocols, an existing computing infrastructure can improve interoperability and utilization without having to reprogram existing applications. Furthermore, an existing application may enhance functionality by integrating with new Web services.

Web services are distinctive in several ways. While a traditional server process is designed to provide function to a particular client, a Web service strives to provide global access to a very specific function. A Web service is not duplicated or moved; it is simply called upon as required at run-time by applications. Furthermore, unlike other distributed application environments, such as CORBA, J2EE, and COM+, Web services do not dictate the underlying communications framework (Singh, Stearns, Johnson, et al., 2002).

Open, standardized interfaces are the heart of Web services. Standards define how a Web service communicates, how it exchanges data, and how it is located. Simple object access protocol (SOAP) is an XML-based protocol for exchanging information in a distributed environment. SOAP is platform independent; it consists of an envelope, a set of encoding rules, and a convention describing procedure calls. A SOAP envelope describes what's inside the message and how the message should be processed. The encoding rules describe the application-specific data types. The conventions describe remote procedure calls and responses. Other standards include the Web services description language (WSDL), which defines the Web service interfaces and the universal description, discovery and integration (UDDI), which allows developers to list/post new Web services and to locate existing Web services (Ewald, 2002).

Table 4 Internet Networking Categories and Components

Internet Networking Category	Components
Network access	Internet access providers Internet connectivity: Dial-up, ISDN, ADSL, HFC, wireless, T1/T3
Network core	Routers and bridges Data routing: circuit-switching, packet-switching
Network edge	Computers, users, applications Internet protocol stack

Networking

The Internet consists of host computers, client computers, routers, applications, protocols, and other hardware and software. As an organizing framework, these technologies may be categorized using three broadly defined functional areas, namely network access, network core, and network edge.

As seen in Table 4, network access describes how devices connect to the Internet. The network core describes the intercommunications among the computing and networking devices. The network edge describes those objects using the Internet such as clients, servers, and applications (Kurose & Ross, 2001; Peterson & Davie, 1999).

Network Access

An Internet access provider (IAP) provides Internet access. The structure of an IAP is roughly hierarchical. At the lowest level, a local Internet service provider (ISP) provides connectivity for residential customers and small businesses. The local ISP connects to a regional ISP. The regional ISP connects to a national/international backbone provider (NBP). The various NBPs interconnect using private connections and/or public network access points (NAP) to form the backbone of the Internet.

To communicate with an IAP, a connection must be established and maintained. Several connection alternatives exist including dial-up, integrated services digital network (ISDN), asymmetric digital subscriber line (ADSL), hybrid fiber coax (HFC, via a cable modem), radio wireless, cellular wireless, satellite wireless, microwave wireless, T1, and T3.

The Network Core

The network core describes how networking devices interconnect with each other. The backbone of the Internet is an extremely large mesh. Data are sent through this mesh using either circuit-switching or packet-switching channels. A circuit-switching network establishes and

Table 5 Comparison of the OSI Model and the Internet Protocol Stack

OSI Model	Internet Protocol Stack	Layer Description	Protocols
Application	Application	Specifies how applications and processes will communicate with each other	HTTP, SMTP, MIME, DNS, NFS. Middleware products: RPC, MOM, CORBA/IIOP, CICS, DTP
Presentation			
Session			
Transport	Transport	Specifies how information is transmitted	TCP, UDP
Network	Network	Specifies host and application addressing	IP
Link	Link	Specifies how the media are shared	PPP, SLIP, ATM, Ethernet
Physical	Physical	Specifies the physical characteristics of the media	100BaseT, IEEE802.5, IEEE802.11, Token Passing, TCS, PDM

maintains a circuit (i.e., a specific network path) for the entire duration of an interaction. A circuit-switching network knows where to look for messages and the data are received in the order in which they are sent. A packet-switching network divides each transmission into a series of individually addressed packets. Since each packet is addressed, the network path need not be determined and packets may be sent using whatever bandwidth exists at the time the message is transmitted. As a result, each packet might take a different network path. The receiver of the message is responsible for unpackaging and sequencing the packets.

The Network Edge

The network edge consists of those objects using the Internet such as clients, servers, and applications. To communicate, objects must adhere to the same networking protocol. A protocol is an agreed-upon set of rules governing a data transmission. The Internet supports a variety of protocols. Some protocols are competing, meaning they serve the same purpose; others are complementary, meaning they serve different purposes.

Internet Protocol Stack

A protocol stack is a framework used to organize and describe networking protocols. Each layer in a protocol stack serves a particular networking need. Furthermore, the lower layers of the stack provide a foundation for the upper layers (Kurose & Ross, 2001; Peterson & Davie, 1999). As seen in Table 5, the Internet protocol stack is a variation of the widely accepted OSI model. The OSI model has the following seven layers: physical, link, network, transport, session, presentation, and application. The Internet protocol stack has the following five layers: physical, link, network, transport, and application. The application layer on the Internet protocol stack envelops the application, presentation, and session layers of the OSI model. A description of each layer of the Internet protocol stack follows.

Physical Layer. The physical layer of the Internet protocol stack describes the physical characteristics of the networking media. Media can be broadly categorized as guided or unguided. Guided media includes copper and fiber optics. Unguided media includes radio, microwave, and satellite. The media type influences bandwidth, security, interference, expandability, contention, and costs. Examples of physical layer protocols include 10BaseT, 100BaseT, Gbit Ethernet, IEEE802.5 Token Passing, IEEE802.11 Wireless, transmission convergence sublayer (TCS) and physical medium dependent (PMD) for asynchronous transfer mode (ATM), and transmission frame structures T1/T3.

Link Layer. The link layer of the Internet protocol stack describes how devices share the physical media. These protocols define host–host connections, host–router connections, and router–router connections. The primary role of link layer protocols is to define flow control (i.e., how to share the media), error detection, and error correction. Link layer protocols include point-to-point (PPP) and serial line internet protocol (SLIP), which allow clients to establish Internet connections with Web servers. Ethernet and ATM are also popular link layer protocols.

Network Layer. The network layer of the Internet protocol stack defines host and application addressing. The Internet protocol (IP) assigns a unique number, called the IP address, to devices connected to the Internet. The IP address uniquely identifies every computer connected to the Internet.

Transport Layer. The transport layer of the Internet protocol stack defines how information is shared among applications. The Internet transport protocols include transmission control protocol (TCP) and user datagram protocol (UDP). TCP is a connection-oriented protocol. A TCP-based application establishes and maintains a connection for the entire duration of each transaction. This connection provides reliability and congestion control. Applications using TCP include e-mail, file transfers, and Web browsing. UDP is a connectionless protocol. An UDP-based application communicates by sending individual datagram packets. Datagrams support applications requiring large bandwidth and those tolerating some degree of data loss. Applications using UDP include telephony, streaming video, and interactive games.

Application Layer. The application layer of the Internet protocol stack defines application–application communications. For example, the HTTP allows Web clients to locate, retrieve, and interpret HTML objects and other Web-based objects (e.g., VBscript, Java Applets, JPG files). SMTP sends and stores Internet e-mail messages. Multipurpose Internet mail extension (MIME) supports e-mail attachments. Post office protocol (POP3) and Internet mail access protocol (IMAP) allow clients to download e-mail messages from e-mail servers. FTP allows file transfers between computers. The domain name system (DNS) resolves IP addresses and universal resource locator (URL) names. Telnet allows for remote terminal access over the Internet. The network file system (NFS) protocol allows for remote storage of files.

CLIENT/SERVER IMPLEMENTATIONS

Internet

The Internet is a network of networks. Hundreds of millions of computers, users, and applications utilize the Internet. The Internet utilizes a variety of protocols including TCP/IP, HTTP, and FTP. The Internet supports Web browsing, online chatting, multiuser gaming, e-mail delivery, fax delivery, and telephony.

Intranet

An intranet is a private network using the same technologies as the Internet. Since the foundation, protocols, and toolsets are the same, an intranet looks, feels, and behaves like the Internet. The difference between an intranet and the Internet is scope. An intranet user is limited to visiting only those Web sites owned and maintained by the company hosting the intranet, whereas an Internet user may visit any publicly accessible Web site. Since intranets are private, individuals outside the organization are unable to access intranet resources. As a result, organizations may publish internal and/or confidential information such as organizational directories, company policies, promotion procedures, and benefits information. A firewall protects an intranet from the nonsecure, public Internet.

Extranet

An extranet is an intranet that provides limited connectivity with the Internet. Specifically, an extranet allows authorized Internet users to access a portion of the company's intranet. This access is granted through a firewall. An Internet visitor submits a username and password to the firewall. If authenticated, the visitor is permitted limited access to the company's internal intranet. Similarly, an extranet may provide authorized internal users limited access to the Internet.

Extranets often support field personnel and employees working from home. In addition, extranets are designed to interconnect suppliers, customers, and other business partners. The exposure of the extranet is based on the relationships a company has with its partners and the sensitivity of the content stored on the extranet. In the most relaxed scenario, individuals gain access to common business materials by completing a brief survey. In more restrictive scenarios, an organization may sign a contract detailing acceptable use of the extranet or consumers may be required to pay subscription fees.

CONCLUSION

Client/server computing is so broadly defined, that it says little about a particular system. A client/server application may provide national security services to a government or it may provide publicly available editorials and commentaries. Additionally, client/sever computing encompasses several architectural interpretations. The client/server *system* architecture describes the physical configuration of the computing and networking devices. In this context, clients and servers are seen as computers. The client/server *software* architecture describes the configuration of the software processes. In this context, clients and servers are seen as software processes. Furthermore, client/server computing utilizes an enormous array of heterogeneous technologies, protocols, platforms, and development environments. While some client/server applications are relatively simple, involving only a few technologies, others are extremely complex, involving a large variety of technologies.

Common to all client/server systems is the partitioning of an application into separate processes. Two general categories of processes exist, those that request services (i.e., clients) and those that provide services (i.e., servers). A client process works together with a server process to provide application functionality.

A client/server classification provides information that describes a particular system. A classification may describe the computational role of the processes, the physical partitioning of an application into tiers, or the functional role of the processes. While these classification methodologies help describe systems, they also highlight the variety and complexity among client/server implementations. The computational and functional role of the processes varies from system to system. Furthermore, a client may interconnect with many servers and a server may interconnect with many clients.

Enabling technologies strive to provide seamless integration of hardware and software in complex environments. Specifically, middleware governs the interactions among the constituent software processes, component software provides the ability to create applications using existing, self-contained software modules, and networking technologies bridge the gap among the computing and networking devices.

Early distributed computing consisted of vendor- and platform-specific implementations. However, the trend in client/server computing is to provide standardized connectivity solutions. Web services represent one of the most promising new client/server developments. Web services strive to utilize the communication infrastructure of the Internet to deploy client/server applications. While it is too early to know whether Web services will fulfill their potential, they promise to change the way application programs are developed and deployed. As the excitement and investments in such technologies continue to grow, the standardization and globalization of client/server computing will likely become a reality in the near future.

GLOSSARY

2-tier An application that is partitioned into two separate processes that work together to provide system functionality.

3-tier An application that is partitioned into three separate processes that work together to provide system functionality.

Client process A software program that requests services from one or more server processes.

Client system A computer that supports a client process and requests services from one or more server systems.

Client/server software architecture The logical and physical partitioning of an application into software processes.

Client/server system architecture The architectural configuration of computing and networking devices supporting a client/server application.

Client/server tier A well-defined, separate process representing a portion of a client/server application.

Component A self-contained, self-describing software module that provides specific functionality, where several can be combined to build larger applications.

Component environment A computing environment providing the ability to locate and communicate with components.

Component model The way components are constructed and the environment in which a component will run, consisting of an interface definition language, a component environment, services, utilities, and specifications.

Enabling technology Provide a client/server application with the ability to locate, communicate with, and/or integrate the constituent processes.

Extranet An intranet that provides limited access to/from the Internet using firewall technology.

Interface definition language (IDL) Defines how a program may communicate with a component.

Internet protocol stack A subset of the OSI model, and a framework that organizes and describes Internet networking protocols.

Internet A global network of networks supporting hundreds of millions of computers, networking devices, applications, and users.

Intranet A private network based on Internet protocols and technologies.

Middleware The software governing the interaction among the client and server processes.

***n*-tier system** An application that is partitioned into an unspecified number of separate processes that work together to provide system functionality.

OSI model A general framework that organizes and describes networking protocols.

P–A–D architecture Defines an application in terms of the following three computational services: presentation services, application services, and data services.

Process An executing program.

Server process A software program that provides services to one or more client processes.

Server system A computer that supports a server process and provides services to one or more client systems.

Collaborative Commerce (C-commerce)

Rodney J. Heisterberg, *Notre Dame de Namur University and Rod Heisterberg Associates*

COLLABORATIVE COMMERCE TRENDS FOR THE REAL-TIME ENTERPRISE

Collaborative commerce (c-commerce) is a strategy for the next stage of electronic business (e-business) evolution. C-commerce business practices enable trading partners to create, manage, and use data in a shared environment to design, build, and support products throughout their life cycles, working separately to leverage their core competencies together in a value chain that forms a virtual enterprise. Sustainable competitive advantage may be realized by adoption of c-commerce strategies and business models.

Today forward-looking enterprises are seeking to achieve the benefits of c-commerce by leveraging the Internet as an enabling technology in order to transform their core business management decision making practices. These real-time enterprise value propositions are based on managing information rather than inventory. The business case for c-commerce is predicated on information technology (IT) investments to facilitate collaborative business practices with shared demand/supply data and virtual enterprise visibility information in real time that will reduce uncertainty to improve decision effectiveness.

Supply chain operations that involve actions outside the enterprise's four walls require monitoring and measuring trading partner performance as never before due to virtual enterprise integration of the core competencies across the value chain. To realize this new capability, enterprises must reengineer their decision-making processes in such a manner so that they are able to adapt to the dynamics needed to synchronize supply with demand. Decision makers must be able to evaluate performance across the virtual enterprise using common metrics in order to make effective decisions for guiding value chain strategies, directing logistics tactics, and managing operational activities in a real-time manner. As c-commerce evolves as the mainstream e-business strategy for effective value chain management, the reengineering of management decision making processes becomes the critical success factor for enterprise profitability and growth in the 21st century.

C-commerce in Perspective

In 1995 something wonderful happened, something quite remarkable—a true phenomenon. During that year the whole world unilaterally adopted the same set of IT infrastructure standards to share business data, the Internet. No governmental edict or channel master command forced this technological paradigm shift. In 1994, the Internet was still an arcane technology primarily known and used by academia, computer scientists, and the military. In 1996, businesses were being established and were generating revenue from commercial buying and selling transactions by leveraging the enabling technology known as the World Wide Web. This seminal event has forever changed the way we do business—now, e-business.

There is a consensus that e-business entered the collective consciousness of the business mainstream in 1995, when the scope of traditional enterprise resource planning (ERP) business applications expanded to embrace trading partners for supply chain management (SCM) and customer relationship management (CRM). This provided the basis for Internet-enabled procurement and triggered deployment of electronic commerce (e-commerce) applications to exchange buy/sell transactions to purchase direct and indirect materials via business-to-business (B2B) supply chain scenarios, as well as finished products and customer services via business-to-consumer (B2C) channels.

C-commerce represents the evolution of e-business beyond e-commerce. Rather than simply exchanging procurement transactions, enterprises are sharing intellectual capital with their trading partners working as a value chain that provides a competitive advantage for the development and distribution of their products. These collaborative business practices are fundamental to the often stated e-business transformation. The convergence of business process reengineering and Internet technology that spawned e-business during the 1990s has set the stage for reengineering the resulting management decision making processes to promote c-commerce as the dominant business model of the first decade of the 21st century.

Note that the collaborative business practices that are fundamental to c-commerce were mature and employed as standard practices in aerospace well before 1995. In fact, the c-commerce "best practices," leveraging Internet-based collaboration in the aerospace industry, had their beginnings in 1985. This should be no surprise when it is realized that it was natural for the aerospace enterprises to collaborate over a communications network to share data with their customers in the Department of Defense (DoD) since they created the Internet. By 1994, leading aerospace prime contractors were providing business and technical applications hosted on integration hub platforms for collaborative product development and logistic support for their DoD customers, as well as for their value-added trading partners and suppliers.

This same integration hub, which is the hallmark of c-commerce architecture, facilitates the sharing of information between trading partners in a value chain that operates as a virtual enterprise. The use of integration hubs, as platforms for private trading exchanges (PTX), by Cisco, Dell, General Electric, and Intel has been widely reported over the past several years. The results of these PTX deployments have been a key factor contributing to these market leaders' ability to realize a sustainable competitive advantage. As with the technology adoption model, which consistently predicts the IT behavior of individual companies, there are also analogous Type A, B, and C industries in terms of the levels of risk tolerance for IT adoption which enables c-commerce business practices. The behavior as exhibited by such industries as aerospace and high tech electronics clearly indicates that they are Type A as pioneers of advanced technologies and aggressively adopt high-risk strategies to gain the high-potential rewards. Use of the integration hub architecture to blend intranet, extranet, and Internet activities into a seamless shared data environment is one of the trademarks of a c-commerce leader.

Such collaborative business practices have begun to migrate from intranets to extranets across a diverse base of enterprises that are market share leaders in all major industrial sectors of our global economy. A recent study, published by Deloitte Research (2002), of 356 enterprises reports that adoption of c-commerce is growing across most industries, including the public sector. This momentum is being accelerated by today's economic climate in order to improve both top-line and bottom-line business performance, where approximately 74% of the enterprises stated that c-commerce is critically important to their business. There is evidence from a recent survey of 300 business-technology executives, who are making IT investments to gain both cost savings and access to information to be able to make better decisions, that the pace of c-commerce adoption is accelerating at an increasing rate (Swanson, 2002). Collaborative initiatives are underway in 69% of the enterprises and another 16% are planning them. The survey reports that 76% of the enterprises are targeting projects with customers, 72% with trading partners, and 61% with suppliers. Such agility is also mission critical in the federal government where the DoD is accelerating its collaborative defense department initiative that will embrace the commercial "best practices" for SCM, as well as collaborative product development (Moad, 2002). It is these c-commerce business processes that form the compelling value propositions for the PTX deployments and successful e-marketplace initiatives that are building the foundation of the 21st century economy.

This convergence of enabling information technology with global marketplace economics has produced an international business climate that drives the demand by trading partners for the ability to securely create, manage, and use data between shared enterprise business processes. The concepts of the integration hub that are embodied in enterprise information portals (EIP), serving as e-business platforms that are available as packaged software products to enable c-commerce, can be utilized to achieve virtual enterprise operations now. The c-commerce strategy for integration hub architecture embraces an open systems environment, and the adoption of international standards, as well as coordination of emerging industry standards and best practices for a secure, shared data environment. The direct benefits are realized in terms of substantial reductions in product time to market and life cycle costs, as well as significant improvements in the quality and performance of the products.

Virtual enterprise management is an information intensive process that involves a value chain to design, build, and support a product throughout its life cycle. The core competencies that enable the full spectrum of c-commerce, as shown in Figure 1, are changing so rapidly that enterprises are finding it difficult to align their business plans with this new market force. This includes integrating internal business processes via intranets, optimizing external business relationships via extranets, as well as leveraging B2B models via a PTX and e-marketplaces as well as B2C channels via Internet Web sites. This wide range of information is created, managed, and shared by a large number of organizations and their trading partners in a value chain that forms a virtual enterprise. Virtual enterprise formation and operation scenarios must be based on trading partner core competencies and value-added capabilities for c-commerce.

The full spectrum c-commerce model is defined in terms of virtual enterprise integration for value chain management of trading partner core competencies. For any enterprise, the operational shared data environment consisting of the evolutionary level of maturity for c-commerce capabilities as a value-added trading partner may be defined as follows:

- Electronic data interchange,
- Enterprise integration,
- Product data interchange,
- Collaborative business practices,
- Outsourcing via e-marketplaces,
- Product development/distribution via value chains, and
- Virtual enterprise operations.

Vertical integration advantages have been overcome by the need for enterprise agility and focus on core competencies. No enterprise is sufficiently large, or financially independent, or organizationally smart enough to be world class in all capabilities needed to design, build, and support complex products throughout their life cycles. Business models formed by vertical integration strategies

are being transformed by convergence of information technology and global marketplace economics into e-business models based on virtual enterprise integration strategies using c-commerce practices.

Critical Success Factors

In our 21st century economy, product development agility and distribution speed are fundamentals, as are operational excellence, customer loyalty, and continuous innovation, as well as sustainable value creation. Yet most enterprises use a business structure and management decision making model inherited from the industrial age of the 19th century with barriers to these critical success factors. Furthermore while e-business strategies for operational excellence have been adopted with success during the 1990s, it may be necessary but not sufficient to achieve a sustainable competitive advantage in an age where information is replacing inventory as the key enterprise asset. Internet technology has enabled SCM tools to provide accurate and timely information on the status of inventory within the enterprise and across the value chain (Murphy, 2002).

Collaborative business practices require the sharing of business and technical data that is often proprietary or at least "competition sensitive" information. Trust and data/process integration standards are imperatives for effective value chain management. This decision making necessitates establishing business rules that are driven by value chain needs in formation and operation of the virtual enterprise based on the trading partners' risk/reward contributions and value-added core competencies. C-commerce critical success factors are

- leveraging Internet technologies for first internal and then external data sharing,
- providing loosely coupled application interoperability via integration hubs across the value chain,
- focusing on core competencies associated with the established collaborative business practices for the demand chain via collaborative product commerce (CPC) models and the supply chain via collaborative planning, forecasting, and replenishment (CPFR),
- building virtual enterprises on trusted value chains to redefine competitive advantage,
- generating real-time visibility, event notification, and performance measurement throughout the value chain, and
- reengineering value chain management decision making processes.

C-commerce strategies are being built around CPC and CPFR business models. While CPC scenarios are most prevalent in the industrial products sector for build-to-order solutions, CPFR was created to solve supply chain problems in the consumer packaged goods (CPG) market space. Leading enterprises are employing both CPC on the demand side and CPFR on the supply side to form the basis of the value chain management decision making.

CPFR was initiated and trademarked in 1998 by the Voluntary Inter-industry Commerce Standards (VICS) association, a nonprofit organization taking a global leadership role in streamlining the flow of product information throughout the retail value chain. This innovative business practice is becoming a leading B2B model for c-commerce in the CPG industry. It uses forecasting models and real-time point-of-sale transaction information to produce a collaborative environment for trading partners to improve efficiencies in inventories, customer service, and bottom-line savings. CPFR facilitates collaborative relationships between buyers and sellers through co-managed processes and shared information. The goal of CPFR is to drive increased interoperability between trading partners so that their different information systems are able to seamlessly share information to realize more effective decision making. The benefits for all of the trading partners in using CPFR are to improve process efficiencies, increase sales, decrease fixed assets and working capital, and reduce inventory for the entire value chain while satisfying consumer needs by synchronizing demand and supply information (VICS, 2002).

Some of the biggest names in retailing such as Proctor & Gamble (P&G), Sears, and Wal-Mart have been early adopters of CPFR, with P&G, as well as Unilever Group and Kimberly-Clark, managing up to half their product lines via CPFR. Results to date are impressive: inventory including safety stock reductions of 10 to 20%, point-of-sale stock out reductions of 2 to 4%, with inventory turnover rates doubled. Heineken has the longest running CPFR initiative with a SCM application that supports 450 distributors by reducing order cycle times from three months to four weeks (Bowman, 2002).

These market leaders have been realizing significant benefits by deploying CPFR business practices via a PTX. CPFR has matured and proven its value proposition as an enabler of c-commerce with analyst estimates of $40 billion a year savings throughout the CPG industry resulting from driving out inaccuracies in information, inefficiencies in processes, as well as reductions in excess inventory that serves as safety stock at each stage of the value chain. Now several e-marketplaces that facilitate CPG value chains have embraced the UCCnet Global Registry data standards as a common language for collaborative SCM dialog (Swanson, 2002; Konicki, 2002). Worldwide Retail Exchange, Transora, and GlobalNetXchange have recognized that the inability to share information in an unambiguous manner has been a barrier to success. P&G is working with Transora to host and incrementally implement its 60,000-item product catalog as it executes a c-commerce strategy as an enterprise CPFR scenario. UCCnet provides links from the registry data to the P&G catalog on Transora to facilitate collaborative ordering, as well as transportation and inventory management activities with retailers.

Although less formally organized than CPFR, demand chain integration is already being realized in many Type A industries as popularized by Dell's B2C success story in the computer industry, using a CPC business model with scenarios such as B2B collaborative product development, build-to-order for mass customization, and collaborative sourcing (Halpern, 2001). CPC is the c-commerce strategy that spans the product life cycle with value chain activities that have reengineered the product definition, development, and delivery business processes. It involves promoting product data as intellectual capital for a shared asset of a virtual enterprise. The adoption of CPC principles is making new product introductions better, faster, and cheaper from such diverse groups as the over 80 companies of the Lockheed Martin Joint Strike Fighter team working in a virtual enterprise to build the new family of stealth aircraft for the United States and its allies to Microsoft and its manufacturing partner Flextronics to bring the new Xbox video game product to market (Keenan & Ante, 2002).

The integration hub architecture is the fundamental e-business platform to enable both CPC and CPFR value chain scenarios. Virtual enterprise data management services are contractually required for trading partner information as part of a service level agreement. They represent the c-commerce value proposition for integration and interoperability success to be realized whether provided by a PTX or e-marketplace. This services-oriented architecture, depicted in Figure 2, supports a virtual enterprise data management model via Web services that facilitate a standards-based, secure, shared data environment enabled by business process workflow technology for value chain management.

The integration services provided by EIPs act as virtual enterprise gateways providing semantic interoperability with diverse applications across multiple PTXs and public e-marketplaces. An integration hub contains a profile of every registered virtual enterprise member, including a catalog of their products, capabilities, and capacities, as well as their trading partner agreement and communication system preferences. This profile provides data directory and dictionary services that describe all the sharable information at the data element level that is owned by a

trading partner, including a security policy to permit the sharing of information with a virtual enterprise customer, but not with a potential competitor.

Virtual enterprise data management services include data format and communication translations as required for messaging services. Collaboration tools can also be provided to support both asynchronous groupware and synchronous real-time, multipoint data conferencing applications for both structured and unstructured data. In addition, an integration hub can offer product data exchange translation in accordance with the governing industry standards, as well as a library of application software for a vertical industry where native data format exchange is considered to be mission critical, such as the aerospace industry.

Core platform services, based on a services-oriented architecture embracing open systems concepts, are hosted on a Web server with firewalls and secure tunneling capable of handling public key encryption transactions. Layered Web services extend outward to support directory and middleware, including interoperable object management services for workflow, documents, and product data; generic business collaboration tools and messaging services; trading partner profile and catalog services to facilitate virtual enterprise partnering; and customizable vertical industry specific tools and application services.

The messaging services provide the enabling technology that is fundamental for decision making in a real-time enterprise. Such c-commerce messaging data provides the status of stock-on-hand that is stored at enterprise and trading partner locations, as well as in-transit across the value chain for inventory visibility. Furthermore, business activity monitoring (BAM) solutions generate event notifications associated with the business rules that reflect the roles and responsibilities of each trading partner. Finally, operational metrics are displayed as real-time dashboards for measurement of trading partner performance in accordance with their service level agreements to support value chain management decision making.

An EIP deployment, using the integration hub sourcing strategies shown in Figure 3, may be outsourced to a trading partner with an IT core competency in order to allow the enterprise to focus on executing its strategic business plan. These integration services will offer virtual enterprise gateways providing semantic interoperability with diverse applications such as a PTX that must operate with several intranets and extranets across multiple vertical industries as well as several public e-marketplaces. In general, enterprises need to build or acquire access to networks outside their four walls that will interoperate as a blend of extranets that consist of PTXs, as well as both public vertical industry and horizontal e-marketplaces that provide business process outsourcing and information integration services such as Exostar serving the aerospace industry and E2open providing supplier onboarding for high-tech electronics value chains.

The imperatives for these extranets can be best understood by emphasizing the need for c-commerce business rules. Enterprises must base these rules on the virtual enterprise data management model in a manner that reflects the unique collaborative needs for the specific set of trading partner networks that support the operation of the virtual enterprise.

In summary, c-commerce critical success factors include leveraging Internet technologies for first internal and then external data sharing; providing loosely coupled semantic interoperability for enterprise applications via integration hubs across the value chain; focusing on core competencies for collaborative business practices;

and building virtual enterprises on trusted value chains to redefine competitive advantage, generating real-time visibility, event notification, and performance measurement throughout the value chain, as well as reengineering value chain management decision making processes.

Future Trends

The e-business transformation that is being realized via c-commerce can be described in terms of management decision making processes utilizing feedback to leverage real-time virtual enterprise information. The two key adaptive strategic planning processes are

Building the virtual enterprise infrastructure using integration hubs, and

Making decisions to optimize value chain business performance.

As previously stated integration hubs, deployed as platforms for either a PTX or e-marketplace, provide the environment that facilitates c-commerce Web services for applications such as inventory visibility, BAM, and performance metrics displayed in real-time dashboards. Identifying and analyzing value chain performance trends enables enterprises to be able to adapt their strategic plans, redesign virtual enterprise configurations, and reallocate resources for their core competencies in order to optimize profitability in response to customer and market dynamics (Hoffman, 2002). The benefits of c-commerce can then be realized via leveraging the Internet as an enabling technology in order to transform enterprise core business management decision making practices.

This trend has renewed business interest in the *Balanced Scorecard* as part of a strategic business planning methodology that is being used to communicate the enterprise business strategy throughout the value chain. Kaplan and Norton (2001), the creators of the balanced scorecard, describe adaptive strategic planning in the context of "making strategy a continual process." Accordingly, there are three key e-business drivers for including the Balanced Scorecard as a fundamental model for the solution to the c-commerce strategy management problem:

Linking strategy and budgeting: Strategic initiatives and performance targets on the Balanced Scorecard link the enterprise strategy to the specific resource allocations for operating each value chain using "rolling forecasts" in a manner that reflects operating in continuously changing environments.

Closing the strategy loop: C-commerce messaging applications including systems displaying performance metrics in real-time dashboards can be linked to the Balanced Scorecard providing a new framework for exception reporting and adaptive business management practices, as well as focus on intangibles with leading indicators, such as intellectual and social capital, management talent, core competencies, and customer loyalty assets that are neglected by traditional lagging financial measurement.

Testing, learning, and adapting: Virtual enterprise management can be more proactive by testing and evaluating strategic value chain hypotheses with the information from the c-commerce messaging applications. Strategies for each value chain can evolve in real time in response to market dynamics.

An adaptive strategic planning system enables value chain management teams to make strategy a continual process by monitoring performance against enterprise and line-of-business strategies, updating the performance measures on the balanced scorecards using actual operations data in real time, collaborating as virtual teams with an executive dashboard to interpret the performance metrics, developing strategic insights with knowledge management tools in order to formulate new competitive directions, and then redetermining enterprise resource allocations to continuously reflect the dynamics of the business environment.

Such a c-commerce planning and control application, implemented as a decision support system (DSS), can be based on an enterprise and line-of-business Balanced Scorecard as well as real-time SCM performance analytics. It enables progress in executing the strategy to be monitored, as well as supports corrective actions to be performed in a timely manner. This adaptive strategic planning system serves as an enabler of a c-commerce strategy improvement process that links the real-time value chain performance, as feedback for the business operations control process, with the enterprise-level strategy.

The most complete and widely disseminated framework for the reengineering of the management decision making process is the *Beyond Budgeting Round Table* (BBRT) model that was developed by the Consortium for Advanced Manufacturing International (CAM-I), a not-for-profit collaborative research group. Sixty enterprises have sponsored the work of the BBRT since it was launched in 1998 to investigate organizations that had replaced their traditional centralized "budgeting" management model with an alternative model. The BBRT model is based on decentralized business decision making and adaptive management practices. The BBRT research shows that fixed strategies prevent agile responses, rigid organization structures inhibit innovation, entrenched functional silos undermine collaborative processes, focus on product targets works against customer loyalty programs, and short-term performance contracts fail to support long-term value creation. Implementing the BBRT model involves introducing new performance management processes, as well as decentralizing decision making power. As a result of embracing BBRT, BP-Amoco and Asea Brown Boveri have integrated budgeting as part of an adaptive strategic planning process, while Ford, Electrolux, and Sprint have leveraged their information infrastructure to enable real-time performance measurement for a "rolling budget" process (Bunce, Fraser, & Hope, 2002).

CAM-I believes that the BBRT initiative has a generic applicability. BBRT research confirms that operational excellence is no longer a sufficient element of a business strategy, although as with total quality, it is still an essential element of enterprise operating capabilities. Therefore, only enterprises that pursue continuous innovation or customer intimacy strategies that employ decentralized and adaptive decision making processes will prosper in the 21st century.

STRATEGIC PLANNING FOR BUILDING C-COMMERCE

Throughout the global marketplace, executive teams are asking the same questions that show concern over enterprise sustainable competitive advantage and even survival:

How are my industry's business models changing?
What candidate business models will work for me?
Where are the gaps in my enterprise readiness?
What road map can I use to manage these changes?

The challenge is to exploit the opportunities presented by c-commerce and then determine what and where the level of investment should be in the enterprise IT portfolio.

C-commerce Strategic Planning Methodology

Enterprises may employ a c-commerce strategic planning methodology to build a road map for the design, development, and deployment of a virtual enterprise enabled by real-time IT services-oriented architecture, as follows.

Step 1: Visioning via the Strategy Framework

During this step, the enterprise must establish a corporate e-business vision, and therefore, a resulting high-level c-commerce strategic direction as to how the enterprise is "To-Be" in the envisioned future. A top-down and bottom-up approach is adopted in Step 1 to ensure that the entire organization has input into establishing the corporate e-business vision of the "To-Be" enterprise and buys into it with CEO leadership.

Strategic CPC and CPFR scenarios using an integration hub services-oriented architecture reflect the different applications of value chain management under four main categories:

Demand chain management,
Customer/partner relationship management,
Supply chain management, and
Supplier relationship management.

Any c-commerce initiative can be positioned according to one of these four headings. Having identified the four ways in which c-commerce can be applied, strategic scenarios are ranked through a robust evaluation process in terms of the value of opportunity each scenario represents to the enterprise as well as the ability to deploy it. The resultant ideal "target zone" can be represented diagrammatically as illustrated in Figure 4.

Enterprises must formally evaluate each of the candidate scenarios against a number of business factors. These business factors relate either to "opportunity" or "capability" and are scored under each heading which generally consists of from 8 to 12 metrics that reflect the enterprise balanced scorecard.

The c-commerce visioning process requires three perspectives. The enterprise perspective provides insight of a company's current capabilities, culture, and vision. The marketplace perspective provides a view of realities and changes in industry practice, barriers to entry, competition, constituent behavior, and offerings. The technology perspective, with its associated policy impacts on the enterprise and marketplace, extends strategic thinking "out of the box" by discounting commonly held beliefs about markets, products, and competition. This forces enterprises to address new methods of doing

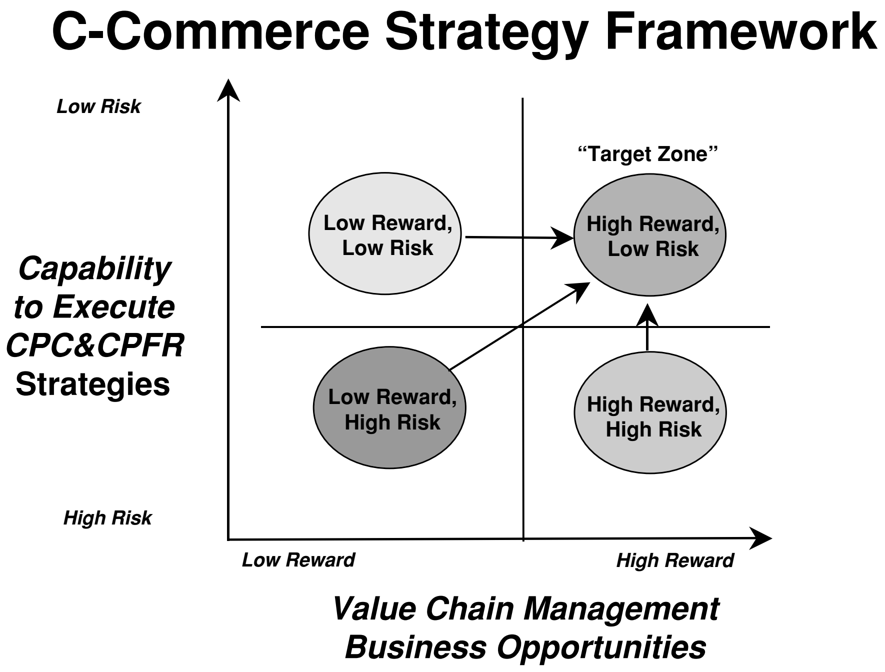

Figure 4: Strategic visioning for c-commerce.

business, new product offerings, and new competitive paradigms.

Development of the e-business vision and c-commerce strategy is not a one-time process. Because of the evolving nature of best practices, state-of-the-art product offerings, quality expectations and cultural changes, strategy development is iterative. C-commerce business models and strategies must be updated on a continuous basis.

Step 2: Virtual Enterprise Readiness Assessment

In Step 2, existing or "As-Is" enterprise processes and infrastructure are formally evaluated in order to establish a baseline of enterprise capabilities. The existing processes will indicate the need for and the ability of the organization to adapt to change. The infrastructure assessment will provide an understanding of the level of investment needed to implement a c-commerce initiative. The combination of these metrics will provide a score that will allow the aforementioned CPC and CPFR scenarios to be positioned in the c-commerce strategy framework.

Enterprises need to assess the maturity of their business, technology, and organization domains for evaluating c-commerce readiness (Sabath & Fontanella, 2002). They must assimilate the information gained through a due-diligence process for assessment of their core competencies and develop a mapping of pertinent IT capabilities to c-commerce business practices. This process should include a review of enabling technology and business model trends in their industry as a benchmark. Solidifying the understanding of the enterprise's technology and business challenges as well as developing the knowledge of core competencies concerning technology, business processes, and organizational capabilities is fundamental to crafting a c-commerce business strategy. The enterprise can then build a trading partner value proposition that can be leveraged in forming or joining virtual enterprises in a way that make strategic business sense.

Enterprises should look at three technology categories to assess their readiness to support a c-commerce business model: application portfolio, systems infrastructure, and network infrastructure. They should compare their "collaborative business vision" to benchmarks pertaining to B2B and B2C e-business models, as well as industry trends for CPC and CPFR value chain scenarios. It is critical for enterprises to evaluate their business process infrastructure, as well as organizational structure with respect to their ability to support customer-centric value chains. Again it is essential for enterprises to understand their core competencies from a product life cycle perspective, in terms of product development through product support, including customer and supplier relationship management capabilities.

Step 3: C-commerce Gap Analysis

Although the preliminary strategies and initiatives were identified in light of both enterprise opportunities and capabilities there is still a need to subject the enterprise c-commerce strategic architecture to a formal "gap analysis." In this step of the c-commerce strategic planning methodology the magnitude of the difference between the current "As-Is" environment as assessed in Step 2 and the future "To-Be" state of the enterprise as envisioned in Step 1 is formally evaluated.

A complete gap analysis, at a corporate level and in relation to each line of business must cover the following four elements:

- E-business drivers,
- Business processes,
- Enabling technologies, and
- Organization and culture.

This gap analysis must precede the next step of the project, which is to make recommendations on the implementation of the strategy. Performing the gap analysis allows for the identification of specific management approaches or activities required ensuring that the lines of business can execute their strategies as planned in support of the corporate business model.

Step 4: Strategic VEI Architecture

Virtual enterprise integration (VEI) is conducted in Step 4. This is where the vision, strategies, and initiatives generated during Step 1 are synthesized into an enterprise c-commerce strategic architecture. This top-level enterprise scenario can then be executed by the operational lines of business and integrated into their c-commerce strategy process with their resulting line of business level Balanced Scorecard performance management system.

The enterprise c-commerce strategic architecture integrates the total of all the initiatives developed within the corporate-level visioning and business-line-level initiatives and collectively represents the associated corporate and lines of business strategic plans. The strategic architecture for VEI comprises

- The e-business vision for c-commerce strategies;
- The core strategies applicable at a corporate level and a business line level, and their prioritization based on the attractiveness blend of the opportunity values and capabilities risks; and
- The c-commerce initiatives that will realize the strategies at corporate- and business-line levels, as well as their relative prioritization.

Note that this concept of VEI utilizes a three architecture approach as a model for c-commerce initiatives that provide real-time decision making for value chain management:

- VEI technology architecture for integration hub platforms via EIP products and Web services provides semantic interoperability for value chain visibility;
- C-commerce application architecture for value chain management integration of demand chain management, customer/partner relationship management, supplier relationship management, and supply chain management provides real-time BAM for event notification; and
- E-business process architecture for CPC and CPFR scenarios provides adaptive performance measurement.

Step 5: Implementation Road Map via Value Chain Analysis

The results of the gap analysis and strategic architecture development must be sequenced and the interproject dependencies must be taken into consideration in order to develop a road map for how to resolve the identified gaps. The implementation recommendations will also provide inputs into the strategic planning process that exists at a line of business level because each of the business lines may need to adopt enterprise recommendations for implementation of their specific initiatives and projects.

It is important for business leaders to understand that pilot testing of emerging collaborative business practices, in a representative management decision-making environment that has been instrumented for business case analysis, is the only rational way to mitigate the change management risks associated with the execution of a comprehensive enterprise strategy. An implementation road map must be orchestrated to identify and evaluate potential business process and enabling technology gaps by use of such a shared data environment capable of supporting the intranet, extranet, and Internet value chain scenarios, as well as to deliver incremental benefits in a self-funding or pay-as-you-go manner. The pilot test and evaluation results will also provide implementation requirements for recommended information technology investments. The pilot testing will further enhance the enterprise c-commerce strategic planning process that exists at a business line level (e.g., value chains for key commodities or customer/trading partner initiatives).

Incremental Implementation Road Map for C-commerce Pilot Projects

Execution of a comprehensive enterprise c-commerce strategy necessitates an endeavor that consists of enabling value chain initiatives and their related implementation road map. The following series of tasks serve as a guideline for navigating the incremental road map to implement the c-commerce pilot projects:

Task 1—Develop c-commerce business model by value chain.

Task 2—Develop e-business services architecture.

Task 3—Define virtual enterprise formation and CPC/CPFR scenarios.

Task 4—Develop intranet/extranet systems configuration.

Task 5—Perform intranet/extranet systems integration.

Task 6—Test c-commerce environment.

Task 7—Deliver lessons learned and business case analyses.

This pilot project incremental implementation road map is a framework for creating and deploying value chain management scenarios. It is further defined in terms of representative EIP service-oriented architecture products which may be used to source a scalable and extensible integration hub platform. Key to an effective EIP product selection is a solid understanding of enterprise requirements and identification of the audiences for which the portal will be targeted. Different audiences (employees vs. suppliers vs. trading partners vs. customers) will have very different needs, tastes, demographics, and requirements. Multiple portals in any large enterprise are quite likely and even desirable, since the EIP product selected must meet the needs of each intended community of interest for their intranet, extranet, or Internet-based value chain management scenarios. Choosing a product requires sound research and expert advice. Enterprises should leverage all available technology resources, perform due diligence on comparable reference implementations, and conduct pilot tests with the EIP product vendors before the selection of the best source for each e-business platform is finalized.

Using the incremental implementation model as a framework for a pilot project road map, enterprises can develop c-commerce competencies by investing in a portfolio of IT initiatives, which may include the following examples:

1. Integration hub infrastructure development via e-business platform,
2. Intranet integration via integration hub,
3. PTX for CPC extranet integration via integration hub, and
4. E-marketplace membership for CPFR Internet integration.

The value of the first project is to acquire the skills and know how to establish a baseline c-commerce capability and reusable enterprise integration technology platform that will meet the enterprise's present and future e-business needs.

The second project will provide a single, unified face to employees, suppliers, and customers as trading partners, worldwide. These intranets enable the enterprise's business lines to organize value chains in response to market dynamics. This results in the realization of virtual enterprise benefits, such as the integration of multiple ERP systems for seamless product transfer from distribution centers located across global operations in order to accommodate localized customer requirements and regional demand spikes. Such a virtual enterprise environment facilitates transformation of low-margin commodities into higher margin products that are differentiated by value-added services and mass customization value propositions.

An extranet implementation, which necessitates semantic interoperability for a more advanced degree of c-commerce maturity, serves as the third project using CPC business models. They employ an integration hub with product development and distribution functionality that facilitates each value chain as appropriate. This will enable the enterprise to control the specification and design of products for mass customization. CPC is a c-commerce strategy for exploiting new Web-enabled opportunities across product life cycle processes. Opportunities include both B2B and B2C business models, such as collaborative product development, customer self-service design, strategic product sourcing, manufacturing/distribution collaboration, and product support self-service portals.

The fourth project focuses on outsourcing via an e-marketplace membership to acquire the trading partner integration services needed by CPFR business models. Such a scenario leverages the public Internet for connectivity and Web services with virtual private networking capabilities to provide a secure shared data environment. These virtual enterprise data management services may be employed on a fee for service basis as appropriate for sharing contractually required trading partner information.

In summary, strategic planning for building c-commerce can incorporate a Balanced Scorecard utilizing a real-time performance management system to facilitate an adaptive strategic planning process for value chain optimization. An individual business case for each c-commerce initiative must be orchestrated in a manner that is logically consistent with the respective enterprise and lines of business balanced scorecards. This c-commerce strategic planning methodology blends CPC and CPFR capabilities in value chain scenarios to provide the basis for a compelling customer value proposition, as well as to realize VEI benefits for a sustainable competitive advantage. The integrated IT investment portfolio of c-commerce initiatives consists of strategic value chain pilot projects. The pilot projects may build on recommendations that enterprises employ a technology approach that evolves c-commerce capabilities to improve overall enterprise readiness and integrate key technical and application architecture components in a customer-centric manner via CPC and CPFR scenarios. The projects may produce pilot value chain solutions that can realize immediate competitive advantage and bottom-line payoff. The portfolio of CPC/CPFR pilots may then serve as a critical e-business transformation model for virtual enterprise change management, as well as provide the fundamental incremental investments for self-funding of c-commerce initiatives.

STRATEGIC PLANNING FOR PERFORMING C-COMMERCE

A challenge in the new 21st century economy is to adapt quickly to new business opportunities or threats by realigning enterprise strategy to efficiently and effectively create value. An adaptive strategic planning solution for enterprise business management decision making can provide a holistic approach to strategy management, business planning, target setting, rolling and event-driven forecasting, and business performance management based on financial and leading nonfinancial key performance indicators (KPIs). DSS applications can be used to support these activities in executing c-commerce strategies across a virtual enterprise that consists of multiple value chains with diverse organizational structures and management decision making processes.

Adaptive Strategic Planning Framework

Enterprises need a framework that facilitates adaptive strategic planning for value chain management. A suite of DSS applications provides the functionality needed to implement c-commerce business models. A continuous c-commerce strategic planning process approach, which adapts to the real-time execution of the business plans, is essential to value chain management success.

The four key DSS framework elements deployed in a service-oriented architecture as a network of integration hub platforms are as follows:

Execute via Balanced Scorecard,
Measure via Business Activity Monitoring,
Analyze via Knowledge Management, and
Model via Dynamic Simulation.

Execute via Balanced Scorecard

The execute function allows an enterprise to continuously translate c-commerce strategy into action within day-to-day business activities and to constantly adapt strategy with real-time feedback based on the actual operational performance of each value chain. Adaptive ability can be expressed in terms of three types of actions resulting from the management decision-making process: predictive, proactive, and reactive. Predictive controls involve anticipating a problem and deploying a solution in time to avoid the adversity. Proactive responses are associated with smooth recovery from a problem before it escalates. Reactive capabilities are limited by supply chain uncertainties to just-in-case deployments of inventory safety stock, as well as excessive resource allocation for production and distribution capacity in order to maintain contractual service level agreements.

Measure via Business Activity Monitoring

The most important feature of the adaptive strategic planning process is the ability to provide feedback by means of real-time performance measurement. As the enterprise executes its c-commerce strategy for each value chain, the world around it changes and that strategy must adapt accordingly. As a strategic management practice, adaptive strategic planning must be a learning process. The DSS should facilitate a dialog throughout the value chain so that performance can be interpreted, knowledge can be transferred, and improvements can be made. Real-time measurement is crucial because the longer the BAM latency the more management is limited to reactive rather than proactive decision making. Leading enterprises are using IT solutions for SCM to speed relevant performance information to the appropriate managers and to display these KPIs in a desktop dashboard as exception reporting to focus decision making attention. Critical success factors involve not only the determination of the correct KPIs, but also the refresh frequency for each KPI on each manager's dashboard.

Analyze via Knowledge Management

Key enabling technology trends in knowledge discovery and business intelligence are making management decision making breakthroughs possible. Data mining techniques permit extracting and transforming of data from multiple sources. Data mining can be classified as either descriptive or predictive, where descriptive mining tasks characterize the general properties of the data while predictive mining tasks perform inferences on the source data. These knowledge discovery techniques can be used to explore trends and relationships across a value chain. Knowledge management enabled by a DSS with these tools and databases can support analytic approaches used to test and evaluate value chain design and operational policy hypotheses, explain the higher level trends associated with the dynamics of supply and demand as part of the value chain management system, or generate new insights that update and refine the c-commerce strategy.

Model via Dynamic Simulation

The use of dynamic simulation of value chain business models will dramatically increase the effective execution of c-commerce strategies. Simulation allows the Balanced Scorecard cause-and-effect linkages of the strategy to be described mathematically and used for testing scenarios. This capability will help companies evaluate "what if" scenarios. It will allow the entire management team to participate in interactive sessions for the real-time development of strategy. Dynamic simulation software will have the same impact on strategic planning that spreadsheet software has had on financial planning.

The DSS for adaptive strategic planning can be applied to a range of business process modeling applications and work with live operational data to dynamically model processes. Such functionality provides a tool that allows users distributed across a virtual enterprise to collaborate in examining the potential opportunities or threats to planned business operations. The result of such collaboration is a clear understanding of the options, the risks, and the impacts across each value chain. Such predictive analyses can be shared across the value chain for joint decision making on the optimal alternatives that facilitate collaborative planning and forecasting activities.

DSS technology is emerging to enable the design and management of complex value chains for strategic, as well as tactical and eventually operational decision making. For example, at a recent Supply-Chain Council seminar (2002), Intel described how it uses a DSS at the strategic level to design a value chain based on validated CPC/CPFR models that ensure that the right product is placed in the right locations in the right amount at the right time based on service level agreement performance objectives. Then the tool can be used tactically to determine if these inventory management decisions are still valid based on the demand dynamics of the marketplace or on daily replenishment priorities, such as adaptive supply chain execution decisions in terms of which distribution center should fulfill an order.

The result is a new type of management tool that helps enterprises quickly identify the impact of changing market conditions on value chain performance and to access the best course of action to minimize risk and maximize revenue based on specified KPIs. It also provides rapid "what if" analysis to make decisions quickly and then can facilitate effective communication of that predicted performance information throughout the virtual enterprise using a service level agreement framework.

Deploying Decision Support for Adaptive Strategic Planning

An incremental implementation road map for a DSS leverages the practical application of various enabling technologies for an adaptive strategic planning framework discussed in the previous section. The fundamental concept is to generate/evaluate a strategic plan that adapts to the tactical and operational-level performance changes based upon the feedback from KPIs.

Such a road map for developing an adaptive strategic planning infrastructure is navigated in accordance with the following tasks:

1. Develop c-commerce business models by value chain. Craft a set of integrated intranet, extranet, and Internet value chain scenarios that represent supply chain optimization opportunities using the leverage of the CPC and CPFR models as a benchmark.
2. Focus on the integration hub service-oriented architecture to evaluate EIP product functionality for providing content management, enterprise application integration, and semantic interoperability services to support a DSS. Such a supply chain integration framework includes a modeling facility with value chain models that are hosted in a model repository featuring analysis and reporting tools that leverages data mining capabilities focusing on integration hub functionality for providing knowledge management capabilities.
3. Identify specific value chain operating scenarios and supply chain management issues within key enterprise initiatives and model the core processes using the dynamic simulation tools. The value chain models are populated with Balanced Scorecard KPIs. These models are then used to identify supply chain bottlenecks and analyze areas for process improvement, evaluate the business case associated with c-commerce initiatives, and design optimal value chains for specific target customer or market initiatives.
4. Focus on developing and testing the feedback mechanisms for Balanced Scorecard KPIs reporting of real-time BAM visibility data and event-based notifications captured from operational transactions that are facilitated by integration hubs. This is a key element of the adaptive decision making process that links supply chain performance management and business operations budgeting with enterprise-level c-commerce strategy.
5. Deployment of this initial adaptive strategic planning DSS completes the initial effort. The DSS facilitates changes to the alternative supply chain systems design and experimentation with potential outcomes as a result of these scenario changes, thereby "evolving" the strategic plan. The DSS provides a knowledge base for investment portfolio management of the c-commerce initiative information needed for the strategic and business planning effort, as well as facilitates the development of business cases supporting these initiatives.
6. For the adaptive strategic planning decision making process reengineering to be fully realized, the successful DSS pilot system implementation must be extended

and rehosted on an enterprise-class server. This provides the scalable integration hub platform needed to support a fully operational competency center for real-time value chain management as part of a multiphase iterative implementation effort to realize incremental benefits. The strategic Balanced Scorecard KPIs are then deployed using a distributed network of integration hubs thereby instrumenting each of the various c-commerce value chain scenarios with the appropriate dashboards. Each dashboard reflects actual KPIs as the performance metrics associated with the individual decision maker's view of the virtual enterprise operations in an actionable way.

The combination of a DSS for strategic planning with an operational value chain management system competency center provides the feedback system to optimize value chain investment, as well as assure virtual enterprise agility. Thus, the benefits of VEI are achieved by implementing an orchestrated choreography of CPC and CPFR scenarios executed in accordance with the appropriate intranet, extranet, and Internet business case analysis.

C-COMMERCE LESSONS LEARNED AND NEXT STEPS

Reengineering the business decision making process is the e-business transformation that is driven by c-commerce. This transformation is already underway by market share leaders in all major industries so that the real-time enterprise is fast becoming a reality (Siegele, 2002). It will be further accelerated by realization of three key issues:

1. Development of intellectual and social capital performance management systems that enable value chain management business case analysis methodologies to evaluate innovation and trust competencies for virtual enterprise formation, especially e-marketplace value propositions in order to facilitate small and medium size enterprises as trading partners.
2. Dissemination of process and data standards, such as UCCnet for retail products, as well as RosettaNet for electronics and ebXML for international trade, to facilitate application integration, as well as shared ontologies and semantics mediation/mapping tools for ubiquitous trading partner interoperability.
3. Creation of value chain management solutions based on Web services technologies for plug-and-play products to support dynamic VEI environments, such as generic "Collaborama" platforms capable of supporting a wide variety of diverse scenarios, including network applications from multiplayer interactive game entertainment to global environmental disaster recovery problem solving.

In conclusion, the two major incentives for trading partners to adopt c-commerce as a business strategy, productivity and competitiveness, have the value chain management model as a common denominator. Continuous productivity improvements are focused on internal enterprise integration endeavors driven by intranet applications and reengineered business practices to decrease costs and increase inherent quality. Sustainable competitive advantages are focused on external enterprise integration opportunities driven by extranet applications and newly created virtual enterprise business processes enabling collaboration to decrease time to market and increase agility. Although competitiveness can be a much greater incentive than productivity, enterprises that have not yet integrated their intranet applications and associated business processes to facilitate collaboration must do so before risking extranet deployment. The business experience and technical infrastructure that an enterprise gains from internal process collaboration and information integration initiatives provide the prerequisite capabilities that extend to trading partners in order to realize value chain management success.

GLOSSARY

Balanced scorecard A strategy and management system that provides a holistic view of enterprise success from the perspective of financial, customer value, business process, and innovation key performance measures that include both leading and lagging indicators linked in cause-and-effect relationships.

Collaborative commerce (c-commerce) A strategy for the next stage of electronic business evolution with business practices enabling trading partners to create, manage, and use data in a shared environment to design, build, and support products throughout their life cycles, working separately to leverage their core competencies together in a value chain that forms a virtual enterprise. Collaborative planning, forecasting, and replenishment (CPFR) and collaborative product commerce (CPC) are the two business collaboration patterns that have achieved broad industry consensus for realizing c-commerce strategies by enabling virtual enterprise integration. CPC applications facilitate mass customization scenarios via demand chain integration while CPFR applications facilitate mass production scenarios via supply chain integration.

Collaborative planning, forecasting, and replenishment A business practice that facilitates mutual risk/reward relationships between buyers and sellers via shared processes and information by synchronizing demand chain and supply chain activities.

Collaborative product commerce A business practice that facilitates product development between trading partners in a value chain by sharing product assets and intellectual property based on mutual business interests.

Decision support system A business management system that employs a suite of application software packages as tools, such as analytical processing and dynamic simulation, designed to assist human decision makers in solving complex problems.

Demand chain The community of organizations with the assets, processes, and information that generate elements of demand for a product.

E-marketplace An environment that operates to aggregate buyers and sellers in various vertical and horizontal industries, offering market intelligence to both parties to understand buying behavior and improve e-procurement processes, as well as collaborate with trading partners in the value chain for increased visibility to reduce inventory and processing costs.

Enterprise information portal A platform that supports targeted user communities for access to relevant structured transactional information, aggregated business intelligence data and trends, unstructured documents and collaborative sources, Internet content, and Web services, as well as interaction with integrated applications and business processes for personalized communications between enterprise trading partners.

Enterprise resource planning An integrated business management system that uses multifunction application software packages designed to serve and support multiple business functions such as planning, manufacturing, sales, marketing, accounting and finance, and human resources. The fundamental ERP platform has been extended using an open architecture with vertical industry-specific functionality to extend the enterprise into the demand chain for customer relationship management and into the supply chain for supply chain management.

Extensible markup language A specification developed by the World Wide Web Consortium, used for defining data elements on a Web page and business-to-business documents. The extensible markup language (XML) uses hypertext markup language (HTML) tag structures. HTML only defines how the elements are displayed; XML defines what the elements contain. This allows the designer to create their own customized tags, enabling the definition, transmission, validation, and interpretation of data between applications and between organizations.

Extranet A data communications network leveraging the Internet as an enabling technology for external enterprise integration.

Integration hub The fundamental c-commerce platform for a standards-based, secure, shared data environment enabled by business process workflow technology for value chain management between trading partners that operate as a virtual enterprise.

Intranet A data communications network leveraging the Internet as an enabling technology for internal enterprise integration.

Private trading exchange An environment that provides real-time interoperability with multiple trading partners, automates and integrates complex business processes across the value chain, secures proprietary information from competitors, and facilitates deployment of agile business models.

Supply chain The community of organizations with the assets, processes, and information that provide elements of supply for a product.

Value chain A trading partner community with mutually beneficial interests spanning from the initial suppliers' supply chain to the final customer's demand chain.

Virtual enterprise integration The use of information technology and collaborative business practices to enable semantic interoperability for the dynamic management of the organizational boundaries in the value chain between trading partners.

Common Gateway Interface (CGI) Scripts

Stan Kurkovsky, *Columbus State University*

INTRODUCTION

Common gateway interface, CGI for short, is the most common method for passing information from an HTML (hypertext markup language) page in the client's browser to an application running on the Web server, which can process that information (Kew, 2000; CGI, 1999). CGI is completely independent from the browser on the client computer. In fact, it works with any browser, because, unlike HTML content, it does not have to be loaded into and interpreted or executed by the client browser. CGI is not a programming language. As the name explains, it is an interface, or a set of rules that allows an external program to receive an input from a Web browser and produce an output in form of an HTML page.

ORIGINS OF CGI

The Internet is ubiquitous these days, but it is far from being a brand new technology. It has always contained a variety of protocols for exchanging information, but the advent of Web browsers induced Internet's sudden explosive growth. Today, when people hear about the Internet, they associate it with the Web. What makes the Web so attractive that it has become a part of our everyday lives and a business vehicle for many companies? What distinguished the Web apart from other Internet technologies, such as Gopher and FTP (file transfer protocol), was its visual appeal and true interactivity. Even the earliest versions of the HTML standard provided tools for adding images to formatted text, which clearly makes the Web more attractive than a typically command line-based FTP. The Web is interactive and it is not only because the users can browse it by following the links leading from one page to another, but also because the Web has become a true dynamic resource. In the early days of the existence of the World Wide Web, it was merely a collection of personal home pages and academic and corporate Web sites containing a variety of information. All these Web sites were static because they did not change from one request to another. CGI was the first technology that allowed the Web to become dynamic. For example, when the user fills out a registration form, a CGI script would verify that all fields are filled in and contain valid information—there is both first and last names, the telephone number contains a 3-digit area code and a 7-digit number, etc. If the form is incomplete or the data appear to be invalid, the same CGI script would present the user with a message explaining how to correct the information on the form. The same script would add this information into the database and inform the user about the successful registration in case if there were no errors in the data submitted from the form.

Despite the fact that there are many technologies competing with CGI, it remains one of the most common platforms for developing Web applications because of its many advantages. The foremost advantage of using CGI scripts is that this is a true cross-platform technology. CGI scripts work with any Web browser; they also work with most (if not all) Web servers running on Windows and UNIX. The second advantage is that CGI scripts can be written in almost any language the programmer chooses. Such languages as C++ or Perl offer the best support for implementing CGI scripts. The interface of CGI is very simple and does not require any special libraries. For the most part, CGI scripts can rely on the operating system's application programming interface (API) for standard input and output and use the environment variables to communicate with the Web server.

CGI ARCHITECTURE

Usually, when the user clicks on a link in an HTML page or simply types a URL directly in the browser's address field, the browser sends a hypertext transport protocol (HTTP) request to the Web server. If the requested document is a static HTML page, the Web server simply finds the corresponding HTML document on its file system. If the requested HTML document was successfully located on the server file system, it is then returned with the server's HTTP response to the client's browser. However, when a Web server receives a request for a CGI script, the Web server passes some parameters to this script and executes it. The script runs and generates some output, which is then collected by the Web server and returned to the client's browser (Figure 1).

Local intranet

Figure 1: HTTP request for a CGI script.

Let us consider this simple CGI script written in Perl:

```
#!/usr/bin/perl -w

print <<HELLO_WORLD;
Content-type: text/html

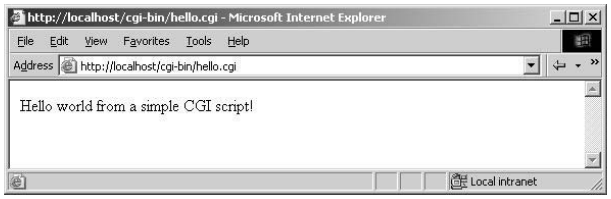
Hello world from a simple CGI script!
HELLO_WORLD
```

Assuming that this script is pointed to by URL http://localhost/cgi-bin/hello.cgi, the user clicks on a link to this URL or simply types this URL in the address field of the browser. These actions will produce the output shown in Figure 2 in Microsoft Internet Explorer 6.

A CGI script has dynamically generated the HTML content, which is displayed in the browser. Before the user could see such an output, the user's Web browser had to send an HTTP request to the Web server. CGI scripts are requested in very much the same way as regular HTML documents—their address is passed to the browser in a URL. Figure 3 presents some common components of a URL that can be used to request a CGI script.

Typically, CGI scripts are stored in a special directory on the Web server's file system, which is mapped into the virtual directory named cgi-bin. Also, CGI scripts commonly have a specific extension, such as .cgi. Data from an HTML page can be passed to a CGI script in the query part of the URL by using an HTTP GET request. CGI scripts can also use an HTTP POST request to receive data from HTML forms. This is discussed later.

The URL used in our first example consists of the components shown in Figure 4.



http://localhost/cgi-bin/hello.cgi - Microsoft Internet Explorer
File Edit View Favorites Tools Help
Address http://localhost/cgi-bin/hello.cgi
Local intranet

Hello world from a simple CGI script!

Figure 2: Output of a simple CGI script.

Requesting such a URL by clicking on a corresponding link would generate the following HTTP GET request:

```
GET /cgi-bin/hello.cgi HTTP/1.1
Host: localhost
```

When the Web server receives such a request, it typically checks the file extension of the requested resource (/cgi-bin/hello.cgi in this case) to determine the type of the document. If the .cgi extension is associated with a CGI script on the Web server and it recognizes the /cgi-bin as the directory for CGI scripts, the Web server will execute script hello.cgi instead of treating it as a static HTML document.

When a CGI script's process is invoked, it exists in an environment created for it by the Web server. Typically, this environment includes certain predefined variables and standard file handles. Specifics of this environment may sometimes vary between different Web servers. Table 1 lists some standard CGI environment variables (*CGI environment variables*, n.d.).

A simple Perl script can be used to produce an alphabetic list of all variables currently defined in the environment of a Web server:

```
#!/usr/bin/perl -w

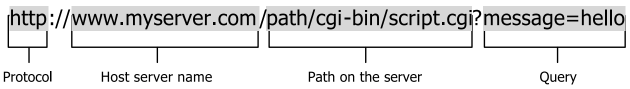
use strict;

print "Content-type: text/html\n\n";

print "<TABLE>";

my $EnvVarName;
foreach $EnvVarName (sort keys %ENV) {
  print "<TR><TD><B>$EnvVarName</B></TD>";
  print "<TD>$ENV{$EnvVarName}</TD></TR>\n";
}

print "</TABLE>"
```



http://www.myserver.com/path/cgi-bin/script.cgi?message=hello
Protocol

Query

Figure 3: Structure of a URL.

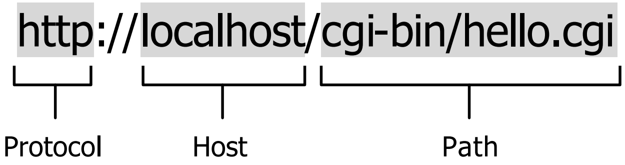

Figure 4: Structure of a simplified URL.

Running the script above on Windows 2000 with Internet Information Services 5.0 produces the output, a fragment of which is shown in Figure 5. Note that not all the standard environment variables are present and several other variables are added by the server.

Beside the environment variables, a Web server creates several standard file handles that are available to the CGI script:

STDIN contains encoded data from an HTML form when it is submitted using POST request. The length of valid data in STDIN is determined by the value of the *content-length* HTTP header. For GET requests, STDIN is empty.

STDOUT is used by CGI scripts to create their HTML output. It may include some HTTP headers.

STDERR output typically is used for logging errors that occurred in a CGI script. However, particular details of handling STDERR output depend on the specifics of the HTTP server.

When a CGI script generates an HTML output, it must be preceded by some HTTP headers to be successfully interpreted by the Web server and then delivered to the client browser. CGI scripts do not need to generate complete HTTP headers—the Web server typically will complete the header as long as one of the following partial headers are present:

```

Figure 5: Output of a CGI script listing standard environment variables.

Content-type specifies the media type that will be produced by the CGI script;

Location specifies a URL and is used for redirecting the output; and

Status header is used to exchange information between the CGI script and the Web server.

In order for the Web server to successfully create an HTTP response and deliver the resulting document to the client browser, the CGI script must indicate the media type that the document contains. In most cases, when a CGI script generates an HTML document, it must include the following content-type header:

```
Content-type: text/html
```

The content-type header may contain any valid media type. For example, the following header indicates that the

Table 1 Some Standard CGI Environment Variables

AUTH_TYPE	If the server supports user authentication, and the script is protected, this is the protocol-specific authentication method used to validate the user.
CONTENT_LENGTH	The length of the said content as given by the client.
CONTENT_TYPE	For queries that have attached information, such as HTTP POST and GET, this is the content type of the data.
GATEWAY_INTERFACE	The revision of the CGI specification to which this server complies.
HTTP_ACCEPT	The MIME types which the client will accept, as given by HTTP headers.
HTTP_USER_AGENT	The browser the client is using to send the request.
PATH_INFO	The extra path information, as given by the client.
PATH_TRANSLATED	The server provides a translated version of PATH_INFO, which takes the path and does any virtual-to-physical mapping to it.
QUERY_STRING	The information which follows the ? in the URL which referenced this script.
REMOTE_ADDR	The IP address of the remote host making the request.
REMOTE_HOST	The hostname making the request.
REQUEST_METHOD	The method with which the request was made.
SCRIPT_NAME	A virtual path to the script being executed, used for self-referencing URLs.
SERVER_NAME	The server's hostname, DNS alias, or IP address as it would appear in self-referencing URLs.
SERVER_PORT	The port number to which the request was sent.
SERVER_PROTOCOL	The name and revision of the information protocol of the request.
SERVER_SOFTWARE	The name and version of the information server software answering the request.

CGI script returns a single JPEG image:

```
Content-type: image/jpeg
```

It is imperative that the content-type header is followed by a blank line. This tells the Web server that all subsequent output generated by a CGI script should be treated as content, but not as a part of HTTP header. The simple Perl script below correctly creates a content-type header that indicates that the CGI script's output contains an XML document:

```
#!/usr/bin/perl -w

print "Content-type: text/xml\n\n";
```

Quite often a CGI script may serve as a sort of dispatcher that, instead of generating customized output, simply returns different URLs upon examining the input. CGI scripts can forward the client browser to a specific URL by using the location header. The following Perl script generates an HTTP header that redirects the client browser to an HTML page mypage.html.

```
#!/usr/bin/perl -w

print "Location: mypage.html\n\n";
```

The location header may contain absolute as well as relative URLs. A relative URL containing a full path is resolved by the Web server, which opens the referenced resource and returns it to the client browser as if it were the output of the CGI script. In all other cases (if it is an absolute URL or a relative URL containing a relative path), the generated URL is sent to the client browser. Now it is a responsibility of the client browser to generate an HTTP request for the resource referenced in the received URL. Most current Web browsers do this automatically.

The status header does not directly map into an HTTP header—it is only used to exchange information between the CGI script and the Web server. If the execution of a CGI script was successful, there is no need to specify the status header. In such a case the Web server will automatically add the following HTTP status headers:

200 OK if the CGI script returned a content-type header, or

302 Found if the CGI script returned a location header.

If the execution of a CGI script was unsuccessful, the status header can be used as a tool to communicate the error code and error message back to the Web server. It is important to use a standard status code (Fielding et al., n.d.). Such a code should be chosen to fit the actual error that occurred in a CGI script. For example, HTTP status code *415 Unsupported Media Type* can be generated by a CGI script, which does not know how to handle a particular media type. Whenever a CGI script chooses to return an error status code, it should also return a content-type header and a user-friendly HTML document describing the nature of the occurred problem in less technical terms.

Local intranet

We have encountered a problem

The requested media type is not supported

Figure 6: Typical use of HTTP status header.

For example, the following Perl script generates such a message:

```
#!/usr/bin/perl

print <<END_OF_ERROR_MSG;
Status: 415 Unsupported Media Type
Content-type: text/html

<HTML>
   <HEAD>
      <TITLE>415 Unsupported Media Type
        </TITLE>
   </HEAD>
   <BODY>
      <H1>We have encountered a problem
        </H1>
          <P>The requested media type is
            not supported</P>
   </BODY>
</HTML>
END_OF_ERROR_MSG
```

The CGI script above generates the output shown in Figure 6.

Approaching this problem from a more practical perspective, nowadays most CGI script developers choose not to use a status header. They simply prefer to write scripts that always return a content-type header (with a success status code added by the Web server by default). If an error occurs they handle it by the logic embedded in their scripts and communicate the nature of the problem to the user by including a corresponding error message in the generated HTML document.

The most common way to invoke a CGI script is by submitting input from an HTML form. Forms provide a very flexible tool for building front-ends for all Web-enabled applications, including those implemented with CGI scripts. In most cases, HTML forms are used for two related purposes: collecting input and accepting commands. These tasks are often related because frequently the nature of a command depends on the context specified in the user input. In a typical interactive Web application, HTML forms can be used to collect data, which is then stored in a database located on the Web server. For example, such an application may maintain a database of its users, who can log in to the Web site to access its personalized content. Figure 7 shows a typical example of a user login form needed to enter the Web application described above.

```
<HTML>
<HEAD>
<TITLE>Login</TITLE>
</HEAD>

<BODY>

<H1>User identification required</H1>

<P>Please enter your login information:</P>

<FORM NAME="LOGIN" ACTION="/cgi-bin/
  login.cgi" METHOD="POST">
<TABLE BORDER="0">
  <TR><TD>User name:</TD>
      <TD><INPUT TYPE="TEXT" NAME=
        "USERNAME"></TD></TR>
  <TR><TD>Preferred language:</TD>
      <TD><SELECT NAME="LANGUAGE" SIZE=3>
          <OPTION SELECTED>English</OPTION>
          <OPTION>Francais</OPTION>
          <OPTION>Deutsch</OPTION>
          </SELECT></TD></TR>
  <TR><TD COLSPAN=2><INPUT TYPE="SUBMIT"
    VALUE="Login">
                  <INPUT TYPE="RESET"
                    VALUE="Reset"></TD>
                    </TR>
</TABLE>
</FORM>

</BODY>
</HTML>
```

It is important to notice the names of the HTML form tags because they are used to pass the entered information to the Web server and then to a CGI script. Clicking the “Login” button on this form would generate the HTTP request

```
POST/cgi-bin/login.cgi HTTP/1.1
Host: localhost
Content-Length: 34
Content-Type: application/x-www-form-
  urlencoded

USERNAME=JohnQDoe&LANGUAGE=English
```

When this request is passed by the Web server to a CGI script, because this is a POST request, the Web server removes all HTTP headers and passes the remainder of the message to the CGI script:

```
USERNAME=JohnQDoe&LANGUAGE=English
```

The difference between POST and GET method, as far as CGI scripts are concerned, lies in the method used for passing on the form data. When a POST request is used, form data are passed through STDIN and the script should read from there. The number of bytes to be read is specified in the content-length header. When a GET request is used, the data are passed in the environment variable QUERY_STRING. The value of the content-type header (typically, application/x-www-form-urlencoded) is the same for both GET and POST requests. If the form shown above were changed to use the GET request, clicking the Login button would generate the HTTP request

```
GET /cgi-bin/login.cgi?USERNAME=JohnQDoe
  &LANGUAGE=English HTTP/1.1
Host: localhost
Content-Type: application/x-www-form-
  urlencoded
```

To process either one of HTTP requests shown above, one might write a CGI script in Perl, C, or any other suitable language. However, processing input generated by HTML forms requires a number of routine manipulations that are reused from one script to another. Perl provides a specialized module, CGI.pm, which is a de facto standard for creating CGI scripts with Perl. Besides parsing the input generated by HTML forms, it also contains routines for generating HTML code fragments including headers and forms. A CGI script taking advantage of CGI.pm module should include the following statement in its beginning:

```
use CGI;
```

A simple CGI script taking advantage of features offered by CGI.pm module can be used to process the input generated by the log-in page presented above. All that needs to be done is to generate appropriate HTTP headers and produce a customized HTML output based on the user selection:

```
#!/usr/bin/perl -w

use strict;
use CGI;

my $cgi = new CGI;
my $message;

print $cgi->header("text/html"),
      $cgi->start_html(-title => "Welcome
        Page");

if ($cgi->param("LANGUAGE") eq "English") {
     $message = "Welcome to our web site,";
}
```

```
elsif ($cgi->param("LANGUAGE") eq
  "Francais") {
      $message = "Bienvenue a notre site
        web,";
}
elsif ($cgi->param("LANGUAGE") eq
  "Deutsch") {
      $message = "Willkommen zu unserer web
        site,";
}
else {
      $message = "We do not know what
        language you speak,";
}
print $cgi->h1($message, $cgi->param
  ("USERNAME"), "!"),
       $cgi->p("We are so glad to let you
         test-drive our CGI scripts written
         with CGI.pm"),
       $cgi->end_html;
```

To access any feature offered in CGI.pm, the script creates a corresponding object called cgi. It includes collection param, which contains parsed parameters received by the Web server from the client and passed into the script. This script also takes advantage of HTML-generating capabilities of CGI.pm and creates the following HTML output (indentations and line breaks have been added):

```
<?xml version="1.0" encoding="utf-8"?>
<!DOCTYPE html
   PUBLIC "-//W3C//DTD XHTML Basic 1.0//EN"
   "http://www.w3.org/TR/xhtml-basic/
     xhtml-basic10.dtd">
<html xmlns="http://www.w3.org/1999/xhtml"
  lang="en-US">
   <head>
      <title>Welcome Page</title>
   </head>
   <body>
      <h1>Welcome to our web site,
        JohnQDoe !</h1>
      <p>We are so glad to let you
        test-drive our CGI scripts written
        with CGI.pm</p>
   </body>
</html>
```

Figure 8 shows what this HTML code looks like when displayed in Internet Explorer 6.

Welcome to our web site, JohnQDoe !

We are so glad to let you test-drive our CGI scripts written with CGI.pm

Figure 8: CGI script output—greetings.

A major challenge of any CGI application is the statelessness of HTTP. Most interactive Web applications must identify the sequence of page requests made by the same user. It is difficult to underestimate the importance of maintaining state and collecting information about each individual user's session (series of interactions with the Web site). For example, many travel Web sites allow their users to build flexible itineraries. In many cases, the user needs to enter some data on every page in a long sequence of pages (enter departure and return date and location, then select the departing flight and then select the return flight). Building a complex itinerary may require entering some information or clicking on buttons on every one of five or more pages. Such a travel Web site must track each user through their individual sequences of visited pages and collect all entered data to assemble a complete itinerary. There are several different ways to maintain state in a CGI application. These methods include using query strings to pass additional parameters, using hidden form fields, and manipulating client-side cookies.

A CGI script behind a large-scale Web application typically would take advantage of many (if not all) HTML form tags. Also, it is typical for the same CGI script not only to process the user input from an HTML form, but also to generate the form itself. Such an approach is illustrated below by a demonstration of a pizza-ordering application implemented as a single CGI script. This is a typical scenario of the user interaction with the CGI script of this application:

The CGI script is reached by an ordinary link or its URL is typed directly in the address field of the browser

Since the CGI script sees no form data, it generates the form.

The user fills this out, and submits it, and the data are sent back to the same CGI script.

Since the CGI script sees that it has been sent data, it now generates the confirmation message.

The following example uses a single CGI script that generates and processes customized pizza orders:

```
#!/usr/bin/perl -w

use strict;
use CGI;

my $cgi = new CGI;
my $error_message;

print $cgi->header("text/html"),
      $cgi->start_html( -title =>
        "Pizza Order");

if(defined ($cgi->param("customer"))) {
   if($cgi->param("customer") eq "") {
      $error_message = $cgi->p($cgi->b
        ("Order incomplete - please enter
        customer name"));
      print_form();
   }
   else {
      print_order();
   }
}
```

Place Order | Clear Form

Figure 9: CGI script output—pizza order form.

```
else {
   print_form();
}

print $cgi->end_html;
```

To determine whether the script currently needs to generate the input form or process the user input from this form, this CGI script checks whether parameter "customer" is defined. CGI.pm generates it upon examining the HTTP GET or POST request passed into the CGI script. The data in this parameter are created by the user input in the form, particularly, by filling out the field "Customer name." If this parameter is not defined, it means that this CGI script was invoked directly and it needs to generate the form. The Perl sub procedure print_form generates the output shown in Figure 9:

Place Order | Clear Form

Figure 10: CGI script output—errors on the form.

Note that the $cgi->start_form call generates a form tag that specifies the current script as the form action. Variable $error_message may contain any error messages that will be included in the output if the submitted information is incomplete. In particular, this script checks whether the customer's name was specified. If it was not, the script will not process the order and display the form once again with the error message indicating any input discrepancies (Figure 10).

Once the order form is complete, this CGI script generates an order confirmation by calling sub procedure print_order. This sub procedure generates the HTML output presented in Figure 11:

```
sub print_order {
   my @toppings_list = $cgi->param
     ("toppings");
```

```
sub print_form {
  print $cgi->h1("Please place your pizza order here"),
     $cgi->hr,
     $error_message,
     $cgi->start_form,
     $cgi->table( { -border => 0},
        $cgi->Tr( [
           $cgi->td( ["Customer name", $cgi->textfield(-name => "customer")]),
           $cgi->td( ["Size," $cgi->popup_menu(-name => "size",
                      -values=> ["Small", "Medium", "Large", "Supreme"]) ]),
           $cgi->td( ["Crust", $cgi->radio_group(-name => "crust",
                      -multiple =>0, -columns=>3,
                      -values => ["Regular", "Thin", "Stuffed"]) ]),
           $cgi->td( ["Toppings", $cgi->checkbox_group(-name =>"toppings",
                      -columns=>3,
                      -values => ["Extra Cheese", "Pepperoni", "Mushrooms",
                      "Ham", "Italian Sausage", "Peppers",
                      "Jalapeno," "Pineapple," "Anchovies"]) ]),
           $cgi->td( [$cgi->submit(-value =>" Place Order "),
                     $cgi->reset(-value =>" Clear Form ") ]),
        ])
     ),
  $cgi->end_form;
}
```

Thank you for placing an order!

John Q Doe - you ordered a Stuffed crust Supreme pizza with the following toppings:
Extra Cheese, Ham, Pepperoni, Italian Sausage, Mushrooms, Peppers

Figure 11: CGI script output—order confirmation.

```
    print $cgi->h1("Thank you for placing
      an order!"),
           $cgi->p($cgi->param("customer"),
             " - you ordered a ",
           $cgi->param("crust"), "crust",
           $cgi->param("size")," pizza with ",
           (@toppings_list ? ("the following
               toppings:",
                          $cgi->br, join(", ",
                            @toppings_list)) :
"no toppings"));
}
```

Such an iterative approach is used in most CGI scripts designed for processing user input. First, the script generates the input form. Second, the same script is used to verify the completeness and correctness of the entered data. Third, the data are processed by the script and typically saved in a server database. Note that instead of verifying the completeness of the data entered in the form with the help of the CGI script on the server side, it is often more convenient to use JavaScript on the client side and make such verifications before the form is submitted to the Web server. Once the data from the form have been accepted and analyzed, CGI script either generates the confirmation output or moves on to presenting the user with the next form. User input in multiple forms may be necessary in large e-commerce applications when there is a need to collect a large amount of information. For example, in an online bookstore, it may be necessary to enter customer information in several steps:

Enter mailing address
Enter payment information
Verify shopping basket content and order amount
Confirm order

CGI LANGUAGES AND ALTERNATIVES TO CGI

Most examples in this article are written in Perl. However, almost any programming language can be used for writing CGI scripts. A programming language must be able to produce an executable program that would satisfy the following two criteria in order to be used for CGI scripting:

The program must be text-based and not require a GUI, and

The program must generate a valid HTML content-type header.

The following is a list of some common programming languages that can be used for writing CGI scripts.

Perl

Currently, Perl is the dominant language for writing CGI scripts (Wall et al., 2000; Castro, 2001). This is because Perl is easy to use and to learn (it is similar to C), it has all the features needed for CGI programming (transparent IO and access to environment variables), and it is a very popular scripting language for UNIX—the first platform to support Web servers. Another factor contributing to the popularity of Perl is a wide availability of libraries that facilitate writing CGI scripts. The CGI.pm module makes a number of CGI-related tasks easier (in particular, it converts the data from form input into a data structure) and usually it is bundled with Perl interpreters. Because Perl was the first widely used CGI programming language, there is a lot of open source CGI scripts that have been written over the years and are freely available on the Internet. Very often it is very easy to download a working script and adapt it to the particular problem at hand. From the programming point of view, Perl is appealing because it contains extremely powerful string manipulation operators, it easily interfaces with external applications, and in cases when errors occur, Perl generates specific and detailed error messages (Guelich, Gundavaram, & Birznieks, 2000). The only possible disadvantage of using Perl for CGI scripting is that it is an interpreted language and therefore its performance may be diminished. However, most implementations of Perl compile source code into low-level intermediate code and then execute them.

C/C++/C#

Just like any other compiled languages capable of creating command-line executables, C and C++ are good candidates as programming languages for writing CGI scripts (Deitel & Deitel, 2002). Compared to the fastest Perl script, most likely a similar C/C++ program will start and execute faster because it has already been compiled, while a Perl script will have to be interpreted before it can be executed.

It is important to compare scripting languages (such as Perl) to compiled languages (such as C/C++) from the perspective of using them for CGI scripting. The main advantages of compiled languages are:

Performance. Programs written in a compiled language are always readily available to execute and do not incur an overhead of loading an interpreter every time they need to run. Performance is crucial in the Web environment when a CGI script may have to process numerous requests in a short period of time.

Flexibility. Most compiled languages are general-purpose languages. That is, they are designed to suit almost any programming task. Scripting languages, in contrast, almost always are designed for a particular type of task. In some cases, scripting languages may lack a particular feature needed to implement a particular CGI script.

The main advantages of scripting languages include:

Rapid development. Most scripting languages have higher-level statements than those of common-purpose compiled languages. For example, Perl has a lot of tools specifically designed to handle strings, regular expressions, and text files. Using C or C++ to write a CGI application with these features would require more lines of code than that of a similar Perl program.

Learning curve. In general, scripting languages are easier to learn than compiled languages. As a rule, scripting languages are more forgiving to a novice programmer and do not require the knowledge of all control structures available in the language to efficiently implement a given task.

Debugging. Given their interpreted nature, programs written in scripting languages do not need to be recompiled each time a change is made during debugging. To some extent, this may speed-up the process of debugging.

Despite the fact that C# belongs to the same family of programming languages as C and C++, C# is not very well suited for writing CGI scripts for a number of reasons. There are C and C++ compilers for virtually any operating system and it makes C/C++ code portable. C# programs can only be compiled and executed on the Microsoft .NET framework. C# programs are compiled into CLR (common language runtime), which caries a typical interpreting overhead, which may not be desired in a time-critical Web application. On the other head, C# and Virtual Basic .NET are perfectly suited for creating ASP.NET applications, which are discussed below.

Java

Java programs must be executed using a Java Virtual Machine and, given its architecture, it is impossible to call a CGI script written in Java directly from a Web server. It is possible, however, to create a simple wrapper program in Perl or C, which would invoke the Java program. This adds a double overhead of first calling a wrapper program and then starting the Java Virtual Machine, which would then run the Java CGI script.

Nevertheless, there are a number of options available for applying Java for creating interactive Web applications, which are discussed below.

CGI has started a revolution intended to change the nature of the Web and make it an interactive medium. It would not be wise to assume that such a good idea could be left without being explored further. CGI has spawned a number of technologies that build upon the same idea—accept and respond to queries from Web browsers and present dynamic content using HTTP protocol. Most of them address the main problem of CGI architecture—creating a separate process on the Web server every time the script is executed. Some of these technologies attempt to remove the distinction between the script and the HTML page by mixing them together.

ASP and ASP.NET

Active Server Pages (ASP) were created by Microsoft and served as a scripting language for the Microsoft Internet Information Server. The main advantage of ASP is that the scripting engine is integrated into the Web server and, therefore, it does not require an additional process to run. ASP code can be mixed together with HTML, which eliminates the need to write separate programs. The most popular language for writing ASP scripts is VBScript, essentially a stripped-down version of Visual Basic. ASP also supports JScript—Microsoft's version of JavaScript; other languages are also available. Initially, ASP was only available on Windows-based servers, but now it has been adapted for other platforms as well.

ASP.NET is a new version of ASP based on the Microsoft.NET framework, which currently supports Visual Basic.NET and C# as scripting languages. ASP.NET also makes a clearer distinction between HTML and code—it somewhat departs from ASP's philosophy of intertwining HTML with scripting statements. Instead, ASP.NET separates the interface of the Web form from its event-driven code, which can be written on any .NET programming language. As of October 2002, the following languages were being adapted to run on the .NET Framework: COBOL, Fortran, Java (J#), Pascal, Perl, and many others.

Java Servlets and JSP

Java servlets follow the same basic idea as CGI scripts in that they run as separate programs that receive requests and generate HTML documents. Java servlets can be thought of as Java applets that run on the server and do not have any graphical user interface. Java servlets are server- and platform-independent and they have full access to the entire family of Java APIs. Java Server Pages (JSP) is an extension to Java servlet technology, and it is very similar to ASP in that it allows developers to embed Java code into HTML pages.

PHP

PHP (PHP: Hypertext Processor) is an open source HTML-embedded scripting language similar to Perland functions in the same fashion as ASP. It was initially developed to run on the Apache server, but has been adapted to run on other Web servers as well.

CGI APPLICATIONS AND THE FUTURE OF CGI

Despite the fact that CGI may be considered an aging technology and the fact that there are many competing technologies, CGI scripts are still very widely used in the Internet and there is no reason to suggest any decline in its popularity. Many Web sites contain directories of freely available CGI scripts that developers can use in their applications (CGI Resource Index, n.d.; HotScripts, n.d.). An extensive list of CGI script directories can be found in the *Google CGI Web Directory* (n.d.). There are several reasons why CGI scripts still remain a viable tool for Web application development:

CGI scripts are platform independent;

CGI is the oldest technology for enabling Web interactivity, and over the years developers have accumulated many CGI scripts that are now available for free; and

CGI scripts can be written in many languages, so developers do not have to learn a new language.

By far, the most popular class of CGI application is the shopping cart. As of October 2002, HotScripts.com was listing over 100 CGI scripts in Perl for creating shopping carts. Overall, the e-commerce category at HotScripts.com was the second most populated, containing about 170 Perl scripts, only trailing behind the general form processors category with 190 entries. Other e-commerce applications, for which there exist Perl CGI scripts, include:

Billing systems;
Credit card processing;
Currency exchange;
Ordering systems; and
PayPal payment processing.

HotScripts.com contains an exhaustive list of CGI scripts categorized by their application and programming language (ASP, C/C++, JavaScript, Perl, PHP, etc). Among many others, this list contains such script categories as:

Advertisement management;
Calendars;
Chat script;
Content management;
Counters;
Database tools;
Discussion boards;
E-commerce;
E-mail systems;
File manipulation;
Guestbooks;
Image galleries;
Mailing list management;
News publishing;
Password protection;
Polls and voting;
Searching;
Security systems;
Tests and quizzes;
Virtual communities;
Web fetching; and
Web traffic analysis.

Middleware products, such as ASP, JSP, and PHP, may seem to push CGI scripts out of the market. Their primary advantage is that they offer performance advantages—they are coupled with the Web servers and execute in-process. Most CGI scripts execute out-of-process; that is, they require launching a separate program (e.g., a Perl interpreter) to execute. However, despite its relative age and disadvantages, such features of CGI as simplicity, extensibility, portability, transparency, and ease of use make it a strong competitor to these new technologies.

CONCLUSION

The common gateway interface has literally revolutionized the way we use the Internet. CGI scripts were the first technology to enable interactivity on the Web. Without CGI scripts and all other technologies spawned by it, we would still be using static Web pages instead of interactive Web applications. CGI scripts provide the mechanism for the Web server to respond to the client requests by generating Web pages with customized and personalized content. The common gateway interface is platform-independent and transparent to the client browsers. CGI scripts can be written in many programming languages capable of producing command-line executables that can generate HTML output. Historically, Perl, “the duct tape of the Internet,” has been the language most widely used for creating CGI scripts. All other technologies for creating interactive Web applications, such as ASP, JSP, and ColdFusion, were born because of what CGI started—the need for making the Interned a true interactive medium. CGI is older than these competing technologies, which may put it at a disadvantage. However, CGI developers benefit from the age of CGI as there are a countless number of CGI scripts available on the Internet. The benefits of using CGI clearly outweigh its disadvantages and because of that, CGI is here to stay.

GLOSSARY

Active Server Pages (ASP) A scripting environment built into Microsoft Internet Information Server, which allows combining HTML with statements in a scripting language, typically VBScript.

Application programming interface (API) Calling conventions used by applications to access services of the operating system or other applications.

Common gateway interface (CGI) A standard for running external programs on a Web server.

Hypertext markup language (HTML) Instructs software on how to render a Web page.

Hypertext transport protocol (HTTP) Stateless protocol that coordinates transport of HTML documents on the Internet.

Java Server Pages (JSP) An extension of Java Servlet API to generate dynamic Web pages.

PHP: Hypertext Processor (PHP) A cross-platform open-source scripting environment similar to ASP.

Computer Literacy

Hossein Bidgoli, *California State University, Bakersfield*

INTRODUCTION

This chapter provides a general computer literacy for readers with little or no computer background. It discusses different data processing systems that were used before the computer era and highlights general capabilities of computers, their unique power, and their applications. The chapter describes the characteristics of successive generations of computers and examines the input-process-output cycle. The chapter explains the differences between data and information and the types of processing including batch and transaction processing. General applications of computers are introduced and basic productivity tools are highlighted. The chapter concludes with a series of guidelines for proper maintenance of a microcomputer system.

WHAT IS COMPUTER LITERACY?

In today's competitive environment, computer literacy is as important as reading and writing literacy. The number of computers in use is increasing on a daily basis throughout the world. Significant price reduction and impressive improvement in their processing power have made microcomputers a household item. There are many different definitions of computer literacy. In this chapter, we define computer literacy as the basic knowledge needed for understanding and using computers for day-to-day tasks. In this regard, the user should have a basic understanding of hardware, software, and the commonly used applications of computers. An increasing number of people are using their microcomputers to connect to the Internet for accessing the wealth of information available in public and private databases. To do this, a basic knowledge of the Web and Web technologies is also needed. Another chapter in this encyclopedia reviews basic Web literacy and instructions for effective utilization of the Internet and its popular applications. In the next section, a brief overview of Internet literacy will be presented. For a comprehensive understanding of computer operations and productivity tools, the references introduced at the end of the chapter should be consulted.

WHAT IS INTERNET LITERACY?

The Internet is a collection of millions of computers and network systems of all sizes. No one actually owns or runs the Internet. Each network is locally administered and funded, in some cases by volunteers. It is estimated that more than 200 countries are directly or indirectly connected to the Internet. This number is increasing on a daily basis and makes the Internet a true companion for both home and office (Bidgoli, 2002).

The Internet started in 1969 as a Defense Department Advanced Research Projects Agency project called ARPANET. It served from 1969 through 1990 as the basis for early networking research, and as a central backbone network during development of the Internet. To use the Internet, a user needs a computer with a modem and an Internet service provider (ISP). As soon as a user is connected, a wealth of information is at his or her fingertips.

Usually most computers are equipped with a graphical browser, such as Microsoft Internet Explorer or Netscape Navigator. An Internet address, or URL (universal resourse locater), is entered through the browser software, and by pressing the Enter key on the keyboard or clicking the mouse, the user is connected to a site. The Internet site could be across the hall or on a different continent! As soon as the URL is entered, the browser software searches the Web and provides the user with the requested information. Throughout this encyclopedia, a wealth of information and many applications that are readily available on the Internet are explored.

Electronic mail (e-mail) is one of the most widely used applications of the Internet. Speed, ease of use, and no cost have made e-mail the communication of choice for millions of individuals around the world. Most browser software offers e-mail capabilities at no additional cost.

COMPUTER APPLICATIONS: AN OVERVIEW

If automobiles had developed as computers have, in the year 2004, a user would be able to buy a Mercedes Benz for under than $2, get over 2 million miles to a gallon, and park up to three dozen cars in the corner of an office! If airplanes had developed as computers have, today a user would be able to go around the globe in under 20 minutes for just 50 cents! The computer that weighed over 18 tons 50 years ago now weighs under 5 pounds. It is 100 times more powerful, and its cost is less than 1% the cost of the first computer (Bidgoli, 1993).

Every day most workers use computers directly or indirectly. For example, in schools, computers prepare transcripts and grade multiple-choice and true/false test questions. In grocery stores, computers manage the inventory systems and cash registers. Point-of-sale (POS) systems have significantly improved the efficiency and effectiveness of grocery chains and department stores. Scanners rapidly scan the universal product code (UPC) of different products and quickly come up with the price of the item being purchased, at the same time keeping track of the most current inventory status. Home appliances such as TVs, VCRs, microwaves, and cameras all use some type of computer.

A cashless and checkless society is just around the corner. Even now, a user can accomplish all his/her financial transactions by using computers. Computers assist bank customers in withdrawing money from accounts, depositing money to accounts, and transferring money from one account to another account, all transactions that could be conducted remotely by using a computer and the Internet.

Executives don't need to leave their offices to attend meetings in different cities, states, or countries. Through computer and video conferencing, an executive can attend meetings in different locations without ever leaving the office. In addition, reports can be prepared and transferred from location to location by means of computers and telecommunication systems. The space program could not have been achieved without computer help. Computers also have played a significant role in medical research and the treatment of various diseases.

Computers have significantly reduced the production time of textbooks and other print media. Authors routinely prepare various drafts of manuscripts on a computer with word processing software. Editors make changes based on comments from reviewers by using the editing features of the same software. Computerized typesetting and printing equipment then produce the book that a user reads. Warehousing, inventory control, shipping, and marketing are all accomplished with the help of computers. For example, the names and addresses of authors of this encyclopedia were stored in a computer file, and the mailing labels and letters sent to these individuals were prepared by means of a computer. Electronic mail kept the editor-in-chief of the encyclopedia in close contact with all the authors, scattered around the world. Several drafts of different chapters were sent back and forth between authors, editors, and reviewers all by using electronic mail. The sales and marketing of the encyclopedia have been significantly improved by using various applications of computers.

Nowadays, publishers can store the entire text of a book in several computer files. When new editions are needed, changes can be made easily by editing existing computer files instead of creating new ones.

Practically speaking, the number of applications performed by computers is unlimited. There is not a single day in which a worker is not affected by the computer. Nearly all business organizations have computers. All educational disciplines, even the humanities, have applications for computers. Every job now involves computers either directly or indirectly. Table 1 summarizes some of the more practical applications of computer technology.

DEFINING A COMPUTER

A computer is a machine that accepts data as input, processes the data without human interference using a set of stored instructions, and outputs information. Instructions are step-by-step directions given to a computer for performing specific tasks. Computer programs consist of instructions written in a language understood by a computer. There are hundreds of computer programs designed for different purposes. Several of them that are related to the Internet, and e-commerce applications are introduced in this encyclopedia.

Any computer system consists of hardware and software. Hardware components are all physical devices, such as a keyboard, monitor, mouse, data tablet, disk drive, zip drive, DVD (digital versatile disc) drive, CD-ROM, printer, modem, and processor unit. The software component consists of computer programs written in different computer languages. The software could be developed in-house or chosen from among the many thousands of commercial software packages readily available on the market for a moderate cost.

To communicate with a computer, a user must talk to it in its own language. There are hundreds of computer languages available. BASIC, FORTRAN (formula translator), COBOL (common business-oriented language), Java, and C++ are some example of computer languages.

A language used by many microcomputers is called BASIC (beginner's all-purpose symbolic instruction code). A simple example of a BASIC program follows:

```
10 A = 10
20 B = 20
30 C = A + B
40 PRINT C
50 END
```

Table 1 Popular Applications of Computers

Industry	Examples of Applications
Space program	Launching of spaceships
Medicine	Drug testing, monitoring vital signs, recording patient history
Geology	Earthquake analysis, soil and mineral analysis
Government	Tracking of Internal Revenue Service and social security information
Business	Accounting and finance for private and public organizations
Education	Computer-aided instruction, remote education sites, distance learning
Manufacturing	Computer-aided design, computer-aided manufacturing, robotics
Traffic control	Provision of more effective traffic systems
Appliances	Microwaves, VCRs, TVs, cameras
Music	Control and creation of sound
Entertainment	Generation of three-dimensional pictures and animation in movies and video
Airlines	Reservation systems, air traffic control systems, and navigation systems

This program instructs the computer to add values A and B, store the result in an address called C, and then print the result. Line 50 tells the computer that this is the end of the program.

The diagram presented in Figure 1 illustrates the building blocks of a computer. The input devices send data and information to the computer. The keyboard is one example of an input device. Other input devices may include mouse, touch screen, light pen, trackball, data tablet, bar code reader, optical character reader (OCR), and magnetic ink character reader (MICR). The output devices receive the output generated by the computer. The output may be presented on a display monitor, CRT (cathode ray tube), or VDT (video display terminal). This type of monitor output is called soft copy. If a printer generates the output, it is called hard copy. In some cases, plotters are used for generating hard-copy output as graphics.

The main memory (primary storage) is like the human brain. Memory is the location in which computers store data and instructions. Floppy disk, magnetic disk, magnetic tape, hard disk, CD-ROM, and zip disk are used as secondary storage devices. The CPU (central processing unit) is the heart of the computer. The CPU is divided into two components: the ALU and the control unit. The ALU (arithmetic/logic unit) performs arithmetic operations (addition, subtraction, multiplication, and division) and logical operations (e.g., comparing numbers). The control unit acts like the captain of a ship. It tells the computer what to do. For example, it tells the computer from which device the data is read or to which device to send the output. Figure 2 shows the components of a data processing system. Other types of memory include RAM, ROM, PROM, and EPROM.

Random access memory (RAM) is a volatile memory. Data stored in RAM will be lost in the event of a power failure. To avoid this type of loss, always, the user must save his/her work on a permanent memory medium (i.e., secondary memory), such as a diskette.

Read-only memory (ROM) is a prefabricated ROM chip supplied by vendors. This memory stores some general-purpose instructions or programs.

Programmable read-only memory (PROM) is memory a user can program by using a special device. However, once programmed, this type of memory cannot be erased.

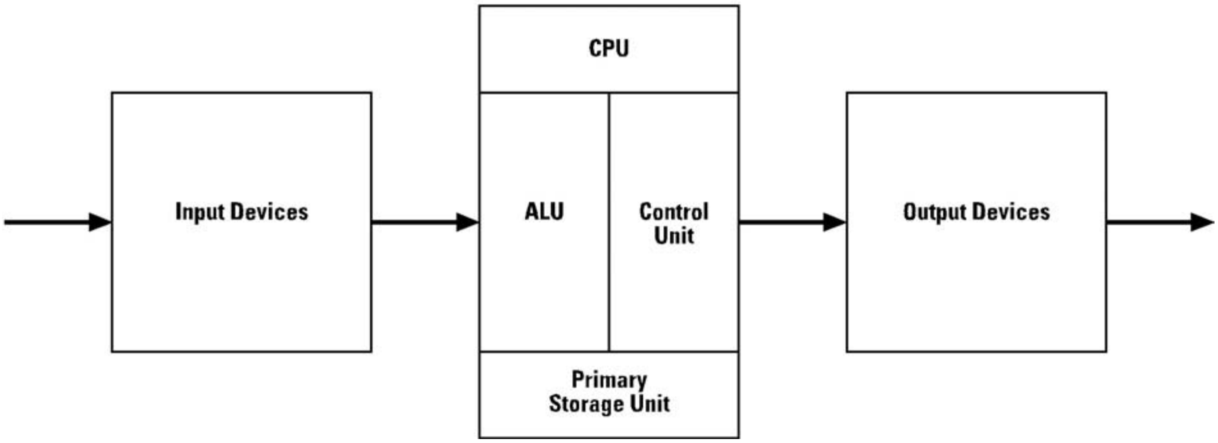

Figure 1: Building blocks of a computer.

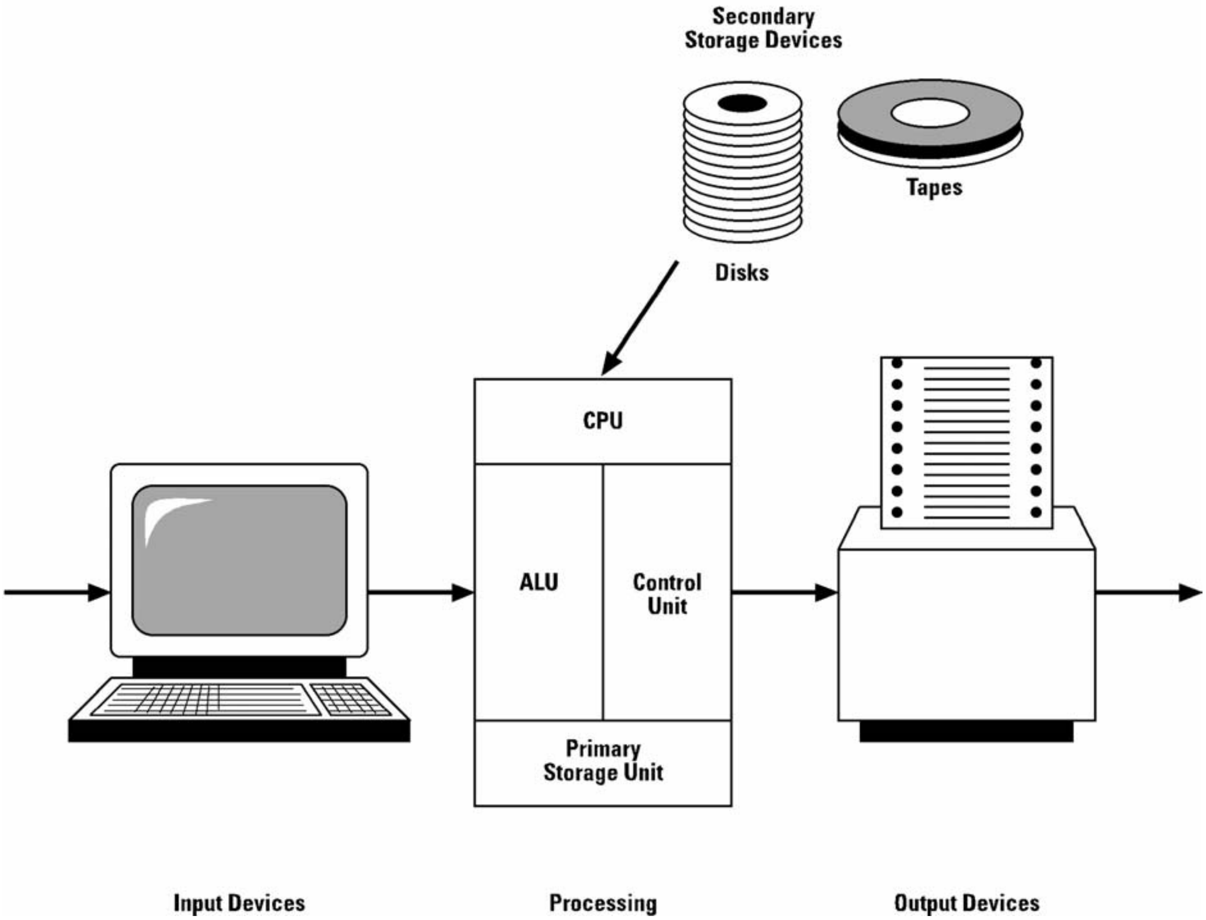

Figure 2: Components of a data processing system.

Erasable programmable read-only memory (EPROM) is read-only memory. It can be programmed by the user and, as the name indicates, erased and programmed again.

CATEGORIES OF COMPUTERS ACCORDING TO THEIR POWER

Computers can be classified in several ways. Usually computers are classified based on cost, memory size, speed, and sophistication (single tasking versus multitasking). A single-tasking computer performs one task at a time; a multitasking computer performs several tasks at a time. Based on these criteria, computers are classified into micro-, mini-, mainframe, and supercomputers. This means that supercomputers are more expensive and faster and possess much more memory than microcomputers, minicomputers, and mainframes. This justification applies to other classes of computers as well. Applications for these computers include everything from homework and home finances (microcomputer) to space shuttle launches (supercomputer). Because both the speed and the sophistication of microcomputers are steadily increasing, it is difficult to draw a clear line between mini- and microcomputer. The microcomputer of today has more power than the mainframe of the 1970s, and all indications suggest that this trend will continue.

CLASSES OF DATA PROCESSING SYSTEMS

Computers as we currently know them have been around for approximately 50 years. What did we do before computers existed? What do developing nations that do not have access to computers do? In these situations, data is processed with devices other than computers. The major classes of data processing systems include manual, mechanical, electromechanical, and electronic (see Figure 3).

Manual Data Processing

A manual data processing system processes data manually, meaning by hand. A user might use paper, pencil, and ledgers. Other devices include the Chinese abacus and the slide rule. Slow processing speed and low degree of accuracy are two major problems associated with this type of data processing.

Mechanical Data Processing

To improve on the inherent drawbacks of manual data processing, mechanical data processing was developed. The credit card imprinter is a mechanical data processing device. Imagine what would happened if every time

Computer System

Figure 3: Data processing systems.

a user used his/her credit card to purchase gas, the operator in the gas station was required to write down all the information displayed on the card. Purchasing gas would be a tedious process, and the accuracy of the information could not be guaranteed. This is, in fact, still the case in some places. In more remote areas of the world, and in stores that do not process many credit cards, at times clerks manually write down credit card information.

Electromechanical Data Processing

Electromechanical systems differ from earlier systems of data processing in that the data or information must be

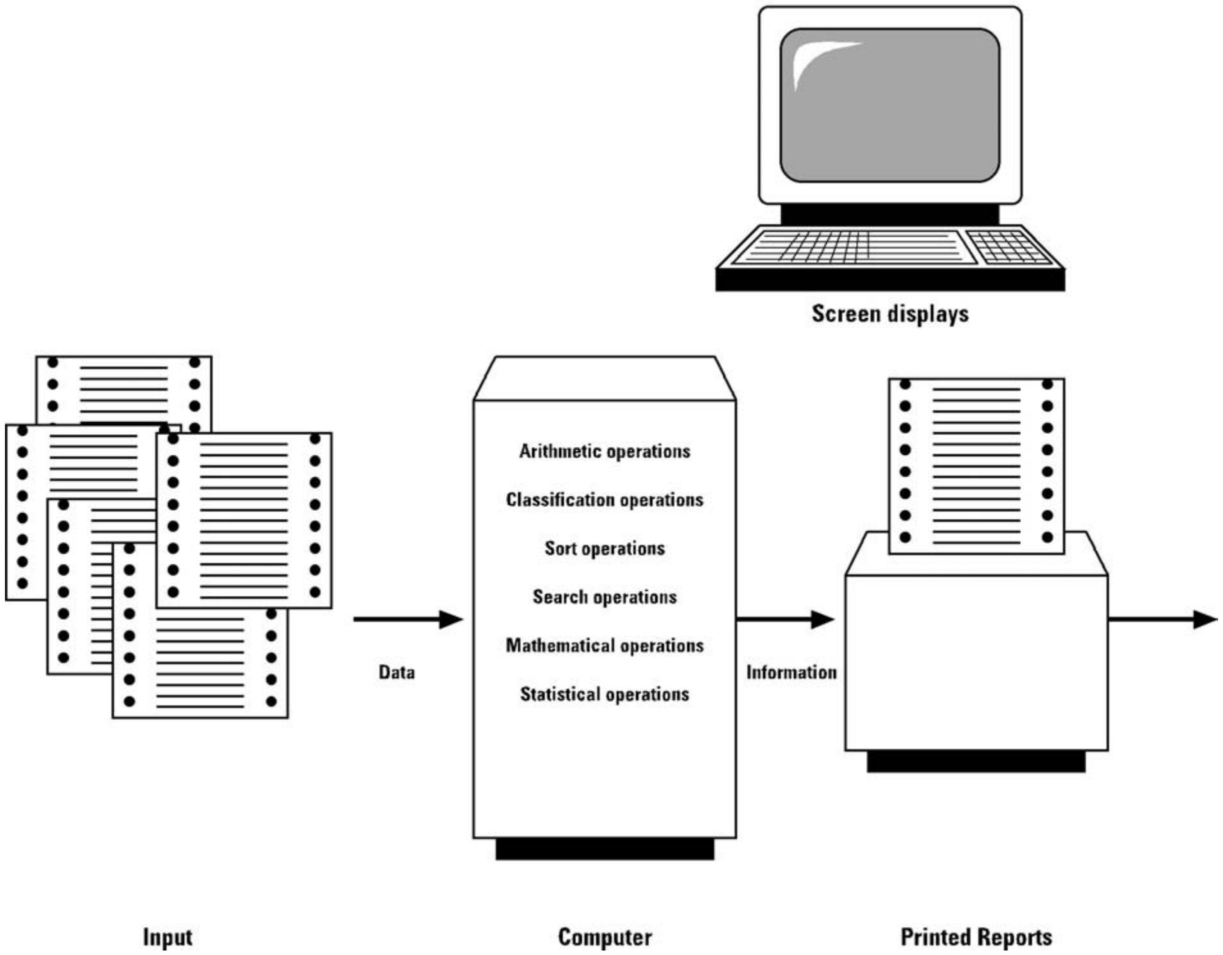

Figure 4: Data processing functions.

in machine-readable form. Punch cards, card readers, and sorters were invented to improve the speed and accuracy of data processing systems. By punching holes on a paper card, a punch-card machine puts data into a computer-readable format, which can be read very quickly. A sorter machine can sort thousands of cards with a high degree of speed and accuracy. A good example is the Hollerith's machine, which helped speed up the U.S. Census process in 1890.

Electronic Data Processing

Electronic data processing (EDP) is the fastest and most accurate of the data processing systems. In this type of data processing, data are entered to the computer through various devices, such as a keyboard or data tablet, and all processing is done electronically, without human intervention. As an example, consider a payroll processing system. The number of work hours and the pay rate of a worker are entered into the computer, his/her deductions are identified, and the computer prints a paycheck. The interesting aspect of EDP is that the same computer program that prints a paycheck for one employee is able to print paychecks for thousands of employees as soon as their employment data are entered. Throughout this encyclopedia, many examples of the amazing power, sophistication, and diverse applications of electronic data processing systems are presented.

DATA VERSUS INFORMATION

Figure 4 shows a simple diagram for a data processing system. The input to a data processing system is raw data. In the payroll example introduced earlier, number of hours and pay rate are examples of raw data. Looking at these two numbers individually, a user will not know how much this employee will earn in a given period, where he/she stands compared with the rest of the employees as far as salary is concerned, and so forth. A computer processes the data, and the results are called information or processed facts. In the payroll example, a paycheck may indicate an example of information.

What is the difference between data and information? Data is raw facts. If a user has only facts (data), he/she cannot make a decision. As an example, consider $210 million sales generated by Company X in their last fiscal quarter. Is this data or information? Using the same analogy as the payroll example above, we could conclude that, again, this is data, because a user will not be able to say anything regarding the performance of the company. Is this a profitable company? Did the company meet their sales objective? Did the sale increase or decrease?

Just looking at this number could raise many other unanswered questions. The entire field of information systems is concerned with the production of timely, accurate, and useful information. Many organizations are data rich but information poor. The real challenge for practitioners in the dynamic field of information processing is to design computer-based information systems to generate accurate, timely, and useful information.

The information needed by a user directly affects the type of data used in an information system. If an organization has defined its strategic goals, objectives, and critical success factors to ensure a viable and growing organization, the data component can be structured rather easily and the information system has potential for success. On the other hand, if there are conflicting goals and objectives, or if the company is not aware of which factors are critical to its success, many problems can occur to destroy confidence in its information system or minimize the system's effectiveness. If the information system is not designed to evolve as changes (both internal and external) take place, then the system may do more damage than good.

Of course, the objectives of the organization ultimately resolve the questions of the sources of data—external or internal sources—and whether the data is past (performance), present (operational), or future (budget or cash flow) oriented. The urgency of need and the availability of data in many forms, including aggregated (lump sum) or disaggregated (itemized), can then be addressed. Disaggregated data is needed when, for instance, sales are analyzed by product, territory, or salesperson, and costs are analyzed by cost center or product. Aggregated data limits the decision maker's ability to focus on specific factors.

DEFINING DATA PROCESSING

When data has been processed to generate information, one or several of the following tasks may have taken place.

Arithmetic Operations

A user might add all the sales generated by each region in the northwest to generate a value that indicates the total sales of a company in the northwest region.

Sort Operations

A user might sort the total sales of a company for all 50 states from the highest to the lowest volume to find the best and the worst sales regions.

Classification Operations

A user might classify a sales data into 10 different product groups. Using this information, a user can see the total sales generated by product group X. This information will help a user choose the best and the worst products in a company on the basis of total sales.

Search Operations

A user may search a database in order to find a specific item that meets certain criteria, for example searching for a sales region that has generated record sales in three or more periods.

Statistical and/or Mathematical Operations

A user may utilize statistical and/or mathematical models in order to generate a sales forecast for the next period. This forecast may serve as the basis for sales planning for the next period.

Figure 4 illustrates data processing functions.

There are many types of data processing that enable a user to convert raw data to information. The method a user chooses depends on the specific situation. Remember, however, that the computer processes only the data it is given. If the data is erroneous, the information provided will be erroneous as well. A user should always remember the principle "garbage in, garbage out" (GIGO). Experts in the field call computers error-free machines, given establishment of proper working conditions. Proper working conditions include factors such as proper room temperature (not too hot or too cold), a dust-free environment, appropriate humidity, and a virus-free computer.

THE POWER OF COMPUTERS

Computers draw their power from three distinguishing factors that far exceed the capacity of any human being: tremendous speed, high degree of accuracy, and immense storage and retrieval capabilities.

Speed

Computers process data with amazing speed. Speed is measured as the number of instructions performed per second, as follows:

Millisecond	=1/1,000 second	=1 thousandth
Microsecond	=1/1,000,000 second	=1 millionth
Nanosecond	=1/1,000,000,000 second	=1 billionth
Picosecond	=1/1,000,000,000,000 second	=1 trillionth

Early microcomputers (1981) operated at a speed of 4.7 megahertz (MHz or sometimes Mhz, a million cycles per second). This is how a microprocessor clock speed is measured. In the year 2003, microcomputers with the processing speeds of 2.4 MHz are readily available.

Accuracy

Computers are error-free machines—they do not make mistakes. To make the accuracy issue more clear, consider the following two numbers:

2.00000000001
2.00000000002

To humans, these numbers are so close that they could be considered equal. To a computer, however, these two numbers are very different. For some computer applications, such as those used in space missions, this level of accuracy and speed is required to bring the space shuttle back to Earth at a given time and in a specific location.

Storage and Retrieval

Storage means saving data or information in the memory of a computer. Retrieval is the act of bringing the data or information back from memory. Computers can store vast quantities of data and can locate specific items very quickly.

COMPUTER OPERATIONS

Computers can perform three basic tasks: arithmetic operations, logical operations, and storage and retrieval operations (as explained above). One or a combination of these tasks accomplishes all other tasks. For example, playing games could be a combination of all three functions.

Arithmetic Operations

Computers can add, subtract, multiply, divide, and raise to power. The five basic operations are as follows:

A + B (addition)	5 + 2 = 7
A − B (subtraction)	5 − 2 = 3
A * B (multiplication)	5 * 2 = 10
A/B (division)	5/2 = 2.5
AˆB (exponentiation)	5ˆ2 = 25

Logical Operations

Computers can perform logical operations by comparing two numbers. For example, a computer can compare *A* and *B* to determine which number is larger.

COMPUTER GENERATIONS

Over the past 5 decades, there have been major advancements in hardware. Computers began with vacuum tube technology. In 1946, rudimentary computers were bulky and unreliable. They generated excessive heat and were very difficult to program. The second generation of computers began in 1957. This generation, which used transistors, was indeed a significant improvement over the first. These computers were faster, more reliable, and easier to program and maintain. The third generation began in 1964 with computers that operated on integrated circuits (IC), which enabled computers to be even smaller, faster, more reliable, and more sophisticated. Remote data entry and telecommunications were introduced during this generation. The fourth generation began about 1970. This generation of computers is associated with several attributes: miniaturization, very-large-scale integration (VLSI) circuits, ultra-large-scale integration (ULSI), and widespread applications of microcomputers, optical disks, and bubble memories. Bubble memory is built on a thin crystalline film (mineral garment). Through polarization of the bubbles, data is presented on this nonvolatile memory. The presence of a bubble represents a one, and the absence of a bubble represents a zero. Two drawbacks of this kind of memory are its high cost and its relatively low speed.

The early 1990s heralded the beginning of the so-called fifth generation of computer technology. The major attributes of this generation include parallel processing, gallium arsenide chips, and optical technologies. A parallel processing computer contains hundreds or thousands of CPUs, which means that the computer is capable of processing data much faster than its predecessors.

Because silicon technology is not able to emit light and has speed limitations, computer designers have concentrated on gallium arsenide technology. Electrons move almost five times faster in gallium arsenide than they do in silicon. Devices made with this synthetic compound can emit light and withstand higher temperatures and survive much higher doses of radiation than silicon devices.

The major problems associated with gallium arsenide are the difficulties in mass production and working with it. Gallium arsenide is soft and fragile compared with silicon; it breaks more easily during slicing and polishing. Currently, because of high costs and difficulty of production, military systems are the major users of this technology. However, research continues to eliminate some of the shortcomings of this impressive technology.

Optical technologies offer at least three features not found in earlier technologies: greater speed, parallelism (several thousand independent light beams can pass through an ordinary device), and interconnection (denser arrays of interconnections are possible because light rays do not affect each other). Optical computing is in its infancy and much more research is needed to produce a full-featured optical computer. Nevertheless, the storage devices using this technology are revolutionizing the computer field by enabling massive amounts of data to be stored in very small spaces.

The fifth generation will include revolutionary architecture that did not exist in the first four generations of computer technology. Fifth-generation computers work with so-called artificial intelligence (AI) technologies. AI is expected to make the computer smarter—so much so that AI computers are expected to do some of the tasks that humans perform. Several AI products are now on the market. Among them are experts systems, robotics, and natural language processing. Table 2 highlights the trends in hardware technology.

In parallel with hardware technology, software technology has also improved significantly. When the first computers were introduced, in the early 1940s, the only language understood by these computers was machine language. Machine language consists of a series of zeros and ones. It is difficult to program a computer using machine language. At that time, the only users of computers were highly trained data processing personnel. The second generation of computer language was called assembly language, and it consisted of a series of short codes, or mnemonics. One can say, in general, that

Table 2 Hardware Trends

Generation	Date	Major Attribute
First	1946–1956	Vacuum tubes
Second	1957–1963	Transistors
Third	1964–1970	Integrated circuits
Fourth	1971–1992	VLSI
Fifth	1992–?	Gallium arsenide, parallel processing

Table 3 Software Trends

Generation	Attribute
First	Machine language
Second	Assembly language
Third	High-level language
Fourth	4GL
Fifth	NLP

assembly language is easier to use and understand than machine language. But, still, rigorous training is needed to become the proficient user of a computer using this language. The third generation of computer languages, called high-level languages, or higher level languages, is more user- and application-oriented. A language like COBOL is self-explanatory.

A user can get a general idea when he/she reads a program written in COBOL. These languages are easier than the first two to learn and use. However, they are still very specific in nature and each is more suitable for one type of application than another. The fourth-level computer languages, or 4GLs, are a lot more forgiving than the first three. They are by far the easiest to learn and use. Much less time is needed to perform a task using these languages compared with their earlier counterparts. However, to use even these languages, the user has to have some basic computer training and should be familiar with the keyboard. The fifth generation of computer languages, natural language processing (NLP), promises a great deal of flexibility and power. If these languages ever become a reality, computers will become a lot easier to use, friendlier, and more flexible. Table 3 highlights the software trends.

INPUT, PROCESS, AND OUTPUT CONCEPTS

Most users and decision makers use a computer as a black box. This means that a user sends data to the computer, the computer performs the processing task, and information is given back to the user on some type of output device. According to the black box theory, the user doesn't need to know what goes on inside the "box." The user provides the input data, tells the computer how this data should be processed, and leaves the rest to the computer. However, to be able to effectively use a computer, basic knowledge of input, processing, and output is essential.

DATA REPRESENTATION

Every character, number, or special symbol that a user types on the keyboard is represented as a binary number in the computer's memory. A binary system consists of 0 and 1. The 1 represents "on" (high voltage), and the 0 represents "off" (low voltage). Figure 5 illustrates this system. To represent these different data items, computers use special formats.

Computers and communications systems use data codes in order to represent and transfer data between various computers and network systems. Three popular types of data codes are (Bidgoli, 2000) Baudot code, ASCII (American standard code for information interchange), and EBCDIC (extended binary coded decimal interchange code).

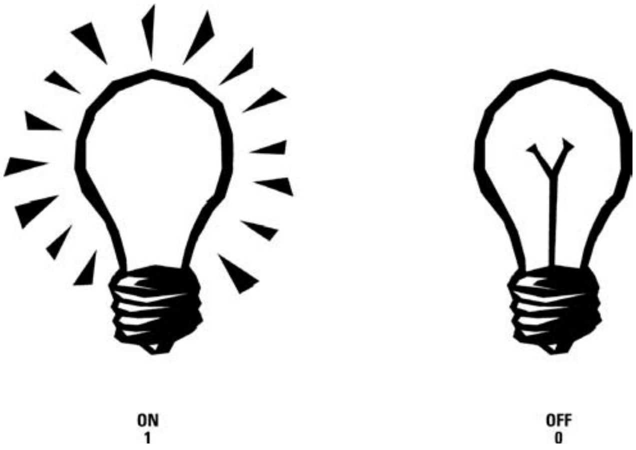

Figure 5: Graphic representation of a binary system.

The *Baudot code* was named after a French engineer, Jean-Maurice Emile Baudot. It was first used to measure the speed of telegraph transmissions. It uses 5-bit patterns to represent the characters A to Z, the numbers 0 to 9, and several special characters. Using Baudot code up to 32 characters can be defined ($2^5 = 32$). This is not enough to represent all the letters of alphabet (uppercase and lowercase) and special characters. To overcome this limitation, Baudot code uses DOWNSHIFT (11111) and UPSHIFT (11011) character code. By doing this, up to 64 different characters can be defined, doubling the code's original size. This process is similar to typing using a keyboard. When a user presses the Caps Lock key on the keyboard, turning on the Caps Lock feature, all the characters typed are transmitted as uppercase. As soon as the user presses the Caps Lock key again, undoing the feature, all the characters are transmitted as lowercase.

Therefore, using Baudot, every character except for a space is either an upshift character or a downshift character. For example, 10001 represents both the letter Z and the + (plus sign). The letter Z is a DOWNSHIFT character and the plus sign is an UPSHIFT character. Baudot code is no longer used. However, it illustrates how information is transmitted by a small number of bit combinations.

The American National Standards Institute (ANSI) developed ASCII (pronounced "ask-ee"). It is the most common format for text files, for PC applications, and on the Internet. In an ASCII file, each alphabetic, numeric, or special character is represented with a 7-bit binary number (a string of seven zeros or ones). Up to 128 characters can be defined ($2^7 = 128$). UNIX- and DOS-based operating systems and a majority of the PC applications use ASCII for text files. Windows NT (2000) uses a newer code, called Unicode. The extended ASCII is an 8-bit code used by IBM mainframe computers, which allows 256 (2^8) characters to be represented.

EBCDIC (pronounced "ehb-suh-dik") is a binary code for alphabetic and numeric characters that IBM

Table 4 Selected Keyboard Symbols in ASCII and EBCDIC

Symbol	ASCII	EBCDIC
Space	0100000	01000000
A	1000001	11000001
B	1000010	11000010
Z	1011010	11101001
a	1100001	10000001
b	1100010	10000010
z	1111101	10101001
*	0101010	01011100
%	0100101	01101100
(	0101000	01001101
0	0110000	11110000
1	0110001	11110001
9	0111001	11111001

developed for its mainframe operating systems. It is the code for text files that is used in IBM's OS/390 operating system running on its S/390 servers, used by many corporations. In an EBCDIC format, each alphabetic, numeric, or special character is represented with an 8-bit binary number (a string of eight zeros or ones). Up to 256 characters (letters of the alphabet, numerals, and special characters) can be defined ($2^8 = 256$). Conversion programs allow different operating systems to convert a file from one code to another. Table 4 illustrates selected examples of ASCII and EBCDIC.

TYPES OF PROCESSING

Computer users can process data either in batch mode or in real-time mode. In batch processing, data is sent to the computer periodically, for example every 24 hours, every 2 weeks, or every month. This type of processing is suitable for applications that don't need an immediate response. Payroll is a good example—hourly employees do not need to be paid each hour.

Many applications, however, require an immediate response. In such applications, a transaction is processed as soon as it occurs. This type of processing is known as real-time processing, or transaction processing. An airline reservation system is a good example of this type of processing. A reservation must be entered into the computer immediately, otherwise one seat may be sold to many customers or a flight may have many empty seats.

DIFFERENT CLASSES OF COMPUTER SOFTWARE

Figure 6 illustrates important software used in a computing environment.

In broad terms, software is divided into two major groups: application software and system software. Application software is associated with what users routinely work with on a daily basis to get their work accomplished. Examples of application software include word processing, spreadsheet, database, desktop publishing, financial planning, and project management. System software is commonly associated with the efficient and reliable functioning of the computer system. Examples of system software include operating system software, utility, and compiler. An operating system is a set of programs that controls and supervises computer hardware and software. Initially, the utility software market niche developed in order to "fill the gaps"—the missing or desired capabilities of operating systems. Since that time, an entire software industry has developed to meet the demand. Some of the utility software applications were developed to give users capabilities that were not available in operating systems (Bidgoli & Prestage, 2003). Other utility software applications were developed to make using operating systems simpler. Virus protection software can be regarded as utility software in that although it does not directly serve the user's information processing needs, it protects the operating system, applications, and data from harm caused by malicious virus applications. A compiler is a program that translates a user program from source code into object code.

To a typical user, application software is more important and more commonly used than other types of software. A microcomputer can perform a variety of tasks by using either commercial software or software developed in-house. Software developed in-house is usually more expensive than commercial software. However, such software is more customized and may better fit the users' needs. There are several thousands of software packages available for PCs. For almost any task a user can think of, there is an appropriate software package on the market. The following are among the most popular productivity packages and applications available for microcomputers.

Word Processing

A microcomputer used as a word processor is similar to a typewriter with a memory. With such a facility, a user can generate documents, reports, and brochures, make deletions and insertions, and cut and paste. Word processing programs are becoming more sophisticated. Some of these programs provide graphics and data management features. With word processing programs, hundreds of hours can be saved by not having to type the same document repeatedly. Organizations often send the same letter to many of their customers. The only differences in these letters are the names and addresses of the customers. Word processing programs include a mail merge feature that allows and expedites mass mailing.

The majority of word processors now include spell checkers that are able to correct most of the misspelled words in a document. The next challenge is the creation of documents that include correct verbs, subjects, and adjectives and a smooth style. Grammar checkers are able to correct a document for grammatical errors. Also, the creation of simple, easy-to-read sentences is of prime importance. Grammar-checking software promotes good writing.

Grammar checkers perform text analyses by using linguistic analysis, parsing, and rule matching. A parser parses, or simply put, it breaks long sentences into shorter ones. Grammar checkers play an especially important role when multiple authors are involved in a project. In such

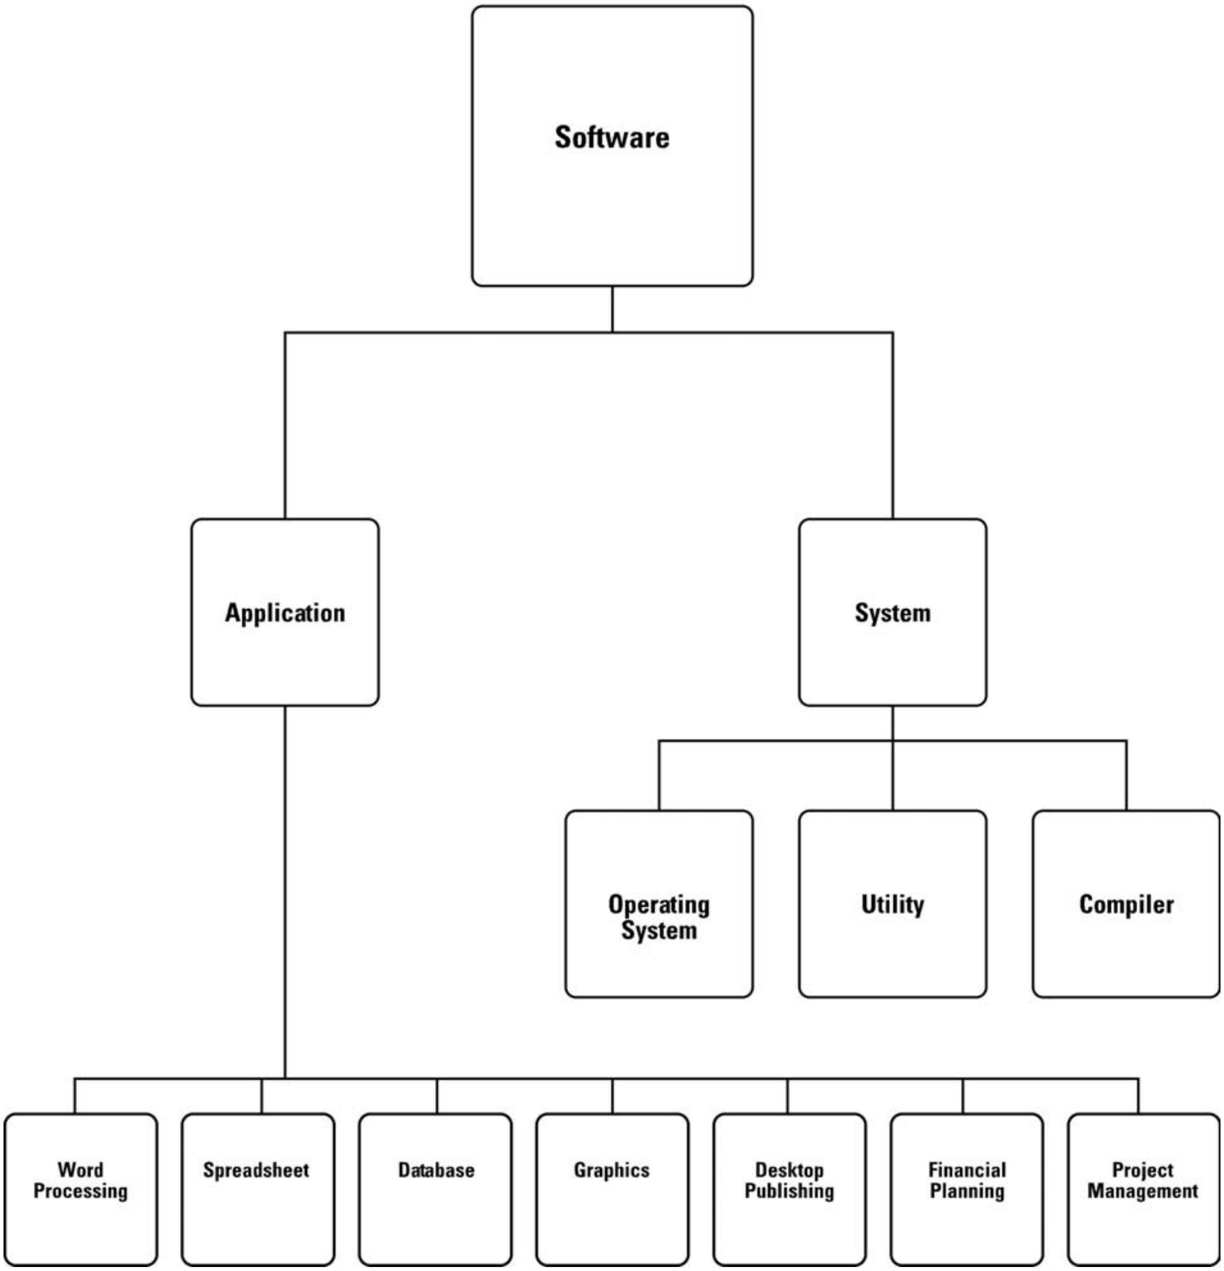

Figure 6: Important software used in a computing environment.

cases, grammar-checking software creates uniformity of tone, reading level, and style. Grammar-checking software is not 100% perfect yet, but it has come a long way.

Spreadsheet

A spreadsheet is a table of rows and columns. Typical spreadsheet software is capable of performing numerous tasks. Microsoft Excel, for example, is capable of performing spreadsheet functions as well as database and graphics functions. The number of tasks that can be performed by a spreadsheet program is almost unlimited. Any application suitable for row and column analysis is a candidate for a typical spreadsheet. For example, a user may use a spreadsheet to prepare a budget. When he/she is done with the budget, some impressive "what-if" analyses can be performed. This means a user may manipulate variables on the spreadsheet, for example reducing the income by 2% and directing the spreadsheet to calculate the effect of this change on other items on the spreadsheet. Or a user may want to see the effect of 2% reduction in the interest rate on a house mortgage.

Database

Database software is designed to perform database operations, such as file creation, deletion, modification, search, sort, merge, and join (combining two files or tables based on a common key). A file is a collection of records. A record is a collection of fields. A field is a collection of characters.

A database can also be compared to a table of rows and columns. The rows correspond to records, and columns correspond to the fields (attributes) within the record. As an example, the ABC Company keeps track of its customers in a database. This database, or table, has 5,000 rows (records) and five columns (fields). The columns keep tracks of names, credit limit, address, income, and years of service. Common applications of database software are sorting and searching records. In sort operations, the user enters a series of records in any order, then asks the database management program to sort the records in ascending or descending order based on the data in the fields. Search operations are more interesting. A user can search for data items that meet certain criteria, for example all customers who have an income greater than $80,000, who live in the southwest, and who have been customers for more than 5 years. Some database management systems allow a user to search for key words within a text file. This type of application is common when a user performs literature research.

Graphics

Graphics software has been designed to present data in graphic format. Data can be converted into a line graph to show a trend, into a pie chart to highlight the components of a data item, and into other types of graphs for various analyses. Masses of data can be converted to a graph, and in an instant, the user can discover the general pattern of the data. Different graphs achieve different tasks. For example, a pie chart shows the components of a data item. It may break down the total cost into raw material costs, labor costs, and advertising costs, as an example. A line graph may show the sales trend of the past 5 years and yet a bar graph compares the profit of the ABC Company for the past 6 years. Graphs can easily highlight patterns and the correlation among data items. They also make data presentation a more manageable task. Graphics are produced either by integrated packages, such as Microsoft Excel, or by dedicated graphics packages, such as Harvard Graphics, by the Harvard Graphics Corporation.

Desktop Publishing

Desktop publishing is used to produce professional-quality documents (with or without graphics) using relatively inexpensive hardware and software. All that is needed are a PC, desktop publishing software, and a laser or letter-quality printer. Desktop publishing has evolved as a result of three major factors: (a) inexpensive PCs, (b) inexpensive laser printers, and (c) sophisticated and easy-to-use desktop publishing software.

Desktop publishing enables a user to produce high-quality screen output and then transfer it to the printer, using the “what you see is what you get,” or WYSIWYG, concept. Major applications of desktop publishing are for creating newsletters, brochures, training manuals, transparencies, posters, and books.

Financial Planning

Financial planning software works with large amounts of data and performs diverse financial analyses. These analyses include present value, future value, rate of return, cash flow analyses, depreciation analyses, retirement planning, and budgeting analyses. Using financial planning software, a user can plan and analyze a financial situation. For example, a user will know how much a $2,000 IRA will be worth at 6% interest in 30 years, and he/she can translate the value of future cash flows into today’s dollars. A user will know how much he/she has to deposit in a bank in order to have $150,000 in 18 years for a child’s education.

Project Management

A project consists of a series of related activities. Building a house, designing an order entry system, and writing theses are examples of projects. The goal of project management software is to help a project manager keep time and budget under control by resolving scheduling problems. Project management software helps managers plan and set achievable goals. It highlights the bottlenecks and the relationships between different activities. This software allows the user to study the cost, time, and resource impact of any change in the schedule.

TAKING CARE OF A MICROCOMPUTER

Maintaining a microcomputer in a proper working condition requires the following:

Protection against dirt, dust, and smoke.

Making backup copies of data for security reasons and keeping backups in different locations in case of data loses, computer crashes, fires and floods.

Avoiding any kind of liquid spills.

Maintaining steady power; using surge protectors for power fluctuations and using lightning arresters in mountainous areas.

Protecting the system from static by using humidifiers or antistatic spray devices.

Not starting a computer using an unfamiliar disk (avoiding computer viruses—dangerous programs that erase and/or corrupt all data).

Not downloading information to a computer from unknown bulletin boards (downloading means to import information from other computers and network systems to the user’s system using a modem and telephone line).

Not opening e-mail attachments that are not expected or that are sent from unknown senders.

Acquiring insurance for computer equipment.

Keeping track of the serial numbers of all computer equipment and software; also, keeping a phone list of all vendors and help desk phone lines and all maintenance contracts.

CONCLUSION

This chapter provided an overview of computer literacy. It explained different types of data processing and the differences between data and information. The unique characteristics of computers, different applications, and different generations of computers were introduced. The chapter reviewed various types of computer memories and basic productivity tools. It reviewed batch processing and transaction processing systems and concluded with guidelines for the proper maintenance of a microcomputer system.

GLOSSARY

Computer A machine that accepts data as input, processes the data without human interference using a set of stored instructions, and outputs information. Instructions are step-by-step directions given to a computer for performing specific tasks.

Computer Generations Different classes of computer technology identified by a distinct architecture and technology; the first generation was vacuum tubes, the second transistors, the third integrated circuits, the fourth very-large-scale integration, and the fifth gallium arsenide and parallel processing.

Computer Literacy The basic knowledge needed for understanding and using the computers for day-to-day tasks.

Erasable Programmable Read-Only Memory (EPROM) A ROM that can be programmed by the user and, as the name indicates, erased and programmed again.

Programmable Read-Only Memory (PROM) Memory that, by using a special device, the user can program. However, once programmed, this type of memory cannot be erased.

Random Access Memory (RAM) A volatile memory that stores data and instructions during a session.

Read-Only Memory (ROM) A prefabricated chip supplied by vendors. This memory stores some general-purpose instructions or programs.

Computer Security Incident Response Teams (CSIRTs)

Raymond R. Panko, *University of Hawaii at Manoa*

INTRODUCTION

Almost all corporations today protect themselves with layered defenses consisting of firewalls, antivirus systems, hardened hosts, and other protections. Even so, security incidents (also called security breaches) sometimes occur.

The firm's on-duty staff may be tasked to handle minor incidents because they can respond immediately and generally effectively. For major incidents, however, such as a major virus attack, a major denial-of-service attack, or the hacking (take-over) of important servers, the firm needs a team approach to stop the breach and get the firm back to normal. To handle major incidents, many firms create computer security incident response teams (CSIRTS), also known as computer emergency response teams (CERTs).

A critical success factor for any CSIRT is rapid response. During a major security breach, a corporation's operations are likely to be disrupted. This can result in the loss of immediate revenues, in the imposition of penalties by business partners and regulators, and by a loss in customer or investor confidence. During the intense stresses of major security incidents, CSIRTs must be able to act very rapidly but correctly.

During emergencies, human beings often are not at their best cognitively. Instead of ensuring that they understand the situation well, they often fixate on a single possible solution that eventually turns out to be fatally flawed. They also tend to make mistakes and work slowly when they are handling complex and difficult tasks for the first time. In addition, teams whose members are unfamiliar with the way their coworkers operate often have communication breakdowns.

Consequently, it is extremely important for CSIRTs to be organized and to conduct live rehearsals before incidents occur. Although first attempts may not be satisfactory, live rehearsals will identify problems that can be corrected so that performance is good during real incidents.

Once a real security breach occurs, the CSIRT's work must proceed through a series of well-considered steps (Panko, 2004). These are the discovery of an incident and its escalation to the status of major incident, the analysis of the incident to understand it, the containment of the attack to stop the spread of damage, repair to get damaged systems cleaned up and operational, the possible punishment of the attacker, the hardening of damaged systems against new attacks, and postmortem analysis.

BEFORE THE INCIDENT

Justifying the CSIRT

CSIRTs are expensive. It is important to be able to justify the cost of having a CSIRT to senior management. It is also important to be able to justify requiring participation from a number of departments, including during live rehearsals, which are very time consuming.

The normal way to justify a CSIRT is to collect data on the frequency of attacks and the damage caused by attacks. One excellent general source is the Computer Emergency Response Team/Coordination Center (http://www.cert.org).

Other good general sources are SecurityFocus (http://www.securityfocus.com) and SANS (http://www.sans.org). The FBI and the Computer Security Institute conduct an annual survey of corporations to assess the frequencies of various kinds of attacks (http://www.gocsi.com). A good source of data on viruses and spam is MessageLabs (http://www.messagelabs.com). In presenting summary information to top management, it is good to have data on both general trends and some examples of serious problems caused by incidents in specific corporations.

This information should be combined with estimates of how much major attacks of various types would cost the firm and, if possible, how having rapid detection and containment through the use of a CSIRT could reduce these costs.

Organizing the CSIRT

The first step is to create the CSIRT. Information technology (IT) security incidents can affect several functional groups in a firm. It usually also takes the staff from several functional areas to handle major IT security incidents. Consequently, the CSIRT must draw on several functional areas for its membership (Panko, 2004): the IT security staff, the IT staff, functional line managers, public relations, the legal department, and external organizations, such as outsourcers and law enforcement agencies.

The IT Security Staff

Obviously, the IT security staff needs to be involved and may lead the CSIRT. Most firms have very small IT security staffs, and when this is the case, it is normal for the entire IT security staff to be on the CSIRT.

The IT Staff

Sometimes, the IT security staff is under the information technology director. This is not ideal because a large fraction of all IT security breaches are committed by the IT staff. It is better for accountability for IT security to be a parallel operation. Another reason for keeping the IT security staff separate is that the IT staff sometimes focuses primarily on technology, while the IT security staff must focus more broadly on organizational issues. On the negative side, separating IT security from IT can result in friction between the two groups in terms of the ownership of server logs and other important matters. In addition, a separated IT security staff cannot "order" the IT staff to take action, and separation frees the IT department from accountability for security.

In CSIRTs, it is important to have members of the IT staff be involved however IT security and IT relate organizationally. It is also important to have operational levels of IT represented as well as IT management because operational employees often have a better picture of what is happening at a detailed level, while IT managers have the broader perspective needed to understand what is happening across systems and needed to understand the corporate implications of IT security breaches and alternative remedies.

Functional Line Managers

Fixing an IT security breach is not simply a technical matter. For example, the simplest and most effective way to contain a hacking intrusion is to terminate a victim computer's network or Internet connection. However, the business implications of "pulling the plug" can be horrendous. It is important for functional line managers in critical areas to be involved in and to approve the CSIRT's actions.

Public Relations

One non-IT group that needs to be strongly involved is the company's public relations department. If there is a serious problem, the company will want to manage communication with the outside world to produce as little damage as possible to public relations. Under no circumstances should an IT or IT security employee talk to the media directly. Many firms also work with external public relations companies, and there are even public relations companies that specialize in incident handling.

Legal Department

It is critical to have members of the legal department on the CSIRT. Lawyers have the specialized knowledge needed for prosecution and to defend the company against liability. (If an attacker compromises a corporate computer and uses it to attack another corporation, the company whose computer was compromised and used may be liable.)

IT Outsourcers

Most companies outsource at least some of their IT activities, and many companies outsource most of their IT. In such cases, the IT outsourcing vendor will have to work closely with the CSIRT. Beyond that, the IT outsourcer must have good internal incident response capabilities, and expertise in incident handling may be a factor in selecting an outsourcer.

Some firms turn to IT security outsourcers to detect problems in internal systems and to provide expertise and actual work in the case of security incidents. One advantage of using IT security outsourcers is that they have constant experience with handling attacks, while internal CSIRTs may handle only a handful of attacks each year.

In any IT outsourcing, it is important to have outsourcers intimately connected to the CSIRT, including participating in rehearsals for security incidents.

Law Enforcement

Although law enforcement agencies will not actually be part of the CSIRT, their expertise is invaluable if action is to be taken against the attacker. It is important for the CSIRT to understand how to interact with law enforcement agencies and to know what services law enforcement agencies can provide, such as the copying and protection of evidence. Law enforcement officers may even participate in CSIRT rehearsals.

Live Rehearsals

Once the CSIRT is formed, it must engage in live rehearsals that take it through realistic emergencies. During these tests, the CSIRT's members may discover that they are missing representation from an important functional area, that their approaches to recovery are not viable, that they have misunderstandings about authority and even terminology, and so forth. Live rehearsals also build confidence and speed.

Technology Base

The CSIRT will need some technology to do its job. Some of it the firm already has. Some of it must be purchased separately.

Protection Technology

By definition, incidents occur when protection technology (firewalls, server hardening, etc.) break down. However, good protection technology may be able to reduce the severity of an attack. Protections are discussed extensively in other chapters in this encyclopedia.

Intrusion Detection Systems (IDSs)

Technologies can also help in the response phase of incidents. Most obviously, intrusion detection systems can alert firms to attacks. In addition, IDS log files can help the firm analyze what has happened during an attack.

File Integrity Checkers

To respond to an incident involving a server compromise, it is important to be able to know what changes the attacker has made. File integrity checkers periodically create message digests of important system programs. After an attack, message digests are again computed and compared with message digests before the attack to see which programs had been changed. Unfortunately, few firms use file integrity checkers.

Evidence Collection Technology

Evidence collection technology allows a firm to capture evidence during an attack. If evidence is not collected rapidly and carefully, it will become almost impossible to prosecute attackers or even to understand the attack well. One action is to back up the hard drive on the compromised computer. In addition, transient information stored in RAM during an attack may be crucial to understanding the attack and prosecuting attackers. Special purpose software can handle backups and capture this transient information in ways that will preserve evidence for presentation in court if necessary.

The Problem of Communication

One inevitable problem in CSIRTs is communication. During an attack, e-mail may be compromised, and it is likely to be too slow anyway for important functions. The CSIRT organizer must maintain up-to-date lists of office telephone numbers, home telephone numbers, pager numbers, short message service cellular telephone numbers, e-mail addresses, and other contact information for each member of the CSIRT. This contact information changes so rapidly that it must be updated frequently and aggressively.

In the same vein, each CSIRT member must designate an alternate team member if he or she is unavailable. The CSIRT leader needs to maintain up-to-date contact information for these alternates as well. Ideally, alternates should participate in tests.

The Decision to Prosecute

One issue should be considered very carefully before any incident occurs. This is whether to attempt to punish the attacker. For internal employees, this usually is a fairly straightforward decision because termination and lesser punishments are easy and usually legally safe to administer.

For external hackers, however, prosecution is very difficult, especially if the attacker is a minor. Furthermore, pursuing prosecution may open the firm up to negative publicity and consequent losses in customer and investor confidence. Before attacks occur, the company should develop a policy regarding external (and internal) prosecution with the aid of the corporate legal department and senior managers.

One consideration in developing prosecution policies is that successful prosecution will require the CSIRT to take certain actions discussed later in this chapter. Evidence must be carefully protected and preserved. In addition, during the attack, it may be necessary to allow the attack to continue long enough to gather sufficient evidence for conviction instead of cutting off the attacker as soon as possible.

DURING THE ATTACK

Although preparation before a security incident is important, how well the CSIRT responds to actual security incidents is the litmus test for success.

Discovery and Escalation

First, the attack must be discovered. Often, the employee who discovers the attack is a low-level IT employee or an employee in a functional area such as marketing. A key question to ask any firm to assess its state of security is, "Do your employees know the telephone number for reporting security concerns?" A sticker with this number should be on every telephone in the organization. Often, this is the telephone number of the firm's general security office. Delays in reporting suspected security breaches often result in severe damage before the CSIRT can even start its work.

In other cases, the IT security or general IT staff detects the incident. Often, the firm's intrusion detection system sets off an alarm when there is suspicious activity in the system.

In addition, the IDS maintains log files of events relevant to security. During the later analysis phase, the analysis of these log files is crucial in understanding the nature of the incident.

The on-duty IT and IT security staffs typically handle small incidents themselves. However, the on-duty staff manager must have clear guidelines for when to escalate an incident, that is, when to declare the situation sufficiently dangerous or damaging to convene the CSIRT. In particular, the firm must have good guidelines for classifying attacks as minor or major.

Analysis

The first action of the CSIRT must be to analyze the situation. There is a tendency to act precipitously even when there is little information available. A short period of incident analysis is critical for later success.

The first step is to classify the security incident. Typically, there are three types of security incidents—widespread virus/worm outbreaks, denial-of-service attacks, and hacking attacks. Hacking is the access of a protected resource without authorization or in excess of authorization. Hacking, in other words, is breaking into a client, server, switch, router, or other computer.

The second step is to understand the attack. What vulnerability allowed the hacker to break into the computer? What has he or she already done? How sophisticated does the attack appear to be? In the case of virus/worm outbreaks, how is the virus or worm propagating, and how rapidly is it propagating?

Although analysis typically focuses on internal data in computer and intrusion detection system log files, the CSIRT may also contact other organizations, including the Computer Emergency Response Team/Coordination Center, which maintains information about common hacking breaches and virus attacks. There is a good chance that the current attack uses a method that is common in recent attacks, is well understood, and for which good defenses are known.

Containment

The next step is containment, which means stopping the attack. As noted earlier, the simplest approach to containment is to unplug affected computers. While this is effective and may even prove to be necessary, it is a drastic step that can have important implications for the firm as a whole if an affected server is vital to the firm's operations. Effectively, unplugging a computer is a self-administered denial-of-service attack.

In addition, it may be desirable to allow the attacker to continue working so that the attack can be better understood. Containing the attacker too soon may simply keep them out for a few minutes, after which they may be able to get back in using the same exploit they used to gain entry in the first place. In a virus or worm attack, containment before understanding may result in immediate reinfection through the same vulnerability.

If legal prosecution is a goal, furthermore, it may be important to continue gathering evidence.

On the negative side, if hackers are given sufficient time, they can scatter backdoor attack programs throughout a server's directories, read sensitive information, and take steps to make themselves difficult to detect. Consequently, containment should be initiated as soon as possible.

Recovery

Recovery, also called repair, means getting the computer system back to the state it was in before the attack. This means removing programs the attacker placed on the computer and cleaning up any altered data files.

Recovery usually focuses on program files, because hackers and virus/worms often litter the computer with attack programs that must be rooted out. Attackers also Trojanize legitimate system programs by overwriting them with an attack program but keeping the name the same. To recover the system of program files on the computer, there are three main options: repair during continued operation, restoration from backup tapes, and reinstallation from original installation media.

Repair During Continued Operation

If a company has a good way to recognize attack programs, it may be able to make program file repairs while the computer is still operational. However, this presumes that the firm has done such things as keep message digests for all program files so that changes can be detected. This seldom is done.

Recovery from Backup Tapes

It is more common to reinstall all system and other program files from the last clean backup tape. This can be effective, but it is important to know when the attack began or the backup files may themselves be suspect. In addition, the restoration of program files from backup tapes often requires the system to be taken offline at least temporarily.

Reinstallation from Original Installation Media

In the worst case, the computer's software will have to be reinstalled using original software installation media. It is important to have these media readily available for such eventualities. It is also important to document all configuration changes made during and since the last installation. For instance, patches frequently need to be applied to remove known vulnerabilities, and there usually are many company-specific and computer-specific configuration changes made for other reasons. Reinstallation from original media typically takes the computer down for several hours.

Data Files

The CSIRT will face special nightmares if the attack damaged (or may have damaged) data files. While restoration from the last clean backup tape will work for older files, all data entered since the last backup will be lost unless a real-time journal of changes has been maintained (which is rare). Laboriously, online files can be compared to backup files to identify safe files and files that must be looked at carefully.

Protection Against Subsequent Attacks

The last action of any CSIRT during an attack is to protect the firm against subsequent attacks. Obviously, the specific vulnerability that allowed the attack to succeed must be fixed. In addition, firewalls should be tuned to stop such attacks if possible, and intrusion detection systems must get filters to warn of subsequent attacks conducted the way the current breach was created.

Second, and more subtly, the server that was attacked must be especially hardened against reattacks. Hardening involves the application of all patches to the system and the general configuring of the system for maximum security.

Internet hackers, to demonstrate their successes, often invite other hackers to get into your system. For some period of time after an attack, your "famous" server will continue to be attacked by hackers. If you repair the specific exploit used in the first place, hackers will attempt to find other vulnerabilities to prove that they could break into the server in ways that the original hacker could not.

AFTER THE ATTACK

Sanctions

Sanctions are punishments that a firm directs at attackers. Although anger usually makes a firm eager to sanction attackers, it is not always practical to do so.

Punishing Employees

If the attacker is a current employee, the firm must weight the benefits of prosecution against the simple expedient of firing the employee. (For minor incidents, more mild sanctions may be appropriate.) Firing an employee typically can be done with no publicity, especially if the employee agrees to keep quiet or face legal prosecution. In addition, while prosecution is difficult, employees usually can be terminated fairly easily for attacking IT resources, and it usually is legally safe to terminate them (although U.S. state laws differ, international laws vary greatly, and union agreements may make sanctions difficult to apply in some firms).

Prosecuting Attackers

Prosecuting employees, ex-employees, or other outside attackers in courts of law requires a firm to prove that a particular person committed the attack. This can be difficult, especially if the attacker is using a spoofed IP address or attacked indirectly from a computer previously compromised instead of his or her own computer.

In addition, as noted earlier, the attacker must be traced doing a series of actions (individual actions may not convince a jury), and this may require allowing the attack to continue longer than it would if prosecution were not a goal.

Successful prosecution will depend heavily on the quality of evidence collected. As soon as possible, crucial information on the attacked computer must be documented or backed up. Otherwise, the defense will argue that the evidence is tainted and that many things could have caused later changes.

In addition, the CSIRT needs to carefully document how evidence was collected and who collected the evidence. After evidence is collected, the firm must maintain a clear chain-of-evidence documenting who had the evidence at all times and how it was collected and protected after collection. Any breakdown in documentation can ruin a case. Judges often will not even allow a jury to see evidence that does not meet strict legal evidence requirements.

For prosecution, it is critical to train the CSIRT beforehand in evidence collection and preservation. In fact, it is highly desirable to call in local authorities or the FBI. They can make backups of your hard drives and collect other information in a way likely to get a conviction. Forensics is the application of science to criminal investigations. (Kruse and Heiser [2002] said that computer forensics involves the preservation, identification, extraction, documentation, and interpretation of computer media for evidentiary and/or root cause analysis.) This is not a field for amateurs.

Lawsuits

For attacks that produce only modest amounts of damage, the authorities often are reluctant to prosecute. A firm may still be able to act through the legal system by suing the attacker for actual damages and perhaps also for punitive damages. These damages and the attacker's cost of legal defense may be a satisfactory way to exact some measure of revenge. However, lawsuits are expensive and reveal the attack to public. In addition, if the lawsuit is viewed by the hacker community as "lame," the firm may become a popular target of revenge attacks by other hackers.

Reprisal Attacks

One option is to attack the attacker back—essentially, hacking the attacker's computer. This may seem attractive, but it is almost always a very bad idea. First, attackers often use intermediate victim computers to launch attacks. Reprisal attacks are likely to hurt an innocent victim. (If a firm feels that companies that allow their computers to be hacked are not innocent, it should keep in mind that it has just been hacked itself.)

Of course, more fundamentally, reprisal attacks are almost always illegal. The jailing of the CSIRT is not a goal of incident response. Also, a CSIRT is an official organization within the firm; liability for a reprisal attack is likely to extend to senior officers and even the board of directors.

Postmortem Analysis

After things have stabilized, it is important to conduct a postmortem analysis to review what happened during the incident. The goal is to improve future responses to incidents. Things that worked well should be noted, but problems also should be highlighted and fixes created for the future. After the exhaustion of an incident and the need to catch up on work postponed during the incident, it is difficult to motivate the CSIRT team members to undertake a postmortem analysis. However, given the valuable information gained during the actual incident, as opposed to simple live rehearsals, the information gathered in the postmortem analysis can produce strong benefits.

There should also be a follow-up analysis one to six months later to determine which recommendations made during a postmortem analysis have been implemented and which have not.

CONCLUSION

When major IT security incidents happen, companies cannot sit back and wonder what they should do. Before the attack, companies need to organize and train cross-disciplinary computer security incident response teams —also called computer emergency response teams. Training using realistic rehearsals is very important for ensuring adequate and rapid CSIRT responses during an emergency.

During an attack, once an incident is discovered and escalated by the on-duty staff to a major incident, the CSIRT is activated. The CSIRT analyzes the attack so that appropriate responses can be made, contains the attack to prevent further damage, recovers program files and perhaps data files, gathers information needed for internal punishment or legal prosecution, hardens the system to prevent reattacks, and conducts a postmortem analysis to refine its incident response abilities.

GLOSSARY

Analysis Incident response phase just after discovery phase. The CSIRT determines how the attack was made and what was done to affected systems.

Breach Another name for a security incident.

Computer emergency response team Another name for computer security incident response team.

Computer security incident response team Cross-disciplinary team created to respond to major security incidents.

Containment Phase in incident response in which the damage to systems is stopped.

Discovery Phase in incident response in which a security incident is first discovered and reported.

Escalation The act of determining that a particular security incident is a major breach and that the CSIRT must be activated.

Forensics The application of science to criminal investigations.

Hacking Taking over a computer. Using a computer without authorization or in excess of authorization.

Hardening Removing vulnerabilities from a host computer and configuring the computer for high security.

Incident Another name for a security incident.

Incident response The multiphase process of responding to a security incident.

Intrusion detection system Tool that signals that an attack appears to be underway and that collects data in log files for analysis during and after an incident.

IT Information technology, computer hardware, computer software, networking, and data.

IT security Security of the IT function, as opposed to physical and building security.

IT security staff The IT security staff given responsibility for IT security, as opposed to physical and building security.

Legal department Department containing the firm's legal staff.

Outsourcer External company that provides IT services to the firm.

Postmortem analysis Assessment conducted after a security incident to determine how to better respond in the future.

Prosecution The attempt to convict an attacker in a court of law.

Public relations Department in a firm charged with communicating with the public and the media on behalf of the firm.

Punishment Taking action against an attacker; both sanctioning employee attackers and prosecuting and suing external attackers.

Repair Phase in incident response in which the damaged system is brought back to correct operation.

Reprisal attack Attacking the attacker (usually illegal).

Security breach Another name for a security incident.

Security incident A virus attack, denial-of-service attack, or hack (computer break-in).

Trojanize Replace a legitimate file by an attacker's file, giving the attacker's file the same name as the legitimate file.

Computer Viruses and Worms

Robert Slade, *Consultant*

INTRODUCTION

Computer viruses are unique among the many security problems in the fact that someone else being infected increases the risk to you. However, viruses also seem to be surrounded by myths and misunderstandings. It is hoped that this chapter will help to set the record straight.

History of Computer Viruses and Worms

Many claims have been made for the existence of viruses prior to the 1980s, but, so far, these claims have not been accompanied by proof. The Core Wars programming contests did involve self-replicating code, but usually within a structured and artificial environment.

The general perception of computer viruses, even among security professionals, has concentrated on their existence in personal computers, and particularly "Wintel" (Windows/Intel)-type systems. This is despite the fact that Fred Cohen's seminal academic work took place on mainframe and minicomputers in the mid-1980s. The first e-mail virus was spread in 1987. The first virus hoax message (then termed a "metavirus") was proposed in 1988. Even so, virus and malware research has been neglected, possibly because malware does not fit easily into the traditional access control security models.

At least two Apple II viruses are known to have been created in the early 1980s. However, it was not until the end of the decade (and 1987 in particular) that knowledge of real viruses became widespread, even among security experts. For many years boot sector infectors and file infectors were the only types of common viruses. These programs spread relatively slowly, primarily distributed on floppy disks, and were thus slow to disseminate geographically. However, these viruses tended to be very long-lived.

During the early 1990s virus writers started experimenting with various functions intended to defeat detection. (Some forms had seen limited trials earlier.) Among these were polymorphism, to change form in order to defeat scanners, and stealth, to attempt to confound any type of detection. None of these virus technologies had a significant impact. Most viruses using these "advanced" technologies were easy to detect because of a necessary increase in program size.

Although demonstration programs had been created earlier, the mid-1990s saw the introduction of macro and script viruses in the wild. These were initially confined to word processing files, particularly files associated with the Microsoft Office Suite. However, the inclusion of programming capabilities eventually led to script viruses in many objects that would normally be considered to contain data only, such as Excel spreadsheets, PowerPoint presentation files, and e-mail messages. This fact led to greatly increased demands for computer resources among antiviral systems, since many more objects had to be tested, and Windows OLE (object linking and embedding) format data files presented substantial complexity to scanners. Macro viruses also increase in new variant forms very quickly, since the virus carries its own source code, and anyone who obtains a copy can generally modify it and create a new member of the virus family.

E-mail viruses became the major new form in the late 1990s and early 2000s. These viruses may use macro capabilities, scripting, or executable attachments to create e-mail messages or attachments sent out to e-mail addresses harvested from the infected machine. E-mail viruses spread with extreme rapidity, distributing themselves worldwide in a matter of hours. Some versions create so many copies of themselves that corporate and even service provider mail servers are flooded and cease to function. E-mail viruses are very visible and so tend to be identified within a short space of time, but many are macros or scripts and so generate many variants.

With the strong integration of the Microsoft Windows operating system with its Internet Explorer browser, Outlook mailer, Office suite, and system scripting, recent viruses have started to blur the normal distinctions. A document sent as an e-mail file attachment can make a call to a Web site that starts active content that installs a remote access tool acting as a portal for the client portion of a distributed-denial-of-service network. Indeed, not only are viruses starting to show characteristics that are similar to each other, but functions from completely different types of malware are beginning to be found together in the same programs, leading to a type of malware convergence.

Recently, many security specialists have stated that the virus threat is reducing, since, despite the total number of virus infections being seen, the prevalent viruses are now almost universally e-mail viruses and therefore constitute a single threat with a single fix. This ignores the fact that although almost all major viruses now use e-mail as a distribution and reproduction mechanism, there are a great many variations in the way e-mail is used. For example, many viruses use Microsoft's Outlook mailer to spread, and reproduction can be prevented simply by removing Outlook from the system. However, other viruses may make direct calls to the Mail Application Programing Interface (MAPI), which is used by a number of mail user programs, while others carry the code for mail server functions within their own body. A number of e-mail viruses distribute themselves to e-mail addresses found in the Microsoft Outlook address book files, while others may harvest addresses from anywhere on the computer hard drive, or may actually take control of the Internet network connection and collect contact data from any source viewed online.

Because the work has had to deal with detailed analysis of low-level code, virus research has led to significant advances in the field of forensic programming. However, to date computer forensic work has concentrated on file recovery and decryption, so the contributions in this area likely still lie in the future.

Many computer pundits, as well as some security experts, have proposed that computer viruses are a result of the fact that currently popular desktop operating systems have only nominal security provisions. They further suggest that viruses will disappear as security functions are added to operating systems. This thesis ignores the fact, well established by Cohen's research and subsequently confirmed, that viruses use the most basic of computer functions, and that a perfect defense against viruses is impossible. This is not to say that an increase in security measures by operating system vendors could not reduce the risk of viruses: the current danger could be drastically reduced with relatively minor modifications to system functions.

It is going too far to say (as some have) that the very existence of viral programs, and the fact that both viral strains and the numbers of individual infections are growing, means that computers are finished. At the present time, the general public is not well informed about the virus threat, and so more copies of viral programs are being produced than are being destroyed.

Indeed, no less an authority than Fred Cohen has championed the idea that viral programs can be used to great effect. An application using a viral form can improve performance in the same way that computer hardware benefits from parallel processors. It is, however, unlikely that viral programs can operate effectively and usefully in the current computer environment without substantial protective measures being built into them. A number of virus and worm programs have been written with the obvious intent of proving that viruses could carry a useful payload, and some have even had a payload that could be said to enhance security. Unfortunately, all such viruses have created serious problems themselves.

Virus Definition

A computer virus is a program written with functions and intent to copy and disperse itself without the knowledge and cooperation of the owner or user of the computer. A final definition has not yet been agreed upon by all researchers. A common definition is "a program which modifies other programs to contain a possibly altered version of itself." This definition is generally attributed to Fred Cohen from his seminal research in the mid-1980s, although Dr. Cohen's actual definition is in mathematical form. Another possible definition is an entity that uses the resources of the host (system or computer) to reproduce itself and spread, without informed operator action.

Cohen is generally held to have defined the term "computer virus" in his thesis (published in 1984). (The suggestion for the use of the term virus is credited to Len Adleman, his seminar advisor.) However, his original definition covers only those sections of code that, when active, attach themselves to other programs. This, however, neglects many of the programs that have been most successful "in the wild." Many researchers still insist on Cohen's definition and use other terms such as "worm" and "bacterium" for those viral programs that do not attack programs. Currently, viruses are generally held to attach themselves to some object, although the object may be a program, disk, document, e-mail message, computer system, or other information entity.

Computer viral programs are not a "natural" occurrence. Viruses are programs written by programmers. They do not just appear through some kind of electronic evolution. Viral programs are written, deliberately, by people. However, the definition of "program" may include many items not normally thought of in terms of programming, such as disk boot sectors, and Microsoft Office documents or data files that also contain macro programming.

Many people have the impression that anything that goes wrong with a computer is caused by a virus. From hardware failures to errors in use, everything is blamed on a virus. A virus is not just any damaging condition. Similarly, it is now popularly believed that any program that may do damage to your data or your access to computing resources is a virus. Viral programs are not simply programs that do damage. Indeed, viral programs are not always damaging, at least not in the sense of being deliberately designed to erase data or disrupt operations. Most viral programs seem to have been designed to be a kind of electronic graffiti: intended to make the writer's mark in the world, if not his or her name. In some cases a name is displayed, on occasion an address, phone number, company name, or political party.

Is My Computer Infected? What Should I Do?

In many books and articles you will find lists of symptoms to watch for in order to determine whether your computer is infected. These signs include things like running out of memory space, running out of disk space, the computer operating slower than normal, files changing size, and so forth. In fact, many factors will create these same effects, and current viruses seldom do. The best way to determine whether you have been infected by a virus is to get and use an antiviral scanner. In fact, get more than one. With the rapid generation of new viruses these days, it is quite possible for a maker of antivirus software to make mistakes in updating signatures. Therefore, having a second check on a suspected virus is always a good idea.

One scanner for the Wintel platform is F-PROT. It is available in a DOS version, free of charge from http://www.f-secure.com. (Look under "Downloads" and "Tools.") Although a DOS scanner has some limitations in a Windows envrionment, it will still be able to identify infected files, and is quite good at picking out virus infections within e-mail system files (the files of messages held on your computer).

Another scanner available for free is AVG, from http://www.grisoft.com. This one also does a good job of scanning, and will even update itself automatically (although that feature is problematic on some machines).

The various commercial antiviral producers generally produce trial versions of their software, usually limited in some way.

In regard to the suggestion to use more than one scanner, it should be noted that a number of successful software publishers have included functions that conflict with software from other vendors. These products should be avoided, because of the previously noted possibility of failure in a single protection program. The use of free software, and the purchase of software from companies that provide such free versions, is recommended, since the existence of these free scanners, and their use by other people, actually reduces your risk, since there will be fewer instances of viruses reproducing and trying to spread.

Readers may be surprised at the recommendation to use free software: there is a general assumption that commercial software must be superior to that provided free of charge. It should be noted that the author of this chapter is a specialist in the evaluation of security and, particularly, antiviral software. The reader can be assured that it can be proven that, in the case of antiviral software, free software is as effective, and in some cases superior to, many very expensive products.

TROJAN HORSES, VIRUSES, WORMS, RATS, AND OTHER BEASTS

Malware is a relatively new term in the security field. It was created to address the need to discuss software or programs intentionally designed to include functions for penetrating a system, breaking security policies, or carrying malicious or damaging payloads. Since this type of software has started to develop a bewildering variety of forms—such as backdoors, data diddlers, DDoS (distributed denial of service), hoax warnings, logic bombs, pranks, RATs (remote access Trojans), Trojans, viruses, worms, and zombies—the term malware has come to be used for the collective class of *mal*icious soft*ware*. The term is, however, often used very loosely simply as a synonym for virus, in the same way that virus is often used simply as a description of any type of computer problem. This chapter will attempt to define the problem more accurately, and to describe the various types of malware.

Viruses are the largest class of malware, both in terms of numbers of known entities and in impact in the current computing environment. Viruses, therefore, tend to be synonymous, in the public mind, with all forms of malware.

Programming bugs or errors are generally not included in the definition of malware, although it is sometimes difficult to make a hard and fast distinction between malware and bugs. For example, if a programmer left a buffer overflow in a system and it creates a loophole that can be used as a backdoor or a maintenance hook, did he do it deliberately? This question cannot be answered technically, although we might be able to guess at it, given the relative ease of use of a given vulnerability.

In addition, it should be noted that malware is not just a collection of utilities for the attacker. Once launched, malware can continue an attack without reference to the author or user, and in some cases will expand the attack to other systems. There is a qualitative difference between malware and the attack tools, kits, or scripts that must operate under an attacker's control and those not considered to fall within the definition of malware. There are gray areas in this aspect as well, since RATs and DDoS zombies provide unattended access to systems, but need to be commanded in order to deliver a payload.

Trojans

Trojans, or Trojan horse programs, are the largest class of malware. However, the term is subject to much confusion, particularly in relation to computer viruses.

A Trojan is a program that pretends to do one thing while performing another, unwanted action. The extent of the "pretense" may vary greatly. Many of the early PC Trojans relied merely on the filename and a description on a bulletin board. "Log-in" Trojans, popular among university student mainframe users, mimicked the screen display and the prompts of the normal log-in program and could, in fact, pass the user name and password along to the valid log-in program at the same time as they stole the user data. Some Trojans may contain actual code that does what it is supposed to be doing while performing additional nasty acts that it does not tell you about.

An additional confusion with viruses involves Trojan horse programs that may be spread by e-mail. In years past, a Trojan program had to be posted on an electronic bulletin board system or a file archive site. Because of the static posting, a malicious program would soon be identified and eliminated. More recently, Trojan programs have been distributed by mass e-mail campaigns, by posting on Usenet newsgroup discussion groups, or through automated distribution agents (bots) on Internet relay chat (IRC) channels. Since source identification in these communications channels can be easily hidden, Trojan programs can be redistributed in a number of disguises, and specific identification of a malicious program has become much more difficult.

Some data security writers consider that a virus is simply a specific example of the class of Trojan horse programs. There is some validity to this usage since a virus is an unknown quantity that is hidden and transmitted along with a legitimate disk or program, and any program can be turned into a Trojan by infecting it with a virus. However, the term virus more properly refers to the added, infectious code rather than the virus/target combination. Therefore, the term trojan refers to a deliberately misleading or modified program that does not reproduce itself.

A major aspect of Trojan design is the social engineering (fraudulent or deceptive) component. Trojan programs are advertised (in some sense) as having a positive component. The term positive can be in dispute, since a great many Trojans promise pornography or access to pornography, and this still seems to be depressingly effective. However, other promises can be made as well. A recent e-mail virus, in generating its messages, carried a list of a huge variety of subject lines, promising pornography, humor, virus information, an antivirus program, and information about abuse of the recipient's e-mail account. Sometimes the message is simply vague and relies on curiosity.

Social engineering really is nothing more than a fancy name for the type of fraud and confidence games that have existed since snakes started selling apples. Security types tend to prefer a more academic sounding definition, such as the use of nontechnical means to circumvent security policies and procedures. Social engineering can range from simple lying (such as a false description of the function of a file) to bullying and intimidation (in order to pressure a low-level employee into disclosing information), to association with a trusted source (such as the user name from an infected machine).

Worms

A worm reproduces and spreads, like a virus, and unlike other forms of malware. Worms are distinct from viruses, although they may have similar results. Most simply, a worm may be thought of as a virus with the capacity to propagate independently of user action. In other words, they do not rely on (usually) human-initiated transfer of data between systems for propagation, but instead spread across networks of their own accord, primarily by exploiting known vulnerabilities in common software.

Originally, the distinction was made that worms used networks and communications links to spread, and that a worm, unlike a virus, did not directly attach to an executable file. In early research into computer viruses, the terms worm and virus tended to be used synonymously, it being felt that the technical distinction was unimportant to most users. The technical origin of the term "worm program" matched that of modern distributed processing experiments: a program with "segments" working on different computers, all communicating over a network (Shoch & Hupp, 1982).

The first worm to garner significant attention was the Internet Worm of 1988, to be discussed in detail in the section Worms (First and Third Generations). Recently, many of the most prolific virus infections have not been strictly viruses but have used a combination of viral and worm techniques to spread more rapidly and effectively. LoveLetter was an example of this convergence of reproductive technologies. Although infected e-mail attachments were perhaps the most widely publicized vector of infection, LoveLetter also spread by actively scanning attached network drives, infecting a variety of common file types. This convergence of technologies will be an increasing problem in the future. Code Red and a number of Linux programs (such as Lion) are modern examples of worms. (Nimda is an example of a worm, but it also spreads in a number of other ways, so it could be considered to be an e-mail virus and multipartite as well.)

Viruses

A virus is defined by its ability to reproduce and spread. A virus is not just anything that goes wrong with a computer, and virus is not simply another name for malware. Trojan horse programs and logic bombs do not reproduce themselves.

A worm, which is sometimes seen as a specialized type of virus, is currently distinguished from a virus because a virus generally requires an action on the part of the user to trigger or aid reproduction and spread. The action on the part of the user is generally a common function, and the user generally does not realize the danger of the action or the fact that he or she is assisting the virus.

The only requirement that defines a program as a virus is that it reproduces. There is no necessity that the virus carries a payload, although a number of viruses do. In many cases (in most cases of "successful" viruses), the payload is limited to some kind of message. A deliberately damaging payload, such as erasure of the disk, or system files, usually restricts the ability of the virus to spread because the virus uses the resources of the host system. In some cases, a virus may carry a logic bomb or time bomb which triggers a damaging payload on a certain date or under a specific, often delayed, condition.

Because a virus spreads and uses the resources of the host, it affords a kind of power to software that parallel processors provide to hardware. Therefore, some have theorized that viral programs could be used for beneficial purposes, similar to the experiments in distributed processing that are testing the limits of cryptographic strength. (Various types of network management functions, and updating of system software, are seen as candidates.) However, the fact that viruses change systems and applications is seen as problematic in its own right. Many viruses that carry no overtly damaging payload still create problems with systems. A number of virus and worm programs have been written with the obvious intent of proving that viruses could carry a useful payload, and some have even had a payload that could be said to enhance security. Unfortunately, all such viruses have created serious problems themselves. The difficulties of controlling viral programs have been addressed in theory, but the solutions are also known to have faults and loopholes.

Logic Bombs

Logic bombs are software modules set up to run in a quiescent state but to monitor for a specific condition, or set of conditions, and to activate their payload under those conditions. A logic bomb is generally implanted in or coded as part of an application under development or maintenance. Unlike a RAT or Trojan it is difficult to implant a logic bomb after the fact. There are numerous examples of this type of activity, usually based upon actions taken by a programmer to deprive a company of needed resources if employment was terminated.

A Trojan or a virus may contain a logic bomb as part of the payload. A logic bomb involves no reproduction, no social engineering.

A persistent legend in regard to logic bombs involves what is known as the salami scam. According to the story, this involves the siphoning off of small amounts on money (in some versions, fractions of a cent) credited to the account of the programmer, over a very large number of transactions. Despite the fact that these stories appear in a number of computer security texts, the author has a standing challenge to anyone to come up with a documented case of such a scam. Over a period of eight years, the closest anyone has come is a story about a fast food clerk who diddled the display on a drive through window, and collected an extra dime or quarter from most customers.

Other Related Terms

Hoax virus warnings or alerts have an odd double relation to viruses. First off, hoaxes are usually warnings about “new” viruses: new viruses that do not, of course, exist. Second, hoaxes generally carry a directive to the user to forward the warning to all addresses available to them. Thus these descendants of chain letters form a kind of self-perpetuating spam.

Hoaxes use an odd kind of social engineering, relying on people’s naturally gregarious nature and desire to communicate, and on a sense of urgency and importance, using the ambition that people have to be the first to provide important new information.

Hoaxes do, however, have common characteristics that can be used to determine whether their warnings may be valid:

- Hoaxes generally ask the reader to forward the message.
- Hoaxes make reference to false authorities such as Microsoft, AOL, IBM, and the FCC (none of which issue virus alerts), or to completely false entities.
- Hoaxes do not give specific information about the individual or office responsible for analyzing the virus or issuing the alert;
- Hoaxes generally state that the new virus is unknown to authorities or researchers.
- Hoaxes often state that there is no means of detecting or removing the virus.
- Many of the original hoax warnings stated only that you should not open a message with a certain phrase in the subject line. (The warning, of course, usually contained that phrase in the subject line. Subject line filtering is known to be a very poor method of detecting malware.)
- Hoaxes often state that the virus does tremendous damage, and is incredibly virulent.
- Hoax warnings very often contain A LOT OF CAPITAL LETTER SHOUTING AND EXCLAMATION MARKS!!!!!!!!!!
- Hoaxes often contain technical sounding nonsense (technobabble), such as references to nonexistent technologies like “nth complexity binary loops.”

It is wisest, in the current environment, to doubt all virus warnings, unless they come from a known and historically accurate source, such as a vendor with a proven record of providing reliable and accurate virus alert information, or preferably an independent researcher or group. It is best to check *any* warnings received against known virus encyclopedia sites. It is best to check more than one such site: in the initial phases of a “fast burner” attack some sites may not have had time to analyze samples to their own satisfaction, and the better sites will not post information they are not sure about.

Remote access Trojans (RATs) are programs designed to be installed, usually remotely, after systems are installed and working (and not in development, as is the case with logic bombs and backdoors). Their authors would generally like to have the programs referred to as remote administration tools, in order to convey a sense of legitimacy.

When a RAT program has been run on a computer, it will install itself in such a way as to be active every time the computer is started subsequent to the installation. Information is sent back to the controlling computer (sometimes via an anonymous channel such as IRC), noting that the system is active. The user of the command computer is now able to explore the target, escalate access to other resources, and install other software, such as DDoS zombies, if so desired.

DDoS (distributed denial of service) is a modified denial of service (DoS) attack. Denial of service attacks do not attempt to destroy or corrupt data, but attempt to use up a computing resource to the point where normal work cannot proceed. The structure of a DDoS attack requires a master computer to control the attack, a target of the attack, and a number of computers in the middle that the master computer uses to generate the attack. These computers in between the master and the target are variously called agents or clients, but are usually referred to as running “zombie” programs. The existence of a large number of agent computers in a DDoS attack acts to multiply the effect of the attack, and also helps to hide the identity of the originator of the attack.

There is a lot of controversy over a number of technologies generally described as adware or spyware. Most people would agree that the marketing functions are not specifically malicious, but what one person sees as "aggressive selling" another will see as an intrusion or invasion of privacy.

Shareware or freeware programs may have advertising for a commercial version or a related product, and users may be asked to provide some personal information for registration or to download the product. For example, an unregistered copy of the WinZip archiving program typically asks the user to register when the program is started, and the free version of the QuickTime video player asks the user to buy the commercial version every time the software is invoked. Adware, however, is generally a separate program installed at the same time as a given utility or package, and continues to advertise products, even when the desired program is not running. Spyware is, again, a system distinct from the software the user installed, and passes more information than simply a user name and address back to the vendor: often these packages will report on Web sites visited or other software installed on the computer, and possibly compile detailed inventories of the interests and activities of a user.

The discussion of spyware often makes reference to cookies or Web bugs. Cookies are small pieces of information in regard to persistent transactions between the user and a Web site, but the information can be greater than the user realizes, for example, in the case of a company that provides content, such as banner ads, to a large number of sites. Cookies, limited to text data, are not malware, and can have no executable malicious content. Web bugs are links on a Web page or embedded in e-mail messages that contain links to different Web sites. A Web bug therefore passes a call, and information, unknown to the user, to a remote site. Most commonly a Web bug is either invisible or unnoticeable (typically it is one pixel in size) in order not to alert the user to its presence. (There is a persistent chain letter hoax that tells people to forward the message because it is part of a test of an e-mail tracking system. Although all such reports to date are false, if such a system were to be implemented, Web bugs would likely be the technology used. Even then the system would not be reliable: Web bugs in e-mail rely on an e-mail system calling a Web browser function, and although this typically happens automatically with systems like Microsoft's Outlook and Internet Explorer, a mailer like Pegasus requires the function call to be established by the user, and warns the user when it is being invoked.

Pranks are very much a part of the computer culture. So much so that you can now buy commercially produced joke packages that allow you to perform "Stupid Mac (or PC, or Windows) Tricks." There are numberless pranks available as shareware. Some make the computer appear to insult the user; some use sound effects or voices; some use special visual effects. A fairly common thread running through most pranks is that the computer is, in some way, nonfunctional. Many pretend to have detected some kind of fault in the computer (and some pretend to rectify such faults, of course making things worse). One entry in the virus field is PARASCAN, the paranoid scanner. It pretends to find large numbers of infected files, although it doesn't actually check for any infections.

Generally speaking, pranks that create some kind of announcement are not malware: viruses that generate a screen or audio display are actually quite rare. The distinction between jokes and Trojans is harder to make, but pranks are intended for amusement. Joke programs may, of course, result in a denial of service if people find the prank message frightening.

One specific type of joke is the "easter egg," a function hidden in a program, and generally accessible only by some arcane sequence of commands. These may be seen as harmless, but note that they do consume resources, even if only disk space, and also make the task of ensuring program integrity very much more difficult.

FIRST GENERATION VIRUSES

Many of the books and articles currently available to explain about viruses were written based on the research that was done on the first generation of viruses. While these programs are still of interest to those who study the internal structures of operating systems, they operated much differently than the current crop of malicious software. First generation viruses tended to spread very slowly but hang around in the environment for a long time. Later viruses tended to spread very rapidly, but also to die out relatively quickly.

Boot Sector Viruses

Viruses are generally partly classified by the objects to which they attach. Worms may be seen as a type of virus that attaches to nothing. Most desktop computer operating systems have some form of boot sector, a specific location on disk that contains programming to bootstrap the startup of a computer. Boot sector infectors (BSIs) replace or redirect this programming in order to have the virus invoked, usually as the first programming running on the computer.

Boot sector infectors would not appear to fit the definition of a virus infecting another program, since BSIs can be spread by disks that do not contain any program files. However, the boot sector of a normal MS-DOS disk, whether or not it is a "system" or bootable disk, always contains a program (even if it only states that the disk is not bootable), and so it can be said that a BSI is a "true" virus.

The terminology of BSIs comes from MS-DOS systems, and this leads to some additional confusion. The physical "first sector" on a hard drive is not the operating system boot sector. On a hard drive the boot sector is the first "logical" sector. The number one position on a hard drive is the master boot record (MBR). Some viral programs, such as the Stoned virus, always attack the physical first sector: the boot sector on floppy disks and the master boot record on hard disks. Thus viral programs that always attack the boot sector might be termed "pure" BSIs, whereas programs like Stoned might be referred to as an "MBR type" of BSI. The term boot sector infector is used for all of them, though, since all of them infect the boot sector on floppy disks.

File-Infecting Viruses

A file infector infects program (object) files. System infectors that infect operating system program files (such as COMMAND.COM in DOS) are also file infectors. File infectors can attach to the front of the object file (prependers), attach to the back of the file and create a jump at the front of the file to the virus code (appenders), or overwrite the file or portions of it (overwriters). A classic is Jerusalem. A bug in early versions caused it to add itself over and over again to files, making the increase in file length detectable. (This has given rise to the persistent myth that it is a characteristic of a virus that it will fill up all disk space eventually: by far the majority of file infectors add minimally to file lengths.)

Polymorphic Viruses

Polymorphism (literally many forms) refers to a number of techniques that attempt to change the code string on each generation of a virus. These vary from using modules that can be rearranged to encrypting the virus code itself, leaving only a stub of code that can decrypt the body of the virus program when invoked. Polymorphism is sometimes also known as self-encryption or self-garbling, but these terms are imprecise and not recommended. Examples of viruses using polymorphism are Whale and Tremor. Many polymorphic viruses use standard "mutation engines" such as MtE. These pieces of code actually aid detection because they have a known signature.

A number of viruses also demonstrate some form of active detection avoidance, which may range from disabling of on-access scanners in memory to deletion of antivirus and other security software (Zonealarm is a favorite target) from the disk.

Virus Creation Kits

The term "kit" usually refers to a program used to produce a virus from a menu or a list of characteristics. Use of a virus kit involves no skill on the part of the user. Fortunately, most virus kits produce easily identifiable code. Packages of antiviral utilities are sometimes referred to as tool kits, occasionally leading to confusion of the terms.

MACRO VIRUSES (SECOND GENERATION)

A macro virus uses macro programming of an application such as a word processor. (Most known macro viruses use Visual Basic for Applications in Microsoft Word: some are able to cross between applications and function in, for example, a PowerPoint presentation and a Word document, but this ability is rare.) Macro viruses infect data files, and tend to remain resident in the application itself by infecting a configuration template such as MS Word's normal.dot. Although macro viruses infect data files, they are not generally considered to be file infectors: a distinction is generally made between program and data files. Macro viruses can operate across hardware or operating system platforms as long as the required application platform is present. (For example, many MS Word macro viruses can operate on both the Windows and Macintosh versions of MS Word.) Examples are Concept and CAP. Melissa is also a macro virus, in addition to being an e-mail virus: it mailed itself around as an infected document.

What Is a Macro?

As noted above, a macro is a small piece of programming contained in a larger data file. This differentiates it from a script virus, which is usually a standalone file that can be executed by an interpreter, such as Microsoft's Windows Script Host (.vbs files). A script virus file can be seen as a data file in that it is generally a simple text file, but it usually does not contain other data, and generally has some indicator (such as the .vbs extension) that it is executable. LoveLetter is a script virus.

Free Technology to Avoid Macro Viruses

A recommended defence is MacroList, written by A. Padgett Peterson. This is a macro itself, available for both Wintel and Macintosh machines. It will list all the macros in a document. Since most documents should not contain macros, any document that does should either have a really good reason for it, or be looked at with suspicion. You can find MacroList at http://www2.gdi.net\~padgett\index.htm.

E-MAIL VIRUSES (THIRD GENERATION)

With the addition of programmable functions to a standard e-mail user agent (usually Microsoft's Outlook), it became possible for viruses to spread worldwide in mere hours, as opposed to months.

The "Start" of E-mail Viruses: Melissa

Melissa was far from the first e-mail virus. The first e-mail virus to successfully spread in the wild was the Christma exec, in the fall of 1987. However, Melissa was certainly the first of the "fast burner" e-mail viruses, and the first to come to wide public attention.

The virus, generally referred to as W97M.Melissa, is a Microsoft Word macro virus. The name "Melissa" comes from the class module that contains the virus. The name is also used in the registry flag set by the virus.

The virus is spread, of course, by infected Word documents. What has made it the "bug du jour" is that it spreads *itself* via e-mail.

Melissa was originally posted to the alt.sex newsgroup. At that time it was list.doc, and purported to be a list of passwords for sex sites.

If you get a message with a Melissa infected document and do whatever you need to do to "invoke" the attachment, and have Word on your system as the default program for .doc files, Word starts up, reads in the document, and the macro is ready to start.

Assuming that the macro starts executing, several things happen.

The virus first checks to see whether Word 97 (Word 8) or Word 2000 (Word 9) is running. If so, it reduces the level of the security warnings on Word so that you will receive no future warnings. In Word 97, the virus disables the Tools/Macro menu commands, the Confirm Conversions option, the MS Word macro virus protection, and the Save Normal Template prompt. It "upconverts" to Word 2000 quite nicely and there disables the Tools/Macro/Security menu.

Specifically, under Word 97 it blocks access to the Tools|Macro menu item, meaning you cannot check any macros. It also turns off the warnings for conversion, macro detection, and saving modifications to the normal.dot file. Under Word 2000 it blocks access to the menu item that allows you to raise your security level and sets your macro virus detection to the lowest level, that is, none. Since the access to the macro security menu item is blocked, you must delete the infected normal.dot file in order to regain control of your security settings. Note that this will also lose all of your global templates and macros. Word users who make extensive use of macros are advised to keep a separate backup copy of a clean normal.dot in some safe location to avoid problems with macro virus infections.

After this, the virus checks for the HKEY_CURRENT_USER\Software\Microsoft\Office\Melissa?\ registry key with a value of "... by Kwyjibo." (The "kwyjibo" entry seems to be a reference to the "Bart the Genius" episode of the "Simpsons" television program where this word was used to win a Scrabble match.)

If this is the first time you have been infected, the macro starts up Outlook 98 or higher, in the background, and sends itself as an attachment to the "top" 50 names in *each* of your address lists. (Melissa will not use Outlook Express. Also, Outlook 97 will not work.) Most people have only one (the default is "Contacts"), but if you have more than one then Outlook will send more than 50 copies of the message. Outlook also sorts address lists such that mailing lists are at the top of the list, so this can get a much wider dispersal than just 50 copies of the message/virus.

Once the messages have been sent, the virus sets the Melissa flag in the registry, and looks for it to check whether to send itself out on subsequent infections. If the flag does not persist, then there will be subsequent mass mailings. Because the key is set in HKEY_CURRENT_USER, system administrators may have set permissions such that changes made are not saved, and thus the key will not persist. In addition, multiple users on the same machine will likely each trigger a separate mailout, and the probability of cross infection on a common machine is very high.

Since it is a macro virus, it will infect your normal.dot, and will infect all documents thereafter. The macro within normal.dot is "Document_Close()" so that any document that is worked on (or created) will be infected when it is closed. When a document is infected the macro inserted is "Document_Open()" so that the macro runs when the document is opened.

Note that not using Outlook does not protect you from the virus, it only means that the 50 copies will not be automatically sent out. If you use Word but not Outlook, you will still be infected and may still send out infected documents on your own. Originally the virus would not invoke the mailout on Macintosh systems. However, infected documents would be stored, and, recently, when Outlook became available for Macs, there was a second wave of Melissa mailings.

The message appears to come from the person just infected, of course, since it really is sent from that machine. This means that when you get an "infected" message it will probably appear to come from someone you know and deal with. The subject line is "Important Message From: [name of sender]" with the name taken from the registration settings in Word. The text of the body states "Here is that document you asked for... don't show anyone else;-)." Thus, the message is easily identifiable: that subject line, the very brief message, and an attached Word document (file with a .doc extension to the filename).

However, note that, as with any Microsoft Word macro virus, the source code travels with the infection, and it was very easy for people to create variations of Melissa. Within days of Melissa there was a similar Excel macro virus, called "Papa."

One rather important point: the document passed is the active document, not necessarily the original posted on alt.sex. So, for example, if I am infected, and prepare some confidential information for you in Word, and send you an attachment with the Word document, containing sensitive information that neither you nor I want made public and you read it in Word, and you have Outlook on your machine, then that document will be mailed out to the top 50 people in your address book, and so forth.

How to Avoid E-mail Viruses

It really is very simple to avoid e-mail viruses: don't double-click on any attachments that come with your e-mail. We used to say not to run any programs that came from someone you don't know, but many e-mail viruses spread using the identity of the owner of the infected computer, so that is no longer any protection. Do not run anything you receive, unless you know, from some separate verification, that this person intended to send you something, and that it is something you need, and that the person sending it is capable of protecting themselves from infection.

It is also somewhat safer to use a mail program other than Outlook, since some versions of Outlook allowed attachments to run even before the user read the message to which they were attached.

WORMS (FIRST AND THIRD GENERATIONS)

In autumn 1988, the Internet/UNIX/Morris Worm did not actually bring the Internet in general and e-mail in particular to the proverbial grinding halt. It was able to run and propagate only on machines running specific versions of the UNIX operating system on specific hardware platforms. However, given that the machines connected to the Internet also compose the transport mechanism for the Internet, a "minority group" of server-class machines, thus affected, degraded the performance of the Net as a whole. Indeed, it can be argued that despite the greater volumes of mail generated by Melissa and LoveLetter and the tendency of some types of mail servers to achieve meltdown when faced with the consequent traffic, the Internet as a whole has proved to be somewhat more resilient in recent years.

During the 1988 mailstorm, a sufficient number of machines had been affected to impair e-mail and distribution-list mailings. Some mail was lost, either by mailers that could not handle the large volumes that "backed up," or by mail queues being dumped in an effort to disinfect systems. Most mail was substantially delayed. In some cases, mail would have been re-routed via a possibly less efficient path after a certain time. In other cases, backbone machines, affected by the problem, were simply much slower at processing mail. In still others, mail routing software would crash or be taken out of service, with a consequent delay in mail delivery. Ironically, electronic mail was the primary means that the various parties attempting to deal with the trouble were trying to use to contact each other.

In many ways, the Internet Worm is the story of data security in miniature. The Worm used "trusted" links, password cracking, security "holes" in standard programs, standard and default operations, and, of course, the power of viral replication.

"Big Iron" mainframes and other multiuser server systems are generally designed to run constantly, and execute various types of programs and procedures in the absence of operator intervention. Many hundreds of functions and processes may be running all the time, expressly designed neither to require nor report to an operator. Some such processes cooperate with each other; others run independently. In the UNIX world, such small utility programs are referred to as daemons, after the supposedly subordinate entities that take over mundane tasks and extend the power of the "wizard," or skilled operator. Many of these utility programs deal with the communications between systems. "Mail," in the network sense, covers much more than the delivery of text messages between users. Network mail between systems may deal with file transfers, the routing of information for reaching remote systems, or even upgrades and patches to system software.

When the Internet Worm was well established on a machine, it would try to infect another. On many systems, this attempt was all too easy, since computers on the Internet are meant to generate activity on each other, and some had no protection in terms of the type of access and activity allowed.

The finger program is one that allows a user to obtain information about another user. The server program, fingerd, is the daemon that listens for calls from the finger client. The version of fingerd common at the time of the Internet Worm had a minor problem: it did not check how much information it was given. It would take as much as it could hold and leave the rest to overflow. "The rest," unfortunately, could be used to start a process on the computer, and this process was used as part of the attack. This kind of buffer overflow attack continues to be very common, taking advantage of similar weaknesses in a wide range of applications and utilities.

The sendmail program is the engine of most mail-oriented processes on UNIX systems connected to the Internet. In principle, it should only allow data received from another system to be passed to a user address. However, there is a debug mode, which allows commands to be passed to the system. Some versions of UNIX were shipped with the debug mode enabled by default. Even worse, the debug mode was often enabled during installation of sendmail for testing and then never turned off.

When the worm accessed a system, it was fed with the main program from the previously infected site. Two programs were used, one for each infected platform. If neither program could work, the worm would erase itself. If the new host was suitable, the worm looked for further hosts and connections.

The program also tried to break into user accounts on the infected machine. It used standard password-cracking techniques such as simple variations on the name of the account and the user. It carried a dictionary of words likely to be used as passwords, and would also look for a dictionary on the new machine and attempt to use that as well. If an account was "cracked," the Worm would look for accounts that this user had on other computers, using standard UNIX tools.

Following the Internet Worm, and a few similar examples in late 1988 and early 1989, worm examples were very infrequent during the 1990s.

By spring 2001, a number of examples of Linux malware had been seen. Interestingly, while the Windows viruses generally followed the Christma exec style of having users run the scripts and programs, the new Linux worms were similar to the Internet/Morris/UNIX worm in that they rely primarily on bugs in automatic networking software.

The Ramen worm makes use of security vulnerabilities in default installations of Red Hat Linux 6.2 and 7.0, using specific versions of the wu-ftp, rpc.statd, and LPRng programs. The worm defaces Web servers by replacing index.html, and scans for other vulnerable systems. It does this initially by opening an ftp connection and checking the remote system's ftp banner message. If the system is vulnerable, the worm uses one of the exploitable services to create a working directory, then downloads a copy of itself from the local (attacking) system.

Lion uses a buffer overflow vulnerability in the bind program to spread. When it infects, Lion sends a copy of output from the ifconfig command,/etc/passwd, and/etc/shadow to an e-mail address in the china.com domain. Next the worm adds an entry to etc/inetd.conf and restarts inetd. This entry would allow Lion to download components from a (now closed) Web server located in China. Subsequently, Lion scans random class B subnets in much the same way as Ramen, looking for vulnerable hosts. The worm may install a rootkit onto infected systems. This backdoor disables the syslogd daemon and adds a Trojanized ssh (secure shell) daemon.

Code Red uses a known vulnerability to target Microsoft IIS (Internet Information Server) Web servers. Despite the fact that a patch for the loophole had been available for five months prior to the release of Code Red, the worm managed to infect 350,000 servers within 9 to 13 hours.

When a host gets infected it starts to scan for other hosts to infect. It probes random IP addresses but the code is flawed by always using the same seed for the random number generator. Therefore, each infected server starts probing the same addresses that have been done before. (It was this bug that allowed the establishment of such a precise count for the number of infections.)

During a certain period of time the worm only spreads, but then it initiated a DoS attack aganist http://www1.whitehouse.gov. However, since this particular machine name was only an overflow server, it was taken offline prior to the attack and no disruptions resulted.

The worm changed the front page of an infected server to display certain text and a background color of red, hence the name of the worm.

Code Red definitely became a media virus. Although it infected at least 350,000 machines within hours, it had probably almost exhausted its target population by that time. Despite this, the FBI held a press conference to warn of the worm.

Code Red seems to have spawned quite a family, each variant improving slightly on the random probing mechanism. In fact, there is considerable evidence that Nimda is a descendent of Code Red.

Nimda variants all use a number of means to spread. Like Code Red, Nimda searches random IP addresses for unpatched Microsoft IIS machines. Nimda will also alter Web pages in order to download and install itself on computers browsing an infected Web site using a known exploit in Microsoft Internet Explorer's handling of Java. Nimda will also mail itself as a file attachment and will install itself on any computer on which the file attachment is executed. Nimda is normally e-mailed in HTML format, and may install automatically when viewed using a known exploit in Microsoft Internet Explorer. Nimda will also create e-mail and news files on network shares and will install itself if these files are opened.

DETECTION TECHNIQUES

All antiviral technologies are based on the three classes outlined by Fred Cohen in his early research. The first type performs an ongoing assessment of the functions taking place in the computer, looking for operations known to be dangerous. The second checks regularly for changes in the computer system where changes should occur only infrequently. The third examines files for known code found in previous viruses.

Within these three basic types of antiviral software, implementation details vary greatly. Some systems are meant only for use on standalone systems, while others provide support for centralized operation on a network. With Internet connections being so important now, many packages can be run in conjunction with content scanning gateways or firewalls.

String Search (Signature-Based)

Scanners examine files, boot sectors, and/or memory for evidence of viral infection. They generally look for viral signatures, sections of program code known to be in specific viral programs but not in most other programs. Because of this, scanning software will generally detect only known viruses and must be updated regularly. Some scanning software has resident versions that check each file as it is run.

Scanners have generally been the most popular form of antiviral software, probably because they make a specific identification. In fact, scanners offer somewhat weak protection, since they require regular updating. Scanner identification of a virus may not always be dependable: a number of scanner products have been known to identify viruses based on common families rather than definitive signatures.

Change Detection (Integrity Checking)

Change detection software examines system and/or program files and configuration, stores the information, and compares it against the actual configuration at a later time. Most of these programs perform a checksum or cyclic redundancy check (CRC) that will detect changes to a file even if the length is unchanged. Some programs will even use sophisticated encryption techniques to generate a signature that is, if not absolutely immune to malicious attack, prohibitively expensive, in processing terms, from the point of view of a piece of malware.

Change detection software should also note the addition of completely new entities to a system. It has been noted that some programs have not done this, and allowed the addition of virus infections or malware.

Change detection software is also often referred to as integrity-checking software, but this term may be somewhat misleading. The integrity of a system may have been compromised before the establishment of the initial baseline of comparison.

A sufficiently advanced change-detection system, which takes all factors including system areas of the disk and the computer memory into account, has the best chance of detecting all current and future viral strains. However, change detection also has the highest probability of false alarms, since it will not know whether a change is viral or valid. The addition of intelligent analysis of the changes detected may assist with this failing.

Real-Time Scanning

Real-time, or on-access, scanning is not really a separate type of antivirus technology. It uses standard signature scanning, but attempts to deal with each file of object as it is accessed, or comes into the machine. Because on-access scanning can affect the performance of the machine, vendors generally try to take shortcuts in order to reduce the delay when a file is read. Therefore, real-time scanning is signifcantly less effective at identifying virus infections than a normal signature scan of all files.

Real-time scanning is one way to protect against viruses on an ongoing basis, but it should be backed up with regular full scans.

Heuristic Scanning

A recent addition to scanners is intelligent analysis of unknown code, currently referred to as heuristic scanning. It should be noted that heuristic scanning does not represent a new type of antiviral software. More closely akin to activity monitoring functions than traditional signature scanning, this looks for "suspicious" sections of code generally found in viral programs. Although it is possible for normal programs to want to "go resident," look for other program files, or even modify their own code, such activities are telltale signs that can help an informed user come to some decision about the advisability of running or installing a given new and unknown program. Heuristics, however, may generate a lot of false alarms, and may either scare novice users or give them a false sense of security after "wolf" has been cried too often.

Permanent Protection

The ultimate object, for computer users, is to find some kind of antiviral system that you can set and forget: that will take care of the problem without further work or attention on your part. Unfortunately, as previously noted, it has been proved that such protection is impossible. On a more practical level, every new advance in computer technology brings more opportunity for viruses and malicious software. As it has been said in political and social terms, so too the price of safe computing is constant vigilance.

Vaccination

In the early days of antiviral technologies, some programs attempted to add change detection to every program on the disk. Unfortunately, these packages, frequently called vaccines, sometimes ran afoul of different functions within normal program that were designed to detect accidental corruption on disk. No program has been found that can fully protect a computer system in more recent operating environments.

Some vendors have experimented with an "autoimmune" system, whereby an unknown program can be sent for assessment, and if found to be malicious, a new set of signatures is created and distributed automatically. This type of activity does show promise, but there are significant problems to be overcome.

Activity Monitoring (Behavior-Based)

An activity monitor performs a task very similar to an automated form of traditional auditing: it watches for suspicious activity. It may, for example, check for any calls to format a disk or attempts to alter or delete a program file while a program other than the operating system is in control. It may be more sophisticated, and check for any program that performs "direct" activities with hardware, without using the standard system calls.

Activity monitors represent some of the oldest examples of antiviral software, and are usually effective against more than just viruses. Generally speaking, such programs followed in the footsteps of the earlier anti-Trojan software, such as BOMBSQAD and WORMCHEK in the MS-DOS arena, which used the same "check what the program tries to do" approach. This tactic can be startlingly effective, particularly given the fact that so much malware is slavishly derivative and tends to use the same functions over and over again.

It is, however, very hard to tell the difference between a word processor updating a file and a virus infecting a file. Activity monitoring programs may be more trouble than they are worth because they can continually ask for confirmation of valid activities. The annals of computer virus research are littered with suggestions for virusproof computers and systems that basically all boil down to the same thing: if the operations that a computer can perform are restricted, viral programs can be eliminated. Unfortunately, so is most of the usefulness of the computer.

PREVENTION AND PROTECTION TECHNIQUES

In regard to protection against viruses, it is germane to mention the legal situation with regard to viruses. Note that a virus may be created in one place and still spread world-wide, so issues of legal jurisdiction may be confused. In addition, specific activity may have a bearing: in the United States: it may be legal to write a virus, but illegal to release it. However, in the first 16 years of the existence of viruses as a serious occurrence in the computing environment, only five people have been convicted in court of writing computer viruses, and in all five cases the defendants entered guilty pleas. Therefore, it is as well not to rely on criminal prosecutions as a defence against viruses.

The converse, however, is not true. If you are infected with a virus, and it can be demonstrated that your system subsequently sent a message that infected someone else, you may be legally liable. Thus, it is important to protect yourself from infection, even if the infection will not inconvenience you or cause loss to your business.

Training and some basic policies can greatly reduce the danger of infection. A few guidelines that can really help in the current environment are the following:

- Do not double-click on attachments.
- When sending attachments, be really specific when describing them.
- Do not blindly use Microsoft products as a company standard.
- Disable Windows Script Host. Disable ActiveX. Disable VBScript.
- Disable JavaScript. Do not send HTML-formatted email.
- Use more than one scanner, and scan everything.

There are now companies that will provide insurance against virus attacks. This insurance is generally an extension of "business loss of use" insurance, and potential buyers would do well to examine the policies very closely to see the requirements for making a claim against it, and also conditions that may invalidate payment.

Unfortunately, the price of safe computing is constant vigilance. Until 1995 it was felt that data files could not be used to transport a virus. Until 1998 it was felt that e-mail could not be used to automatically infect a machine. Advances in technology are providing new viruses with new means of reproduction and spread. Two online virus encyclopedias are listed in the Further Reading Section, and information about new viruses can be reliably determined at these sites.

NON-PC PLATFORM VIRUSES

As noted, many see viruses only in terms of DOS- or Windows-based programs on the Intel platform. Although there are many more PC viruses than on other platforms (primarily because there are more PCs in use than other computers), other platforms have many examples of viruses. Indeed, I pointed out earlier that the first successful viruses were probably created on the Apple II computer.

Christma exec, the Christmas Tree Virus/Worm, sometimes referred to as the Bitnet chain letter, was probably the first major malware attack across networks. It was launched on the 9th of December 1987 and spread widely on Bitnet, Earn, and IBM's internal network (VNet). It has a number of claims to a small place in history. It was written, unusually, in REXX, a scripting system used to aid with the automating of simple user processes. It was mainframe-hosted (on VM/CMS systems) rather than microcomputer-hosted, quaint though that distinction-sounds nowadays when the humblest PC can run UNIX.

Christma presented itself as a chain letter inviting the recipient to execute its code. This involvement of the user leads to the definition of the first e-mail virus, rather than a worm. When it was executed, the program drew a Christmas tree and mailed a copy of itself to everyone in the account holder's equivalent to an address book, the user files Names and Netlog. Conceptually, there is a direct line of succession from this worm to the social engineering worm/Trojan hybrids of today.

In the beginning of the existence of computer viruses actually proliferating in the wild, the Macintosh computer seemed to have as many interesting viruses as those in the DOS world. The Brandau, or "Peace" virus, became the first to infect commercially distributed software, while the nVIR virus sometimes infected as many as 30% of the computers in a given area. However, over time it has become evident that any computer can be made to spread a virus, and the fact that certain systems have more than others seems to be simply a factor of the number of computers, of a given type, in use.

CONCLUSION

Malware is a problem that is not going away. Unless systems are designed with security as an explicit business requirement, which current businesses are not supporting through their purchasing decisions, malware will be an increasingly significant problem for networked systems.

It is the nature of networks that what is a problem for a neighboring machine may well become a problem for local systems. In order to prevent this, it is critical that the information security professional help business leaders recognize the risks incurred by their decisions, and help to mitigate those risks as effectively and economically as possible. With computer viruses and similar phenomena, each system inadequately protected increases the risk to all systems to which it is connected. Each system compromised can become a system that infects others. If you are not part of the solution, in the world of malware, you are most definitely part of the problem.

GLOSSARY

Terms are derived from the "Glossary of Communications, Computer, Data, and Information Security Terms" posted online at http://victoria.tc.ca/techrev/secgloss.htm and http://sun.soci.niu.edu/~rslade/secgloss.htm.

Activity monitor A type of antiviral software that checks for signs of suspicious activity, such as attempts to rewrite program files, format disks, and so forth; some versions will generate an alert for such operations, while others will block the behavior.

Change detection Antiviral software that looks for changes in the computer system. A virus must change something, and it is assumed that program files, disk system areas, and certain areas of memory should not change. This software is very often referred to as "integrity checking" software, but it does not necessarily protect the integrity of data, nor does it always assess the reasons for a possibly valid change. Also known as authentication software when strong encryption is used.

False negative One of two types of "false" reports from antiviral software generated where no viral activity or presence is reported, even though there is a virus present; references are usually only made in technical reports. Most people simply refer to an antiviral as "missing" a virus. Also known in general security terms as a false acceptance, or Type II error.

False positive One of two types of "false" reports from antiviral software that states the activity or presence of a virus when there is, in fact, no virus. Very widely used among those who know about viral and antiviral programs, while very few use the analogous term, "false alarm." Also known in general security terms as a false rejection, or Type I error.

Heuristic Trial-and-error or seat-of-the-pants thinking rather than formal rules. In antiviral jargon: the examination of program code for functions or opcode strings known to be associated with viral activity. In most cases this is similar to activity monitoring but without actually executing the program; in other cases, code is run under some type of emulation. Recently the meaning has expanded to include generic signature scanning meant to catch a group of viruses without making definite identifications.

In the wild Viral programs that have been released into, and successfully spread in, the normal computer user community and environment; used to distinguish viral programs written and tested in a controlled research environment, without escaping, from those uncontrolled "in the wild."

Macro (virus) A small piece of programming in a simple language, used to perform a simple, repetitive function. Microsoft's Word Basic and VBA macro languages can include macros in data files, and have sufficient functionality to write complete viruses.

Malware All forms of malicious or damaging software, including viral programs, Trojans, logic bombs, and the like.

Multipartite Formerly a viral program that would infect both boot sectors and files; now a virus that will infect multiple types of objects, or that reproduces in multiple ways.

Payload The code in a viral program not concerned with reproduction or detection avoidance; often a message but is sometimes code to corrupt or erase data.

Polymorphism Techniques that use some system of changing the "form" of the virus on each infection to try and avoid detection by signature scanning software. Less sophisticated systems are referred to as self-encrypting.

Scanner A program that reads the contents of a file looking for code known to exist in specific viral programs. Also known as a signature scanner.

Stealth Various technologies used by viral programs to avoid detection on disk. The term properly refers to the technology, and not a particular virus.

Trojan horse A program that either pretends to have, or is described as having, a (beneficial) set of features but which, either instead or in addition, contains a damaging payload; most frequently shortened to Trojan.

Virus "A program which modifies other programs to contain a possibly altered version of itself" (attributed to Dr. Fred Cohen, although his actual definition is in mathematical form); "an entity which uses the resources of the host (system or computer) to reproduce itself and spread, without informed operator action."

Worm A self-reproducing program that is distinguished from a virus by copying itself without being attached to a program file, or that spreads over computer networks, particularly via e-mail; can spread without user action, for example, by taking advantage of loopholes and trap doors in software.

Conducted Communications Media

Thomas L. Pigg, *Jackson State Community College*

INTRODUCTION

The Internet consists of millions of digital passages that carry signals all over the world. These conduits, which connect us to the World Wide Web, come in many shapes, sizes, and modes. The bewildering assortment and seemingly endless conduits, more commonly referred to as communication media, that are used to connect computers together can be boiled down to two types: conductive cable and wireless. Conductive media is simply a hard-wired connection, which requires someone to physically join network devices with some type of cable. The three major types of cable are coaxial, twisted pair, and fiber optic. The focus of this article will be on conducted communications media. Wireless communication is the alternative to conducted communications media. This is accomplished using a variety of broadcast transmission technologies, including terrestrial microwave and satellite communications. Wireless communications is covered in another chapter in this encyclopedia.

To aid in understanding conductive communications media, a short explanation of network transmission basics will be discussed. This will be followed by a detailed exploration of the three major types of media, mentioned above. In addition, there will be a presentation of the similarities and contrasts between these media. Finally, the suitability and application of each type of conducted media will be discussed.

OVERVIEW OF NETWORK TRANSMISSION BASICS

Network Transmission Basics

When computers communicate over the Internet or on private networks, they must follow certain communication protocols. In short, each computer that connects to a network must follow rules that govern the type of hardware and software that is used for access to the network. The protocols consist of signal types and speeds, cable layouts, and communications access schemes.

Baseband and Broadband

Bandwidth is the range of frequencies that a particular network transmission media can carry. It also reveals the maximum amount of data that can be carried on the medium. A baseband transmission is a single, fixed signal that uses the entire available bandwidth. Baseband signals use a single channel to communicate with devices on a network, which allows computers to transmit and receive data on one cable (Tittel & Johnson, 2001). Baseband communications are typically used for local area network (LANs). This environment is ideal for baseband transmissions because it is self-contained within a single location, where network traffic can be easily monitored and controlled. When LANs expand into a metropolitan area network (MAN) or a wide area network (WAN), baseband systems do not provide the bandwidths that are adequate for these larger networks. A MAN consists of several LANs within a metropolitan area. WANs are similar to MANs in that they cover a wider, possibly international, geographical area.

Network connections that attach several LANs together, such as MANs or WANs, or that allow remote access from external users or networks to local servers often require multichannel bandwidths because of increased signal traffic flow. Broadband transmissions help to meet these needs. In contrast to the discrete digital signals produced in baseband communications, broadband transmission generates an analog carrier frequency, which carries multiple digital signals or multiple channels. This concept is much like cable television systems that carry many channels on one cable.

The decision to use baseband or broadband is determined by the application. If the network consists of a single LAN, baseband would be the best choice. If an organization has computer networks that spread over several geographical areas, there might be a need for multiple channels of communications between locations, which can be achieved only through broadband applications. It is important to note that it is not necessarily the transmission media that determines whether a signal is baseband or broadband. It is the function of the devices that connect to the cable.

Cable Access Methods

A cable access method is how data is placed on the transmission media. Data is formatted into small pieces called packets. A packet contains header and trailer information about the contents, destination, error checking, and the actual data. Packets contain a specific amount of information, normally 1–2 kbytes, as defined by the particular network protocol being used. It is a lot like an envelope that is used to hold a letter to be mailed. The outside of the envelope contains a destination address along with sender information. This information is used by the United States Postal Service to deliver the mail to its destination. When a wrong destination address is used, the postal service can notify the sender by means of the return address. Network packets are handled in a similar way (Tittel & Johnson, 2001).

There are several ways in which packets are placed on the communications line. Ethernet uses a method called carrier sense multiple access with collision detection (CSMA-CD). This method is a lot like a two-way radio, which allows only one person to talk at one time. CSMA-CD requires each participating network workstation to first listen to the communication line to determine whether it is clear before attempting to broadcast a packet of information. Because of the high rates of access and speed associated with computer networks, it is very likely that two workstations may attempt to broadcast packets at the same time. If this occurs, the collision detection (CD) feature of CSMA-CD will instruct the conflicting workstations to cease transmissions and assign a random delay before they are allowed to attempt to send another packet of data. Without a random delay, the colliding workstations would continue to attempt to rebroadcast at the same time, causing more collisions. Occasionally, a defective network interface card (NIC) may cause excessive collisions by constantly broadcasting packets. This is called a broadcast storm (Tittel & Johnson, 2001).

A similar access method, used by Apple Talk networks, is called carrier sense multiple access with collision avoidance (CSMA-CA). This scheme is similar to CSMA-CD except that CSMA-CA attempts to avoid collisions altogether. Network devices accomplish this by sending a short broadcast requesting control of the network segment prior to sending a packet. This helps prevent collisions of complete packets, thus reducing the need to rebroadcast packets (Tittel & Johnson, 2001).

Another type of access method is called token passing, used by token ring and ARCNet (attached resource computer network) protocols. A token is similar to a packet. Token passing eliminates network collisions altogether by passing a token from node to node on the network in one direction. When a network device receives a token, it examines it to determine whether its contents are for that particular node. If not, the network node rebroadcasts the token to the next device on the network. When the token finds its destination, it unloads the data and rebroadcasts an empty token to the next device. The empty token will ask each passing node whether it has any data to send. If not, the empty token is passed on down the line until a device generates information to place in the empty token (Tittel & Johnson, 2001).

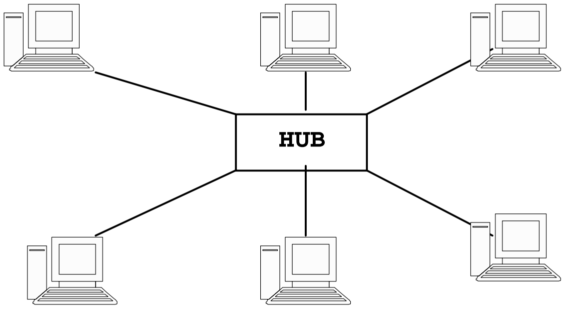

Figure 1: Star topology.

Network Topologies

A network topology is the physical cable layout or configuration. There are three basic types: star, bus, and ring. To some degree, the type of cable used will determine the type of topology used. Each network protocol (i.e., Ethernet, token ring) will specify the cable type and topology supported. The star topology, as illustrated in Figure 1, requires a central wiring point for all network devices on a particular network segment. A device called a hub or concentrator is used to serve this purpose. A hub is a multiport repeater that regenerates signals received. In some applications a device called a switch is used. A switch is more intelligent than a hub because it can learn which devices are connected to its ports and send packets directly to the destination port only, thus reducing broadcast traffic.

The bus topology (see Figure 2) requires no special external device for computers to connect to. It consists of network nodes connected to the communications media via a special T-connector that connects the computer's NIC to the bus (see Figure 3). You will notice in Figure 2 that a small box is shown at both ends of the bus. This represents a terminator that is required for this cable layout (see Figure 4). Its purpose is to prevent signal bounce, which occurs when a cable is not terminated. Signal bounce is the result of a broadcast signal that continues to oscillate. The terminator is used to absorb the signal once it has reached the end of the cable, thus eliminating signal bounce.

The ring topology (see Figure 5) is similar to bus topology in that each computer is connected directly to its neighbor without the need for a hub or other special device. The big difference between the two is that ring topology provides a closed-loop design, which does not require termination.

In some applications more than one topology may be used. For example, the token-ring protocol uses a topology called a star-wired ring, as shown in Figure 6. In this example, multistation access units (MAU or MSAU) or concentrators are used to connect the network devices. The MAUs are then connected to each other in a ring configuration.

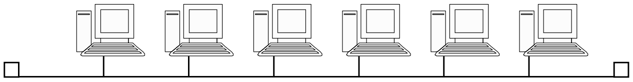

Figure 2: Bus topology.

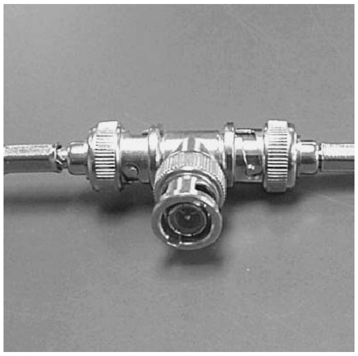

Figure 3: T-connector.

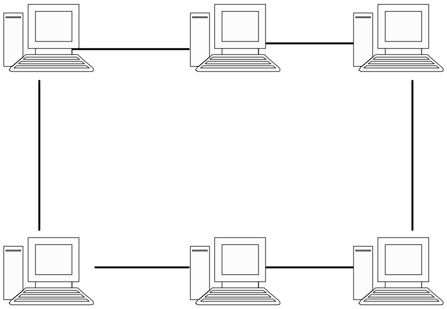

Figure 5: Ring topology.

Each topology has its advantages and disadvantages. For example, the bus topology has the advantage of low cost because it does not require any special devices to connect computers. However, a disadvantage is that if there is a break in any of the cables, the entire network segment will go down because of a loss of termination. On the other hand, computers connected to a star topology would most likely remain operating on the network if one of the cables malfunctioned between a device and a hub. Star topology requires more wire than a bus topology and it also requires hubs or switches, which is more costly. Ring topology has an advantage over bus and star tpologies because it typically provides an alternate path for data transmission in case of a cable break. Token-ring networks use this redundancy feature with star-wired ring topology.

The purpose of this section on network transmission basics is to help you understand the concepts and characteristics, discussed in the next section, related to conducted transmission cable. Each media type differs in physical and electrical/optical characteristics, as well as in application. The following section will discuss the three major types of conducted transmission cable: coaxial, twisted pair, and fiber optic.

COAXIAL CABLE

Coaxial (coax) cable is used in a wide range of applications, including television, radio, and computer network communications. This section looks at the physical makeup of coaxial cable and the specific characteristics that distinguish the different types of coax.

Components

Coaxial cable consists of an inner and outer conductor that share the same axis, which is how it got its name, coaxial (Carr, 1999). The inner conductor, sometimes called the conducting core, is typically made of a copper alloy. Most applications use a solid core, except where flexibility is required, and then a stranded core may be used. The outer conductor is either braided metal or foil, which acts as a conductor and a shield to reduce interference. An insulator, or more accurately a dielectric, is between the two conductors. Depending on the type of coax, this material is made out of Teflon or an inert gas. Finally, for protection, there is an outer sheath that surrounds the inner components. This is made from PVC (polyvinyl chloride), or special fire retardant material, for installations where wire must be run in the plenum areas above the false ceilings in a building (Carr, 1999; Tittel & Johnson, 2001).

Coaxial cables come in a variety of forms: flexible, helical line, and hard line. Flexible coax is made of flexible material in the outer conductor, typically braid or foil. This cable is mostly found in LANs and home television-to-antenna connections. Helical line coax is a semiflexible cable that consists of a slightly more rigid, spiral-wound outer conductor. Normally, this type of cable is used for network backbones or interconnections between networksthat require long cable runs. This type

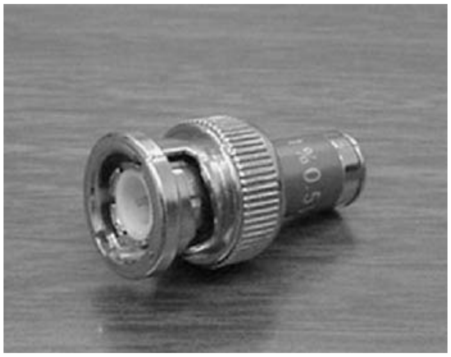

Figure 4: Terminator.

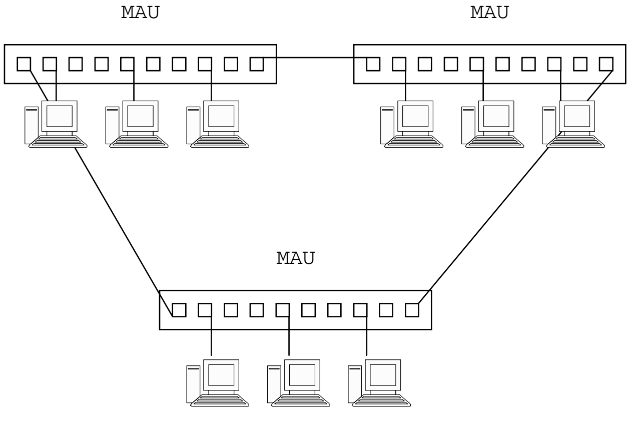

Figure 6: Star-wired ring.

of cable is able to carry a signal over longer distances at higher frequencies than can flexible cable types. Hard-line coaxial cable is used to connect equipment that transmits in the microwave frequency range. This form of coax uses a thin-walled pipe as an outer conductor, which is rigid and very difficult to work with. As the frequency of a transmitted signal increases, there is a greater chance of the signal radiating beyond the outer conductor, which also acts as a shield, thus resulting in signal loss, or in the case of external electromagnetic interference (EMI), the type of outer conductor will determine what frequencies will be rejected from the transmitted signal (Carr, 1999).

Another characteristic of coaxial cable is its impedance. Impedance is the resistance of a cable to the transmitted signal, which is measured in ohms (Tittel & Johnson, 2001). Carr (1999) states that the lowest loss of signal occurs at higher impedances; however, more power can be achieved when the impedance is low. Cable television uses coaxial cable rated at 75-ohms impedance because of its lower signal attenuation with long cable runs. Most network and radio applications use 50-ohm impedance as a middle ground between low signal loss and more power.

Cable manufacturers use a radio government (RG) specification for the coaxial cables they produce. Cable television uses either RG-6-, RG11-, or RG-59-spec cable. All of these are rated at 75 ohms. RG-6 and RG-11 are larger diameter cables used for major trunk lines. RG-59 is employed between the trunk lines and the customer's television.

RG-58 and RG-8 are 50-ohm cables used for computer network communications. As does cable television, computer networks use trunk lines to connect network segments together. RG-8 is the cable used for trunk lines or network backbones and is often referred to as thick-wire Ethernet, or thicknet for short. RG-58 is used with thin-wire Ethernet, or thinnet, to interconnect smaller segments of the network (Tittel & Johnson, 2001).

Coaxial Cable Network Applications

Thick-Wire Ethernet

Thicknet (RG-8) is typically used as an Ethernet backbone to connect various network segments together. Thicknet can be used to directly interconnect devices on the network, but usually thin-wire Ethernet is used for this purpose. Coaxial cable typically uses the bus topology. Thicknet is no exception. A thick-wire Ethernet backbone will consist of a length of RG-8 with several devices, such as hubs, connected to it throughout its length. Each device connected to the backbone requires a special device called a transceiver. The transceiver is connected to the coax by use of a vampire tap (see Figure 7). A special cable then attaches the transceiver to the device through its AUI (attachment unit interface) port (see Figure 8).

Each conducted transmission cable will exhibit certain standardized characteristics that describe its advantages and disadvantages within network applications. Table 1 describes thick-wire Ethernet characteristics. Each cable type reviewed contains similar specifications. The reason there is a maximum length is because of attenuation, which is the reduction in signal strength that occurs as cable lengths increase. At some point, the signal loss becomes excessive and causes the network to stop functioning. As with this and other wire specifications, cable manufacturers rely on IEEE (Institute of Electrical and Electronics Engineers) standards when producing their products. The Ethernet standards for thicknet and thinnet are covered in the IEEE 802.3 specification (Tittel & Johnson, 2001).

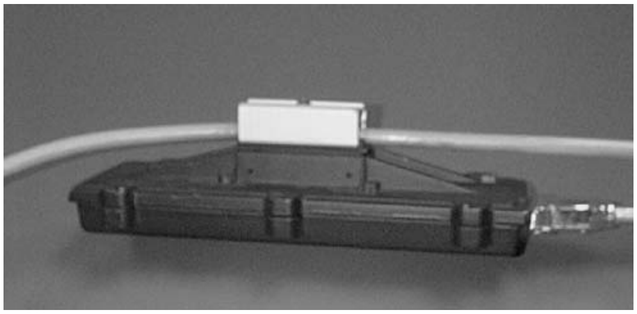

Figure 7: Thick-wire coax attached to transceiver via vampire tap.

Table 1 shows a total network cable length of 2,500 m, which is based on the 5-4-3 rule. This rule states that each network cannot exceed a total of five cable segments connected by four repeaters, with not more than three of the segments populated by nodes (see Figure 9).

Figure 9 shows five complete cable segments. Each segment is connected to a device called a repeater. A repeater is used to compensate for the attenuation caused by cable lengths that exceed 500 m for thicknet. Its function is to amplify and repeat what it receives so that its signal will be strong enough to reach another repeater or the end of the next cable segment. Note that two segments do not have any network devices connected to them. This implies that only three of the five segments may have network devices attached. Tittel and Johnson (2001) state that in reality, what this means is that any two network devices cannot be separated by more than four repeaters (five segments) with three populated segments. So, the 5-4-3 rule does not say a network is limited to only five segments. It states only that network devices cannot communicate with each other if they are separated by more than five segments.

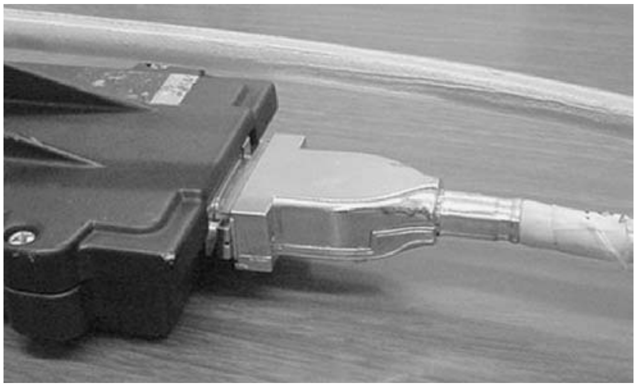

Figure 8: AUX cable connected to a transceiver.

Table 1 Thick-Wire Ethernet Specifications

Characteristic	Specification
Maximum cable segment length	500 meters
Maximum total network length	2500 meters
AUX (drop cable length)	50 meters
Maximum number of devices per segment	100
Maximum number of segments	5 connected by 4 repeaters, with not more than 3 populated segments
Bandwidth	10 Mbps (megabits per second)
Termination	50 Ohms
Cable Access Method	CSMA-CD

The AUX or drop cable length refers to the cable that attaches to the transceiver unit connected via the vampire tap to the thick-wire Ethernet backbone. This type of connection is used to connect such devices as repeaters or hubs to the Ethernet backbone. The AUX cable must be fewer than 50 m long.

Table 1 shows a maximum of 100 devices per segment for thick-wire Ethernet. Every time a device is attached to an Ethernet backbone, there will be some signal loss. Any device attached beyond the limit is not guaranteed to function properly. When designing a network, these limits should not be pushed. If a segment is fully populated, there is no room for expanding your network without adding another segment, assuming that the network is not already comprised of the maximum allowable five segments.

Some IEEE specifications, such as bandwidth, are preset and cannot be altered. If the network bandwidth will not support the needs of the network, a new protocol or standard will need to be used. The bandwidth specification of 10 Mbps for thick-wire Ethernet describes how much data can be transmitted, which ultimately determines the speed of communications. As with all bus topologies using coax, a terminator is required at both ends of the bus to eliminate signal bounce. Because thicknet coaxial cable is designed for 50-ohm impedance, a 50-ohm terminator is required. A terminator is simply a connector that has been retrofitted with a 50-ohm resistor between the inner and outer conductors.

Finally, Ethernet packets are transmitted using the CSMA-CD cable access method. You will recall that this manner of access is a lot like a two-way radio, which requires the user to monitor the radio for traffic before he or she attempts to talk or transmit. This is also true of CSMA-CD, except it is the responsibility of the NIC and the communications software to monitor the network traffic.

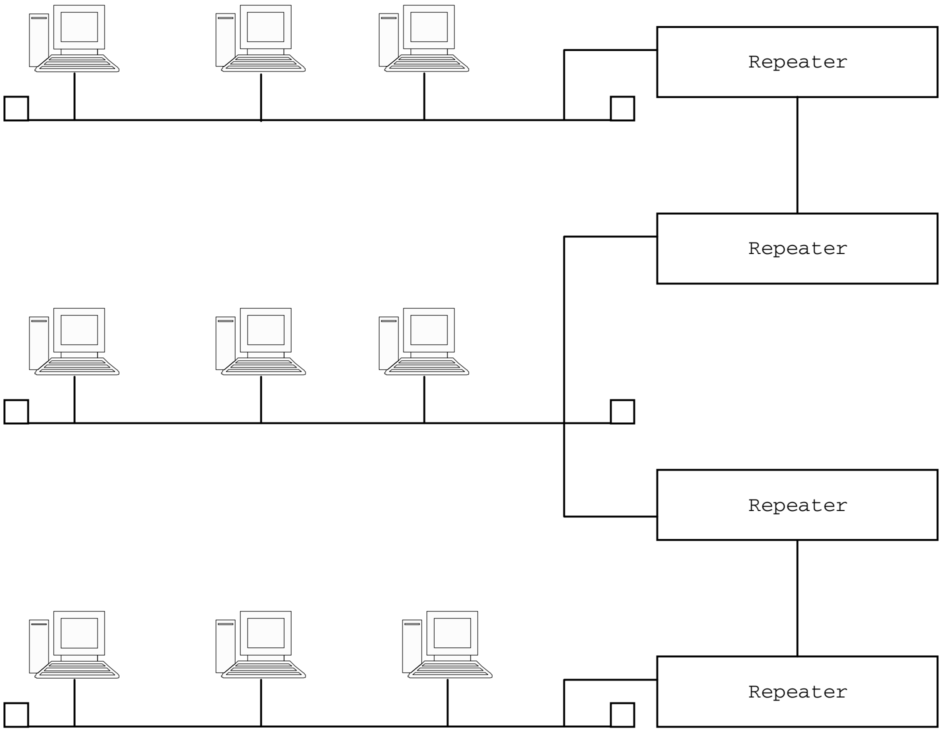

Figure 9: 5-4-3 rule diagram.

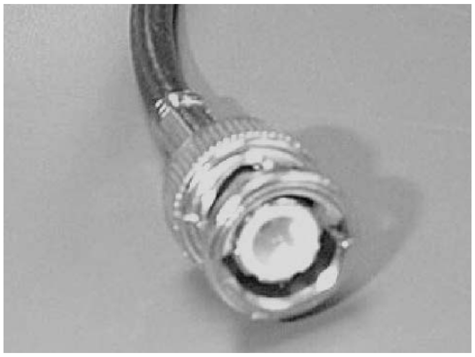

Figure 10: BNC connector.

The collision detection (CD) feature provides a means of rebroadcasting a packet of data when the occasional collision occurs.

Thinwire Ethernet

A network can be quickly set up using very little more than RG-58 cable and a few connectors. Thin-wire cable is commonly used to interconnect computers or other network devices on a network segment using the bus topology. In the past, thinnet was one of the most popular transmission cables for Ethernet networks because of its low cost and ease of set up.

Thinnet cable uses a special connector, called a BNC (British naval connector or bayonet nut connector) connector (see Figure 10). Computers and other network devices are connected to the bus topology by way of a BNC T-connector (see Figure 3), which connects to the NIC. The NIC is a transceiver that provides the physical connection between the network device and the transmission media. In addition, the NIC is responsible for packaging the data coming from the network device into a form acceptable to the network cable.

As with thicknet, thinnet follows the IEEE 802.3 standard with regard to the use of RG-58 coaxial cable. Table 2 summarizes these cable specifications. You will notice that thinnet characteristics are similar to thicknet except in cable lengths and number of devices per segment. Also, there is no specification for a drop cable for thin-wire Ethernet because the NIC card serves the same function as the external transceiver used by thicknet (Tittel & Johnson, 2001).

The physical characteristics of thin-wire coax attenuates signals over shorter distances than does thick wire. This is not really a big problem because thinnet is normally used to interconnect computers within a relatively small area. In situations where computers need to be separated by more than 185 m, a repeater can be used to accommodate these devices. The low cost of thin wire far outweighs the distance limitations.

The number of devices that can be attached to a thinnet bus topology is 30. This is fewer than can be attached to thicknet because of the reasons noted in the previous paragraph for cable length. Be aware that a network can have more than one segment. With repeaters, thin-wire Ethernet can support multiple populated segments. The 802.3 standard specifies a maximum of 1,024 devices per network as long as the 5-4-3 rule is followed (Tittel & Johnson, 2001).

In addition to network protocol standards for Ethernet and token ring, IEEE references cable-type standards such as 10Base5 and 10Base2 for thick wire and thin wire, respectively. The number 10 represents the bandwidth of the cable specification. Base refers to a baseband (single-channel) signal type and the last number represents the maximum length of a network segment in meters rounded to the nearest hundred. For example, 10Base5 refers to a coaxial cable that carries a baseband signal transmitted at 10 Mbps with a maximum segment length of 500 m (thicknet). Thinnet is referenced by 10Base2, meaning a baseband signal with a 10-Mbps bandwidth at 200 m, approximately. In reality, thin-wire Ethernet can only support 185-m segments. Twisted-pair and fiber-optic cables carry 10BaseT and 10BaseF IEEE cable standards. These are discussed in more detail later.

One other coaxial cable application that has decreased in use over the past few years is ARCnet. ARCnet uses an RG-62, 93-ohm impedance, coaxial cable. This was a fairly popular media back in the 1980s, but because of its low bandwidth (2.5 Mbps), it is not used as much anymore. One of its major benefits was its support of longer cable segments, 610 m (Tittel & Johnson, 2001).

There are several advantages to using coaxial cables for computer networks. For LANs, RG-58 uses the bus topology, which offers lower cost options and ease of installation. Also, the outer shielding of coax provides moderate protection from interference. 10Base2 applications allow for fairly long cable runs compared with other cables, such as twisted pair. The major drawback of coax is its narrow bandwidth compared with contemporary applications using twisted-pair and fiber-optic cable. Plus, thicknet installations can be somewhat difficult and

Table 2 Thin-Wire Ethernet Specifications

Characteristic	Specification
Maximum cable segment length	185 meters
Maximum total network length	925 meters
Maximum number of devices per segment	30
Maximum number of segments	5 connected by 4 repeaters, with 3 populated segments
Bandwidth	10 Mbps (megabits per second)
Termination	50 Ohms
Cable Access Method	CSMA-CD

expensive because of the rigidity of the cable, the rather difficult task of installing network connections, and the overall cost of the interface devices.

TWISTED-PAIR CABLE

Twisted-pair cable consists of one or more pairs of twisted wire. Twisted pair has a longer history than coaxial cable, but its usage was restricted to voice only until the 1980s. Omninet or 10Net began to use twisted pair in the early 1980s for PC-based LANs. One of the first PC applications using twisted-pair cable was in 1984, when IBM introduced the token ring network protocol. By the end of the 1980s, Ethernet technology began using twisted pair. Some advantages of twisted-pair over coax cable include its lightweight and flexibility, and in some cases, existing twisted-pair cables within buildings can be used without having to install new wiring (*Network Magazine,* 1999).

Components

Twisted-pair media comes in one of two forms: STP (shielded twisted pair) or UTP (unshielded twisted pair). STP consists of several pairs of twisted wires that are surrounded by a foil shielding and an outer jacket or sheath. The number of wire pairs can vary from either two or four for basic telephone and network applications, to hundreds of pairs for major communication trunk lines. Each wire within the pair consists of a solid or stranded copper center core surrounded by an insulating cover. Stranded wire is typically used where greater flexibility is required.

The reason for the twist in each pair of wire is to reduce cross talk. When a signal travels down the wire it produces a magnetic field. If not controlled in some way, this can produce unwanted interference with other pairs of wire within the same cable (cross talk). The twist in the pairs works to reduce the effects of cross talk. It also helps to reduce the magnetic field's effect on other pairs. Cables with more twists per foot offer the best performance and are normally more expensive. The foil shielding that surrounds the twisted pairs block sources of interference from electronic noise outside of the cable in addition to keeping stray noise from escaping to the outside world. STP is often the choice of transmission media when heavy electrical or electronic equipment exists near cable runs.

The outer sheath exists to protect the inner components of the cable. Like many cables, twisted-pair jackets are made of some form of PVC or special plenum sheaths that are used in applications that require nontoxic and fire-resistant cable.

UTP is basically the same as STP except that it does not have a foil shield (see Figure 11). Without the shield, it is more prone to cross talk and other forms of interference, although some cross talk is reduced because of the twists in the pairs of wire.

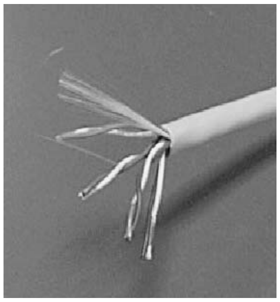

Figure 11: UTP cable.

UTP is probably the most popular cable type for networks today. The Electronic Industries Alliance (EIA) and the Telecommunications Industries Association (TIA), with the endorsement of the American National Standards Institute (ANSI) have defined several categories of UTP cable for different applications (Tittel & Johnson, 2001; *Network Magazine,* 1999; Fogle, 1995). Category 1 is traditionally used for telephone/voice transmissions. Category 2 is capable of data transmissions of up to 4 Mbps. Category 3 is certified for up to 10 Mbps for 10BaseT Ethernet and suitable for 4-Mbps token ring. New technology applications, including 100BaseT4 and 100Base-VG AnyLAN, can utilize this lower-rated cable for 100-Mbps bandwidth. Category 4 can handle up to 16 Mbps, which includes token ring 16 Mbps and 10-Mbps Ethernet applications. Category 5 cable type supports bandwidths of up to 100 Mbps. This is probably the most popular cable in use today. Category 5E cable has been tested up to 400 MHz and supports 1000 Mbps under the 1000BaseT (gigabit Ethernet) standard. Category 6, 6E, and 7 are newly developed or in the development stage. These cables will basically support higher bandwidths, further reductions in cross talk, and increased stability at frequencies above 500 MHz (Global Technologies, 2002).

Twisted-Pair Cable Network Applications

Twisted-pair cable uses a special modular connector. Standard telephone wire uses a four-connection plug called an RJ-11. For network applications, an eight-connector RJ-45 is used (see Figure 12). UTP cables often consist of a solid core with a thin layer of insulation. RJ-45 connectors, called insulation displacement connectors (IDCs), require a special tool that pushes the insulated wire into the connector. When each wire is pushed into the connector, the insulation is sliced just enough to make contact with the center core of the wire (Spurgeon, 2000).

Twisted-pair cable is typically used for point-to-point wiring, such as with star topology configurations. UTP is connected to a network device via a NIC card's RJ-45 jack (see Figure 13), with the other end connected to a hub, switch, or router. In some cases a patch panel or

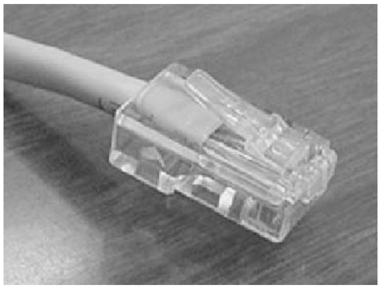

Figure 12: RJ-45 connector.

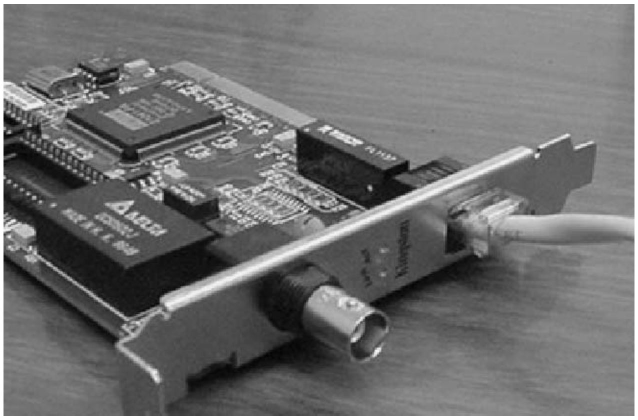

Figure 13: RJ-45 connection to a NIC.

punch-down block may be used to better organize cabling before it is attached to the devices.

There are several IEEE Ethernet standards for twisted-pair media. The most documented are the 10BaseT, 100BaseT, and 1000BaseT standards (see Table 3). All twisted-pair Ethernet standards require a maximum cable length of 100 m and use star topology, which allows only one network connection for each cable segment. You may note that this is considerably less than the coaxial cable specifications. It is much more difficult to control high-frequency signals over twisted pair; thus, shorter cable runs are used to cut down on the effects of a harsher electrical environment (Spurgeon, 2000). The major differences between 10BaseT, 100BaseT, and 1000BaseT are their bandwidths: 10, 100, and 1000 Mbps, respectively.

Each IEEE cable type specifies which wire type is most suitable for a particular application. Category 3 cable is adequate for 10BaseT applications. In fact, only two of the four pairs of wire are actually used. The 100BaseT standard is a bit more complicated. There are three cable configurations for the 100BaseT standard: 100BaseT4, 100BaseTX, and 100BaseFX. 100BaseT4 can produce 100-Mbps bandwidth using all four pairs of category 3, 4, and 5 cables. With 100BaseTX, only two pairs of category 5 cable are used to transmit and receive at 100 Mbps. 100BaseFX is the fiber optic extension for 100BaseT. 100BaseT is often referred to as fast Ethernet. One of the newest technologies, gigabit Ethernet, transmits 250 Mbps over each of the four pairs of category 5 wire simultaneously for a total bandwidth of 1 Gbps (Tittel & Johnson, 2001).

Ethernet standards for UTP follow TIA/EIA 568 standards. Wire pairs within a particular category of cable are color coded. The preferred 568 standard dictates that wire pairs will consist of a green wire paired with a white wire with a green stripe, an orange wire paired with a white wire with an orange stripe, a blue wire paired with a white wire with a blue stripe, and a brown wire paired with a white wire with a brown stripe. Some cable manufacturers will put a white stripe on top of the solid color within each pair. Each pair will be attached to a specific connection on the RJ-45 connector (see Figure 14). Tip and ring are used to identify the connections made by each pair. These terms come from the old telephone systems, which required a patch cable to connect one telephone line to another. The connector on the patch cable consisted of a tip at the end and a ring separated by an insulator that separated the two conductors. These two conductors provided the path for transmitting or receiving communications. Traditional analog telephone lines require only one pair for operation. Network transmissions typically require two or four pairs. Note the discussion above regarding the required pairs for each of the Ethernet standards 10BaseT, 100BaseT, and 1000BaseT (Spurgeon, 2000).

The majority of network device connections using UTP use straight-through wiring, which means that both ends of the RJ-45 connector are wired exactly the same way. Each pair of cable either transmits or receives data. Likewise, each NIC card transmits data through certain connections and receives through others via its RJ-45 port. If a straight cable was connected to two NIC ports, the result would be that the transmit connections of both ports would be connected to each other, as would the receive links. It should be apparent that when one NIC card transmitted, the other would not receive it because of the direct connections between the ports. Therefore, there must be some kind of crossover that makes a connection between the transmit and the receive pairs. In reality, most network connections between devices are made via hubs or switches. These devices provide the crossover for the transmit and receive pairs.

There are some applications where a special cable called a crossover cable is required. A crossover cable is made by crossing pairs two and three on the opposite end

Table 3 Ethernet Twisted-Pair Cable Specifications

Characteristic	Specification
Maximum cable segment length	100 meters
Maximum number of devices per segment	1
Bandwidth	
10BaseT	10 Mbps
100BaseT4, 100BaseTX	100 Mbps
1000BaseT	1000 Mbps
Topology	Star
Cable Access Method	CSMA-CD

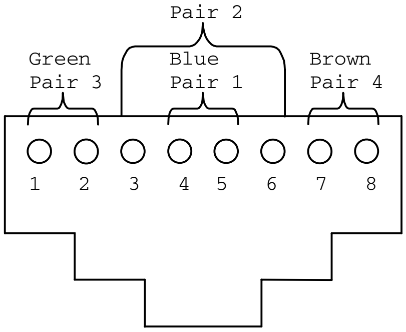

Figure 14: T568 wiring scheme.

of the connecting cable. This allows you to connect two network devices together independently without using a hub or other central wiring point. For example, if you had a small office with two computers that you wanted to network, you could build or buy a crossover cable and connect the NICs from both computers together to form a small network without the expense of a hub. Crossover cables are also used to connect hubs or switches together if they are not supplied with an uplink port. Uplink ports are optional ports that take care of uncrossing the links between these centralized wiring points.

In comparison, there are several advantages and disadvantages to twisted-pair and coaxial cabling. By far, coax has the distance contest won; however, it does not seem that coax has been keeping up with the network cabling race with regard to bandwidth. During the mid-to-late 1980s, coax was the wire of choice, but the torch has now been passed to twisted pair in the LAN interconnection race. Twisted-pair cable offers great flexibility within network design and layout. Even though maximum cable runs are shorter than coax, 100 m is still a significant distance for most network connections. With applications being developed to use the newest categories of UTP, categories 6 and 7, the potential advances for twisted-pair cable are very encouraging with regard to increased bandwidth and expanded connection options.

Token Ring Cabling

In the mid-1980s, IBM developed the token ring architecture. This network protocol used a special type of twisted-pair wiring. IBM engineered a cabling system that included nine different cable types, numbered from one to nine. These cable types included STP, UTP, and fiber optic mediums. For token ring networks, types 1 (STP) and 3 (UTP) were the most prevalent. Type 1 cable allowed for lengths of up to 101 m, with a maximum bandwidth of 16 Mbps. Because of its lack of shielding, type 3 cable runs were limited to 45 m and a bandwidth of 4 Mbps (Tittel & Johnson, 2001). Today, most token ring applications use UTP category 3 or 5 cable with RJ-45 connectors. As noted in Table 4, there have been some improvements in cable lengths with the use of this media (Feit, 2000).

The IEEE specification for token ring is 802.5. This standard describes a bandwidth of 4 or 16 Mbps using the token passing cable access method, which is described in the first part of this chapter. Token ring uses a star-wired ring topology (see Figure 6). Fault tolerance is probably the biggest advantage the token ring architecture has to offer. The star-wired ring topology, using the IBM cable system, provides a dual path for data transmission. Theoretically, if a cable is cut, the token ring network can continue to operate because of the redundant path. Another plus is the use of the token passing access method, which all but eliminates collisions (Tittel & Johnson, 2001; Feit, 2000).

Table 4 Token Ring Cable Specifications

Characteristic	Specification
Maximum cable segment length	101 meters (type 1) 45 meters (type 3) 100 meters (Cat 3) 225 meters (Cat 5) 400 meters (STP)
IEEE specification	802.5
Bandwidth	4/16 Mbps
Topology	Star-wired ring
Cable access method	Token passing

FIBER OPTIC CABLE

Consider that the capacity of a simple telephone line to carry data is equivalent to the flow of liquid through a drinking straw. It would take a tunnel large enough to drive a bus through to equal the bandwidth of a single fiber optic strand using today's technologies. Furthermore, if technology existed to fully utilize fiber optic capabilities, it would take a tunnel the diameter of the moon to handle the flow of liquid equal to its potential bandwidth (Jamison, 2001).

Fiber optic cable carries optical pulses rather than electrical signals. An optical signal virtually eliminates any possible electrical interference. The potential for electronic eavesdropping is completely eradicated. Fiber optic cable lengths are measured in kilometers rather than meters, which greatly reduces the number of signal repeating devices required for long-distance cable runs. One of the most impressive characteristics is the high volumes of data that can be pumped through optical fibers. All this makes fiber optic cable the medium of choice for many WAN applications, where network traffic can cause major bottlenecks (Tittel & Johnson, 2001). In addition, there are many people who believe that fiber optic cables may become the norm rather than the exception for interconnecting network devices on a LAN (Kostal, 2001; Sinks & Balch, 2001; Vickers, 2001).

Components

Fiber optic cable consists of three components: a fiber core, cladding, and a protective outer sheath. The inner core is either glass or plastic fiber. Plastic is used when a flexible cable is needed; however, plastic cable is more susceptible to attenuation than glass, which limits the length of the cable. Cladding provides a coating the keeps the light waves within the fiber. The outer protective jacket is used to protect the fiber inside (Tittel & Johnson, 2001).

Fiber Modes

Fiber optic cable comes in two forms, single and multiple mode. Single-mode fiber is best for applications that require great distances. This fiber is very narrow and requires an extremely focused source of data transmission that can keep the light waves on a straight, continuous path. The narrow internal core makes room for one-way traffic only. This reduces obstacles (stray light) that might interfere with the delivery of packets, resulting in more reliable transmissions over longer distances. A laser is normally used as the generating source for single-mode transmissions because it can produce the narrow band of light needed (Jamison, 2001).

Multimode fiber (MMF) is a cheaper alternative to single-mode because of lower cost transmission devices such as LEDs (light emitting diodes). MMF has a larger core than does single mode, which allows more room for the light signal to travel, allowing lower cost transmission devices. With a wider core and less precise light-emitting sources, there is more information loss due to light dispersion. A larger core allows the light wave to bounce around, which results in shorter transmission distances. However, the connections to the fiber are easier to make to the larger core. MMF is ideal for shorter cable runs within single buildings for LAN backbones (Jamison, 2001).

Fiber Optic Cable Network Applications

There are four major types of fiber connectors: straight (ST), straight connection (SC), medium interface connector (MIC), and subminiature type A (SMA). ST is often used for interconnections between individual fibers and optical devices. When joining optical fibers, an SC connector may be used. This connector consists of connections for two fibers: one for receiving and the other for sending. MIC connectors are one-piece connectors similar to the SC used to connect both the transmit and the receive fibers. It is primarily used with the fiber distributed data interface (FDDI) protocol. As with the ST connector, SMA uses individual connectors for each fiber. The major difference is that SMA uses either a straight or a stepped ferrule in order to ensure a precise fit, whereas the ST connector uses a bayonet twist-lock connection (Tittel & Johnson, 2001).

The major differences between fiber optic and other cable types are fiber optics long-distance cable runs and high bandwidth. For example, the maximum fiber length for the 100BaseFX Ethernet standard is 2000 m and the bandwidth for 1000baseSX tops out at 2000 Mbps. These specifications easily exceed other cable specifications. The potential of fiber optic cable is limited to the technology that exists today.

There are applications where fiber optic is needed not for its high bandwidth but to facilitate long cable lengths or to block unwanted electrical interference. For example, the 100BaseFX specification supports the use of fiber optic cable. With the exception of distance, the other specifications for 100BaseFX are essentially the same as that described for UTP cabling (see Table 5). Token ring also has a cable specification for the use of fiber optic for connecting its MAUs (MSAUs). Again, this does not fully utilize fiber optic's full bandwidth potential, but it allows for longer cable runs.

Table 5 Fiber Optic Cable Specifications

Characteristic	Specification
Maximum cable segment length	2000 meters
IEEE specification	802.3
Bandwidth	100 Mbps
Topology	Star
Cable access method	CSMA/CD

Fiber optic applications do not stop at 100 Mbps. Gigabit Ethernet, 1000BaseLX and 1000BaseSX, each sport bandwidths of 1000 Mbps. The major difference in these two standards is the type of laser used. 1000BaseLX uses a long-wavelength laser that can transmit a signal over 5000 m of fiber in full-duplex mode. A short-wavelength laser is used in 1000BaseSX applications, which support a maximum cable length of 550 m and 2000 Mbps bandwidth in full-duplex mode (Tittel & Johnson, 2001).

The only thing holding fiber optic transmission rates at bay is the devices used to drive the signals through the fibers. As noted at the beginning of this section, the potential of fiber optic media is truly grand. Currently the primary application for fiber optic cabling is for long connections and network backbones. There are some limited applications of direct connections between individual computers and hubs, but many people feel that this will increase over time as cost continues to decrease and installation of fiber becomes easier.

COMPARISONS AND CONTRASTS

When comparing and contrasting the advantages and disadvantages of the different types of cables, you must look at the particular application. It may be true that fiber optic cable has the potential to transmit data much faster than UTP; however, if bandwidth is not an issue, the added complexity involved in installing fiber optic where it is not needed would make it a bad choice. One must look at all the characteristics of the transmission medium before choices are made. In some cases, a network may require a mixture of cables to meet specific needs for data transmission. Table 6 compares and contrasts each cable type discussed in this article, showing more clearly how a particular cable can applied (Tittel & Johnson, 2001).

CONCLUSION

Conductive transmission cables provide the highway for data communications. This article has discussed the most

Table 6 Comparison of Cable Types

Cable	Bandwidth	Length	Interference	Installation	Cost
Thinwire coax	10 Mbps	185 m	Moderate	Easy	Low
Thickwire coax	10 Mbps	500 m	Low	Hard	High
UTP	100 Mbps	100 m	High	Easy	Low
STP	1000 Mbps	100 m	Moderate	Moderate	Moderate
Fiber optic	10 Gbps	100 km	None	Rather hard	Expensive

popular types of cable in use today. As times change, the applications and uses for these different cable types will change. The most limiting factors for conductive transmission media are the devices that drive the packets of information through them. We saw that bandwidths for twisted pairs have increased from around 1 to 1000 Mbps. Transmissions speeds over fiber optic cable are only now being realized. What are the limits? What does the future hold for conductive transmission cables? How do wireless technologies fit into network communications? No one knows the answers to these questions, but at least the questions are being asked, so researchers can continue to experiment and produce new applications for all transmission options.

GLOSSARY

Bandwidth The maximum range of frequencies a communications media can carry.

Cross Talk An electromagnetic field surrounding certain types of cable that may interfere with adjacent wires.

Hub A central wiring point for network devices configured in a star topology. Its purpose is to repeat the broadcast packets to all network nodes.

Impedance The resistance of conducted communications media to a transmitted signal.

Insertion Loss The loss or attenuation of a signal that occurs each time a device is inserted into a network using conductive communications media.

LAN Local area network; a collection of computers connected to a network within a single building or location.

NIC Network interface card; an electronic device that is installed in a network node that provides a link to the network media.

Node Any device connected directly to a network.

Packet Contained data, destination, origination, and error-checking information that is transmitted over a network.

Protocols A set of rules or specifications for different types of network communications.

Signal Attenuation The loss of signal caused by increasing lengths of cable.

Terminator A device attached to a cable configured with a bus topology that eliminates signal bounce.

Topology The physical cabling configuration of a network.

Consumer Behavior

Mary Finley Wolfinbarger, *California State University, Long Beach*
Mary C. Gilly, *University of California, Irvine*

INTRODUCTION

Despite the recent shakeout in Internet retailing, particularly pureplays, online shopping continues to grow, from $42.4 billion in 2000 to $47.6 billion in 2001 (Forrester Research, 2002); by 2005, business-to-consumer (B2C) revenue is forecasted to be $156 billion. In May 2002, the number of monthly active Internet users in the United States was close to 107 million (Nielsen-Netratings, May 2002), and Jupiter Media Metrix estimates that the number of those users who are online shoppers is currently 67 million, a number predicted to reach 132 million by the year 2006. Moreover, the demographics of online shoppers are increasingly expected to reflect offline demographics; as well, shoppers will eventually make higher priced expenditures and buy items, like apparel, that in the past have been considered too risky to purchase online. Jupiter Media Metrix also predicts that over the next 5 years, the majority of online shoppers in the United States are more likely to be older than 35 and to have incomes of $30,000 to $75,000, compared with the current online buying population, which is somewhat younger and more affluent (Tedeschi, 2002).

Although the United States is the world's largest market for online shopping, advanced European markets such as Germany and Britain are expected to grow as well (Center for Media Research, 2001). Forrester Research predicts that the online retail sector in Europe will be 32.8 billion Euros in 2002; moreover, European consumers are expected to increase their online spending more than 50% in 2003 compared with 2002 (Pastore, 2002). According to the annual *World E-Commerce and Internet Market Report* (WECIM), produced by the META Group, northern European countries in particular have adopted technology faster than southern European countries (Pastore, 2001a). In Asia, South Korea and Malaysia are emerging as leaders in the area of e-commerce. Other countries with a growing online e-commerce presence include Canada, Australia, and New Zealand.

So, e-commerce continues to increase in the United States and is spreading to many countries around the world. But what do we know about the wants, needs, and experiences of online consumers? In this chapter, we address the factors that predict online shopping and discuss motivations for online shopping. Next, we present Technographics, a segmentation scheme that classifies U.S. consumers based on their attitudes toward technology, their primary use of the Internet, and their income. As well, we review what is known about the attributes that consumers desire when using websites to make online purchases. We conclude by speculating about the future of online shopping.

FACTORS PREDICTING ONLINE SHOPPING

Scholars and market researchers have suggested several factors that make shopping online more likely for a consumer. Compatibility with a consumer's lifestyle plays a strong role, with positive attitudes toward technology, adoption of multiple kinds of new technologies, online skill, and longer online experience all predicting a stronger likelihood of living a wired lifestyle, including making online purchases (Bellman, Lohse, & Johnson, 1999; Lohse, Bellman, & Johnson, 2000; Modahl, 2000; Hoffman, Novak, & Schlosser, 2000). Previous use of catalogs also predicts that online shopping will be more compatible with a consumer's lifestyle; consistent with this line of reasoning, consumers utilizing catalogs were among the early adopters of online shopping (Pastore, 1999). Those consumers who feel that they must physically examine products are less likely to shop online (Li, Kuo, & Russell, 1999). Over time, visual experiences have been consistently improved online so that products can be better examined; nevertheless, haptic devices, which might give consumers the experience of touching objects, are only in the very earliest stages of development.

Consumers with goal-oriented personalities, or in other words those with an internal rather than an external locus of control, are more likely to shop online (Novak, Hoffman, & Yung, 2000). Perhaps goal-oriented consumers feel more time starved; research suggests that time starvation also predicts the likelihood of adopting online shopping. Partially because higher income, career-oriented consumers are more likely to feel that they are time starved, they are more likely to shop online (Modahl, 2000). Situational factors also enter the picture, including type of product; computers and software, travel, music and videos, and books have the highest category penetration rates (Silverstein, Stanger, & Abdelmessih, 2001). Shopping mind-set also affects the propensity to shop online, as consumers are more likely to choose online shopping when their motivations are goal-directed rather than experiential (Wolfinbarger & Gilly, 2001). Consistent with the association of motivations with shopping outlet, toy retailer KB Toys has found that more impulsive experiential shoppers purchased toys at their land-based stores whereas goal-focused consumers were more likely to shop online; thus, the shopping outlets compliment rather than compete with each other. Following, we discuss in more detail how goal-oriented and experiential motivations affect the tendency to shop online.

CONSUMER MIND-SETS AND ONLINE SHOPPING: GOAL-ORIENTED VERSUS EXPERIENTIAL SHOPPING ONLINE

Consumer shopping mind-sets may be experiential or goal-oriented (Babin, Darden, & Griffen, 1994); both mind-sets are found in online as well as offline shopping. However, online buyers are more likely to be goal focused rather than experiential; nevertheless, some online shoppers are experiential and are thus shopping for fun. Experiential behavior is more likely in categories where shoppers have an ongoing, hobby-type interest, where the search for that special something is as enjoyable as adding to the collection. As well, when consumers feel they have time available to surf to see what's "out there," the result is more experiential shopping behavior. Research indicates that the enjoyment associated with experiential behavior results in a number of benefits for online marketers. These benefits include a more positive mood, greater shopping satisfaction, and a higher likelihood of impulse purchasing.

Goal-oriented or utilitarian shopping is efficient and deliberate, with a preplanned purchase in mind. Thus, goal focused shoppers "buy" rather than "shop" and want to do so quickly and without distraction. Two thirds to four fifths of Internet buyers are goal-oriented, performing narrowly defined searches for specific products online rather than browsing (Solomon, 1999; Wolfinbarger & Gilly, 2001). Analysis of clickstream data of major e-commerce sites also suggests that most online consumers are goal-focused, as goal-oriented shoppers are expected to spend less time at a site (Hoffman & Novak, 1996). In topline clickstream data posted weekly at Nielsen-NetRatings (http://www.nielsen-netratings.com), the average length of visits at major e-commerce sites (with the significant exception of e-Bay) is shown largely to be 10 min or less.

E-tailing consumers are expected to be goal focused for several reasons. First, time-starved consumers are especially likely to be online shoppers (Bellman, Lohse, & Johnson, 1999), going online to buy rather than browse. Second, early and heavy users of the Internet tended to have a strong internal locus of control, resulting in goal-oriented personalities who express these personalities in their online shopping behavior (Hoffman, Novak, & Schlosser, 2000). Also, search costs for product information are dramatically reduced online, facilitating goal-oriented searches (Klein, 1998).

Research of online shopping behavior suggests that goal-oriented shoppers are interested in e-tailing because it offers the following: (a) convenience and accessibility, (b) selection, (c) availability of information, and (d) lack of sociality. Further, shoppers associate these goal- oriented attributes explicitly with increased freedom and control over their purchase transactions (Wolfinbarger & Gilly, 2001).

Although goal-oriented motivations predominate in online shopping, some online shoppers do engage in experiential shopping, or shopping for fun. These experiential shoppers enjoy (a) auctions, (b) involvement with a hobby/product class, and (c) bargain hunting; thus, these experiential shoppers usually focus on the enjoyment of shopping as much or more than they focus on product acquisition (see Tables 1–4).

Goal-Oriented Shopping Behavior

Goal-oriented shoppers frequently talk about the freedom and control they experience while shopping online and how much more freedom and control they have online relative to offline. Consumers often decide to go online to shop only when seeking a specific purchase, with most describing online buying as consisting almost entirely of planned purchases. In contrast, shoppers overwhelmingly report that they tend to be more impulsive offline than online (except at auction sites, with their experiential attraction). The tendency to be rational rather than impulsive during online shopping arises from several factors, including the inability to obtain goods immediately, the ease of returning virtually whenever they want to buy the goods after further thought (no driving or walking), and the inconvenience of having to return unwanted items. The ease of getting online to buy whenever they decide they really want an item appeals to consumers, decreasing their sense of commitment to making a purchase during a particular visit and increasing their sense of control over purchase situations (Wolfinbarger & Gilly, 2001).

In summary, goal-oriented shoppers appreciate the freedom and control coupled with the lack of commitment to purchase immediately that they experience in the online environment. They typically experience little prepurchase pressure and are thus less likely to be impulsive. It is important that goal-oriented consumers particularly associate four attributes of online shopping—convenience,

Table 1 Motivations for Shopping Online

Shopping Mood	Important Factors	Outcome Desired
Goal-oriented	Accessibility/convenience Selection Information availability Lack of sociality	Freedom, control Commitment to goal, not experience
Experiential	Involvement with product class Positive sociality Positive surprise Bargain hunting	Fun Commitment to experience as important or more important than goal

Note. Source: Wolfinbarger & Gilly (2001).

Table 2 Focus Group Participants' Descriptions of Online Shopping

Goal-Oriented Shopping	Experiential Shopping
Accomplishment	Enjoyment
Going to specific site	Surfing/trying new sites
Looking for specific product	Looking for new things
Saving time	Killing time
Having a purpose in mind	Looking for ideas
Making repeat purchases	Checking favorite sites regularly
Finding the best price for a specific item	Bargain hunting for what's on sale

Note. Source: Wolfinbarger & Gilly (2001).

Table 3 Focus Group Participants' Desires When Shopping Online

Goal-Oriented Shopping	Experiential Shopping
To get in and out quickly (fewest clicks)	A welcoming site that draws me in
To do it myself	To interact with other consumers
To not waste time	To have lots of choices
To get immediate response to questions	To browse sites related to my hobby
Ease of use	A unique experience

Note. Source: Wolfinbarger & Gilly (2001).

Table 4 Focus Group Participants' Descriptors of Shopping Online

Freedom and Control	Fun
Control what information I receive	Read reviews (but don't believe them)
No salespeople	Get drawn in
No lines/crowds	Excitement of bidding
Only brands/sites I know	Window shopping
Can come back anytime/delay purchase	Am impulsive
Have options	Have to limit myself
Show me what I want	Surprises

Note. Source: Wolfinbarger & Gilly (2001).

informativeness, selection, and lack of sociality—with increased freedom and control. We discuss each of these attributes below.

Convenience and Accessibility

For consumers, online purchase is the ultimate in saving time and effort, which is made possible by the continuous, 24 hours a day/7 days a week/52 weeks a year accessibility of online stores. Many consumers shop at work and school, in part because of the availability of faster Internet connections. Overall buying effort is also reduced online because shoppers do not need to worry about their appearance; in fact, as one Earthlink billboard proclaimed, they can even "Shop Naked."

Although making an online transaction is often more convenient, consumers are nevertheless unable to touch or try on items. Virtual model technologies are not yet adequate substitutes for trying things on, and zooming in on pictures and rotating them does not represent the texture and feel of most items. Consumers who need a product immediately—for example, a last-minute anniversary gift—cannot obtain it. The difficulty of experiencing some qualities of products online together with the inability to take immediate possession of goods mutes experiential shopping impulses in the online environment.

Selection

Online shoppers frequently offer increased product selection as a goal-directed reason to shop online. Some online buyers have to drive long distances to get to products they need or want; for them, buying tools on the Internet rather than driving an hour to Sears is often preferable. Specialty products and sizes can be efficiently offered on the Internet, where geographically dispersed customers can be aggregated and thus profitably served. For example, Eddie Bauer offers petite and large sizes through their Web site, but not their stores, because of insufficient demand for these sizes in the stores' geographic markets.

Online shoppers look to Web sites to extend the inventory available locally. This extended inventory and selection can be offered in-store through kiosks; while shopping at REI, consumers can access the company's Web site and get an extended selection of specialized products for hiking, mountain climbing, rock climbing, and biking that are not in stock in the store (Schwartz, 2001).

Availability of Information

Availability of information is an important resource cited by consumers using the Internet for specific product searches; the availability and depth of information that allow consumers to feel comfortable that they are making good purchase decisions are reasons that many buyers view online search and purchase as a goal-directed activity. The cost of searching in terms of time spent is dramatically reduced online. Improvements over bricks-and-mortar stores include the reduction of irrelevant information, better information organization, and useful information processing aids.

Another aspect of information important to customers is the interactivity of some e-commerce sites. For example, making plane reservations online gives buyers the feeling that they more fully control their investigation of options than they do offline. Information gotten online can be printed out and saved, unlike that gotten in a phone conversation with a travel agent. In addition to cost savings for the airlines, the ability of consumers to easily access comparative information for different times of day and various airlines is a reason that penetration of airline ticket sales online is expected to grow; in fact, Boston Consulting Group reports that by 2005, fully one third of consumers anticipate spending more than half of their travel budgets on trips that were arranged online (Silverstein, Stanger, & Abdlemissih, 2001). Price comparison sites such as Dealtime.com and MySimon.com enable consumers to choose specific products and then get listings comparing prices at several different online e-tailers. Again, using these sites increases consumer perceptions of control over purchase transactions.

Lack of Sociality

It is interesting that online buyers are quite positive about the relative lack of social interaction experienced while buying online. Salespeople, spouses, crowds, and lines don't exist at e-tailing Web sites. Moreover, the ability to locate the information they need and to complete their transaction without having to interact with a human being increases their sense of freedom and control. Anonymity represents another positive aspect of feeling alone while shopping at Web sites; some online buyers visit sites of stores where they might be intimidated or embarrassed to shop offline, such as Victoria's Secret or Armani.

Consumers appreciate the absence of retail workers online because salespeople are often perceived to be unhelpful or uninformed. In addition, salespeople may pressure buyers or make them feel obligated, giving them a sense of less control over the buying situation. In fact, some consumers even prefer to avoid helpful salespeople because they dislike feeling obligated to purchase. As with other goal-directed themes, the lack of people to interact with online, including a spouse, who might hurry them along or wander off on unplanned buying forays, is associated with freedom. Despite the fact that online consumers largely like being able to avoid people online, they do sometimes require help and want to interact with a human being when they do. E-mail assistance helps satisfy the online need for help, but it is sometimes perceived as being too slow or as not really useful for answering questions. E-commerce providers can improve their sites by combining the properties of impersonal mass communication with more personal communication, utilizing e-mail, chat rooms, or telephones. Users, however, want options as to what medium they use to contact a company and expect responsive service whenever it is needed.

The Experiential Motives of Online Shoppers

Although most online shopping trips are goal focused, as many as one third are experiential (Wolfinbarger & Gilly, 2001). Experiential shopping occurs at Web sites when consumers are browsing largely to be entertained; experiential shopping is associated with increased impulse spending in both online and offline shopping. Experiential buyers browse for three main reasons: auctions, ongoing hobby-type activities, and bargain hunting (as compared to price comparison for a specific preplanned purchase). When asked about browsing online, experiential consumers mention auction activities and ongoing hobby-type searches most frequently. Auctions such as eBay have greater "stickiness" than other e-commerce sites; visits to eBay consistently average an astounding 45 minutes to more than an hour, according to weekly NielsenNetratings. Auctions present several experiential benefits. Products on auction sites change often and many of the products are unusual, unique, or collectible. Bidding for products introduces an element of risk and gaming. Good surprises, unique products, and excitement are all experiential benefits associated with auction sites. More than two thirds of auction participants shop with experiential motivations.

Experiential online shoppers often report hobbies that they actively pursue while online. The most natural hobby is computers and software, but online environments support a wide range of hobby-oriented communities and e-commerce sites as well, such as for campers, snowboarders, Barbie collectors, Texas Instrument calculator enthusiasts, and bibliophiles. These enthusiasts check sites related to their hobbies regularly, looking for new items and considering planned future purchases. Like auction participants, hobbyists are more likely than nonhobbyists to be interested in surprises, new features and items, and online community. A third activity that results in experiential browsing online is looking for deals. While goal-directed shoppers often seek comparative price information, they do so to comparison shop for a specific product rather than to hunt for previously unplanned purchases that happen to be bargains. A relationship between deal seeking and experiential motivations has been found in offline contexts as well.

Multichannel Shopping

It is important that most customers are now engaging in multichannel shopping. Those consumers who shop in more than one channel tend to spend more than those who shop only in the offline store. Many shoppers appreciate the advantages of multichannel shopping: going to an offline store where they can examine and try merchandise before buying online, or doing their information search and pricing online and then purchasing in stores. Industry analysts and consultants such as Jupiter Media Metrix are working to conceptualize valuation models that include the value of a Web site in creating offline as well as online purchases. Companies that focus exclusively on online purchases in calculating the return on investment in their Web sites may be seriously undervaluing their online efforts (Pastore, 2001b).

Although consumers like to shop online when they are goal-oriented, they shop offline when they want to physically examine items and enjoy the stimulation of being out. Consumers can be goal focused when they are time starved and experiential when they have the time to enjoy the experience of shopping. Consumer desires for multisensory experiences are much more likely to be met offline; when consumers desire these experiences, they are unlikely to shop online. For this reason, online shopping is unlikely to outweigh offline shopping for most product categories for the foreseeable future. Those product categories that are most likely to reach the highest online penetration rates are the following: (a) Products for which rich information is helpful in purchase, (b) commodities like books and CDs, (c) product categories in which extensive selection is important to a sizable niche of consumers, and (d) any product that can be downloaded, for example software and event tickets.

Meeting the Needs of Goal-Focused Online Shoppers

Given the fact that most online consumers are goal-oriented, marketers must design Web-based features that facilitate the efficiency these shoppers demand. Only experiential consumers desire community and nonproduct content, and many e-commerce sites may find that they have too few experiential consumers to merit special features designed for them. Even luxury brands like Tiffany's are finding that online consumers are not browsing; they are looking for an easy-to-use site that facilitates product search and easy transactions. A Forrester study found that two thirds of all e-commerce transactions that are begun are never completed, mostly because shoppers cannot find the information they need to complete the purchase (Haney, 2000). E-tailers must largely learn to ignore the siren call to implement attractive, technologically innovative, and clever features that nevertheless do not make a shopper's experience easier or more efficient. Thus, companies that implement experiential features in their site may be overlooking the needs of goal-oriented customers. Web site developers need to accept that online consumers will become loyal customers when they are well served (Reichheld & Schefter, 2000). For most online consumers, being well served means finding the product selection and information they desire, making the transaction easily, and receiving the product in a timely fashion. The importance goal-oriented consumers place on freedom from salespeople, spouses, and crowds at least partially explains why many efforts designed to integrate community with commercial sites have met with limited success.

Meeting the Needs of Experiential Consumers

Although the majority of online consumers tend to be goal oriented, experiential browsing behavior is desirable for online marketers because it often results in increased impulse purchases (Solomon, 1999). As young Internet users who have grown up on the net become independent consumers and broadband use becomes more widespread, experiential benefits may become desirable to more consumers. Before emphasizing such benefits, however, marketers must first make sure that the Web site is easy to search and navigate. Moreover, analysis must establish that the site will draw a sizable proportion of experiential shoppers to the product category. As they do at retail stores (Babin, Darden, & Griffen, 1994), experiential shoppers spend more time at sites and visit more often. Thus, using clickstream data, companies can estimate what proportion of visits are experiential by identifying consumers who visit more often, access more pages, and spend more time at the Web site (Hoffman & Novak, 1996).

SEGMENTING ONLINE CONSUMERS

Up until now, we have characterized shopping moods, rather than shoppers, and suggested that consumers who are goal oriented are more likely to shop online. However, it is useful to segment and describe the shoppers themselves as well. Forrester's *Technographics,* which is widely published, segments consumers into 10 segments based on attitude toward technology (positive or negative), income (high or low), and motivation to use technology (career, family, or entertainment). Although higher income ($40,000+) consumers are more likely to be technology optimists, a surprising 40% of the higher income category is made up of technology pessimists. The 10 groups can be categorized into three larger groups. Early adopters are characterized as Fast Forwards, New Age Nurturers, and Mouse Potatoes (29%) The mainstream group is as much as 2 years behind the early adopters; they are Techno Strivers, Digital Hopefuls, Gadget Grabbers, Handshakers, Traditionalists, and Media Junkies (43%). Laggards are sidelined citizens (28%).

Among the early adopters are the earliest of adopters, the Fast Forwards. The earliest and heaviest Internet shoppers, they are high income, motivated to use the Internet primarily by career needs, and likely to own many consumer technology products. They are largely efficient, focused shoppers and are not particularly price oriented. A second early adopter group is the New Age Nurturers. This group is also high income, but compared to the Fast Forwards, they're more likely to be motivated to use the Internet to facilitate their interests in family and community. New Age Nurturers are more price oriented than Fast Forwards. Forrester believes that New Age Nurturers are more likely to be credible opinion leaders for mainstream users and thus are more influential to later adopters than are the more innovative Fast Forwards. The growing popularity of clicks-and-mortar businesses is partially due to the influence of New Age Nurturers. A final segment is also included among the early adopters, the Mouse Potatoes. Mouse Potatoes use technology for fun, enjoy sports sites and adult entertainment, and play online games. They are more likely to be male, less likely than other early adopters to have children, and have a median age of 40. Like other early adopters, they are high income, but instead of being deliberate shoppers like the Fast Forwards, they tend to buy on impulse.

The second group of segments expected to adopt online shopping are called the Mainstream. As mentioned in the chapter's introduction, the next generation of online shoppers is anticipated to be more representative of middle-class America, with nearly half of new online shoppers' household incomes ranging from $30,000 to $75,000 between 2002 and 2006. The mainstream includes consumers who are high-income technology pessimists and low-income technology optimists. Among the high-income pessimists are the career-oriented Handshakers, the family and community-oriented Traditionalists, and the entertainment-oriented Media Junkies, who like fun, but nevertheless aren't very interested in technology. Mary Modahl writes:

> Demographically, the [technology] pessimists look just like the optimists—middle aged, well educated, family householders. High-income pessimists like to drive Jeeps, Volvos, and Toyotas, just like high-income optimists. What's more, high-income consumers share tastes in media. Both like newsmagazine shows and major sporting and entertainment events (2000, p. 49).

Thus, high-income pessimists are much like high-income optimists except for their attitudes toward technology.

The low-income technology optimists include the Techno Strivers, Gadget Grabbers, and Digital Hopefuls. The Techno Strivers are career oriented whereas the gadget grabbers are fun oriented. Techno Strivers and Gadget Grabbers are demographically diverse and include strong representation of both males and females, almost one quarter are minorities, and they engage in online activities. They don't yet earn much, mostly because they're just starting out. They tend to be single, college educated, and white collar. The last group of low-income optimists is Digital Hopefuls, a very large group of family-oriented retirees using the Internet to stay in touch. In fact, although retirees do not yet participate in the Internet in proportion to their number in the population, those who do participate spend more time online per week than do people from any other age group. The last segment of consumers is not likely to become Internet savvy at all. They are Sidelined Citizens. As Modahl summarizes:

> These consumers are pessimistic about technology. Even if they could afford a home PC, most probably wouldn't buy one. And if they had a PC, it is unlikely that these consumers would use it for online shopping . . . [F]ewer than 50 percent of Sidelined Citizens use the automated teller machines at their bank for making deposits and withdrawals. That technology is free, and it has been around for more than 20 years. (2000, p. 68)

RELATIONSHIP OF ATTRIBUTES OF ONLINE SHOPPING TO CONSUMER JUDGEMENTS OF QUALITY AND SATISFACTION

We have established that online shopping tends to be solitary and purposive rather than interpersonal and social by nature. But what do consumers really want from their online shopping experiences? What attributes are most important in their judgments of quality, satisfaction, and loyalty? These questions are important; buyers' perceptions of quality are likely to play a role in "e-loyalty" and profitability (Reichheld & Schefter, 2000).

Along with an increase in consumer experience online comes an increase in expectations of online businesses. Market research and consulting firms have been particularly interested in measuring e-commerce quality. A well-known example is Bizrate.com: measurements are based on intercept surveys customers receive immediately after making an online purchase. Bizrate measures ease of ordering, product selection, product information, price, on-time delivery, product representation, customer support, privacy policies, and shipping and handling. Scholars have studied a variety of factors, including usability, information content, selection of products, fulfillment, customer service, privacy/security, and Web site atmospherics. Following is a review of each of these factors and their impact on consumer evaluations of Web sites.

Usability

Before the Internet was widely available, information systems scholars and practitioners studied usability as it applied to computer systems, usually in work rather than home settings (Cooper, 2000). In general, usability studies examine user/technology interfaces in order to improve design so that it is more user oriented (Lohse & Spiller, 1998; Nielsen, 1993, 2000). Applied to Web sites, the term usability means intuitive navigation, a good search function, and easy checkout. Usability elements affect the ease of use and amount of mental effort required to browse and buy at an e-tailing site; a Web site that is difficult to use deters online consumers, especially less-experienced Internet users (Lohse & Spiller, 1999; Montoya-Weiss, Voss, & Grewal, 2000). Slow downloading raises the likelihood that customers will abandon the site (Nielsen, 2000; Dallaert & Kahn, 1999). Although consumer technology affects waiting time, consumers know which sites are quicker relative to the computer they normally use. E-tailing sites should test their Web site designs with 10–15 consumers directed to carry out specific instructions regarding the site. Interviewing consumers while they are carrying out these instructions will identify the major usability problems that can occur at e-tailing Web sites (Nielsen, 2000).

Information Content

An important advantage of online shopping is the availability of information, including the reduction in search effort and time for products and product-related information. The easy availability of in-depth information, as long as it is well organized and easy to access, is an important reason consumers shop online (Alba, et al., 1997; Ariel, 2000; Lynch & Ariely, 2000; Van den Poel & Leunis, 1999; Wolfinbarger & Gilly, 2000). As we have already discussed, such information does not just simply “replace” a salesperson; many online buyers report that they appreciate obtaining, and prefer to obtain, information directly, without having to go through a salesperson or retail worker. In addition, online information is perceived as superior to catalog shopping, as more information is available online and queries can be answered (Ariel, 2000; Van den Poel & Leunis, 1999; Venkatesh, 1998).

The ability of online consumers to search and compare price and quality information across Web sites increases their satisfaction with the shopping experience and the purchased product. As well, the belief that a Web site has useful information is associated with intentions to revisit the Web site and to repurchase. Further, interactive control of the content, order, and duration of product-relevant information improves consumers’ ability to integrate, remember, and use information (Lynch & Ariely, 2000).

Fulfillment/Reliability

Reliability, a key services quality concept typically rated as the most important to consumers (Zeithaml, Berry, & Parasuraman, 1993), is related to consumer perceptions of online transaction quality. Online e-tailers need to convince buyers that they can deliver products and services reliably and at the promised level of quality. In e-tailing, qualities associated with reliability are related to fulfillment and include on-time delivery, having products in stock, and effectively portraying the product on the Web site so that what is received is what the consumer expected to receive. Consumer ratings of fulfillment together with those of security/privacy strongly predict consumer trust of an individual Web site (Jarvenpaa & Tractinsky, 1999; Palmer, Bailey, & Faraj, 1999).

Customer Service

In the retailing literature, the level of service received by customers is frequently noted as a component of store image (Louviere & Johnson, 1990; Reardon, Miller, & Coe, 1995). In their measurement of services quality, Parasuraman, Zeithaml, and Berry (1988) included responsiveness, which is defined as the willingness to help customers, and empathy, defined as caring, individualized attention. In addition to the empathy and responsiveness of live customer service personnel, there are unique aspects of customer service in online retailing. Fast response to e-mail inquiries is an important attribute of online customer service. As well, ease of returning items is especially important to consumers in online environments and is thus a factor in their rating of online customer service. Customer service is particularly important when an online customer has a problem; because of the intangible nature of Web sites, customer service is a key in reassuring consumers that the company has real people who will solve their real problems (Wolfinbarger & Gilly, 2001).

Product Selection

Because researchers of computer-mediated environments until recently have focused on Internet use generally, rather than e-tailers specifically, scholars have not addressed online selection as extensively as other elements of the online shopping experience. As earlier reviewed in this chapter, increased product selection is an important motivation for consumers to buy online rather than offline. Moreover, because selection has been found to be consistently important in the literature concerning bricks-and-mortar retailers, it is expected that selection will be important to customers of online retailers as well (e.g., Reardon, Miller, & Coe, 1995; Samli, Kelly, & Hunt, 1998).

Privacy/Security

In the online arena, a sense of assurance is likely to be defined by consumers as adequate security and privacy (Culnan & Armstrong, 1999; Culnan, 1993; Hoffman, Novak, & Peralta, 1999). Security risk is the risk that credit card information is not safe. A second online risk is privacy risk, which involves the possibility that personal information shared with a Web site will be used for a secondary purpose without the consent of consumers (Culnan, 1993; Hoffman, Novak, & Peralta, 1999). Online shoppers largely understand that detailed information can be collected online concerning their search and purchase behaviors (Hoffman, Novak, & Peralta, 1999). In fact, in a Harris Interactive Study, fully 45% of people in the United States said they believed that online buying is a threat to privacy. Moreover, over two thirds of Internet users cite three concerns regarding online privacy: (a) Companies will provide their information to other companies without permission; (b) their transactions with companies may not be secure; and (c) hackers could steal their personal data from companies (Emarketer.com, 2002).

People who buy online are slightly more likely to trust Web sites than others (Ulsaner, 2000). Because consumers do not have the expertise to determine whether a Web site is safe, consumers see symbols such as the padlock-and-key icon or the TRUSTe seal as evidence for site security (Friedman, Kahn, & Howe, 2000); however, many consumers remain distrustful of sites despite their posted privacy policies and use of the key icon. The success of retailers already well trusted in the offline environment can be attributed partially to the belief that these companies are more likely than unknown companies to protect customer privacy and credit card security. Appearance and functionality of the Web site is related to consumers' perceptions of privacy and security risks. As consumers in offline environments have shown, they will rely on available tangible cues when they have uncertainty about a retailer (Doney & Canon, 1997).

Web Site Atmosphere

A more inviting Web site atmosphere may draw more experiential shoppers. More experiential shopping is desirable for e-tailers, as it has been associated with playfulness, positive feelings, and increased time spent online (Novak, Hoffman, & Yung, 2000). As well, in offline environments, experiential shopping has been associated with more impulsive and increased spending (Babin, Dardin, & Griffen, 1994). Hoffman and Novak (1996) write extensively on the possibility for online "flow," which involves loss of self-focus, intense involvement during an Internet session, and loss of a sense of time. It is important that the authors suggest that flow underlies a "compelling online customer experience." Marketers have speculated that creating "a compelling online experience" is likely to be strategically important, given that increasingly transparent information environments have been created on the Internet (Häubl & Trifts, 2000; Lynch & Ariely, 2000). However, it is unclear whether atmosphere is part of that compelling experience or even whether it is possible to create an atmosphere in an online store; it may be that Web site usability is more important in creating a compelling experience than is atmosphere. Moreover, the predominance of goal focused shopping online casts doubt on the importance of Web site atmospherics; currently, the effect of an attractive and pleasing Web site design along with various personalization techniques is not yet fully understood.

In offline retailing, consumer evaluation of a store's appearance and atmosphere is one of several predictors of store image ratings (cf. Doney & Canon, 1997). The graphic style of a Web site is similar to the interior and exterior appearance of a bricks-and-mortar store; as with offline stores, the style and appearance of a Web site provide messages about the positioning of the site. Nevertheless, it is unclear how atmospheric elements can be created that are experiential but which do not interfere with the needs of goal-oriented consumers. To date, consumers have consistently expressed dissatisfaction with experiential graphic features that are attractive, but which slow downloads and impede usability. The splash sequences widely used by Web sites in 1998 and 1999 that impeded entry into a Web site are an excellent example of an attractive design feature that consumers largely rejected (Nielsen, 2000).

One element that may contribute to an inviting Web site atmosphere is appropriate personalization. Personalization is providing "users with what they want or need without requiring them to ask for it explicitly" (Mulvenna, Anand, & Buchner, 2000, p. 123). In the online setting, personalization includes recommendation systems based on collaborative filtering or observational techniques, customization, and adaptive Web sites (Sipiliopoulou, 2000). However, a majority of Web users find online solicitations to be intrusive, which suggests that e-tailers must walk a fine line between personalization and personal intrusion. In addition to being related to the atmosphere of a Web site, personalization is also related to usability, as personalization can result in making the site more intuitive and easy to use. Personalization is seen as positive to users when it includes features that increase the user's sense of control and freedom, such as order tracking, purchase histories, saving information for quicker transactions during future sessions, and opt-in e-mail notification of new products and special deals. Personalization is seen as negative, however, when the result is unsolicited offers or if users feel less anonymous. These intrusive features decrease users' perceived control and freedom (Wolfinbarger & Gilly, 2001).

Measuring Online Quality From the Consumers Point of View

Scholars and researchers have recently begun to model and measure the dimensions of quality of the online buying experience. These research efforts vary in focus and, thus, measure differing aspects of e-commerce quality. For example, WEBQUAL (Loiacono, Watson, & Goodhue, 2002) measures various dimensions of the Web site interface or design, including information fit-to-task, interactivity, trust, response time, ease of use, entertainment, consistent image, online completeness, and substitutability for offline channels. Symananski and Hise (2000) study “e-satisfaction” and conclude that online convenience, merchandising (product offerings and information), site design, and financial security all contribute to customer satisfaction. Left out of both WEBQUAL and Symanski’s and Hise’s e-satisfaction, however, are customer experiences with fulfillment and customer service.

Two recent scale efforts have some commonalities both in their approach and in their outcomes, eTailQ (Wolfinbarger & Gilly, 2002, in press) and eSQ (Zeithaml, Parasuraman, & Malhotra, 2000, 2002). Both efforts include measurements of the entire process of making an online purchase, from looking for information at the Web site, to making a transaction, to product delivery and customer service. Following is a more in-depth description of eSQ and eTailQ.

eTailQ: Dimensionalizing, Measuring, and Predicting Online Quality

eTailQ is based on a three-step development effort, including (a) focus groups to uncover attributes of importance, (b) an intermediate step in which online consumers categorize attributes into meaningful groups, and (c) an online survey utilizing consumers from Harris Interactive’s online research panel. The developers of eTailQ conclude that across auction and e-tailing settings, browsing versus buying purchase situations, and a variety of product categories, four higher level constructs predict customer judgments of online quality (see Table 5): Web site design (conceived of broadly as information availability, usability, product selection, and appropriate personalization), fulfillment/reliability (receiving the product ordered within the time promised), security/privacy (security of credit card payments and privacy of shared information), and customer service (responding to e-mails, handling returns, answering questions, and being responsive and helpful).

Table 5 eTailQ Items (short version)

Web site design
The Web site provides in-depth information.
The site doesn’t waste my time.
It is quick and easy to complete a transaction at this Web site.
The level of personalization at this site is about right, not too much or too little.
This Web site has good selection.
Reliability/fulfillment
The product that came was represented accurately by the Web site.
You get what you order from this Web site.
The product is delivered by the time promised by the company.
Privacy/security
I feel my privacy is protected at this site.
I feel safe in my transactions with this Web site.
This Web site has adequate security features.
Customer service
The company is willing and ready to respond to customer needs.
When you have a problem, the Web site shows a sincere interest in solving it.
Inquiries are answered promptly.

Graphic design was not as important to online consumers as other Web site design features and was not included in the final eTailQ measurement instrument. The factors having the strongest impact on both customer satisfaction and quality judgments are Web site design and fulfillment. Customer ratings of overall quality predict that about half of the variance in customer satisfaction is related to their most recent online purchase, while pricing explains an additional 25%.

Perhaps most surprising is the role of security/privacy, which does not predict customers’ rating of Web site quality, except among the most frequent buyers at the site. It is important that security/privacy is strongly correlated with consumers’ evaluations of Web site design; thus, it appears that inferences of security/privacy are largely made from Web site design when consumers do not yet have experiences with a Web site. In focus groups, online consumers say that they have difficulty judging the privacy and security of a site, even after checking that the site is secure when making transactions and after reading a statement of privacy that in their minds was legalistic. Thus, customers assess the professional look and feel of a Web site, the functionality of a Web site, and the company reputation, and they extrapolate from that to judge privacy/security. Usable and professional sites require greater resources and investment and thus inspire greater consumer trust. Similarly, in a brick-and-mortar context, consumer trust is affected by a seller’s perceived investment in a facility (Doney & Canon, 1997).

Although Web site design and fulfillment are about equally predictive of customer ratings of Web site quality, loyalty and repurchase intentions are most strongly related to Web site design elements. This is likely to be because of the fact that even when the product and the delivery are satisfactory, if the Web site experience is not, customers are much less apt to return to the Web site for future purchases. The experience consumers have at a Web site takes on added strategic importance when you consider that many more consumers purchase products offline as a result of online information search than actually buy online; these online shoppers who are not online buyers are likely to have experiences with Web site design but not with the other three quality factors—fulfillment/reliability, security/privacy, and Web site customer service.

eSQ: Conceptualizing Online Experiences as Services

The eSQ scale was developed through a three-stage process using exploratory focus groups and two phases of survey data collection and analysis (Zeithaml, Parasuraman, & Malhotra, 2002a). eSQ suggests that four dimensions form “core” service—efficiency (ease of Web site use), fulfillment, privacy, and technical reliability. Efficiency, fulfillment, and privacy are very similar to eTailQ’s Web site design, fulfillment/reliability, and privacy/security dimensions, respectively. The similarity in findings concerning these three dimensions across two research efforts provides support for their importance in predicting quality. The fourth core dimension, technical reliability, is not included in eTailQ and refers to correct technical functioning and availability of the Web site.

Rather than view customer service as a core element of a typical online purchase experience, as does eTailQ, eSQ suggests that customer service comes into play only when a customer problem occurs. The customer service scale includes three elements of "recovery" service—responsiveness, compensation, and contact. Responsiveness is defined as "the ability of e-tailers to provide appropriate information to customers when a problem occurs, have mechanisms for handling returns, and providing online guarantees" (Zeithaml, Parasuraman, & Malhotra, 2002a, p. 15). Compensation involves crediting money to consumers and handling returns. Contact is the ability to speak live with customer service personnel, either through online chat rooms or on the phone.

The authors of eSQ conceptualize four potential gaps in online service quality (Parasurman, Ziethaml, & Malhotra, 2000): The *information gap* is the difference between what managers believe consumers desire in Web site design and operations and what customers actually want. If consumer needs and wants with regards to desired Web site attributes are not continuously monitored, an information gap will exist. A *design gap* occurs when a company with accurate knowledge fails to incorporate its findings into Web site design and supporting operations such as customer service and fulfillment. A *communications gap* occurs when more is promised at the Web site than can be delivered, often a result of competitive pressures. For example, quicker delivery dates than are actually possible may be promised by the marketing department when, in fact, these promises cannot be supported by the shipping department. A *fulfillment gap* is the sum total of all discrepancies between what customers wanted and expected and what they actually received. All three of the other gaps contribute to the fulfillment gap.

The development and conceptualization of online e-commerce quality is just now emerging, and all the proposed scales will benefit from further tests of their psychometric properties. The validity and reliability of the Bizrate.com online purchase satisfaction scale has not been established. Moreover, it is through repeated usage and improvement that scales such as WEBQUAL, eTailQ and eSQ will become most useful to e-commerce researchers and managers (Zeithaml, Parasuraman, & Malhotra, 2002b).

CONCLUSION: FUTURE OF ONLINE SHOPPING

Online shopping will continue to grow among mainstream segments in the United States in the next few years. At the same time, online shopping is growing in more advanced European markets, South Korea, Malaysia, Australia, Canada, and New Zealand. It is important to note that technology will impact the growth of online shopping. Broadband makes online shopping easier and more convenient; as well, broadband will enable the creation of more sophisticated Web sites with enhanced functionality, which will increase the comfort level of online buyers. Perhaps more experiential Web site design features will be preferred by customers as broadband diffuses more widely. Mobile commerce (m-commerce) may also open up new possibilities, allowing, for example, your local favorite restaurant to send special offers to your cell phone when you're in the neighborhood, or your dry cleaner to offer a new service—cell phone notification when your dry cleaning is ready. Marketers are also experimenting with interactive television (ITV), which could allow users to order furniture, jewelry, clothing, or other products that appear in regular TV programming. ITV could also be used to allow consumers to request additional information about advertised products. These e-commerce applications and others will be successful to the degree that they are compatible with consumer lifestyles, are responsive to consumer motivations for shopping using a particular technology, offer advantages over current methods consumers use to buy products, and are easy to use, requiring limited learning on the part of consumers.

GLOSSARY

Bricks and Mortar A physical space where consumers may shop for and purchase products; the terms is also sometimes used to describe retailers who own physical retail stores.

Clicks and Mortar A retailer that sells products both online and offline.

Community A virtual online gathering place for Internet users.

Content Any kind of information on a Web site; in an e-commerce context, however, "content" may refer both to information about products and to articles and outside information at Web sites that are indirectly product related; an example is the content at imdb.com (the Internet Movie Database), which is utilized by consumers to facilitate information search about movies and by Amazon.com to support sales of videotapes, DVDs, and CDs through links back to Amazon.

Experiential shopping Shopping primarily for fun rather than to make a preplanned purchase.

Fulfillment/reliability As seen from the consumer's point of view, fulfillment involves displaying and describing a product accurately on the Web so that what customers receive is what they thought they ordered, having the product in stock, and delivering the right product within the time frame promised.

Goal-directed shopping Shopping with a predetermined goal, usually to purchase or search for information for specific products; although such shopping may be enjoyable, the primary purpose of goal-directed shopping is product acquisition.

Haptics The science concerned with tactile senses; haptic devices allow users to experience the sensation of touch remotely.

Internal locus of control A personality characteristic marked by the tendency to be driven by internal goals and needs rather than external cues.

Multichannel shopping Shopping through two or more channels (online shopping, catalog shopping, and/or land-based shopping); for example, consumers may search for product information online and then purchase offline, or they may purchase in both the bricks-and-mortar and online stores of a particular retailer.

Personalization Any Web site strategy that involves customizing Web site appearance and functionality and/or making offers to consumers based on past behavior at a Web site.

Pureplay A company that only has an online presence without a bricks-and-mortar counterpart.

Sociality The state or quality of being sociable; sociability.

Technology optimism The belief that technology improves living; an orientation that predicts acceptance of new technologies.

Web site design All elements of the consumer's experience at the Web site (except for customer service), including navigation, information search, order processing, appropriate personalization, and product selection.

Wired lifestyle A lifestyle wherein individuals use the Internet for many purposes and thus naturally turn to the Internet to search for product information and to buy products and services.

Consumer-Oriented Electronic Commerce

Henry Chan, *The Hong Kong Polytechnic University, China*

INTRODUCTION

The beginning of the 21st century has marked the beginning of a global entity with a duplex (physical plus digital) market. Enabled by various Internet technologies, e-commerce forms a global marketspace, introducing numerous new services to consumers and creating a paradigm shift in many businesses. As complements to each other, the physical marketplace and the electronic or digital marketspace are leading us into a new generation of the economy. (See for example Rayport & Sviokla, 1995, and Rayport & Sviokla, 1994, about marketspace and marketplace.)

E-commerce is commonly related to the sale and purchase of goods and services by electronic or digital mechanisms. (See Kalakota & Whinston, 1997, for definitions of e-commerce from different perspectives.) It is usually associated with sales transactions on the Internet, although it is not confined to those activities. The predecessors of e-commerce are generally agreed to be electronic funds transfer and electronic data interchange services (Kalakota & Whinston, 1997; Zwass, n.d.), which are mainly concerned with interbusiness transactions. In contrast, today's e-commerce covers both business-oriented and consumer-oriented aspects. More important, e-commerce can now be supported over a public network (i.e., the Internet), thus facilitating its development and expansion.

As shown in Figure 1, there are two major types of e-commerce: consumer-oriented e-commerce and business-oriented e-commerce. Consumer-oriented e-commerce can be further divided into three types: business-to-consumer (B2C), consumer-to-consumer (C2C), and consumer-to-business (C2B) (Korper and Ellis, 2001; Turban, King, Lee, Warkentin, & Chung, 2002). Resembling a traditional retail business, B2C e-commerce is about the sale of goods or services to consumers through a business called an electronic retailer (e-retailer or e-tailer) on the Internet. "Brick-and-mortar" and "click-and-mortar" have become two popular terms to distinguish a traditional (physical) retailer from a hybrid (physical and electronic) retailer, respectively. Common features provided by an e-retailer include a search engine to facilitate searching for a product, an electronic catalog (e-catalog) to show product information, a virtual shopping cart to store selected goods, communication facilities to provide customer support and order handling functions to handle payment and product delivery (Schneider & Perry, 2001; Chan, Lee, Dillon, & Chang, 2001). For C2C e-commerce, both the buyers and sellers are consumers. Traditionally, used goods are often sold among consumers by means of classified advertisements. With the advent of Internet-based e-commerce, the auction model is becoming more popular. Emerging as a new mechanism, C2B e-commerce provides a buyer-centric and highly customized solution to fulfill a consumer's need. In contrast to consumer-oriented e-commerce, business-oriented e-commerce is concerned with commercial transactions between business partners. It can often be viewed as an essential back-end process to support consumer-oriented e-commerce. Business-oriented e-commerce generally covers supply chain management and associated transactions (Kalakota & Whinston, 1997).

In this chapter, an overview of e-commerce is presented with a focus on its consumer-oriented aspects. The organization of the rest of this chapter is as follows. The next section provides an overview of the consumer buying process. I then present different consumer-oriented e-commerce models and discuss the enabling technologies for consumer-oriented e-commerce. Next, I present two major developments in consumer-oriented e-commerce. The Conclusion provides a summary.

OVERVIEW OF THE CONSUMER BUYING PROCESS

Before discussing consumer-oriented e-commerce in detail, we return to the basics of consumer buying process. In fact, many consumer-oriented e-commerce models are designed to address this fundamental issue. In general, the consumer buying process consists of the following stages (Etzel, Walker, & Stanton, 2001):

Specify need(s),
Search for the alternatives,
Compare or evaluate the alternatives,

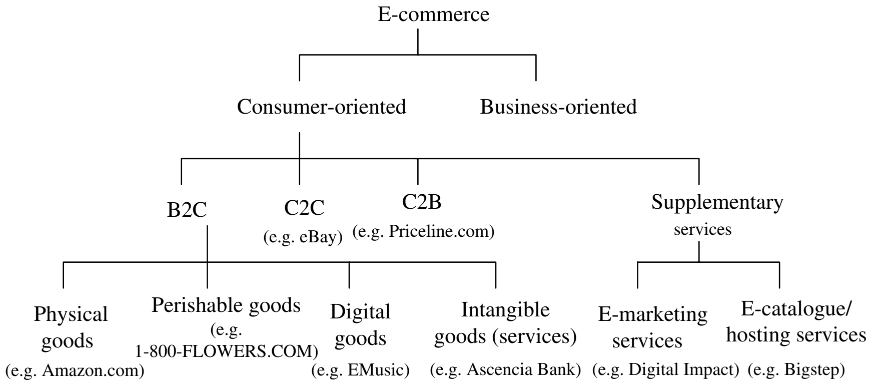

Figure 1: Different types of e-commerce.

Buy selected goods or services, and

Carry out other postpurchase activities.

It is best to explain this process with an example. (See also Etzel et al., 2001; Schneider & Perry, 2001; and Turban et al., 2002 for discussion on this process.) Suppose a consumer wants to learn more about e-commerce. Obviously, there are many alternatives. For example, he/she may buy a book (e.g., the *Internet Encyclopedia*), take a training course, or study for a formal degree. Hence, the first task is to define his/her needs more clearly. Let us assume that this consumer chooses to purchase a book on e-commerce. Next, he/she needs to search for the alternatives in the market by visiting bookstores. Having determined the alternatives, he/she needs to evaluate them. In the case of a book, the decision factors are likely to be price, experience of the authors and publishers, and whether the book is easy to read and understand. The consumer also needs to consider where to buy the book because the same book may be priced differently in various bookstores. After considering all these decision factors, he/she makes the decision and purchases the book from the selected bookstore. For nonstandard or semi-standard goods such as computers, further negotiations may be carried out to finalize the deal (e.g., to obtain a better service guarantee). Furthermore, for goods such as computers, there are also postpurchase activities such as technical support services.

In general, e-commerce can greatly facilitate the consumer buying process. In the physical commerce system, searching for information is often limited by various geographical constraints. For example, one can only visit the shops within a certain area. In other words, a consumer may not get sufficient information for comparison or evaluation purposes. In contrast, searching can be done more effectively in cyberspace. A consumer can also obtain more information to enable better decision making. E-commerce also facilitates evaluation, in particular, price comparison. To find the best available price of a product in the global marketspace, some price-comparison services are available on the Internet. For instance, a consumer may visit Best Web Buys (http://www.bestwebbuys.com) or mySimon (http://www.mysimon.com) to inquire about prices easily. Last, but not least, e-commerce also facilitates the purchase stage because consumers have better control (e.g., ease in changing the delivery information) and the process is automated. In the case of digital goods, consumers can obtain the goods instantly via the Internet. In summary, to buy something on the Internet, a consumer first searches for and evaluates the products through the use of directory services (e.g., Yahoo!; http://www.yahoo.com), search engines (e.g., Google; http://www.google.com) and price-comparison services (e.g., Best Web Buys or mySimon). Then he/she visits the virtual shop to complete the purchase. Finally, the purchased goods are delivered by physical or digital means. The buying process is also supported by other related services (e.g., payment services).

DIFFERENT CONSUMER-ORIENTED E-COMMERCE MODELS

The focus of this chapter is on consumer-oriented e-commerce in general and B2C e-commerce in particular. Inspired by some case studies presented in Chan, Lee, Dillon, and Chang (2001); Deitel, Deitel, and Steinbuhler (2001); Derfler et al. (2001); Korper and Ellis (2001); Schneider and Perry (2001); Turban et al. (2002); and the information obtained from the respective Web sites, various consumer-oriented e-commerce models and two supplementary services are discussed in the following sections and subsections.

B2C E-commerce

As noted earlier, B2C e-commerce involves the selling of goods or services by a business to consumers. It may be used to sell different types of goods including standard goods (e.g., books), perishable goods (e.g., flowers), digital goods (e.g., music), and intangible goods (e.g., banking services) as discussed in the following sections.

Selling Standard Goods: Amazon.com

Amazon.com (http://www.amazon.com) is an e-retailer established by Jeff Bezos for selling books. Because books are standard goods, they are suitable for sale through the Internet (Schneider & Perry, 2001); it makes little difference whether a book is bought from a physical or a cyber bookstore. In other words, the fact that consumers cannot check a book physically has little effect on their decision

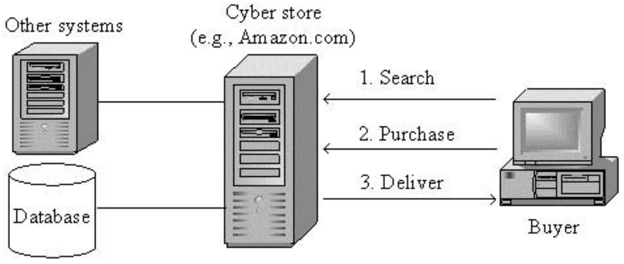

Figure 2: Cyberstore model.

to purchase it. From a business perspective, it is less costly to run a cyber bookstore than a physical bookstore.

Let us study how Amazon.com operates in the context of the consumer buying process (see Figure 2). When consumers visit Amazon.com, they can search for books through various mechanisms. In a physical bookstore, books are placed in labeled bookshelves according to their subjects. Using a similar arrangement, books are sorted by subject at Amazon.com to facilitate searching. Effectively, this can be viewed as a "translational" feature (i.e., to translate a physical feature into an equivalent electronic feature). In addition, Amazon.com also provides two "transformational" search features (i.e., they are not available in the traditional physical bookstore). The first feature is the search box, where a consumer can search for books by providing one or more keywords. Based on the keywords, a list of books will be displayed accordingly. The second feature is a proactive search feature called the recommendation system. By using data mining and other advanced computing techniques, Amazon.com can recommend books for consumers based on their interests (e.g., the books he/she has chosen before) and the buying behavior of other consumers. For example, if a buyer selects a book on e-commerce, Amazon.com will likely recommend other popular books on e-commerce to that person. In many cases, consumers will find the recommendations attractive and useful. Again, this transformational search feature greatly facilitates the search process.

Having found some books, the consumer can evaluate and compare them. Amazon.com offers some readers' ratings or scores and reviewer comments for reference. By reading the comments of other readers, the consumer can find out more about a book that he/she is interested in. Once the consumer has selected a book, he/she can store it in an electronic shopping cart and then choose the next book if required. Finally, the consumer can purchase the books in the shopping cart by going to the payment section. If registered with Amazon.com, the consumer may order through the 1-Click service by clicking the computer mouse once. Basically, the 1-Click service completes the order information (e.g., credit card number, delivery information, etc.), based on registered information. The shopping cart facility, together with this 1-Click service, greatly facilitates the purchase stage of the consumer buying process. Besides selling books, Amazon.com has now expanded "horizontally" to become a super e-store, selling many other goods (e.g., computers, kitchen appliances, software).

Like many other B2C Web sites, Amazon.com supports personalization and customization. Consumers registered with Amazon.com will see a personalized "hello" message with their names. Furthermore, Amazon.com allows its registered customers to build personalized stores. To reach as many consumers as possible, Amazon.com employs an affiliate scheme. This is a referral mechanism, in which an affiliate can link or refer its visitors to Amazon.com via Amazon.com's icon or even Amazon.com's search box. If a referred customer purchases something, the referring affiliate gets a commission. By using this incentive-based promotion service, Amazon.com can extend its coverage in cyberspace. In fact, the affiliate scheme has become a common and effective marketing technique adopted by many e-retailers.

Selling Perishable Goods: 1-800-FLOWERS.COM

1-800-FLOWERS.COM (http://www.1800flowers.com) sells flowers to consumers on the Internet. Similar to Amazon.com, it has the standard B2C features (e.g., a search engine, a shopping basket, communication and help facilities, payment functions) for facilitating a consumer buying process. It is also different from Amazon.com, however. Unlike books, flowers are perishable, so they need to be delivered in a timely manner and with great care. To cater to this important requirement, 1-800-FLOWERS.COM has many associated flower shops. The ordered flowers are delivered through these physical shops and other distribution outlets to the consumers. This example shows how e-commerce can work in conjunction with traditional commerce to satisfy a consumer need more effectively. Unlike books, flowers are seasonal products, and many people like to purchase flowers, for different occasions, on a regular basis. For example, a husband might like to buy flowers for his wife on her birthday each year. Furthermore, flowers are not standard goods because they can be packaged in a customized manner. Because of these special characteristics, 1-800-FLOWERS.COM provides many distinctive features compared with other e-retailers selling standard goods. First, the flowers are sorted by different means such as by occasion and price. Of course, 1-800-FLOWERS.COM also features some special and seasonal offers or promotional flowers in its e-catalog. Registered consumers (members) can enjoy a useful gift reminder service for the dates that they provide, and 1-800-FLOWERS.COM will remind them of those important days via e-mail. This is an effective way to generate steady revenue. In addition, members can also enjoy many other services, such as securely stored credit card information for subsequent orders, promotional e-mails, and Web-based order tracking.

Like Amazon.com, 1-800-FLOWERS.COM employs a commission-based affiliate scheme to extend its presence to many B2C sites. In terms of business development, however, it adopts a different strategy. Unlike Amazon.com, which has expanded horizontally to become a super e-store, 1-800-FLOWERS.COM has expanded vertically to sell various gift products. In other words, it has remained a specialized gift seller rather than a generalized super e-store. In addition to flowers and various gift products, 1-800-FLOWERS.COM also sells digital gift certificates. Upon receiving a prepaid digital gift certificate by e-mail, the recipient can use it to buy flowers or other gifts at 1-800-FLOWERS.COM.

Selling Digital Goods: EMusic

Obviously, digital goods (e.g., digital songs) are particularly suitable for e-commerce because they can be distributed directly through the Internet. As an example, let us study EMusic (http://www.emusic.com), which sells music (in MP3 format) through the Internet using a subscription-based business model. Note that MP3 is a widely used file compression format for music. Like other e-retailers, EMusic provides a search engine, a product directory, and help functions. The music can be searched for by artist, musical style, and so on. Furthermore, EMusic provides different charts to show the top songs and artists. Because of the special nature of digital goods, there are a number of distinctive features compared with other e-retailers that sell physical goods. In particular, subscribers are allowed to download as many songs as they want. Note that this feature is possible because, unlike physical goods, digital goods have extremely small variable costs. Upon downloading songs, a customer can also save them in compact discs or other devices for personal use. To download, listen, and organize MP3 songs, a software application called the audio player is required. In fact, many audio players are available free of charge on the Internet. Like other e-retailers, EMusic also uses an affiliate scheme to attract new customers or subscribers.

Selling Banking and Account Aggregation Services: Ascencia Bank and Yodlee

Besides selling tangible goods (e.g., books and flowers), the Web is also suitable for supporting different types of services (i.e., “intangible goods”) such as consumer banking services. In recent years, nearly all conventional banks have introduced supplementary Internet-based banking services. At the same time, a number of cyberbanks have been established that only serve their customers through the Internet (i.e., they do not have any physical branches). Nevertheless, they can still provide a wide range of banking services. Because they do not need to maintain any physical branches, significant operating costs can be saved, thus they can usually offer better interest rates than traditional banks. In fact, this is one of the key selling points of the cyberbanks. A U.S. cyberbank, Ascencia Bank (http://www.ascenciabank.com), serves as an example here. From the perspective of the services it provides, Ascencia Bank is almost the same as a conventional bank except that all banking services are provided via the Web or telephone. In particular, like other conventional banks, deposits up to a certain amount is protected (i.e., insured). Different types of bank accounts, such as personal and business accounts are available. Through a Web browser, users can check their account statements and transfer money at any time and anywhere. Of course, information access is protected by means of a username and password and other Internet security techniques (e.g., secure socket layer, discussed later). If a user has several bank accounts, he/she can access them through a single interface. Other services provided by Ascencia Bank include online investment (e.g., buying and selling stocks) and bill payment. In terms of help and communications, users can contact the bank by phone, e-mail, and fax.

A number of account aggregators, such as Yodlee (http://www.yodlee.com), have emerged in recent years (Deitel et al., 2001). These services allow users to access multiple bank accounts (even accounts from different banks) in an integrated manner via a single interface. In fact, Ascencia Bank also provides this aggregation service in cooperation with Yodlee. The basic operation is as shown in Figure 3. After authentication, the account aggregator serves as a proxy to get the information from the required banks for the user. The information is aggregated and possibly processed before being displayed to the user. Obviously, this service offers some advantages to consumers. It also presents a security issue, however, because users need to release sensitive personal information (e.g., account passwords) to the account aggregator for authetication purposes.

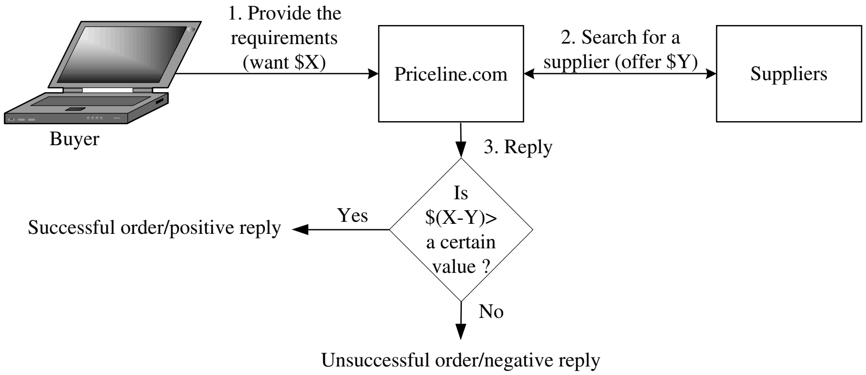
C2B E-commerce

The traditional retailing model is seller-centric, which means that the consumers need to find out what each seller can offer. With the advent of the Internet, a buyer-centric model becomes feasible. In contrast to the seller-centric model, in the buyer-centric model each seller needs to find out what the consumers want. A representative example is Priceline.com (http://www.priceline.com), which provides a “name your price” service (or a demand collection service). For illustration purposes, the basic operation of the service is shown in Figure 4. Imagine that a traveler wants to book a five-star hotel room in a city. To use the service, he/she should provide the booking information and, most important, the desirable price. He/she also needs to provide a credit card number for payment. According to his/her requirements, Priceline.com searches for a hotel (supplier) that can satisfy his/her needs while fulfilling the required profit margin. Upon finding the supplier, Priceline.com gains the price difference as a service charge. If such a supplier cannot be found, a negative reply is returned to the consumer. The basic rule in using the service is that once a supplier is found, the buyer cannot refuse it (i.e., no objections and no refunds) and the credit card provided by the consumer will be charged. The products sold by Priceline.com have a special price–time relationship. Basically, the suppliers are operating with a high fixed cost but a relatively low variable cost. Furthermore, if a product cannot be sold before a certain deadline, the resource will be wasted (e.g., a vacant hotel room). For this reason, the seller may be



1. Provide the requirements (want $X)
Priceline.com
2. Search for a supplier (offer $Y)
Suppliers
Buyer
3. Reply

willing to accept an extremely low price—one much lower than the normal price but that is sufficient to cover the variable cost and perhaps part of the fixed cost. Apart from reserving hotel rooms, Priceline.com also sells other products including airline tickets and even home mortgages using a similar mechanism (i.e., the name-your-price approach).

C2C E-commerce

eBay (http://www.eBay.com) provides a Web-based auction service for consumers to trade goods, especially preowned goods, among themselves. Traditionally, classified advertisements are a common channel for selling used goods among consumers. Using Internet technologies, eBay offers an alternative and more effective solution. The basic operation is shown in Figure 5. To sell something, a seller initiates an auction by providing the required information. Buyers can search for the items they want and then bid for them. In most situations, the English auction method is used. This means that the buyers keep on bidding before the deadline; the buyer with the largest bid price gets the goods. For the English auction method, the bidding information is announced so that any interested buyer can easily check the latest bid and the bidding history. Based on the bidding information, a buyer can decide whether to submit a bid.

Besides product information, buyers can also check the track record of a seller, which is based on ratings provided by successful bidders having bought something from the seller. This feature is particularly useful, because in most cases buyers do not know the seller. In the simplest service, eBay only acts like a middleman to facilitate the consumer-to-consumer trading process. Upon completing an auction, the auction result is sent to the seller and the successful bidder by e-mail. Subsequently, the seller and the successful bidder need to make further arrangements to complete the deal (e.g., arrange delivery and payment). In terms of revenue, eBay gains a commission for each auction. As an additional service, eBay also provides an Internet-based payment method through PayPal (an associated company), which allows the seller and successful bidder to handle the payment on the Internet. Similar to many other auction sites, eBay also offers an escrow service. With this service, the successful bidder can pay the seller through eBay, but the seller will not get payment unless the goods have been delivered according to the agreement. Besides the English auction service, eBay also supports other auction methods (e.g., Dutch auction), and it provides specialized auction services (e.g., for selling motor cars) and live auction services.

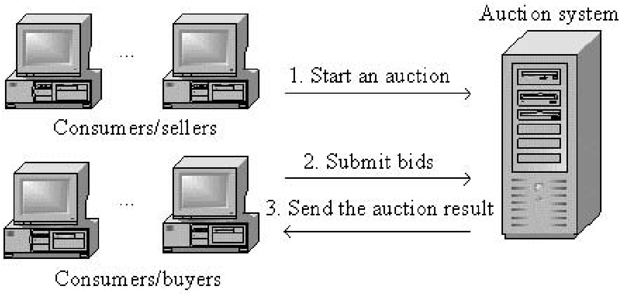

Figure 5: A consumer-to-consumer auction service.

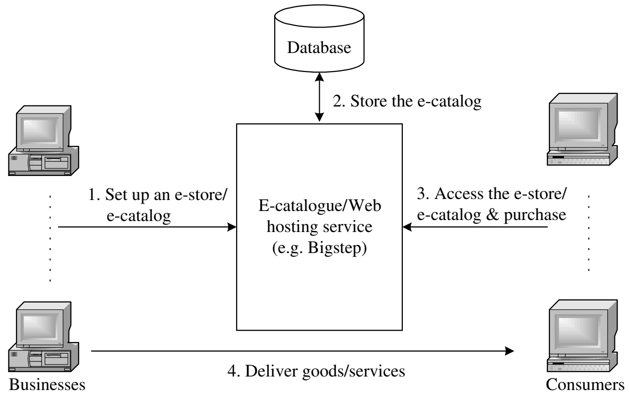
In fact, eBay provides not only Web-based auction services but also a consumer-oriented community. At eBay, consumers can chat with each other in the online chat rooms and participate in many discussion groups covering various topics. All these community-oriented features aim at enhancing the stickiness of the Web site and strengthening customer loyalty. Apart from the auction services, eBay also has an associated company called Half.com, which allows consumers to sell used goods at a fixed (low) price instead of using an auction.

Supplementary Services

Other supplementary services exist to support consumer-oriented e-commerce. Two examples are e-marketing services (e.g., direct e-mail services) and e-catalog or Web hosting services. In the following sections, two case studies are presented.

E-catalog/Web Hosting Services: Bigstep

In general, small companies and home businesses may find it difficult to develop their own B2C Web sites from scratch. Fortunately, they can still enjoy the benefits of e-commerce through the use of Web hosting services provided by companies such as Bigstep (http://go.bigstep.com). In particular, these services help



Database

small companies and home businesses to set up a Web site and an e-catalog cost-effectively by following standard procedures.

Figure 6 shows an example of the Bigstep service. By paying a monthly charge, a company can build a B2C Web site and then host it at Bigstep. Through the Web site located at Bigstep's server(s), the company can receive customer orders. By using the hosting service, companies can concentrate on their core businesses because their B2C sites are maintained by experts. To develop an e-catalog, a user can choose a store template together with other design parameters. It can be customized with descriptions and images, and so on. More sophisticated users can even add their own client-side programs (e.g., Hypertext Markup Language and JavaScript codes). Apart from providing a service for setting up a basic e-catalog, Bigstep also provides users with other e-retailer features, such as shopping carts, ordering handling facilities, and e-mail functions. In addition, users are provided with various reports to evaluate business performance and to understand the customer buying behavior. Bigstep also helps its users to market their e-stores by sending electronic newsletters to consumers and registering the sites with popular search engines. To a certain extent, Bigstep functions like a traditional shopping mall because it allows companies to set up independent e-stores at a centralized location. Note, however, that unlike a traditional shopping mall, e-stores can be set up by companies at different locations around the world.

Direct E-mail Services: Digital Impact

To become a successful e-commerce company, it is important to build a strong brand in cyberspace (Carpenter, 2000) and to use a wide range of marketing services to promote goods or services to the consumers. One of the effective marketing services is direct e-mail. There are three types of companies associated with direct e-mail services as described in Deitel et al. (2001). First, companies such as PostMasterDirect (http://www.postmasterdirect.com) keep recipient lists by encouraging consumers to register for inclusion in their database. Second, companies such as Digital Impact (http://www.digitalimpact.com) help businesses to implement direct e-mail programs. Third, supplementing text-based e-mails, some companies such as Avalon (http://www.mindarrow.com) provide multimedia attachments (e.g., animated demos and digital videos).

As an example, the service provided by Digital Impact is presented as follows. Direct e-mail is a focused (one-to-one) marketing technique). (See the white papers at http://www.digitalimpact.com for details, particularly Digital Impact, n.d., cited in the reference list.) Figure 7 shows the basic concept. A business first initiates an e-mail campaign by providing the marketing requirements. According to the requirements, Digital Impact prepares the promotional e-mail and the recipient list with the assistance of a database. The e-mail, possibly with multimedia attachment(s), is sent to the recipients. Interested recipients then visit the business's Web site through the link in the e-mail. It is hoped that some of the visitors will make a purchase. Moreover, the business can potentially identify each customer through the e-mail link and monitor his or her behavior. For example, the business may find that a particular customer is interested in some products. This information would allow the business to send customized e-mails to that person in the future. To enhance the effectiveness of a campaign, each e-mail usually provides an easy-to-use forwarding function to encourage the recipients to forward the e-mail to other people.

ENABLING TECHNOLOGIES FOR CONSUMER-ORIENTED E-COMMERCE

There are basically five technical building blocks for consumer-oriented e-commerce systems: communication infrastructure, programming languages, security techniques, payment methods, and other supporting technologies (Figure 8). An overview of these technologies

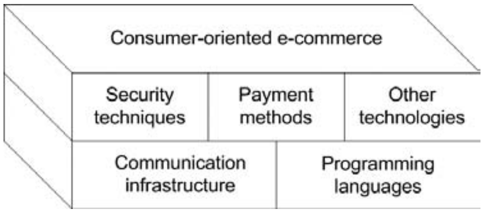

Figure 8: Technical building blocks for consumer-oriented e-commerce.

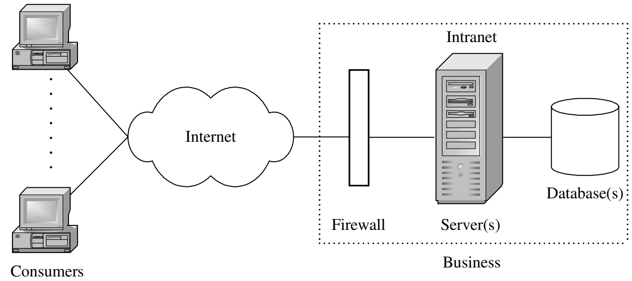

Figure 9: Basic system architecture for consumer-oriented e-commerce.

can be found in Chan et al. (2001). Currently, the World Wide Web provides the basic communication infrastructure or framework for supporting consumer-oriented e-commerce. As illustrated in Figure 9, a consumer accesses a Web server through his or her Web browser using the Hypertext Transfer Protocol (HTTP). The client interface is formatted based on the Hypertext Markup Language (HTML). On the server side, various programs (e.g., written in Active Server Page, Java Server Page, Java Servlet, etc.) are available to enable a server to interact with the clients, as well as with backend databases. Essentially, these server-side programs are used to generate dynamic Web pages in general and customized e-catalogs in particular. Note that in many cases, "cookies" (i.e., client-specific data or information transferred from the client-side to the server-side) are used for tracking sessions so that a server can send customized responses (e.g., customized e-catalogs) to clients.

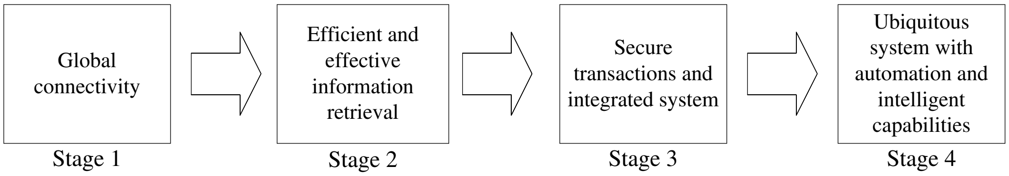
Obviously, security is extremely essential in e-commerce. With the advent of various security technologies, secure transactions can now be conducted over the Internet. These security technologies include encryption techniques to safeguard data confidentiality, digital signature methods to ensure data integrity, and the digital certificate framework to support authentication (Stallings, 1999). Gathering together various security technologies, a number of protocols have been developed to address security requirements. In particular, the secure socket layer protocol is designed to protect the transfer of sensitive information (e.g., credit card information) between a client and a server. Firewalls are typically used to safeguard an Intranet against external security attacks (see Figure 9). For business-oriented e-commerce, Internet Protocol Security (IPSec) protocol is employed to set up virtual private networks (VPNs) for securing inter-business transactions.

Payment is an important function for supporting e-commerce. At present, credit cards are the most popular payment method for consumer-oriented e-commerce. With the support of major credit card companies, an application protocol called Secure Electronic Transaction (SET) has been developed for secure credit card payment over the Internet. Besides using credit cards, electronic cash protocols and electronic check systems are also available to emulate physical cash and check payments on the Internet, respectively. Apart from the traditional payment methods, a number of micropayment schemes are being developed to process low-value transactions, such as paying a few dollars to see a short video. Details of these payment solutions can be found in (O'Mahony, Peirce, & Tewari, 1997).

Last but not least, a number of supporting technologies are becoming increasingly important in e-commerce. For instance, software agents are used to facilitate searching and negotiation (see the next section). Many electronic customer relationship management systems make use of data mining and artificial intelligence techniques to make e-commerce more intelligent and user-friendly. The eXtensible Markup Language (XML) has been developed to facilitate information exchange, searching, and data presentation.

FUTURE DEVELOPMENTS OF CONSUMER-ORIENTED E-COMMERCE

Inspired by some of the ideas presented in Chan et al. (2001) and Hartman and Sifonis (2000), the development of consumer-oriented e-commerce can be divided into four stages (Figure 10). In the first stage, the Internet allowed global connectivity, thus forming a global entity and facilitating effective and efficient communications (e.g., using e-mails and File Transfer Protocol). In the second stage, the invention of the World Wide Web allowed efficient information retrieval over the global Internet. In this early stage of e-commerce, most companies only employed the Web for publicity purposes because purchase orders could not be taken securely. The third stage overcame this limitation by supporting secure transactions over the Internet. Furthermore, it also allowed the integration of Web systems with existing information systems and business processes. It is expected that the last stage will be a ubiquitous and fully automated e-commerce system that is created by integrating the existing e-commerce systems, mobile computing technologies, and software agents. Generally, the existing e-commerce systems allow consumers to search for information easily and make purchases conveniently. The last stage tackles two remaining problems: automation and mobility. The following paragraphs highlight the current developments in these two areas.



Global connectivity
Stage 1
Efficient and effective information retrieval
Stage 2
Secure transactions and integrated system
Stage 3
Ubiquitous system with automation and intelligent capabilities
Stage 4

Figure 11: Business-to-consumer and consumer-to-consumer MAGICS (Mobile AGent–based Internet Commerce System). (Adapted from Chan et al., 2002 and Ho & Chan, 2002.)

It is expected that software agents (or simply agents) will become important in next-generation consumer-oriented e-commerce systems (Moukas, Zacharia, Guttman, & Maes, 2000). Generally, agents are self-contained software programs that can perform specific tasks for human users. Because of their autonomy and communication capabilities, they are particularly suitable for assisting the consumer buying process. Early agent-based systems typically address the search and evaluation stages of the consumer buying process. In recent years, advanced agent-based systems have also been developed to handle more complex tasks, such as carrying out negotiations and even completing a sale transaction. Some examples include Tete-and-Tete and Kasbah (Moukas et al., 2000). In Kasbah, for instance, a seller or buyer can use a mathematical function to control how the selling or buying price should vary with time. Using the price–time functions, the selling and buying agents can negotiate with each other accordingly. There has also been considerable interest in investigating mobile agent-based systems (Lange & Oshima, 1998). Mobile agents can move around the Internet to complete the assigned tasks. Effectively, they can travel in cyberspace, like humans walking in a physical place. Three examples of mobile agent-based e-commerce systems are Nomad (Sandholm & Huai, 2000), MAgNET (Dasgupta, Narasimhan, Moser, & Melliar-Smith, 1999), and MAGICS (Chan, Chen, Dillon, Cao, & Lee, 2002).

Here we take MAGICS (Mobile AGent–based Internet Commerce System) as an example, which is being developed at The Hong Kong Polytechnic University. Inspired by various agent-based e-commerce systems, particularly Kasbah, Nomad, and MAgNET (please refer to the respective references), MAGICS currently provides two subsystems for B2C and C2C e-commerce. For the B2C MAGICS (see Figure 11), the buying process is summarized as follows based on the description in Chan et al. (2002). To use the service, a consumer connects to a special server through his/her Web browser or a mobile terminal (e.g., WAP phone). According to the buyer's requirement(s), some mobile agents are sent to look for the required goods and visit the e-retailers. The responses are then evaluated in accordance with the specified requirement(s), such as price. Finally, a buying agent is sent to the selected e-retailer to buy the goods. In addition to this shopping system, we are also working on C2C MAGICS, a mobile agent–based auction system (see Figure 11) (Ho & Chan, 2002). In this case, a consumer can create a mobile agent (or more than one), give it a bidding strategy, and then send the agent to the required auction server(s) to conduct the bidding. If several auction agents are generated for bidding at different servers, the agents may also coordinate the bidding themselves. In some advanced agent-based systems, it is even possible to create an intelligent agent that can learn about certain characteristics of its owner's behavior. This learning capability can be used to create many, more intelligent e-commerce services.

As mentioned earlier, another development in consumer-oriented e-commerce is to support mobility and ubiquitous access. Because mobile terminals and wireless networks have many limitations in respect of terminal capability, bandwidth, and so on, the existing Web system and protocol cannot be employed directly in the wireless environment (Mann, 2000). To build a mobile commerce system, it is necessary to address three fundamental issues. First, a high-speed access protocol is required for mobile terminals to utilize the wireless channel effectively and efficiently. Currently, mobile phone services are mostly supported by means of time division multiple access and frequency division multiple access. In the next generation mobile communication systems, a new technique called code division multiple access is likely to be used for supporting multimedia communications. Second, a simplified version of HTTP is required to allow mobile terminals to access a Web server through a proxy gateway. The Wireless Application Protocol (WAP) is devoted to this purpose. (See Mann [2000] for details). Third, a mini-version of HTML is needed to present Web or WAP pages on mobile terminals with tiny screen sizes. Currently, this is achieved by using the XML-based Wireless Markup Language. By employing these and other enabling technologies, various mobile commerce applications can be developed. Some examples include the following (Ahonen, 2002; Kalakota & Robinson, 2002; Turban et al., 2002):

Information inquiry—consumers obtain information to facilitate product comparison (e.g., inquire about product prices).

Location information—consumers get location information such as someone's location.

Mobile messaging—consumers read short messages through wireless terminals.

Mobile payment—a mobile terminal can function as a mobile digital wallet for payment purposes.

Mobile purchase—consumers carry out a sale transaction through pocket personal computers (e.g., buy a digital film ticket and even store the ticket in the terminal).

Multimedia entertainment—a typical example is the buying and playing of multimedia games through wireless terminals.

By combining mobile computing technologies and mobile agents, more innovative and useful consumer-oriented services can be provided. For instance, imagine that a mobile consumer needs to buy a film ticket as quickly as possible. He/she can create a mobile agent at his/her mobile terminal and then send it to the Internet to purchase the ticket in order to see the film at the closest cinema. Note that the buying process is fully automated because the agent can identify the consumer's location through a location tracking system and then search for the potential cinemas via other agents or search engines. (See Moukas et al., 2000, for similar examples.)

CONCLUSION

This chapter has provided an overview of e-commerce in general and consumer-oriented e-commerce in particular. With the aim of selling different goods and services on the Internet and facilitating the consumer buying process, many consumer-oriented e-commerce models have been developed. These e-commerce applications can provide many benefits to both consumers and businesses. To implement various consumer-oriented e-commerce applications, a client-server architecture is used, and the technical building blocks include communication infrastructure, programming languages, security techniques, payment methods, and other technologies. It is predicted that the current e-commerce system will evolve to a ubiquitous system that offers more automation and increasingly intelligent functions.

ACKNOWLEDGMENTS AND NOTE

This chapter was supported in part by a Competitive Earmarked Research Grant from the Research Grants Council, the Hong Kong Special Administrative Region, China under account number PolyU 5078/01E and by the Department of Computing of the Hong Kong Polytechnic University under account number 4-Z006. We thank Ms. Irene Ho, Mr. Peter Meldrum, and Ms. Perry Lam for their help in the preparation of this chapter. We also thank the reviewers for their valuable comments. Note that the trademarks and service marks mentioned in this chapter belong to their respective companies or owners. They are only used for identification purposes.

GLOSSARY

Account aggregators A system that allows a user to handle several accounts (e.g., various bank accounts) via a single (and possibly customized) interface.

Affiliate scheme A commission-based marketing technique for a business to refer its visitors or customers to another business over the Internet.

Auction A dynamic pricing technique for facilitating a sale transaction.

Business-to-consumer (B2C) e-commerce One type of e-commerce involving the sale of goods or services from a business to a consumer.

Consumer-to-consumer (C2C) e-commerce One type of e-commerce involving the sale or purchase of goods among consumers.

Consumer-to-business (C2B) e-commerce A buyer-oriented e-commerce model enabling a business to provide a customized solution to satisfy a consumer need.

Cookies Client-specific data or information forwarded from a Web client to a Web server (e.g., for generating a customized response).

E-commerce Sale and purchase of goods or services by electronic mechanisms in general or over the Internet in particular.

Extensible Markup Language (XML) A general markup language for users to specify their own tags.

Hypertext Markup Language (HTML) A markup language for formatting or showing Web pages by employing standard tags.

Hypertext Transfer Protocol (HTTP) A request/response protocol for supporting the Web system.

Internet Protocol Security (IPSec) A security mechanism for the Internet protocol (IP) to support data confidentiality and/or data integrity.

Mobile agent A mobile software program which moves around the Internet to complete a predefined mission automatically.

Micropayment methods Payment methods for processing low-value transactions.

Secure Electronic Transaction (SET) An application protocol for secure credit card payments over the Internet.

Secure Socket Layer Protocol A transport layer security protocol typically for protecting the connection between a Web server and a Web client.

Software agent A special computer (software) program capable of completing a mission in an autonomous manner.

Wireless Application Protocol (WAP) An application protocol for a mobile/wireless terminal to access a Web server through a gateway.

Wireless Markup Language (WML) A simplified version of HTML for showing Web (WAP) pages on mobile or wireless terminals (e.g., mobile phones).

Convergence of Data, Sound, and Video

Gary J. Krug, *Eastern Washington University*

INTRODUCTION

In recent decades, video, data, and audio material have become increasingly combined into new forms that are more than the sum of their parts. This convergence of different forms of representation is made possible by many technological and social factors including the emergence of new technologies, a deregulated telecommunications industry, and a growing consumer, corporate, and institutional interest in multimedia. Many universities, museums, and corporations now include multimedia (including three-dimensional effects, animations, sound, and video) on their Web sites, and multimedia compact discs (CDs) are increasingly distributed either in place of or in conjunction with printed promotional materials. With increasing sales of digital video and still cameras, flatbed scanners, and inexpensive video, imaging, and audio editing software, multimedia production and deployment are becoming commonplace for many computer users. There remain limitations, however, to the development and spread of multimedia, and the social effects of multimedia use and deployment remain largely unknown.

Only with the advent of CDs, relatively high-speed dial-up connections, and broadband did the merger of data, sound, and video become possible on the personal computer, thus providing the most ubiquitous form of multimedia. This is changing, however, for multimedia has begun to appear in wireless forms as well. Increasingly, cellular phone systems are converging with graphic uses such as text messaging and Internet access. Both new digital phones and the hybrid personal digital assistants (PDAs) incorporate aspects of the personal computer with telephone technology. Corporate collaborations such as that of Verizon Wireless and Microsoft to provide wireless data services to telephone customers will further the development of this convergence, although it is unlikely that wireless will in the short term displace other forms of multimedia delivery. Nonetheless, such delivery systems may make these forms omnipresent in everyday life, delivering e-mail and Web sites as well as advertising wherever one is. A more likely outcome is that wireless services will function as supplementary forms to other multimedia uses extending the use multimedia into new contexts. The current deployment of 3G (third-generation) wireless telephony is driven largely by its ability to provide these functions and services.

Convergence

The convergence of data, sound, and video brings together different forms of information into an integrated, multimedia construction. The advantage of providing these three dimensions of sensory experience at one time is that a depth of information about a topic may be experienced in a single page or demonstration. These additional forms of representation may convey more information about the writer's thoughts or attitudes, or they may provide information not easily described or related in writing. For example, some limitations of writing, and hence of purely textual information, have historically been the lack of clues about authorial intention and the emotional inflection of the words and phrases that appear in the text. These additional dimensions of the communicative act must be inferred through contextual clues. An equivalent of this contextual information may be given in video or audio forms or through other frameworks that create a relationship between the reader and the text so that particular understandings of the text are more likely than others. Such information stands in addition to traditional textual framings that also contribute to the way in which a text is read and understood by readers. These traditional framings, such as a knowledge of the author, an expectation of the genre, and previous experience with a publisher, to name a few, give the reader clues about whether a particular work is fiction, science, news, and so on and thus influence the range of possible meanings that the reader may construe.

Multimedia information may thus facilitate some communication by allowing for the inclusion of additional contexts for communication. Some kinds of complex information are best conveyed in images and illustrations, and the accompaniment of video within a text delivers a high density of information that may elaborate the intended message of the written text. Whereas print has long been able to produce illustrations, pictures, and diagrams to accompany textual material, early digital media did not. The subsequent accompaniment of text with sound and video in addition to images requires a reexamination of the relationships between various media as well as a reconsideration of what a text is and how it functions within larger semiotic systems.

Multimedia formats for creating electronic pages, especially those deriving from HTML (hypertext markup language), are often referred to as being "interactive" media because the viewer has some choice in controlling what parts of the multimedia are presented and the order in which this presentation occurs. The word interactive is a misnomer, however, implying that one has a degree of control over the content of the message, that is, that the message is in fact changed or created by the viewer. Meaning is not so indeterminate in most multimedia presentations. As noted earlier, various other technologies within the text, as well as the reader's experience with prior texts, overdetermine the general frame in which the text is read and thus guide the reader to a preferred meaning of the text. In many settings, the "interactive" aspect of media is completely subsumed by the form of the text itself: Short, clear, and immediately conveying the intended message, the multimedia page often discourages ambiguity and multiple interpretations.

MULTIMEDIA IN THE CONTEXT OF REPRESENTATION

Multimedias contribute to the creation of virtual worlds, that is, representations of real or imaginary places complete with images, video, and sound. In this way, they may present varying degrees of verisimilitude of the real. One may thus have a virtual visit to another place or time. This may be helpful for people considering a move to a city, company, or school that they have never visited. When using multimedia for these sorts of virtual visits, however, one should remember that the materials presented are selective and most certainly are designed to present the best possible face. That is, all productions are engineered to produce a specific effect and to guide the viewer or reader to a specific subjective experience of the text and so to some specific meaning, attitude, or relationship to the presentation.

The history of media in general is also the history of divergences and convergences of different modes and formats of representation. Painting and music existed in social and cultural contexts that guided the person experiencing them toward particular kinds of meaning: For example, a painting in a museum is a work of art, whereas a painting on a wall is an act of vandalism. With telecommunications, the contexts of communicative forms are often missing from the message. Multimedia create new contexts through associating aspects of the message with other media forms. A work of music accompanying a text will alter how the meanings of the text are made. Almost from its earliest days, film has exploited the semiotic relationship between sound, music, image, and narrative to achieve specific ends.

The elements of a multimedia construction together constitute something new that is more than the sum of its parts. Text, music, images, and video create a field of representation in which each combines with the others to create a larger impression that in turn adheres to the topic of the multimedia presentation and colors the entire experience. As such, a study of multimedia should include an examination of earlier attempts to integrate sound, visual effects, and even live action, as in opera, ballet, and theater. In appearing with text, however, the multimedia construction borrows as well from some conventions of reading and writing while introducing aesthetic traditions and grammars of sense-making from the video, filmic, and photographic conventions. The relationship between multimedia and other forms extends beyond simple layout and page design and already is creating new forms for each of these constituent elements as well as new experiences of reading and creating multimedia texts.

All forms of representation—writing, pictures, diagrams, video—are limited in what they can convey and in the sorts of messages that can be inferred from them. Furthermore, the function of some representations is not to communicate some specific information but to serve what James W. Carey (1991) called a ritual function, that is, providing some part of the mundane background of shared everyday life. This view of communication and media is shared by Luhman (2000). Beyond the phatic dimension of communication, ideological functions contribute to the formation of subjectivities of identity by presenting templates for normative forms of class, race, age group, gender, and so on. As multimedia grows in popularity and as large corporation increase the use of multimedia in cross promotion of products and services, a greater conventionality of presentation will emerge, and these conventions will become associated with the representations of corporate products. Thus, the whole of the primary aesthetic of multimedia may well become standardized in the forms of advertising and public relations.

TECHNOLOGIES

In assessing the growth of multimedia, it is important to understand that technologies do not in themselves create new fields and activities. Rather, technologies emerge into specific forms based on the culture and time in which they are developed. Much of the computer revolution is an offshoot of research and development in military applications, and this applies as well to technologies associated with multimedia. This historical and cultural grounding of media suggest as well that the uses to which new technologies are put are also influenced by the social and cultural settings into which they emerge. The relationship between technology and the social is not determined by either but arises from the relationship they form with one another.

Jacques Ellul noted that "Each new machine disturbs the equilibrium of production; the restoration of equilibrium entails the production of one or more additional machines in other areas of operation" (1964, p. 112). Equilibrium is, however, never established. Technology leads to the endless displacement of existing practices in the constant introduction of new devices and their use, but, as with the promise of the "paperless office," the expected goal is seldom achieved. For example, the introduction of the computer unleashed unprecedented amounts of information into the social world. This necessitated the establishment of systems for exchanging information (the Internet, local area networks, etc.). The proliferation of information managers and workers in turn created a need for simpler, more user-friendly interfaces, and so on. Each material development of a technology creates the need for subsequent machines, devices, and technologies, and each of these in turn influences changes in the manner and form of the workplace, the relations of workers to the job, to each other, to the institution, and so on. Technological change thus appears as an ongoing renewal and recreation of the world, but technology also comes to appear as an autonomous force in the world.

The following history briefly touches on some of the key components and moments in the development of digital multimedia.

History: Phones, Photographs, Video, and Television

Data in the form of digital telegraphic signals was the first electronically transmitted information. Patented in 1839, the telegraph established the pattern for subsequent communication system deployments, quickly becoming important in domestic and international politics and business in the industrialized nations. Before the American Civil War, there were already attempts at laying transatlantic submarine cables, and by 1872 the British had successfully linked their Australian holdings to England with telegraph lines. Major international rivalries developed over telegraph monopolies, particularly between England and Germany in the late 19th century. At the time, there was considerable expectation that these electronic linkages of people as well as other advances in communications, such as the Penny Post (1840), would unify the world and usher in a new age of peace and universal understanding.

Neither the amount of communication nor the speed at which it took place could produce the shared values and understandings necessary for a utopian world, but communications did establish linkages between economic markets. Among the great successful commercial applications of telegraphy was the ticker tape that conveyed stock prices from major markets to subscribers at speeds approaching real time transmission. While this technology centralized and linked markets together, it also made possible sudden shifts in the market by speeding up trades, and the increased speed may have contributed to the emergence of trading in futures.

Despite its popularity with business and governments, telegraphy remained a technology with which most people would have little direct contact. The telephone would be the first technological system to reach into the homes and lives of ordinary people, and although the basic device was demonstrated by the middle of the 19th century, it did not become commonplace until the 1900s. Telephone technology developed rapidly, creating the physical infrastructure of main lines, switchboards, and drops to individual homes and offices. By the 1930s, rotary dial telephones were introduced making automatic mechanical switching of telephone calls possible and beginning the automation of the system, eliminating the manual connection of calls by operators.

Photography emerged in 1839 with the metal plate process developed by Niepce and Daguerre in France and the paper negative calotype developed by Talbot in England. Bayard, another Frenchman, also developed a paper negative system at the same time. Although high-quality permanent images could be made by both processes, no inexpensive means of producing large numbers of copies existed until the 1870s. As such, photography was limited in its uses and dissemination. Although illustrations had accompanied text from at least late antiquity or early medieval times and woodblock printing was widely used, photographic reproduction did not commonly appear in books until the late 19th century. Among the early publications were Charles Darwin and O. G. Rejlander's *The Expression of Emotions in Man and Animals* (1872) and John Thomson's *Street Life in London* (1877). These works, and other uses in fields such as astronomy and biology, demonstrated that photographic images and written words in combination could convey scientific observation as well as social commentary in more powerful forms than had previously existed.

The use of the apparently "genuine" image created a new sense of verisimilitude of pictures: A photo does not lie. Over time, however, the proliferation of images as well as photographic effects (for example, multiple exposures) undermined the credibility of the medium itself. Nonetheless, photography exerted powerful social effects. Darwin's book marked the beginning of a tradition of presenting the empirical evidence of science in images which the text expanded and commented on. Thomson's works stood at the beginning of a tradition that would develop into the social reform movements and muckraking journalism and so influence social development by conveying in realist detail the lives of the poor. Additionally, photography made affordable for many people the individual and the family portrait.

Moving images were first developed in the 1890s and enjoyed immediate popularity worldwide. The motion picture extended the illusion of verisimilitude across time: Movies portray not a frozen, fixed moment but a duration or span of time. Sound was synchronized with the images in the 1920s, becoming widely used in the 1930s and 1940s, and color film began to be widely used during World War II. Still dependent on film stock and projectors, however, moving pictures were largely confined to the social spaces of cinemas. Home movies in the popular 8-mm format were limited in resolution and short in duration, and most home film equipment was silent.

Although some advances were made in the 1920s and 1930s, it was not until after World War II that electronic transmission of sound combined with video became viable. Philo Farnsworth and Vladimir Zworykin demonstrated the technology for capturing and transmitting images electronically in the 1920s, and in 1939 public broadcasting began in the United States. Interrupted by the war, commercial television broadcasting on a large scale began in the in 1947.

Television began the domestication of video, bringing it out of the theater and into the home. Television, itself incorporating several existing technologies, would prove to be one site on which further technologies would converge. One of the most significant was the development of the VCR. First released commercially by Ampex in 1956, the video tape recorder (VTR) underwent several refinements on its way to becoming the video cassette recorder. Although Sony had experimented with home use VTRs, Philips introduced the first VCR for home use in 1972, and by 1977 the VHS system was marketed. In the following decade, the VCR exploded in popularity, and for the first time, television could be recorded and edited. The VCR introduced wholly new practices to video watching such as time shifting, that is, watching broadcasts at later times. This practice enabled another: recording one channel while watching something else. To the dismay of advertisers, this technology also allowed people to engage in "commercial zapping," that is, fast-forwarding through commercials.

Capturing two or more channels simultaneously became more important as cable television became a major mode of distribution increasing the number of available channels and fostering the growth of niche market programming. Although CATV (community antenna television) had been in use since the late 1940s, it was not until the 1970s that satellite links to cable delivery became widespread. This new system not only greatly increased the number of channels available but also produced the infrastructure for broadband terrestrial delivery of television and other services. Video on demand (VOD) and other forms of pay-per-view systems restructured the television industry, and, as television distribution became increasingly digital, other convergences of technology would produce both new industry practices and new ways of using the devices. In the 1990s, the television and the personal computer (PC) began to appear to be converging into one device.

Socially interactive systems, such as Qube TV, did not become popular for various reasons and have largely disappeared. Interactive television technology is now largely limited to the choice of product for consumption (such as pay-per-view) and the limited provision of textual information about a program. To date, television and PCs remain quite different devices, although the emergence of digital television fostered the rise of devices such as TIVO, which are capable of capturing and storing digital video for later playback to a television or for capture on a computer.

Television and its associated technologies did, however, introduce the moving image into everyday life and produced a level of understanding of both the grammar of the video form and the technology associated with it. Rather than being an occasional experience at the cinema, video became a significant part of everyday life as well as a major source of revenue for the motion picture industry. The Video Software Dealers Association reported that the videotape rental industry accounted for $7 billion in rental revenue in 2002. In comparison, DVD (digital versatile disk) rentals accounted for $1.4 billion in the same year.

Hardware Development

As early as the 1970s, researchers such as Douglas Englebart were exploring ways of using shared-screen telephone conferencing in conjunction with other computer technologies. Envisioned primarily as a tool for the workplace, these early forays into multimedia laid the groundwork for many subsequent developments in computing, and they contributed significantly toward the idea of making computers accessible and user-friendly. Many scholars have recognized the contribution of Vaneveer Bush and particularly of a piece Bush published in the *Atlantic Monthly* in 1945 entitled "As We May Think." In this work, Bush envisioned an integrated workstation which, using predigital technologies, would allow researchers to access vast stores of information and then store the cross-references, which he called "associations." Thus, a conceptual form of hypertext emerged while computers were still in their infancy.

Personal Computers

The growing use of increasingly powerful and versatile PCs capable of high-resolution image production combined with sound was driven, in part, by the popular videogame industry. Growing sophistication in software, sound, and graphics, quickly overwhelmed the limited storage capacity of 1.44-MB floppy disks and fueled the growing use of alternative storage media such as the CD and DVD.

The inclusion of images, sound, and video with textual materials did not become viable until various hardware and software criteria were met. Images and video are processor and memory intensive. Digitized, or sampled, music of high-quality creates large files. Thus, in the SOHO (small office, home office) and consumer markets, multimedia helped generate the demand for powerful processors, extensive video and system RAM, and large storage systems, especially hard disk drives (HDDs) and optical storage systems such as CDs and DVDs. In processors, the MM technology from Intel and the 3DNow technology from AMD incorporated special instructions into the processor's language enabling faster handling of image processing and video compression and /decompression. Apple Computer was also a major player in the development of image and sound processing equipment. As early as 1984, using the Motorola 68000 processor chip, Apple was establishing itself as a preferred platform for many video and graphics creators and users.

CDs and DVDs

The CD is a transportable, high-capacity storage system, holding about 640 MB of data on a standard disk. Developed by the Phillips Company in 1979 and initially released as a videodisk system, the audio CD was launched in 1983. The DVD is capable of holding up to 4.7 GB of data on each side of a disk. This means that about 133 minutes of high-quality video and sound or up to eight hours of music can be stored on a DVD. Advances in DVD technology are set to increase this to 17 GB or higher.

The CD remains a common multimedia delivery format, although increases in bandwidth continue to erode its popularity and shift delivery away from this last significant link to the physical medium. The CD format provided a significant improvement in transportable storage systems, enabling for the first time the distribution of large amounts of text and multimedia in a small and easy to use system. For the first time, traditional publications such as encyclopedias were no longer limited to text-based forms. Examples of music, high-quality images, animations, and fragments of historically significant video are now standard components of the multimedia encyclopedias. As such, the encyclopedia is becoming indistinguishable in form and in the ways that it is used from any other multimedia product.

Bandwidth

The limitation to large size, high-speed data transfer has traditionally been the scarcity of bandwidth in existing communications networks. In the early days of data transfer, 300 baud was satisfactory for simple exchanges. Images, however, even if compressed with "lossey" algorithms such as JPEG files, require large amounts of bandwidth relative to text. Files such as bitmaps, TIFF, and GIF files are even larger and require even more bandwidth to transmit. Current video transmission rates on most Internet providers are geared to what may effectively be conveyed over a 32-KB system. As a result, the frame rate and resolution are reduced, causing significant losses in smoothness and quality of image. As of 2000, about 80% of U.S. homes did not have broadband service, and little progress in rollout has been made in the subsequent two years.

The limitation of bandwidth was addressed by various multiplexing systems, beginning with frequency-division methods that gave way to time-division technologies. These significantly reduced the size of transmissions and enabled larger numbers of users to simultaneously share the same physical lines.

The development of a high-capacity backbone may be traced to the emergence of the L1 coaxial backbone in 1946. Coaxial cables greatly increased the carrying capabilities of telephone lines over copper pairs. As digital technologies multiplied in the 1980s and 1990s, a dedicated digital backbone for both voice and data was deployed using a combination of digital multiplexing over terrestrial lines, satellites, and microwave relay towers. These are now supplemented with fiber-optic cables. In 2000, global Internet capacity surpassed voice call capacity worldwide for the first time, demonstrating that data transmission requires design changes to the telecommunications infrastructure. One such change has been the development of MPLS (multiprotocol label switching) to allow the more efficient routing of data packets within Internet routing computers. This technology allows the sender of a packet to specify the priority to be given to a packet based on the needed QoS (quality of service) and may even specify some steps in routing the packet to improve speed. For example, data transmission may suffer pauses and slowdowns without the user noticing, but VoIP (voice over Internet protocols) and video would suffer noticeable gaps and unacceptable interruptions. Thus, with transmission of these sorts of data, the QoS demand will be higher, and the data packets will receive a higher priority in routing at each node of the transmission.

Further transmission technologies more suited to small, localized settings such as homes and small business continue to develop, examples being various DSL (digital subscriber line) technologies: ADSL (asynchronous digital subscriber line), VDSL (very high data rate digital subscriber line), and so on. New developments also offer the possibility of high bandwidth transmission through existing power lines and circuits.

Recent extensions of the fiber optic network such as the Southern Cross extension in Australasia and the FLAG (fiber-optic link around the globe) submarine cables have significantly increased data bandwidths and allowed the replacement of geosynchronous satellite relays, which produce a time lag in transmission, with faster, more reliable landlines. In addition to providing significant increases in bandwidth over satellite transmission, terrestrial cables are less affected by atmospheric and solar conditions and have fewer security problems associated with data interception.

The Last Mile

The great bottleneck in providing high-speed data services has always been what is called "the last mile" of the network. However advanced the data transmission backbone may be, the linkage between that source of high-density data transfer and the end user often presents problems. In many settings, population density is not high enough to justify extending the high-speed data connection directly to the doors of individual consumers, especially domestic consumers. Direct satellite connection is often a viable solution in these cases. Indonesia, which is an archipelago of many islands, was one of the first countries to exploit satellite technology as a telecommunication backbone. In other countries, a high population density combined with national interests in developing extensive digital communications technologies have engendered plans to upgrade delivery significantly. Singapore, for example, is rolling out fiber-optic cabling to nearly every home and office in the country and has achieved some of the highest rates of computer ownership and Internet use in the world.

Bandwidth remains an issue in providing data services over existing phone lines. Among the current systems for high bandwidth delivery within the U.S. are ISDN (integrated services digital network), DSL, and T1 lines, which use the existing telephone system, digital cable, and direct satellite. ISDN and T1 both require dedicated lines, whereas DSL uses a frequency division system of transmitting over the twisted copper wire pairs of a POTS (plain old telephone system). Although the speed of ADSL is related to the distance from the central switching unit, rates of data transfer in excess of one MB/s are possible. Other possibilities for the local loop include cable service which can offer digital speeds comparable to DSL. Although widely available, one drawback of cable modem service is that the bandwidth available to the individual user drops with increasing numbers of subscribers. Technologies are constantly being deployed, such as high speed data over ac power lines, which became commercially available in Scotland in 2003.

Within the United States, the loop between the individual user and the telephone switching office had been preserved by federal law and policy as a monopoly for local telephone companies. The Telecommunications Act of 1996 (Benton Foundation, 1996) deregulated this and other areas of the telecommunications market, allowing other businesses and corporations to compete in service delivery. Although technically allowing cable companies and even local utilities to provide telephonic systems to the home, to date few nontelephone companies have launched these services. The most successful nontelephone broadband service in the United States continues to be cable television. Most of Europe and many cities in the United States have established complete connection of digital telephone exchanges to local telephone service, however.

Overall, broadband has not been widely taken up in the United States. An estimated 70% of U.S. homes have broadband service available to them, but only 10 to 12% currently use such a service. Although there are an estimated 18.5 million DSL users worldwide, making DSL the most commonly used form of broadband access from home, this is a small fraction of the roughly 500 million personal computers estimated by the International Telecommunications Union to be currently in use (ITU, 2003).

Data Compression Technologies

One answer to the bandwidth problem has been the development of more efficient compression algorithms and, in some cases, hardware support for these. The Motion Picture Experts Group (MPEG) develops standards in video compression that also have applications to audio. Their standards are designated as MPEG and employ various algorithms and technologies for reducing the size of video and sound files. MPEG-1 is generally used in transmissions up to 1.5 MBS. MPEG-2 is the standard compression technology of DVDs and digital television. MPEG-3, also commonly known as MP3, enjoys great popularity as a music compression format.

According to some industry analysts, a predicted growth in broadband home access combined with new data compression technologies will enable a much larger deployment of video on demand over the Internet. Traditional media companies such as Disney, AOL Time Warner, and Viacom will look to Internet delivery of their programming to increase market share. At the same time, other companies will be looking to expand into delivering Internet services over televisions. Clearly the emerging convergence of traditional broadcasting and the Internet services will be speeded by the change from analog to digital television, and continuing convergences of technologies, corporations, and content will bring PCs and television closer together in the near future.

USES

In general, the convergence of technologies emerges in the context of changing alignments of social institutions. Lines between traditional corporations blur, as do the divisions between previously distinct genre and forms of information. The deregulated environment in the United States following the 1996 Telecommunications Act significantly increased the number of participants providing services and allowed companies to develop innovative combinations of services.

Rather than producing the diversification of service providers that was predicted by supporters of deregulation, however, the industry has seen a growth in consolidation and centralization of ownership through a series of large mergers, the most famous of which was the AOL–Time Warner Merger in 2001. This deal surpassed the previous record for communication corporation mergers set in 1999 by the Viacom takeover of CBS. Media companies are seeking to avoid being overtaken by emerging Internet services, and so it makes good corporate sense for them to become involved in ownership of online services.

As major media corporations become involved in online content delivery, those Internet content providers lacking the financial and content resources to compete find themselves marginalized on the Web. Furthermore, as traditional media giants extend their reach into the Internet, they are able to use Internet sites as promotional support both for other online material and for their broadcast, film, or video activities.

The end result is a corporatized internet promoting the goods, services, and values of major companies and their subsidiaries. Links on such pages are to other sites that typically are within the corporate family, and the material and advertising create a closed world of cross-promotional corporate content. The corporate term for this practice is “synergy.” However desirable synergy may appear to the corporate planners, from social and aesthetic points of view, such circular linkages limit content and choice.

New Organizations

News sites routinely incorporate multimedia materials into their Web sites. Traditional text and images are often liked to video or audio links providing additional commentary on news stories. Such multimedia linkages may bring together previously diverse corporate divisions, as in the case of the BBC news Web page (http://news.bbc.co.uk). Linkages to audio formats from BBC radio and video from the television division combine with text to provide different dimensions of the story derived often from differing styles of reporting.

The video used on such sites is generally in a streaming video format and thus has low frame rates compared with television. The videos are often jerky and with poor resolution. Nonetheless, the use of this streaming video technology is becoming more common in reporting from the field and was often used during the 2002 U.S. invasion of Afghanistan. Using cellular phones or satellite uplinks, reporters with personal computers and Web cams presented live video reportage from places with insufficient infrastructure and access to earth stations to support standard satellite uplinks.

Such reporting practices make clear that, just as the personal computer and the Internet made publishing a possibility for anyone with the equipment, so other activities, such as video reporting, are now technologically available to large segments of the population. The video camcorder spawned both new dimensions to news reporting, with amateur footage being used in news broadcasts of local, national, and international significance. From house fires to the Rodney King beating to the impact of the second plane into the World Trade Center on September 11, 2001, amateur video is becoming a significant supplier of news. Such content conveys the illusion that local or individual citizens have input into media narratives or forms, however. The opposite is increasingly true: Mass media create the aesthetics for home video and for much of multimedia.

The Entertainment Industries

In addition to news organizations, multimedia has allowed the development of numerous new corporate forms of the entertainment industry. One of the most significant corporate groups in pioneering new multimedia technologies and in commercializing the online services is the pornography and erotic materials industry. These companies were among the first to deploy secure payment systems and to use live Web cams and real-time streaming video. Adult sites draw significant percentages of Internet traffic and generate large amounts of profit, although estimates of the amount they contribute to total traffic are contested and difficult to verify. Nonetheless, it is clear that much of the popular technology of multimedia has been driven by the adult entertainment industry.

The future of the pay-per-view industry is probably foreshadowed in the history of the pornographic film deliveries. Recently, sales and rentals of adult erotic videos began to plateau, and on-demand television rentals and online rentals continued to grow. As quality and speed of delivery improve, it is likely that many people will begin to order other forms of video in this way rather than renting or purchasing VCR or DVD copies. With the penetration of DVD home recording, such delivery systems will grow in popularity as the transference of video from cable to homemade DVDs becomes as common as the burning of CDs. As with VCRs, MP3, and CDs, the use of home DVDs well undoubtedly trigger a round of debate and litigation regarding copyright issues.

Telecommuting and Teleconferencing

Telecommuting and teleconferencing have suffered from the same problems as other business areas: poor bandwidth, complex software, and a lack of consumer familiarity with the technology. Just as these barriers are being hurdled in video delivery, increased simplicity in software and growing high-speed connectivity are likely to make these uses of digital technology more commonplace. As video and audio quality in real time approach television standards, teleconferencing with video will become increasingly popular and more widely used, especially in business and education. Furthermore, many corporations are beginning to consider the need to incorporate broadband infrastructure into building design and renovation as the horizon of these technologies moves closer.

Many of the applications of converged video and text are already in growing use in education. Traditional methods of distance or mixed delivery mode course provision are easily supplemented with multimedia materials, either online or delivered on CD. Not only have remote classes, taught over CCTV, become more common, but with improvements in streaming video quality, two-way interactive classes taught over the Internet are likely to also grow in popularity. The screen compositions in such online classes increasingly feature integrated sound, text, and video. The trend toward this form of distance education is being fueled by a shrinking pool of traditional students, and growing competition among domestic and overseas universities. The technology is proving integral to the widespread Anglo-American establishment of degree programs overseas, particularly in Asian countries.

SOCIAL EFFECTS

Convergences of technology allow people to conduct conversations, meetings, classes, and other social activities even when they are not physically in the same place. They also challenge traditional ideas of what constitutes a text, how knowledge functions, and raise issues regarding the differences between the represented world of text and media and the physical world.

Glocalization

Glocalization is a contraction of “global” and “local” and indicates that a virtual environment may have some of the characteristics of being both decentralized and still connected to some central hierarchy. For example, telecommuting and other changes in workplaces undermine the traditional separations between home and office. Such changes have consequences for both the worker and for the company. The culture of the office or corporation, for example, is difficult to establish and maintain if people do not share the same physical environment and have some face-to-face interaction with one another.

At the level of the social, glocalization may contribute to the de-realization of the world. As representations of the world grow in number and levels of verisimilitude, the tendency is to accept that the representations are the world. In other words, the growth of virtual worlds may contribute to what Jean Baudrillard called “simulation,” that is, a social system of images and words that is endlessly self-referential without having any reference to a “real” world. In a similar vein, Paul Virilio (1997) writes that the virtual world displaces the sense of the real world, substituting itself for the real. The political and social implications of these two positions are numerous.

Increasing simulation of the real or providing a substitute for it may encourage people to alter the ways that they interact with the world and with other people. Online gaming, cybersex, and chat rooms have already shown that traditional social markers such as gender, race, and age are frequently changed by people who meet only in a digital environment. Identity itself may become more fluid as people change their digital persona to fit situations without reference to a known or widely recognized core self. As a consequence, virtues such as honesty and integrity, become more contextual and transitive. The digital world does not link identity the uniqueness of given localities in the physical world.

“Data Smog”

Data smog refers to the problem of sorting meaningful information from increasingly large amounts of material with which one is presented (Schenk, 1997). Visual and audio effects may add little of use to messages in some cases and may tend simply to create large amounts of noise or “data smog” by inflating information amounts without adding to meaning, context, or content. The proliferation of information both on a social level and at the level of the individual message create problems for the reader. It may be difficult to sort through the volume of information present to determine what is of interest and importance.

Too much information on a single page overwhelms the viewer or reader. It also increases download times and produces congestion, especially on intranets and wide area networks (WANs). The end result may be that the information page is too cluttered to be easily accessed or navigated. Without simple guides and menus, a page may require too much time to evaluate. This is especially true with multimedia pages that often reflect a greater interest in displaying the "bells and whistles" of the new technology rather than serving the needs and interests of the viewer.

At the social level, it is difficult to sort important information from the background of available materials. Traditionally, the organization of news and information was the job of editors, publishers, and librarians. They performed the gate-keeping function of selecting and presenting information. With the number of publications available online, however, additional filters and strategies for organizing materials are often needed. One consequence of the amount of available materials online is the growing sophistication and use of search engines with which people may locate their own news reports on topics of interest to them rather than relying on traditional news organizations. To date, most people continue to use the same news sources online as they do otherwise. Nonetheless, niche publications have proliferated as many costs associated with printing and distribution do not arise in online production.

Continuation and Extension of the Digital Divide

The distinctions between the information haves and the have-nots continue to expand and multiply. Larger numbers of people find themselves excluded from each new technology by their inability to afford them. New technologies tend to be expensive, and even after economies of scale have made technologies more inexpensive, they still remain beyond the reach of many. Poorer persons and even whole countries may lack the resources to afford the hardware and the infrastructure required by new technological developments, and as such may be excluded from participating in developing the forms and uses of new technologies.

Furthermore, as some companies and countries automate services such as banking, education, and access to government services, people without the technology are excluded. Local banks may close branches, government forms and documents may be unavailable, products may be unobtainable, and educational opportunities may be lost if such radical monopolies of digital culture replace traditional ways of providing goods and services within the community. Local services, such as loan offices, schools, and government departments, are easily transferred to remote offices that have no local knowledge of individual people's lives and circumstances. In such ways convergent technologies can contribute to the corporatization of everyday life by eliminating face-to-face interaction and the possibility of people's doing things together.

EDITING AND CREATING NEW TEXTS

New Textualities

Some writers have suggested that the combination of data, video, text, and other elements in a single digital form creates new forms of textuality and so changes the ways in which readers approach and use texts. Another way of stating this is to say that the new technologies allow textual forms to emerge which have been described and theorized in critical theory and some branches of linguistics, particularly poststructuralist theory. The long-term implications of these new textualities are not yet clear. On one hand, such new, multimedia textual forms may open up techniques for expression that are not possible with standard printed texts. On the other hand, new textual forms may contribute to the demise of certain ways of reading and writing, and with them, the focused, concentrated attention and logic of thinking for which they acted as templates may also be lost.

Printed texts are generally read in a linear way, and the traditions of reading developed around logical patterns of exposition, narrative, and explanation. Digital and multimedia texts, particularly when combined with hypertext forms allow and even encourage the reader to follow nonlinear lines of argument that extend beyond the text at hand and that may encompass other texts, images, sounds, and so on. As such, the convergence of diverse kinds of representation may change traditional ways of reading as well as traditional attitudes toward the text. Ideas such as authorship and authorial control of a work require redefinition under these new conditions in which there may be no single author or group of authors and the text itself may incorporate numerous texts. In similar ways, the current definitions of intellectual property and copyright are already proving inadequate for some emerging forms of text.

Certainly the designing, editing, and reading of multimedia require new sets of skills and knowledges, and these change both how the text is read and what kinds of knowledge are extracted from the multimedia text. Images and video, although seeming to present more complete information than text, are problematic. The selection of particular images, issues of video editing, and the contexts in which these images appear all influence the meanings that are taken from them. Yet images have an immediacy and power that text lacks. Additional strategies for critical reading of multimedia are required that would allow readers to evaluate the function and operation of images and video and to make informed decisions regarding the validity and use of those images.

Most people, however, tend to read multimedia pages using techniques learned from film, television, and reading, and these are largely the products of mass-media corporations and are designed to appeal to large audiences. As such, the liberating potential that some see for the new textualities remains unrealized. The skills that one learns from mass corporate media are largely the skills required to consume more media as well as ancillary products which are advertised in cross-marketing schemes. The limitation of media literacy to mass-media and corporate forms constitutes a kind of gate keeping that establishes the norms of representation. Whatever does not fit both in narrative and in format declines in status and popularity. Other gate-keeping functions of print-based text, such as a known publisher, a physical form for the text, and literate conventions regarding how one reads, continue to help determine the ways in which texts are understood, fostering the expectation that texts contained a single or preferred meaning. This stability constituted an implied contract between the author and the reader that certain conventions would be followed that would lead to certain kinds of understandings of the text.

Nonetheless, as the skills and technologies for generating multimedia become more widely available and used, a democratization of skills will follow, just as printing produced the amount of materials necessary for general literacy. As people learned to read, they also began to write and to use that technology in unanticipated ways, creating new kinds of writing. Just as writing became a general skill, differentiated from reading, in early modern times, audio and video editing, combined with HTML composition, may well become standard skills. Already, Web sites exploring alternative approaches to organizing and arranging multimedia are demonstrating possibilities for multimedia outside of the conventions of advertising, film, and traditional aesthetics.

GLOSSARY

Digital subscriber line (DSL) A technique for transmitting broadband digital data over paired copper telephone lines.

Motion picture expert group (MPEG) A group which sets standards for compressing digital video data to reduce the size of the file.

Multi-protocol label switching (MPLS) A protocol for attaching a label to a data packet that contains information regarding its routing and priority and other information.

Phatic communication An exchange between human beings that conveys little apparent content and the primary purpose of which is to establish or to acknowledge mutual recognition.

SOHO An acronym for small office, home office.

Quality of Service (QoS) A determination that a particular transmission is satisfactory for the users.

Voice over Internet protocol (VOIP) The digitizing of voice, such as telephony, and its transmission over Internet servers to a receiver.

Copyright Law

Gerald R. Ferrera, *Bentley College*

INTRODUCTION

E-commerce transactions create unique copyright issues as digital content is transmitted over the Internet. Digital content may take the form of words, videos, music, and terms of use and privacy policies that are commonly found on Web sites. Provided this digital content is an "original work," it is the appropriate subject matter of copyright protection and federal registration in the United States Copyright Office.

Because federal copyright law provides the owner with exclusive rights, primarily to reproduce the original work, copyright ownership incurs a special significance on the Internet where Web site design and development are costly ventures and valuable assets to the e-business. Because online content is digitized, the user has the ability to reproduce and send it immediately to countless others in violation of the copyright owner's exclusive right to reproduce the work. Software programs, such as Lotus Notes, allow a user to send e-mail with attached copyrighted documents that are reproduced in perfect form and may be sent on innumerable occasions to a vast global audience. This poses special and unique problems for copyright protection on the Internet.

Federal copyright law is found in the Copyright Act [17 U.S.C. 101–1205], which protects the authors (or transferees and licensees of copyright material) from copyright infringement for "original works of authorship fixed in a tangible medium of expression" [17 U.S.C. Sec. 40l (d)]. A licensee of a copyrighted work infringes a copyright by exceeding the terms and conditions of the copyright license (see *S&H Computer Sys, Inc. v. SAS Inst., Inc.*, 1983). Although copyright registration is not required in the United States, there are advantages to federal registration in the U.S. Copyright Office. Registration does not confer ownership of a creative work, but rather statutory benefits. Among these benefits are (a) access to the federal court system, unless the copyright has been registered a court may dismiss an action for infringement [17 U.S.C. sec. 411 (a)], (b) statutory damages in lieu of actual damages that may be difficult to prove [17 U.S.C. sec. 412 (2)], and (c) presumption of the validity of the copyright [17 U.S.C. sec. 410 (c)]. Depending on the nature of the e-business, federal registration may be more suitable for some companies than for others. Because the original content on Web pages qualifies for federal registration of the site in the U.S. Copyright Office, one of the first orders of business for an e-company should be to consult with legal counsel concerning the advantages of filing its Web pages with the U.S. Copyright Office for federal copyright registration.

COPYRIGHT AS INTELLECTUAL PROPERTY

Copyright is only one piece of intellectual property historically comprising four pillars: copyrights, trademarks, patents, and trade secrets. The first English copyright act, the 1710 Statute of Anne was the origin of U.S. copyright law. The U.S. Constitution provides the foundation for copyrights found in Article I, Sec. 8, clause 8, that states in part "Congress shall have the Power to promote the Progress of Science anduseful Arts, by securing for limited

Times to Authors and Inventors the exclusive Right to their respective Writings and Discoveries." Hence, the authors of original works of authorship have the right to preclude others from the use of those works during the limited time determined by Congress. In a significant case, *Computer Assoc. Int'l. v. Altai, Inc*., 982 F.2d 693, 696 (2d Cir. 1992), the court stated that

> the copyright law seeks to establish a delicate equilibrium. On the one hand, it affords protection to authors as an incentive to create, and, on the other, it must appropriately limit the extent of that protection so as to avoid the effects of monopolistic stagnation. In applying the federal act to new types of cases, courts must always keep this symmetry in mind.

Copyright law provides a balance between the public's use of the work and the granting of exclusive rights to the author. In *Suntrust Bank v. Houghton Mifflin Co.* (2001) the court stated, "the Copyright Act promotes public access to knowledge because it provides an economic incentive for authors to publish books and disseminate ideas to the public." The exclusive rights granted to copyright owners is limited for a fixed duration, however.

Duration of a Copyright

In October 1998, Congress enacted the Sonny Bono Copyright Term Extension Act. The Act extends the time of most copyrights for 20 years. Copyright material created by individuals was previously for the life of the author plus 50 years and is now for the life of the author plus 70 years. After that time, the copyright falls into the category of public domain for the benefit of the common good where the work may be reproduced without copyright infringement. Corporations owning copyrights were also granted an additional 20 years from the 75-year period for works created for hire, bringing the term for corporations to 95 years from the date of the first copyrighted work. The extension of the term for 20 years is consistent with the copyright law granted by the European Union. Copyright durations have been amended over the years and the applicable duration will vary depending on the facts of each case.

Copyright Duration Challenged: *Eldred v. Ashcroft*

The United States Supreme Court has decided the case of *Eldred v. Ashcroft* (2003) on the issue of whether the constitutional limits of the congressional power to extend the term of copyright has been exceeded as provided in the Copyright Clause. Congress has the authority to issue copyrights "for limited times" to "promote the progress of science and useful arts." This copyright protection is a monopoly giving exclusive rights to the copyright owner with some limitations for fair use during the copyright period. The basis for that entitlement is to give the authors incentive to write and publish material and at the same time to promote the progress of the arts. One could argue as our cultural heritage is transmitted from one generation to the next, it is necessary at some point for this copyright protection to end and for the copyrighted work to fall into the realm of public domain. The retroactive extension for 20 years granted in the Sonny Bono Copyright Term Extension Act of 1998 has a delaying effect on the public domain's reception of expired copyrighted works. The right of Congress to grant a monopoly to copyright owners is subject to the limited time provision of the U.S. Constitution to ensure a vast public domain of free works available for the common good. However, in upholding the congressional power to extend the copyright term in the *Eldred* case the U.S. Supreme court ruled

> Copyright purpose is to promote the publication of free expression. The Framers intended copyright itself to be the engine of free expression. By establishing a marketable right to the use of one's expression, copyright supplies the economic incentive to create and disseminate ideas. As we read the Framers' instructions, the Copyright Clause empowers Congress to determine the intellectual property regimes that, overall, in that body's judgment will serve the ends of the Clause. The wisdom of Congress' action, however, is not within our province to second guess.

Works Made for Hire

A work for hire is a work specially created by an employee within the scope of his or her employment that is specially ordered or commissioned under the Copyright Act, sec. 101, discussed later in this chapter. For instance, a creative employee working for an e-business may produce, develop, or upgrade a Web site for the company. Can the employee later claim a copyright interest in the creative work? The answer to that question depends on whether the employee was acting within the scope of his or her employment or the work was expressly or implicitly found to be a work for hire or commissioned works; if so, the company would own the copyrighted work and would be considered the author for copyright purposes. In most instances, the employer owns the creative works of its employees. The status of the individual creating the copyrighted work is determined under the agency principles relative to an employer–employee relationship. The courts will look at the degree of supervision and control exercised by the employer over the employee in creating the work.

A checklist based on a test determined by a famous Supreme Court case, *Community for Creative Nonviolence v. Reid* (1989), commonly referred to as the "Reid" test, provides guidelines for ascertaining who owns the copyright in the creative work. The court considered:

- The employer's right to control the manner and means of the employee's work (the more control exercised by the employer, the more likely the creative work is a work for hire and owned by the employer)
- The level of skill required to create the work
- The sources of tools and instruments necessary to create the work

- The location of the work
- The duration of the relationship between the employer and the employee
- The employer's right to assign additional projects to the employee
- The method of payment
- The tax treatment of the relationship of the parties
- Whether the project is part of the regular business of the employer

A company should consider a discussion with its attorney about amending the employee's job description so that it includes the production by the employee of original and creative works that may be copyrighted and further that those works are owned by the employer. The employment agreement should provide for the assignment of the employee's works to the employer in the event that the creative works are not works for hire.

Selectively Ordered or Commissioned Works

Section 101 of the Copyright Act defines a work for hire as

> a work prepared by an employee within the scope of his or her employment or a work specially ordered or commissioned for use as a contribution to a collective work, as a part of a motion picture or other work, as a translation, as a supplementary work, as a compilation, as an instructional text, as a test, as answer material for a test, or as an atlas, if the parties expressly agree in a written instrument signed by them that the work shall be considered a work for hire.
>
> If a company hires an independent contractor, it must have a written contract expressly stating that the specially ordered or commissioned works should be considered a work for hire.

Registration in the U.S. Copyright Office

The moment the original work is created and "fixed in a tangible medium of expression," copyright law protects it, even if it is never federally registered (see *Data Gen. v. Grumman Sys. Support Corp.*, 1994: "copyright protection attaches the day original expression is fixed in a tangible medium"). Although copyright law protects an original and creative work, filing for the registration in the U.S. Copyright Office is a prerequisite for initiating a legal claim for copyright infringement in the federal court system. The courts have held that "[t]he registration requirement is a jurisdictional prerequisite to an infringement suit" (*M.C.B. Homes, Inc. v. Ameron Homes, Inc.*, 1990).

Plaintiff's Burden of Proof in a Copyright Infringement Case

A person or company bringing a copyright suit must prove that it is the owner of the copyright and that an unauthorized copying has occurred in violation of an exclusive right and a specific theory of copyright infringement against the defendant. In *Computer Assocs. Int'l v. Altai, Inc.* (1992), the court ruled that "[i]n any suit for copyright infringement, the plaintiff must establish its ownership of a valid copyright, and that the defendant copied the copyrighted work." A defendant may be primarily liable as a direct infringer or secondarily liable as a person or company that contributes to the infringement in some manner or a vicarious infringer. These theories of copyright infringement will be discussed later.

Subject Matter of Copyright

The subject matter of what is appropriate material for copyright protection is vast. It includes "literary, musical, dramatic, and choreographic works, pantomimes, and pictorial, graphic, or sculptural works, including the individual images of a motion picture or other audio visual works" (U.S. Copyright Act, §1027). Web page content often includes literary, pictorial, graphic works, and images of motion pictures or audiovisual works that are all the appropriate subject matter of copyright protection.

Exclusive Rights of the Copyright Owner

When federal registration is obtained, the copyright owner is granted exclusive statutory rights found in section 106 of the Copyright Act as follows:

- The right to reproduce the work
- The right to prepare derivative works based on the original material (in *Synercom Technology, Inc. v. University Computing Co*. 1978, the court ruled as follows: "[I]t is as clear an infringement to translate a computer program from, for example, FORTRAN to ALGOL, as it is to translate a novel or play from English to French. In each case the substance of the expression (if one may speak in such contradictory language) is the same between original and copy, with only the external manifestation of the expression changing. Likewise, it would probably be a violation to take a detailed description of a particular problem solution, such as a flow chart of step-by-step set of prose instructions, written in human language, and program such a description in computer language.")
- The right to distribute copies of the work to the public by sale, rental, lease or lending
- The right to perform the work publicly, (in the case of literary, musical, dramatic, and other such types of work)
- The right to display the copyrighted work publicly (in the case of literary, musical, graphic, sculptural and other such types of works)
- The right with sound recordings to perform the work publicly by means of digital audio transmission

Web pages can be given the same copyright protection as books, music, and movies, preventing others from reproducing the work without express permission from the copyright owner. There are limitations on the copyright owner's exclusive rights that will be addressed later.

Linking

Web users are accustomed to link from one site to another in their search for reliable information. Web site operators commonly link pages without permission of the owner on the assumption that posting a site on the Internet grants an implied license to link it to another Web site. They would argue that, because there is no copying of the content but rather a connection to the site, there is no copyright violation.

In a federal court case, *Intellectual Reserve, Inc. v. Utah Lighthouse Ministries, Inc.* (1999), copyrighted documents from the Church of Jesus Christ of Latter-Day Saints containing infringed materials were knowingly posted on defendant's Web site without authorization from the owner. The court ruled that

> when a person browses a Web site, and by so doing displays the Handbook, a copy of the Handbook is made in the computer's random access memory (RAM), to permit viewing of the material, and in making a copy, even a temporary one, the person who browsed infringes the copyright.

Based on the theory that posting of the links on defendant's Web site to the copyrighted documents facilitated infringements by Web users, the court found the owner of the linking site liable for contributory infringement (discussed below) and granted a preliminary injunction ordering the defendant to remove the infringing materials. Web site managers should consult with their lawyers on links to sites that may contain infringing material and perhaps consider obtaining permission to link from the copyright owner.

Inline Linking

In *Kelly v. Arriba Soft Corp.* (2002), the plaintiff, Leslie Kelly, owner of copyrighted photographs, sued the defendant, the operator of a search engine that displayed "thumbnail" or small pictures of Kelly's works, for copyright infringement. The defendant, without permission, lifted the photographs directly from Kelly's Web site and then displayed them on its search engine. This practice infringed upon Kelly's exclusive right to "display the copyright work publicly." The court ruled as follows:

> Arriba is directly liable for infringement. Arriba actively participated in displaying Kelly's images by trolling the web, finding Kelly's images, and then having its program inline link and frame those images within its own web site. Arriba acted as more than a passive conduit of the images by establishing a direct link to the copyrighted images. Therefore, Arrriba is liable for publicly displaying Kelly's copyrighted images without his permission.

This case is a reminder that search engine operators should have their legal counsel review how it obtains its database of materials to assure copyright compliance.

Originality of the Work

The statutory requirement that the author produce an "original work" is not in the same category as the originality of a patent. Mere factual material, however, is not copyrightable unless it is accompanied by explanatory text. This raises the issue as to whether a database is a copyright production.

Databases

Because it is a fundamental legal principle that only "original" works may be copyrighted, the question arises whether the material found in a database qualifies for copyright protection. When Web sites use "cookies" to collect click-stream information from users and compile that information in their database for possible sales to marketers, the question arises as to whether the database is copyrightable material.

Providing the material in the database is not merely factual representations but rather the author's creative selection and arrangement of the data, it may be copyrightable. In a famous copyright infringement case, *Feist Publications, Inc., v. Rural Telephone Services Inc*. (1991), the defendant was the publisher of a telephone directory that reproduced more than 1,000 of the plaintiff's telephone numbers without its consent. The court held that the plaintiff's mere arrangement of factual material lacked originality because

> facts, whether alone or as part of a compilation, are not original and therefore may not be copyrighted. A factual compilation is eligible for copyright if it features an original selection and arrangement of facts, but the copyright is limited to the particular selection or arrangement. In no event may copyright extend to the facts themselves.

If factual information about a consumer is compiled in a manner that the author selects as optional features in a unique fashion, the material may be copyrighted. In a federal court case, *CCC Information Services, Inc., v. McAllen Hunter Market Reports, Inc*. (1994), the facts involved the "Red Book" that listed the retail value of used automobiles. The court held that the listing in the defendant's Red Book were original because the Book made an adjustment for mileage in 5,000-mile increments and used the concept of an "average" vehicle as the subject matter of its evaluation.

Other issues regarding databases used and reproduced by online service providers pertain to information aggregators on the Internet. Can an online service provider of information legally protect that information from redistribution by another online service provider? A recent case between eBay, Inc. and Bidder's Edge, *eBay, Inc. v. Bidder's Edge, Inc*. (2000), involved a program whereby Bidder's Edge allowed consumers to request specific products at a specific price by searching Web sites. Bidder's Edge "crawlers" accomplish this copying of product information from eBay and other Web sites. Consumer could access this product information on the Bidder's Edge Web site. eBay claimed use of the content collected by Bidder's

Edge constituted an unlawful trespass on the eBay computer system. The court issued a preliminary injunction against Bidder's Edge restricting it from accessing the eBay site.

Because information aggregators provide important information to consumers, the courts will continue to seek a balance between the content ownership of data (e.g., in a database) and the reproduction of that information. Database access and use restrictions will continue to be addressed by the courts and the legislature.

THEORIES OF COPYRIGHT INFRINGEMENT

Exclusive statutory rights granted to a copyright owner are protected in the federal court system. Once a copyright owner establishes in court that it is the owner of the original work and that the defendant has infringed on that work by copying it in some fashion without the owner's permission, then the plaintiff/owner must proceed by proving the case under an established theory of copyright infringement. The theories of copyright infringement are not stated in the Copyright Act but have been developed by the courts and are now part of our copyright law. There are three theories of copyright infringement: direct, contributory, and vicarious.

Direct Infringement (Primary Liability)

A direct infringer is the person, company, or agent that violates one of the copyright owner's exclusive statutory rights. An online newsletter using copyrighted information without the author's permission and posting it online would be a direct infringer. Direct infringement is also known as primary liability.

Contributory Infringement (Secondary Liability)

Contributory infringement is similar to the liability assessed to a person who assists another in committing a tort in the civil law. One does not have to be the direct actor in a wrongful act to be legally responsible and accountable in a court of law for the loss to the defendant. There is, however, a prerequisite that a contributory infringer must have *knowledge or have reason to know of the direct infringement* to establish liability. Once that fact is established, a party "with knowledge of the [direct] infringing activity, induces, causes, or materially contributes to the infringing conduct of another, may be held liable as a contributory infringer" (*Gershwin Publ'g Corp. v Columbia Artist Mgmt., Inc.*, 1971).

In a famous U.S. Supreme Court case, *Sony Corporation of America v. Universal City Studios, Inc.* (1984), Sony, which manufactures and sells home videotape recorders, was sued by Universal, which owned copyrights on some of the television programs broadcast on public airwaves. The public used Sony's videotape recorders to record some of the broadcast. The court stated, "This practice, known as 'time-shifting,' enlarges the television viewing audience." In refusing to find contributory liability on behalf of Sony, the court noted that

> contributory infringement has been applied in a number of . . . copyright cases involving an ongoing relationship between the direct infringer and the contributory infringer at the time the infringing conduct occurred. . . . The only contact between Sony and the users of the Betamax . . . occurred at the moment of sale. . . . One may search the Copyright Act in vain for any sign that the elective representatives of the millions of people who watch television every day have made it unlawful to copy a program for later viewing at home, or have enacted a flat prohibition against the sale of machines that make such copying possible.

Knowledge of the infringement may be based on the direct perception of the contributory infringer or on the knowledge that *a reasonable person in a similar set of circumstances* would have. In the now famous *A&M Records, Inc., v. Napster, Inc.* (2001), the U.S. Court of Appeals found Napster to be secondarily liable for copyright infringement based on the system it provided that allowed the users to download copyrighted music. The court ruled that Napster had actual knowledge that specific infringing material was available on its system and that it could have blocked access to this system and failed to do so, and this conduct materially contributed to the direct infringement.

The standard is whether a reasonable person, in that environment, would have been aware of the direct infringement. The doctrine of contributory infringement may pose special problems to an online business venture because the traditional way of limiting personal liability would be to incorporate the electronic business. If the directors, officers, stockholders, or venture capitalists that funded the business knew or had reason to know of the direct infringement and allowed it to continue, it is arguable that they could be personally sued for contributory infringement and not have the benefit of limited liability provided by corporate law.

For example, suppose the investors, stockholders, and corporate directors all knew that the program and business model used on the company Web site allowed others to download copyrighted material. It is possible under the doctrine of contributory copyright infringement they could all be jointly liable to the copyright owner.

Vicarious Infringement

Vicarious infringement, similar to contributory infringement, has its origin in the common law based on court decisions. The doctrine of vicarious copyright liability is established on the theory that the defendant has the right and ability to supervise the direct infringement and also has a direct financial interest in the infringed copyrighted work. This test does not require active supervision. Vicarious liability is found in the ancient employment doctrine of *respondeat superior* based on the theory that an employer is responsible for the carelessness of its employees while they are carrying on business activities. Provided that the employees are acting within the scope of their employment contract, the employer has the right to supervise and control employees' activities and is legally responsible for their wrongful acts causing injuries to others. Vicarious liability also includes independent contractors who have the right and ability to control others and maintain a direct financial interest in the copyrighted material.

An e-business could be liable for copyright infringement if one of its employees violated a copyright law while engaging in company business. Vicarious copyright infringement liability does not require an employer–employee relationship. Liability is based on the fact that the vicarious infringer had the right to control and stop the direct infringing and, in addition, that he or she received a financial benefit from the infringement.

DEFENSES TO COPYRIGHT INFRINGEMENT

Copyright Law was intended to establish a balance between the exclusive rights of authors to use for a limited period of time their original works and at the same time, under limited circumstances, to provide the public with that information. This is a recognition by Congress that our copyright policy, although it grants an exclusive use to the copyright owner, also allows that information, within limited circumstances, to flow for the benefit of the public good. One of the most important doctrines found in the Copyright Act that allows for this process is the theory of fair use.

Fair Use

Certain infringements are excused from liability when the use is "fair." Fair use had its origin in case law long before it was adopted by Congress and became part of the U.S. Copyright Act. Judges recognized that in limited circumstances the general public should have the right to reproduce copyrighted material for the benefit of the common good. As early as 1995 in *Bateman v. Mnemonic, Inc*., the court noted,

> Originally, as a judicial doctrine without any statutory bases, fair use was an infringement that was excused—this is presumably why it was treated as a defense. As a statutory doctrine, however, fair use is not an infringement. Thus, since the passage of the 1976 [Copyright] Act, fair use should no longer be considered an infringement to be excused, instead, it is logical to view fair use as a right.

In *Steward v. Abend* (1990), the U.S. Supreme Court ruled the purpose of the fair use doctrine is to "avoid rigid application of the copyright statute when, on occasion, it would stifle the very creativity that the law is designed to foster." That judicial theory has been implemented in the Copyright Act in section 107 as a limitation on the exclusive rights of the copyright owner. The burden of proof is on the defendant who claims the affirmative defense of fair use and must establish that the copying was used within the statutory parameters set out in section 107 that states, "the fair use of a copyright work, including such use by reproduction in copies or phonocopies or by any other means . . . for purposes such as criticism, comment, news reporting, teaching . . . scholarship, or research is not an infringement of copyright." The statute enumerates four nonexclusive factors that make up the doctrine of fair use and the courts must consider all of them in each case:

> (1) the purpose and character of the use including whether such use is of a commercial nature or is for non-profit educational purposes; (2) the nature of the copyright work; (3) the amount and substantiality of the portion used in relation to the copyright work as a whole and (4) the effect of the use upon the potential market for or value of the copyright work.

Nonprofit educational purposes allow these institutions to use copyrighted works within a limited framework. State corporate law provides authorization for an enterprise to be organized as a nonprofit corporation. Federal and state eligibility for a nonprofit results in a two-way tax proposition useful for these ventures. The person contributing to the nonprofit is allowed to take a tax deduction, and the nonprofit receives that income tax free. There are countless numbers of Web sites that are nonprofit entities. If those Web sites were to display copyright priority over copyright material and the other factors are satisfied, the defendant may be able to argue fair use over the objection that the publication constituted a copyright infringement. The fact that a company is a nonprofit and is using copyrighted material is not conclusive evidence that it fits within the doctrine of fair use. Social expression and the free flow of ideas, especially within an educational context, takes priority over a copyrighted work. The court ruled in *Universal City, Inc. v. Reinerdes* (2000) that the [fair use] "doctrine . . . limits the exclusive rights of a copyright holder by permitting others to make limited use of portions of the copyrighted work, for appropriate purposes, free of liability for copyright infringement." For example, it is permissible for someone other than the copyright owner to reprint or quote a suitable part of a copyrighted book or article in certain circumstances. The doctrine traditionally has facilitated literary and artistic criticism, teaching and scholarship, and other socially useful forms of expression. The courts have viewed it as a safety valve that accommodates the exclusive rights conferred by copyright within the freedom of expression guaranteed by the First Amendment (*New Era Publ'ns Int'l, ApS v. Henry Holt & Co., Inc*., 1989: "the fair use doctrine encompasses all claims of first amendment in the copyright field").

First Sale Doctrine

The First Sale Doctrine, found in section 109 of the Copyright Act, limits the copyright owner's exclusive right to distribute publicly a copy of the work providing the copyright material was lawfully acquired by another person. Under the Copyright Act, "the owner of a copy is entitled, without the authority of a copyright owner, to sell that copy" (sec. 19). The purchaser of a copyrighted work can generally sell that material to another without violating the copyright law. One must be cautioned, however, that if there is a licensing agreement of a copyrighted work, the copyright owner under that agreement could retain the right of distribution. For example, software may be downloaded under a licensing agreement whereby the computer software company may continue to own the copyrighted information on the program while the licensee maintains use of the program consistent with the licensing agreement. The courts are split on the issue of whether a user manifests assent to a licensing agreement merely by opening a software package and using the software (cf. *Step-Saver Data Sys., Inc. v. Wyse Tech., Inc.*, 1991 [no shrink-wrap license found by opening the box] and *ProCD, Inc. v. Zeidenberg*, 1996 [shrink-wrap license found binding on the user]).

REMEDIES FOR COPYRIGHT INFRINGEMENT

The copyright owner can seek various remedies under the Copyright Act. These include injunctive relief in which the court may force the infringer to stop the copying and may also award monetary damages. A court in its discretion has the authority to issue a temporary or permanent injunction to prevent or restrain copyright infringement (Copyright Act, sec. 502).

The copyright owner may recover actual damages suffered as a result of the infringement plus any of the infringer's profits "that are attributable to the infringer and are not taken into account in computing the actual damages" [Copyright Act, sec. 504(b)]. Proving actual damages by the plaintiff based on a copyright infringement requires the plaintiff to show an actual loss. The statute establishes the liability of a copyright infringer for either "the copyright owner's actual damages and any additional profits of the infringer" or statutory damages [sec. 504 (a)]. The plaintiff can also recover any profits that the copyright infringer made by virtue of the infringement. Here the copyright owner need only prove the infringer's gross revenue, and the infringer must prove its deductible expenses and profits not related to the infringement [sec. 504 (b)]. The Copyright Act allows recovery by way of statutory damages, in lieu of actual damages, based on the discretion of the trial judge. Statutory damages range from $750 to $30,000 for each copyrighted work infringed [sec. 504 (c)(1)]. If the court finds that the infringed material was willful, statutory damages can run as high as $150,000 per work infringed [sec. 504 (c) (2)]. In addition, the plaintiff may ask for court costs and reasonable attorney's fees in the discretion of the trial judge. Courts have awarded prejudgment interest on damages for copyright infringement (*Kleier Adver., Inc. v. Premier Pontiac, Inc.,* 1990).

THE DIGITAL MILLENNIUM COPYRIGHT ACT

On October 28, 1998, Title 17 of the Copyright Act was amended by the Digital Millennium Copyright Act (DMCA). Its purpose, in general, is to protect copyright owners from the circumvention of technologies used by them to manage the control and use of the digital content of their copyrighted works and, in certain circumstances, to limit the liability of online service providers for infringement. The broader purpose of the DMCA was to have the copyright act comply with the World Intellectual Property Organization (WIPO) copyright treaty adopted by many countries.

Circumvention of "Digital Locks"

Digitized copyrighted material allows a user to make perfect multiple copies at practically no expense. For example, digitized music, movies, video games, and e-books can be reproduced and sent to countless others in violation of a copyright owner's exclusive statutory rights. Copyright owners may prevent massive reproductions of their protected works by using software products that provide technological locks and controls. The DMCA prohibits a user from decrypting digital locks by circumvention access commonly referred to as the anti-circumvention provision [Copyright Act, sec. 1201 (a)(l)(A)].

Copyright and Management Systems

The DMCA provides that circumvention of a digital lock on a digitized product such as a DVD, e-book, or video game is to "descramble a scrambled work, to decrypt an encrypted work, or otherwise avoid, bypass, remove, deactivate, or impair a technological protection measure" [Copyright Act, sec. 1201 (a)(2000)]. Management systems that use digital locks on their copyrighted works deny access to the digitized product. It is now a violation of the DMCA to circumvent this access control, including the free distribution of software that might provide such anticircumvention.

The DMCA provides copyright owners with the right to use circumvention technology that gives them the ability to manage the use of their copyrighted works with respect to how many copies, if any, can be made of the work, how long the copyrighted digitized work will last, or any other control they may wish to place on the reproduction of the original copyrighted work. As software engineers continue to discover ways of controlling digitized products, there is a growing controversy regarding the balance in the copyright act between the rights of the copyright owner and the "fair use" of others.

Trafficking in Circumvention Tools

The DMCA defines the trafficking in circumvention tools as "the manufacture, import, [or] offer to the public, [of] any technology designed for the purpose of circumventing a technological measure that effectively controls access to a work protected under this title" [Copyright Act, §1201 (2)]. This trafficking provision was addressed in a DVD encryption case, *Universal v. Corley* (2001). In this case, motion picture studios brought a lawsuit under the DMCA to enjoin Internet Web owners from posting computer software that decrypted digitally encrypted movies on DVDs and from posting hyperlinks to Web sites that made decryption software available. The lower court granted an injunction of the online distribution of DeCSS that was a circumvention software product used to decrypt the DVD movie. The appellant court affirmed the judgment and ruled as follows:

> we know of no authority for the proposition that fair use, as protected by the Copyright Act, much less the Constitution, guarantees copying by the optimum method or in the identical format of the original . . . the DMCA does not impose even an arguable limitation on the opportunity to make a variety of traditional fair use of DVD movies, such as commenting on their content, quoting excerpts from their screenplays, and even recording portions of the video images and sounds on film or tape by pointing a camera, a microphone at a monitor as it displays the DVD movie.

This case establishes a prohibition on trafficking in decrypting digital encrypted movies but continues to allow the limited application of fair use of copyrighted material.

Exemptions to the Circumvention Provisions

The DMCA has seven exemptions that, in limited circumstances, allow institutions and individuals to circumvent encryption devices used by copyright owners. They are as follows:

- Libraries, archives and educational institutions [sec. 1201 (d)]
- Law enforcement and intelligence gathering agencies [sec. 1201 (e)]
- Reverse engineering [sec. 1201 (f)]
- Encryption research [sec. 1201 (g)]
- Protecting minors from objectionable material [sec. 1201 (h)]
- Protecting the privacy of personal identifying information [sec. 1201 (i)]
- Security testing [sec. 1201 (j)]

Libraries

If a library were to receive an e-book or a DVD video and wanted to have it reviewed by a number of scholars before it decided to acquire it as part of its collection, would the digital lock on the DVD or e-book prevent it from having the material reviewed simultaneously by various scholars? This exemption has serious limitations on its use. The DMCA allows the exemption only for the limited time it takes the library to make the acquisition decision [17 U.S.C. sec. 1201 (d)(1)(A)]. Decrypting the DVD or other digitized product could be a serious budgetary constraint in that employing cryptographers to engage in this process may, in effect, eliminate this exemption.

Law Enforcement Agencies

This exemption has special application in government antiterrorist activities. Law enforcement agencies can circumvent digital locks in any system that places the government's computer systems at risk.

Reverse Engineering

Assuming that reverse engineering is permitted under copyright law, a software engineer may reverse a copyrighted program to determine whether it can achieve interoperative ability of its own computer program with other programs.

Encryption Research

Encryption research is a discipline of encryption technology in which software engineers and others engage in research to break digital locks. This decryption technology is allowed when the researcher attempted to obtain authorization from the copyright owner before the circumvention of the encrypted program. The DMCA further provides three additional factors to determine whether the court should grant the exemption to the encryption researcher: the encryption research must be "reasonably calculated to advance research on encryption technology in a manner that facilitates infringement" [sec. 1201 (g)(3)(A)], "the researcher must qualify as being trained or experienced in the field of encryption technology" [sec. 1201 (g)(3)(B)], and the encryption researcher must notify the copyright owner of its findings on the research [sec. 1201 (g)(3)(C)]. A serious question to consider and debate is whether this provision has a chilling effect on encryption research because it requires the researcher to notify the copyright owner who may then initiate a claim based on violation of the DMCA.

Protecting Minors From Objectionable Material on the Internet

This provision of the DMCA would allow software products that circumvent the distribution of pornographic sites on the Internet to prevent minors from accessing this objectionable material [17 U.S.C. sec. 1201 (h)].

Privacy Protection

Collection of personal information by a computer user on a device similar to "cookies" used by a Web site may be circumvented under this exemption that has a number of significant limitations. If the Web site posts a privacy policy that provided adequate notice to the user that "cookies" are employed to collect personal identifying information, the exemption would not apply [sec. 1201 (i)(1)(B)]. As stated under the exemption for libraries, consumers could not afford to analyze source code and decrypt a digital protection system such as "cookies" to prevent the dissemination of their personal information.

Security Testing

Testing security systems, such as firewalls, is an important part of electronic commerce. For instance, the security of financial information including credit card information used to purchase a product online must be tested constantly to ensure its security. The DMCA allows circumvention to test security systems [sec. 1201 (j)]. The information acquired from testing this security system must be used exclusively to improve the security and not to infringe the copyrighted product.

Civil and Criminal Remedies for Violating the DMCA

Because the DMCA is a federal statute, a copyright owner alleging infringement must bring a suit in the federal district court. The trial judge has the authority to grant injunctive relief or monetary damages (or both) if there is a violation of the DMCA anticircumvention provisions. The statute allows for the recovery of actual damages as well as reasonable attorney's fees. In the event that there is a willful violation of the anticircumvention provisions of the DMCA used for commercial, private, or financial gain, the court can order significant fines or a criminal action can be prosecuted to imprison the violator.

One can readily see that the DMCA is a statutory system granting new rights to digital copyright owners who attempt to use encryption technology such as "digital locks" to prevent others from copying, viewing more than once, or in various ways attempting to prevent the technological managing of its copyrighted material.

Safe Harbor (Section 512) for Online Service Providers Under the DMCA

In 1998, Congress codified the online copyright Infringement Liability Limitation Act as Section 512 of the Digital Millennium Copyright Act. The purpose behind the safe harbor is to provide to those entities that qualify as service providers, limitations on the remedies available to the copyright owner. The theory is that service providers act only as a conduit for another's infringing material. In certain instances, the service provider should not be held liable for the monetary damages resulting from this infringement.

Online Service Providers

Search engines, Internet service providers, hosting services, and Web sites with multiple links to third parties provide network access to subscribers and customers who may post materials that infringe on copyrights. In this capacity, the customers or subscribers are direct infringers violating the copyright owner's exclusive statutory rights to reproduce the work. The direct infringer is held primarily liable for the infringement.

Copyright law also allows claims against secondary infringers under the tort theories of contributory infringement and vicarious infringement, however. A contributory infringer is a person or entity that has knowledge or had reason to know of the direct infringement and provides a facility for that infringing process. A vicarious infringer need not have knowledge of the direct infringement but had the right to supervise and control the infringers' activities and incurred a financial benefit as a result of the direct infringement. Both contributory infringement and vicarious infringement are referred to as secondary liability.

The federal common law judicial doctrines of the copyright infringement theories of direct and secondary liability become potential copyright claims in view of the function of online service providers. They may be directly liable for copyright infringement by violating the owner's exclusive reproduction rights by intentionally permanently posting copyrighted material on its bulletin board system. If the service provider was properly notified of the infringement and failed to take down the infringing material that, under the circumstances, materially caused or contributed to the infringement, it could be liable for contributory infringement.

Section 512's safe harbor allows avoidance of secondary liability when a service provider posts infringing material on a bulletin board without knowledge, notice, or awareness of its infringing nature and "takes down" the infringing material "expeditiously" after receiving notice of the infringement by the copyright owner [sec. 512 (c)]. The courts generally first determine if contributory liability exists under the federal common law apart from Section 512's safe harbor.

Activities Eligible for Safe Harbor

To qualify for the safe harbor provisions the service provided must engage in any of the following activities:

- Transient holding and transmission of content without modification (so-called store and forward services in which the service provider does not select or review the material)
- Temporary storage of content provided by others ("system caching" in which the service provider temporarily stores someone else's material to provide user's access)
- Storage of material at the user's discretion ("posting" of another's material on a "bulletin board service")
- Linking users to other online locations posting infringing material ("linking" has special significance to a site with multiple links)

Limitation on Remedies Under the Safe Harbor

Section 512 limits the remedies available to the copyright holder. If the defendant fits one of the eligibility categories, Section 512(a) precludes monetary liability and limits injunctive relief to removing the infringing material.

Eligibility for Section 512 "Safe Harbor"

A service provider must comply with the following statutory requirements to be eligible for the safe harbor's limitation on remedies: (a) it must adopt and implement a policy for terminating subscribers and account holders who are repeat infringers and for notifying them of that policy, (b) it must "accommodate and . . . not interfere with standard technical measures" for protecting copyright works [sec. 512 (i)(1)(B)].

Statutory compliance. The limitation on remedies on all of the service providers activities requires further compliance with Section 512. In each case, the service provider cannot have actual notice of the copyright infringement nor can it acquire any financial gain as a result of the infringement. Furthermore, the statute states that the limitation on liability for the online service provider applies only if the service provider has designated an agent to receive notification of the claimed copyright infringement.

Notice on the online service provider's terms of use. A proper notice, generally found on the Web site's terms of use, includes identification of the agent to receive notice of an alleged infringement. This notice is further made accessible to the public by providing to the U.S. Copyright Office the following information: the name, address, phone number, e-mail address of the agent to receive notice, and other information that the registrar of copyright may deem appropriate.

Register of copyright directory of agents. Section 512 of the DMCA further provides that "the registrar of copyrights shall maintain a current directory of agents available to the public for inspection, including through the Internet, in both electronic and hardcopy formats, and payment of a fee by a service provider to cover the cost of maintaining the directory."

Replacement by the online service provider of removed material claimed to be a copyright infringement. Under the DMCA, an online service provider is entitled to notify its customers when their materials have been removed based on a copyright infringement claim [sec. 512 (g)]. The statute provides " upon receipt of a *counter notification*, the online service provider may replace the removed material and notify the copyright owner, wherein the owner has 14 days to file an action in the Federal district court for copyright infringement against the direct infringer."

Contents of the counter-notification. The contents of the counter-notification must include substantially the following material: (a) a physical or electronic signature of the subscriber, (b) identification of the material that has been removed or to which access has been disabled, (c) the location at which the material appeared before it was removed, (d) a good-faith belief that the material was removed as a result of mistake, (e) the subscriber's name, (f) misidentification of the material, (g) subscriber's address and telephone number, and (h) a statement that the subscriber's consent to the jurisdiction of the federal district court for the judicial district in which the address is located.

Limitation on the liability of nonprofit educational institutions. Under employment law, an employer is liable for the wrongdoing of its employees causing injury to others while carrying on employment business. An exception is made to this doctrine when a public or other nonprofit organization of higher education is an online service provider. The statute provides the following under Section 512 (e)(1): "when a faculty member or graduate student who is an employee of such institution is performing a teaching or research function, such faculty member or graduate student shall be considered to be a person other than the institution and their knowledge or awareness of the infringing activity shall not be attributed to the institution." This exemption from liability of the faculty member or graduate student is available providing the educational institution has not, within the preceding three-year period of notice of the infringement, received more than two notifications of claimed infringement by that faculty member or graduate student and that the educational institution provides to all users of its online system compliance with the laws of the United States relating to copyright. Educational institutions must have copyright law policy that is adequately published requiring all faculty members to immediately notify the institution of any alleged infringements based upon material that may be posted on their Web sites. Section 512 of the DMCA presents a public policy position that service providers of such essential functions on the Internet as search engines, bulletin board services, Web sites with multiple links, educational institutions, and others that may qualify as an online service provider are granted federal immunity from contributory or vicarious infringement based on their relationships with their customers or subscribers who may be direct infringers. Strict compliance with the DMCA is necessary for the online service provider to have the benefit of this safe harbor provision.

INTERNATIONAL COPYRIGHT LAWS

Because the Internet is an international medium, courts around the world hear copyright infringement cases. The World Trade Organization (WTO) comprises a number of countries, including the United States. It observes the provisions of intellectual property agreements signed by the member countries. Two of the most important agreements are the Berne Convention for the Protection of Literary and Artistic Works (Berne Convention) and the Trade-Related Aspects of Intellectual Rights.

WTO member countries agree to a dispute-resolution policy established by WTO that resolves intellectual property copyright disputes between its member countries. The Berne Convention mandates its members to protect copyrighted works, and it established four principles of membership compliance. These include similar national treatment for all member countries, nonconditional protection so that no formalities are required to protect a copyrighted work (such as the use of the copyright symbol, ©). Although no longer required by the Berne Convention, use of the symbol remains good practice to disclose the intent of preserving the copyrighted material by including on documents, including a Web site, the copyright symbol followed by the year and the name of the entity claiming ownership in the work. This has the secondary effect of making it difficult for an infringer to claim that this was an innocent infringement and argue for a consequent reduction in damages. The third principle provided by the Berne Convention provides that there is copyright protection independent of the country of origin so that registration in one member country protects in all member countries. The fourth principle provides for common rules that establish procedures for granting copyright protection.

The World Intellectual Property Organization Copyright Treaty has extended the Berne Convention's copyright protection to include computer software (see http://wipo.int; accessed August 18, 2002). Businesses that intend to market their product internationally should be aware that there is no worldwide automatic protection of copyright. National laws of every country and various treaties that a country may have entered regarding copyright protection should be explored through appropriate legal counsel (Copyright Circular 38A; available at http://lcweb.loc.gov/copyright; accessed August 18, 2002).

CONCLUSION

Digital content on Web pages that are original and creative are appropriate subject matter for copyright protection. Although registration is not necessary to create a copyright, upon federal registration in the Copyright Office, the copyright author, who may be a company or an individual, is granted statutory benefits including exclusive statutory rights over the content of the Web pages, access to the federal court for an infringement suit, statutory damages in lieu of actual damages, and a presumption of copyright ownership. The benefits of copyright registration in the Copyright Office should always be discussed with legal counsel.

If an e-business Web site is interactive through the use of a bulletin board service, a search engine, or multiple links, the site may qualify as a service provider under the Digital Millennium Copyright Act and be granted the benefits of "safe harbor," which limits the remedies available to the copyright owner. Vigilant copyright management should be an important function of the e-business to protect its valuable intellectual copyright property. Management should work closely with legal counsel to constantly ensure statutory compliance with the Copyright Act and, when applicable, foreign copyright laws.

GLOSSARY

Circumvention under the DMCA Bypassing a technological device used by the copyright owner to prevent copying of the work.

Contributory copyright infringement A person who knew, or should have known, of the direct infringement and who thus induces, causes, or materially contributes to the infringing conduct of another.

Copyright Act Federal statutory law that grants to authors of original works, for a limited time, exclusive statutory rights over the copyrighted works.

Digital Millennium Copyright Act (DMCA) A federal statute that generally prohibits circumvention of any device used by the copyright owner to prevent copying of the work; it further provides a "safe harbor" for online service providers who show copyrighted works on its Web site.

Direct copyright infringement The entity that performs the copyright infringement.

Exclusive rights of copyright owner Statutory rights, under the Copyright Act, granted to the author of original works for a limited time.

Fair use A common law doctrine now part of the Copyright Act that allows limited use of the copyright material if it is educational, a small part of the copyright work, and does not affect the potential or actual value of the work.

First sale doctrine Right of the purchaser of a copyright work to dispose of it in any way, including selling it.

Independent contractor A person hired to work on a project without the supervision and control of another.

Information location tool Under the DMCA, a directory, index, reference, pointer, or multiple hypertext link.

Online service provider An entity offering connections for digital online communications.

Primary infringement liability *See* direct infringement.

"Safe Harbor" provision of the DMCA A process to limit the remedies of a copyright owner brought against an online service provider.

Secondary infringement liability Contributory infringement or vicarious infringement, providing there is evidence of a direct infringement.

Sonny Bono Copyright Term Extension Act (1998) Federal law that extended the duration of a copyright by 20 years.

Theories of copyright infringement The plaintiff in a copyright case must prove ownership of the copyright, violation of an exclusive right, and a theory of copyright infringement that must include a direct infringement and may include a contributory or a vicarious infringer.

Vicarious copyright infringement An entity that has the right and ability to supervise the direst infringement and had a financial interest in the infringed copyrighted work.

Work for hire Copyrighted work authored by an employee, as part of an employment contract, that is owned by the employer.

World Trade Organization An international group of nations (including the United States) that overviews the provisions of intellectual property signed by member countries.

Customer Relationship Management on the Web

Russell S. Winer, *New York University*

INTRODUCTION

The essence of the information technology (IT) revolution and, in particular, the World Wide Web is the opportunity afforded companies to improve their interactions with their customers. The Web allows companies to build better relationships with customers than was previously possible in the offline world. By combining the abilities to respond directly to customer requests and to provide the customer with a highly interactive, customized experience, companies have a greater ability today to establish, nurture, and sustain long-term customer relationships than ever before. These online capabilities complement personal interactions provided through salespeople, customer service representatives, and call centers. At the same time, companies can choose to exploit the low cost of Web customer service to reduce their service costs and offer lower quality service by permitting only electronic contact. The flexibility of Web-based interactions thus permits firms to choose to whom they wish to offer services and at what quality level.

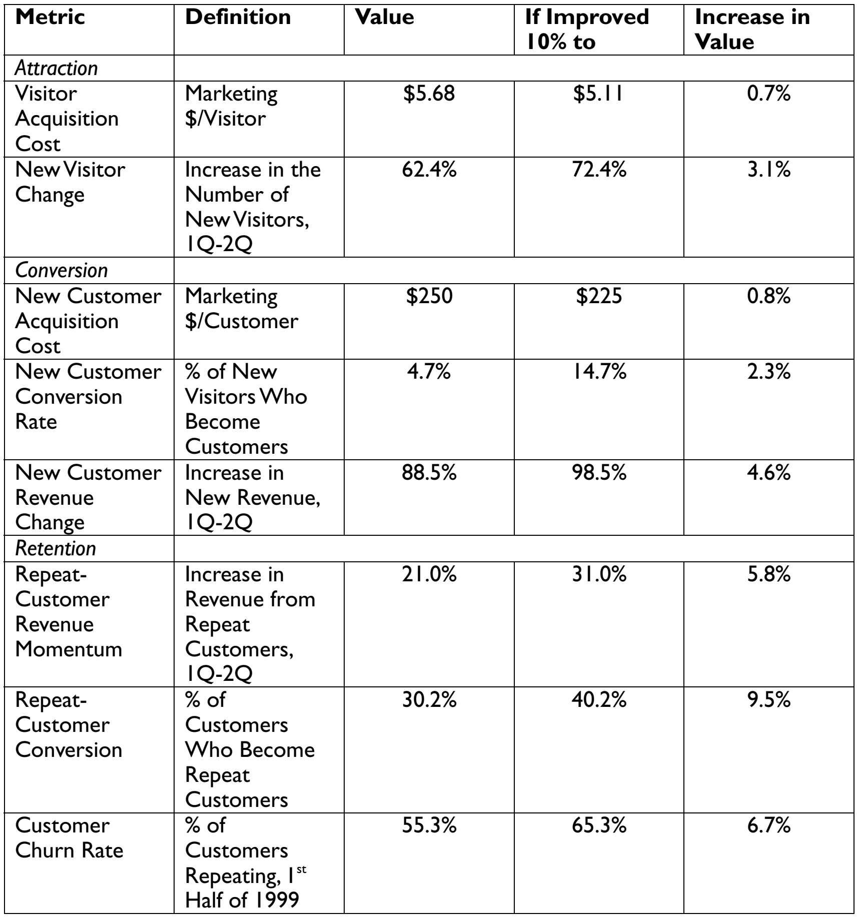
Indeed, this revolution in customer relationship management (CRM) has been referred to as the new “mantra” of marketing. (If all of the components of the CRM system are Web-based, the term “eCRM” (electronic CRM) is sometimes used.) Companies such as Siebel, E.piphany, Oracle, Broadvision, Net Perceptions, Kana, Salesforce.com, and others have developed CRM products that do everything from track customer behavior on the Web, to predicting their future moves, to sending direct e-mail communications. Although the IT spending slowdown of 2000–2002 has put a crimp in the industry’s sales, Morgan Stanley Dean Witter & Co. estimates the total potential for CRM software to be more than $48 billion (Enrado, 2002).

The need to better understand customer behavior and the interest of many managers to focus on those customers who can deliver long-term profits has changed how marketers view the world. Traditionally, marketers have been trained to acquire customers, either new ones who have not bought the product before or those who are currently competitors’ customers. This has required heavy doses of mass advertising and price-oriented promotions to customers and channel members. Although the revolution in improved customer service programs and measurement since the 1980s brought a welcome emphasis on the customer, today, particularly for the company’s “best” customers, the tone of the conversation has changed from customer acquisition to retention. This requires a different mindset and a new set of tools. A good thought experiment for an executive audience is to ask them how much they spend or focus on acquisition versus retention activities. It is difficult to perfectly distinguish the two activities from each other, but the answer is usually that acquisition dominates retention.

The impetus for this interest in CRM came from Reichheld (1996), who demonstrated dramatic increase in profits from small increases in customer retention rates and popularized the notion of the lifetime value of customers. His studies showed that as little as a 5% increase in retention had impacts as high as 95% on the net present value delivered by customers. Other studies done by consultants such as McKinsey have shown that repeat customers generate more than twice as much gross income as new customers. The considerable improvements in technology and innovation in CRM-related products have made it much easier to deliver on the promise of greater profitability from reduced customer “churn.”

For example, Figure 1 shows the results from a 1999 McKinsey study on the simulated impact of improvements in a number of customer-based metrics on the market value of Internet companies. The metrics are divided into three categories: customer attraction, customer conversion, and customer retention. As can be seen, the greatest leverage comes from investments in retention. If revenues from repeat customers, the percentage of customers who repeat purchase, and the customer churn rate each improves by 10%, the company value was found to increase (theoretically) by 5.8%, 9.5%, and 6.7%, respectively.

A problem is that although managers understand what the letters CRM stand for, the interpretation of the concept can vary by person. For some companies, the main CRM application is a telephone call center. For others, it is mass customization or developing products that fit individual customers’ needs. For salespeople, it means sophisticated customer contact software. For IT consultants, CRM translates into complicated technical jargon related



Metric	Definition	Value	If Improved 10% to	Increase in Value
Attraction				
Visitor Acquisition Cost	Marketing $/Visitor	$5.68	$5.11	0.7%
New Visitor Change	Increase in the Number of New Visitors, 1Q-2Q	62.4%	72.4%	3.1%
Conversion				
New Customer Acquisition Cost	Marketing $/Customer	$250	$225	0.8%
New Customer Conversion Rate	% of New Visitors Who Become Customers	4.7%	14.7%	2.3%
New Customer Revenue Change	Increase in New Revenue, 1Q-2Q	88.5%	98.5%	4.6%
Retention				
Repeat-Customer Revenue Momentum	Increase in Revenue from Repeat Customers, 1Q-2Q	21.0%	31.0%	5.8%
Repeat-Customer Conversion	% of Customers Who Become Repeat Customers	30.2%	40.2%	9.5%
Customer Churn Rate	% of Customers Repeating, 1st Half of 1999	55.3%	65.3%	6.7%

Figure 1: Impact of a 10% improvement in indicator on the current value of e-commerce firms. Source: Cigliano, Georgiadia, Pleasance, & Whalley (2000).

to terms such as OLAP (online analytical processing) and CICs (customer interaction centers).

One way to better understand CRM is to decompose it term by term:

1. *Customer.* Clearly, an important focus of CRM is on customers,but which customers? Although it is most natural to consider customers as being those parties that purchase a company's services or products, Siebel has developed a version of its software for internal, human resource management use for retaining valued employees.
2. *Relationship.* Marketers have studied brand loyalty for nearly 50 years. Thus, the notions that repeat purchasing is important and loyal customers are valuable are not new. The key to CRM, however, is understanding that different customers want different kinds of relationships—some want to single source products, some want multiple vendors. The idea of CRM is to customize the relationship to what benefits and keeps the customer.
3. *Management.* The point of the "M" is that relationships have to be managed; they do not survive without the active participation of the company seeking to extend them.

To better implement CRM within organizations, I have developed a series of steps that managers should follow in implementing a CRM program. What do managers need to know about their customers, and how is that information used to develop a complete CRM perspective? Figure 2 shows a basic model, which contains a set of seven basic components:

1. A database of customer activity;
2. Analyses of the database;
3. In light of these analyses, decisions about which customers to target;
4. Tools for targeting the customers;
5. Knowledge of how to build relationships with the targeted customers;
6. Awareness of privacy issues; and
7. Metrics for measuring the success of the CRM program.

Note that these steps are generic in nature, that is, they apply whether the context is Web-based or non-Web-based CRM. The basics are the same in either context. The Web has made the goal of improved customer satisfaction and retention easier to reach, however, because of the increased interactivity and personalization that the medium affords. Taken together, these two characteristics

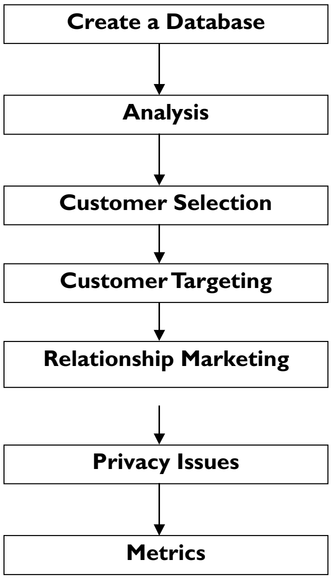


Figure 2: Customer relationship management model.

of the Web have made customer retention activities resonate with customers as they are tailored to them. The purpose of this chapter is to provide the reader with an understanding about how interactivity and personalization have dramatically improved the generic CRM system.

CREATING A CUSTOMER DATABASE

A necessary first step to a complete CRM solution is the construction of a customer database or information file (Glazer, 1999). This is the foundation for any CRM activity. For Web-based businesses, constructing a database should be a relatively straightforward task as the customer transaction and contact information is accumulated as a natural part of the interaction with customers. For existing companies that have not previously collected much customer information and are moving to the Web, the task will involve merging historical customer contact data from internal sources such as accounting and customer service with the data provided by the Web-based interactions.

What should be collected for the database? Ideally, the database should contain information about the following:

- *Transactions*—This should include a complete purchase history with accompanying details (price paid, SKU, delivery date).
- *Customer contacts*—Today there is an increasing number of customer contact points from multiple channels and contexts. This should include not only sales calls and service requests, but any customer- or company-initiated contact.
- *Descriptive information*—This is for segmentation and other data analysis purposes. Useful information here would include address and demographic information for consumers and location and company information for business customers.
- *Responses to marketing stimuli*—This part of the information file should contain whether the customer responded to a direct marketing initiative, a sales contact, or any other direct contact.
- *The value of the customer*—Many companies calculate the value of each customer, both the current and the long-term or lifetime value. This provides a valuable basis for making resource allocation decisions at the customer level.

The data should also be represented over time.

Companies have traditionally used a variety of methods to construct their databases. Durable goods manufacturers use information from warranty cards for basic descriptive information. Unfortunately, response rates to warranty cards are in the 20–30% range leaving big gaps in the databases. Service businesses are normally in better shape because the nature of the product involves the kind of customer-company interaction that naturally leads to better data collection. For example, banks have been in the forefront of CRM activities for a number of years. Telecom-related industries (long distance, wireless, cable services) similarly have a large amount of customer information. Catalog companies (e.g., Lands' End) also have excellent customer information files.

The following are illustrations of some corporate database-building efforts:

- The networking company 3Com created a worldwide customer database from 50 "legacy" databases scattered throughout their global operations. They built customer records from e-mails, direct mail, telemarketing, and other customer contacts, with descriptive information by department, division, and location.
- Thomson Holidays, the British tour company, developed a Preferred Agents Scheme to enlist the assistance of travel agents in building the database. They collect customer descriptive information and data on trips taken. This enables them to calculate the profit on a per-customer-trip basis.
- Taylor Made, the golf equipment manufacturer, has a database of more than 1.5 million golfers with their names, addresses, e-mail addresses, birthdays, types of courses played, and vacations taken.

These databases are generally made available to all relevant managers through an intranet or some other Web-based interface. This permits managers anywhere in the world to access and add to the customer information.

Companies such as Procter & Gamble and Unilever that sell frequently purchased consumer products have greater problems constructing databases because of a lack of systematic information about their millions of customers and the fact that they use intermediaries (i.e., supermarkets, drugstores) that prohibit direct contact. The challenge is to create opportunities for customer interaction and, therefore, data collection. This can be from running contests to encouraging customer visits to Web sites.

		Customer Interaction	
		Direct	Indirect
Interaction Frequency	High	Banks Telecom Retail	Airlines Packaged Goods Drugs
	Low	Personal Computers Internet Infrastructure	Furniture Autos

Figure 3: Getting more customer interaction. Courtesy of Professor Florian Zettelmeyer of the University of California at Berkeley.

Figure 3 gives a general framework for considering the problems in database construction. Firms in the upper-left-hand quadrant have many direct customer interactions (banks, retail) and therefore have a relatively easy job constructing a database. Firms in the lower-right-hand quadrant have the most difficult job because they interact less frequently with customers and those interactions are indirect (through channels) in nature. Auto and furniture manufacturers are examples here. The other two boxes represent intermediate situations.

The point of this framework is that unless you are in the high-direct box, you have to work harder to build a database. The Thomson Holidays example provides a good illustration of company that uses channel incentives to take a low-frequency product and still obtain customer information. Kellogg has developed a creative solution to the problem through its "Eat and Earn" program where children find a 15-digit code inside cereal boxes and then go to the company's Web site, enter some personal information, and become eligible for free toys. The task for companies is then to move toward the upper-left-hand quadrant through increased customer contact and "event" marketing.

ANALYZING THE DATABASE

Traditionally, customer databases have been analyzed with the intent to define customer segments. A variety of multivariate statistical methods such as cluster and discriminant analysis have been used to group together customers with similar behavioral patterns and descriptive data which are then used to develop different product offerings or direct marketing campaigns (see, for example, Wedel and Kamakura, 1999). Direct marketers have used such techniques for many years. Their goals are to target the most profitable prospects for catalog mailings and to tailor the catalogs to different groups.

More recently, such segmentation approaches have been criticized for the assumption that segments are even reasonably homogeneous (Peppers & Rogers, 1993). Taking a large number of customers and forming groups or segments presumes a marketing effort toward an "average" customer in the group. Given the range of marketing tools available that can reach customers one at a time using tailored messages designed for small groups of customers (what has been referred to as "1-to-1" marketing), there is less need to consider the usual market segmentation schemes that contain large groups of customers (e.g., women 18–24 years of age). Rather, there is increased attention being paid to understanding each "row" of the database—that is, understanding each customer and what he or she can deliver to the company in terms of profits and then, depending on the nature of the product or service, addressing either customers individually or in small clusters.

As a result, although we are not at the point where we can say that segmentation is a dead concept, a new term, "lifetime customer value" (LCV), has been introduced into the lexicon of marketers. The idea is that each row (customer) of the database should be analyzed in terms of current and future profitability to the firm. When a profit figure can be assigned to each customer, the marketing manager can then decide which customers to target.

Although there are a number of formulas that can be used to estimate LCV, one way to start is with a relatively simple formula that uses only the available purchase information in the CIF to calculate each customer's cumulative profitability to the present time:

$$\text{Customer profitability} = \sum_{t} \left[\sum_{j} (\mathrm{P_j}-\mathrm{C_j}) - \sum_{\mathrm{k}} \mathrm{MC_k} \right]$$

where t = the number of past and current time periods measured, j = the number of products purchased in a time period, k = the number of marketing tools used in a time period, P = price, c = cost, and mc = cost of marketing tool (e.g., direct mail).

The formula computes the total profits generated by a customer by taking the total margin generated by the customer (P – C) in each time period from all products and services purchased, subtracting the traceable marketing costs attributable to each customer and then summing over all time periods in the database.

This formula is useful for purposes other than computing customer profitability. An examination of its components shows the levers for increasing individual customer profitability. Profits can be increased by

- Increasing P and j by cross-selling (purchasing more products) or up-selling (purchasing more expensive products),
- Reducing the marketing costs MC over time as the customer loyalty becomes better established, and
- Increasing the number of time periods t that the customer purchases.

To compute the LCV, one must project the customer's generated margins and marketing costs into the future and discount back. This requires a number of assumptions about the nature of a customer's purchasing pattern in the future. A back-of-the-envelope approach to calculating LCV is a margin "multiple" that can be used to multiply the current margin generated by each customer to estimate the LCV (Gupta & Lehmann, 2003). This multiple is

$$R/(1 + I–R).$$

In this formula, R is the retention (loyalty) rate for the product and I is the discount or cost of capital rate used by the company. Thus, for a product with a retention rate of 70% and a discount rate of 12%, one takes the margin generated by each customer and multiplies it by 1.67. This approximates the LCV for that customer.

Other kinds of data analyses besides LCV are appropriate for CRM purposes. Marketers are interested in what products are often purchased together, frequently referred to as market basket analysis. Complementary products can then be displayed on the same page on a Web site. Internet-based firms such as Amazon use collaborative filtering mechanisms that match a customer's past buying habits with similar customers to make product recommendations (Ansari, Essegaier, & Kohli, 2000).

As noted, a new kind of analysis born from the Internet is the clickstream analysis. In this kind of data analysis, patterns of mouse "clicks" are examined from cyberstore visits and purchases to better understand and predict customer behavior (see, for example, Moe & Fader, 2001). The goals are to increase "conversion" rates, the percentage of browsing customers to actual buyers, and sales per customer. For example, companies such as Blue Martini and Net Perceptions sell software that enables Web-based stores to customize their sites in real time depending on the type of customers visiting—that is, their previous buying patterns, other sites visited during the current session, and their search pattern in the cyberstore. An advantage of the Internet is that customer movements on the Web can be tracked, stored, and analyzed in real time to form the basis of increasingly customizable offerings. Brooks Brothers, the retailer of classic men's and women's clothing, is testing a new approach to increasing it e-commerce sales. When a visitor comes to http://www.brooksbrothers.com, software scans the visitor's computer for its Internet (IP, or Internet protocol) address and the user's list of previously visited sites. It then develops a profile of the visitor based on trying to match the information with others in a database of 100 million people. The visitors are then sorted in real time by the site's best guess on gender, marital status, and geography. Subsequently, the visitor is presented with a Web page based on that guess. As a result, a (hypothesized) single male would receive a different page than a woman and an urban male would receive a different product assortment than a rural male.

CUSTOMER SELECTION

Given the construction and analysis of the customer information contained in the database, the next step is to consider which customers to target with the firm's Internet-based and other direct marketing programs. The results from the analysis can be of various types. If segmentation analyses are performed on purchasing or related behavior, the customers in the most desired segments (e.g., highest purchasing rates, greatest brand loyalty) would normally be selected first for retention programs. Other segments can also be chosen depending on additional factors. For example, for promotions delivered by targeted e-mail, if the customers in the heaviest purchasing segment already buy at a rate that implies further purchasing is unlikely, a second tier with more potential would also be attractive. The descriptor variables for these segments (e.g., age, industry type) provide information for deploying the marketing tools. In addition, these variables can be matched with commercially available databases of names to find additional customers matching the profiles of those chosen from the database.

For example, Rust, Lemon and Zeithaml (2000) divide the customer base into Platinum, Gold, Iron, and Lead with decreasing levels of profitability and increasing price sensitivity. The challenge is to develop profiles that clearly distinguish between the segments of the customer "pyramid" so that the marketing manager can develop communications programs to reach them. If individual customer-based profitability is also available through LCV or similar analysis, it would seem to be a simple task to determine on which customers to focus. The marketing manager can use a number of criteria such as simply choosing those customers that are profitable (or projected to be) or imposing an ROI hurdle. The goal is to use the customer profitability analysis to separate customers who will provide the most long-term profits from those who are currently hurting profits. This allows the manager to identify customers who are too costly to serve relative to the revenues being produced and then develop programs that allow them to either become profitable or switch to another supplier. Although this may seem contrary to being customer-oriented, the basis of the time-honored "marketing concept," in fact, there is nothing that says that marketing and profits are contradictions in terms. The 80/20 rule of thumb often holds in approximation: Most of a company's profits are derived from a small percentage of their customers. For example,

- AT&T offers different levels of customer service depending on a customer's profitability in their long-distance telephone business. For highly profitable customers, they offer personalized service. For less profitable customers, you get automated, menu-driven service.
- The wireless provider PageNet raised monthly rates for unprofitable subscribers. Clearly, the intent was to either make them profitable or for them to leave for another company.
- Similarly, Federal Express raised shipping rates for residential customers in expensive-to-serve areas where their volume did not justify normal rates.

The point is that without understanding customer profitability, these kinds of decisions cannot be made.

On what basis should these customer selection decisions be made? One approach would be to take the current profitability based on the above equation. An obvious problem is that by not accounting for a customer's possible growth in purchasing, you could be eliminating a potentially important customer. Customers with high LCV could be chosen, because this does a better job incorporating potential purchases. These customers are difficult to predict, however, and one might include a large number of unprofitable customers in the selected group. No matter what criterion is employed, de-selected customers need to be chosen with care. Once driven away or ignored, unhappy customers can spread negative word-of-mouth quickly, particularly in today's Internet age.

TARGETING THE CUSTOMERS

Mass marketing approaches, such as television, radio, or print advertising, are useful for generating awareness and achieving other communications objectives, but they are poorly suited for CRM because of their impersonal nature. More conventional approaches for targeting selected customers include a portfolio of direct marketing methods such as telemarketing, direct mail, and, when the nature of the product is suitable, direct sales. Writers such as Peppers and Rogers (1993) urged companies to begin to dialogue with their customers through these targeted approaches rather than talking "at" customers with mass media.

In particular, the new mantra, "1-to-1" marketing, has come to mean using the Internet to facilitate individual relationship building with customers. An extremely popular form of Internet-based direct marketing is the use of personalized e-mails. When this form of direct marketing first appeared, customers considered it no different from the "junk" mail that they receive at home and treated it as such, with quick hits on the keyboard's delete button. Sparked by Godin's (1999) call for "permission" based programs whereby customers must first "opt-in" or agree to receive messages from a company, however, direct e-mail has become a popular and effective method for targeting customers for CRM purposes.Companies such as Kana and Digital Impact can send sophisticated e-mails including video, audio, and Web pages. Targeted e-mails have become so popular that an estimated 430 billion e-mail advertisements will be sent in 2002 (O'Connell, 2002).

A study by Forrester Research shows why this is so (Nail, 2000). Figure 4 demonstrates that e-mail is a cost-effective approach to customer retention. Through lower cost per 1,000 names by using the company's own database (the "house" list) and greater clickthrough rates than those afforded by banner advertisements and e-mails sent to lists rented from suppliers, companies can reduce their cost per sale dramatically.

Some examples are the following:

- Southwest Airlines' e-mail-based Click 'n Save program has 2.7 million subscribers. Every Tuesday, the airline sends out e-mails to this database of loyal users containing special fare offers.
- The bookseller Borders (Borders.com, Borders and Waldenbooks offline retailers) collected all of its customer information into a single database. The company then uses e-mails tailored to customers' reading interests to alert them about upcoming releases.
- The Phoenix Suns basketball team sends streaming video messages from its players promoting new

	Customer Acquisition			Customer Retention	
	Direct Mail to Rented list	Banner Advertising	E-mail to Rented List	Direct Mail to "House" List	E-mail to "House" List
Cost Per 1,000	$850	$16	$200	$686	$5
Click-Through Rate	N/A	0.8%	3.5%	N/A	10%
Purchase Rate	1.2%	2.0%	2.0%	3.9%	2.5%
Cost Per Sale	$71	$100	$286	$18	$2

Figure 4: E-mail generates the lowest retention costs. Source: Nail, J., 2000.

ticket packages and pointing them to the team's Web site.

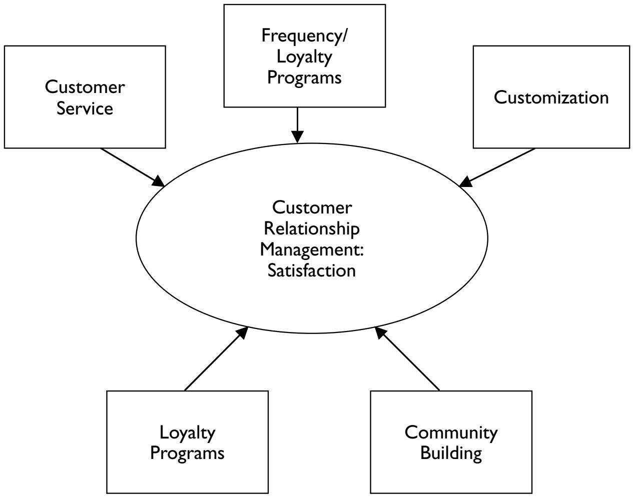
The problem with targeted e-mails today is that many companies are not using the permission-based approach that Godin advocated, resulting in consumer dissatisfaction with increased "spam," because perhaps as many as one third of all the e-mail messages that individuals receive are uninvited. This has reduced the clickthrough rates on rented lists from the 3.5% shown in Figure 4 to about 1.8% in 2002.

RELATIONSHIP PROGRAMS

The overall goal of relationship programs is to deliver a higher level of customer satisfaction than competing firms deliver. There has been a large volume of research in this area (see, for example, Oliver, 1997, and Zeithaml & Bitner, 2000). From this research, managers today realize that customers match realizations and expectations of product performance and that it is critical for them to deliver such performance at higher and higher levels as expectations increase because of competition, marketing communications, and changing customer needs. In addition, research has shown that there is a strong, positive relationship between customer satisfaction and profits (Anderson, Fornell, & Lehmann, 1994). Thus, managers must constantly measure satisfaction levels and develop programs that help to deliver performance beyond targeted customer expectations.

Although customer contact through direct e-mail offerings is a useful component of CRM, it is more of a technique for implementing CRM than a program itself. Relationships are not built and sustained with direct e-mails themselves but rather through the types of programs that are available for which e-mail may be a delivery mechanism.

A comprehensive set of relationship programs is shown in Figure 5 and includes customer service, frequency and loyalty programs, customization, rewards programs, and community building.



Customer Service
Frequency/ Loyalty Programs
Customization

Loyalty Programs
Community Building

Figure 5: Customer retention programs.

Customer Service

Because customers have more choices today and the targeted customers are most valuable to the company, customer service must receive a high priority within the company. In a general sense, any contact or "touch points" that a customer has with a firm is a customer service encounter and has the potential either to gain repeat business and help CRM or to have the opposite effect. Programs designed to enhance customer service are normally of two types. *Reactive* service is where the customer has a problem (product failure, question about a bill, product return) and contacts the company to solve it. Most companies today have established infrastructures to deal with reactive service situations through 800 telephone numbers, faxback systems (automated systems by which customers request information from a menu, and the response is faxed back), e-mail addresses, and a variety of other solutions. *Proactive* service is a different matter; this is a situation in which the manager has decided not to wait for customers to contact the firm but rather to be aggressive in establishing a dialogue with customers before complaining or other behavior sparks a reactive solution. This is more a matter of good account management where the sales force or other people dealing with specific customers are trained to reach out and anticipate customers' needs.

A variety of systems leveraging the Web assist both kinds of service. Charles Schwab has established MySchwab, which allows customers to create personal Web pages linking them to all Schwab services, including stock quotes, trading, and retirement planning analyses. In this way, the company empowers customers to deliver their own service. Other Web-based services such as LivePerson and netCustomer are software products that, when added to a company's Web site, provide customers with the ability to interact with service representatives in real time. Companies such as Kmart are investing large amounts of money into kiosks that provide information on product availability, order status, and a variety of other service-related topics.

Loyalty and Frequency Programs

Loyalty programs (also called frequency programs) provide rewards to customers for repeat purchasing. A recent McKinsey study (Cigliano, Georgiadis, Pleasance, & Whalley, 2000) found that about half of the 10 largest U.S. retailers in each of the top seven sectors (category killers such as Home Depot, department stores, drugstores, gasoline, grocery, mass merchandisers, specialty apparel) have such programs, and there have been similar findings in the United Kingdom. The McKinsey study also identified the three leading problems with these programs: they are expensive, mistakes can be difficult to correct because customers see the company as taking away benefits, and, perhaps most important, there are large questions about whether they work to increase loyalty or average spending behavior (Dowling & Uncles, 1997; Reinartz & Kumar, 2000). A problem that can be added to this list is that because of the ubiquity of these programs, it is increasingly difficult to gain competitive advantage. As the managers for the airlines will attest, however, loyalty programs can be successful by increasing customer switching costs and building barriers to entry. In addition, in some industries, such programs have become a competitive necessity.

Some Web-based companies provide incentives for repeat visits to Web sites, the most notable being MyPoints.com. Although these have not been wildly successful (a number of them crashed and burned in the Internet implosion), it is clear that the price orientation of many Web shoppers creates the need for programs that can generate loyal behavior.

Customization

The notion of mass customization goes beyond 1-to-1 marketing because it implies the creation of products and services for individual customers, not simply communicating with them. Dell Computer popularized the concept with its build-to-order Web site. Other companies such as Levi Strauss, Nike, and Mattel have developed processes and systems for creating customized products according to customers' tastes. Slywotzky (2000) referred to this process as a "choiceboard" by which customers take a list of product attributes and determine which they want. The idea is that it has turned customers into product *makers* rather than simply product *takers*.

For example, a visit to the Levi Strauss Original Spin Web page (http://www.levi.com/Original_Spin/) vividly demonstrates the choiceboard concept. After providing size information at an Original Spin retail store, the customer has a choice of 7 models of jeans (e.g., classic, low cut), 8 leg openings (e.g., tapered, straight), 13 fabrics, and 2 flys (button, zipper). This gives the customer 1,456 options with a perfect fit.

Shapiro and Varian (1999) argued that customization or "versioning" is cheap and easy to do with information goods. In this instance, although a different product would not be built for each individual customer as in the Levi's case, it is relatively easy to develop a number of product configurations for various market segments based on their needs. It is, of course, easier to do this for services and intangible information goods than for products, but the examples given here show that even manufacturers can take advantage of the increased information available from customers to tailor products that at least give the appearance of being customized even if they are simply variations on a common base.

Community

One of the major uses of the Web for both online and offline businesses is to build a network of customers for exchanging product-related information and to create relationships between the customers and the company or brand. These networks and relationships are called communities. The goal is to take a prospective relationship with a product and turn it into something more personal. In this way, the manager can build an environment that makes it more difficult for the customer to leave the "family" of other people who also purchase from the company.

For example, the software company Adobe builds community by devoting a section of its Web site to users and developers. They exchange tips and other information, which binds them more to the company and its brands. By giving the customers the impression that they own this section of the site and by being open to the community about product information, Adobe creates a more personal relationship with its customers. Even companies that sell low-involvement, frequently purchased products attempt to enhance their brands using Web-based communities. For example, Procter & Gamble's Crest brand has a Web site (http://www.crest.com) that invites families to participate in games and obtain information.

Taken together, these relationship programs help to implement the concept of personalization introduced in the introduction. Web-based customer service, loyalty programs, customized products and services, and communities all bring a sense of an individual relationship between company and customer that has been difficult and costly to implement before the commercialization of the Internet.

PRIVACY ISSUES

The CRM system depends on a database of customer information and analysis of that data for more effective targeting of marketing communications and relationship-building activities. There is an obvious trade-off between the ability of companies to deliver customized products and services more effectively and the amount of information necessary to enable this delivery. Particularly with the popularity of the Internet, many consumers and advocacy groups are concerned about the amount of personal information that is contained in databases and how it is being used. Thus, the privacy issue extends all the way through the hierarchy of steps outlined in Figure 1.

This is not a new issue. Direct marketers have mined databases for many years, using analyses based on census tract data, motor vehicle records, magazine subscriptions, credit card transactions, and many other sources of information. With the "in your face" nature of unwanted direct e-mails and the increasing amount of information that is being collected surreptitiously as people browse the Web through ubiquitous "cookies," these concerns have received even more prominence. (For an interesting analysis of how much information can be obtained merely from the user's computer connection to the Internet, visit http://www.privacy.net.) The defining moment in Web privacy occurred in 1999 when the Web ad serving company Doubleclick announced that it was acquiring the direct marketing database company Abacus Direct, with intentions to cross-reference Web browsing and buying behavior with real names and addresses. The public outcry was so strong that Doubleclick had to state that it would not combine information from the two companies.

A study by Forrester Research found a continuum of privacy concerns (Stanley, 2000):

- Simple irritation—primarily the result of unwanted e-mails.
- Feelings of violation—"How do they know that about me?"
- Fear of harm—fears that browsing X-rated sites or booking travel that a consumer does not want others to know about can be revealed, that the Internet can allow others

to access financial or health information, and other concerns.

- Nightmarish visions: Concerns of surveillance by the Internal Revenue Service or "Big Brother" and similar thoughts.

As of this writing, there are eight Internet privacy bills being considered by Congress. The current debate about privacy and the debate in Congress centers around how much control Web surfers should have over their own information. Although many argue that it is in customers' best interest to provide as much data as possible to gain maximum benefit of what the Web has to offer, many disagree. The opponents formalize their arguments in the following two options:

"Opt-in"—In this case, Web users must consent to the collection and use of personal data. This gives the customer more control over his or her own information and helps to build industry confidence. From the marketer's perspective, however, this may substantially reduce the amount of information available in databases.

"Opt-out"—This is the Web version of the direct marketing "negative reply" whereby a customer has to forbid explicitly the collection and use of personal data. This gives more information to marketers and therefore potentially improves the products and services available to customers. The customers bear the loss of control.

These issues are only going to become thornier as the proliferation of wireless devices means more information about customers is available over time. As a result, the main goal of corporate users of Web-based CRM programs should be to build trust between the customer and the company. A large variety of mechanisms for doing this have been proposed (see, for example, Sultan, Urban, Shankar, & Bart, 2002).

METRICS

The increased attention paid to CRM means that the traditional metrics used by managers to measure the success of their products and services in the marketplace have to be updated. Financial and market-based indicators such as profitability, market share, and profit margins have been and will continue to be important. In a CRM world, however, increased emphasis is placed on developing measures that are customer-centric and give managers a better idea of how their CRM policies and programs are working.

Some of these CRM-based measures, both Web- and non-Web-based, are customer acquisition costs, conversion rates (from visitors to buyers), retention/churn rates, same customer sales rates, loyalty measures, and customer share or share of requirements (the share of a customer's purchases in a category devoted to a brand; see Lehmann & Winer, 2002). All of these measures require managers to do a better job acquiring and processing internal data to focus on how the company is performing at the customer level.

THE FUTURE OF CRM

With the increased penetration of CRM philosophies in organizations and the concomitant rise in spending on people and products to implement them, it is clear that we will see improvements in how companies work to establish long-term relationships with their customers. There is, however, a big difference between spending money on these people and products and making it all work: implementation of CRM practices is still far short of ideal. Everyone has his or her own stories about poor customer service and e-mails sent to companies without hearing a response. Despite several years of experience, Web-based companies still did not fulfill many Christmas orders in 2001, and customers continue to have difficulties returning unwanted or defective products. In addition, even those companies who have made large investments in CRM report being dissatisfied with their expenditures on CRM-related hardware and software.

We can expect that the technologies and methodologies employed to implement the steps shown in Figure 1 will improve as they usually do. More companies are recognizing the importance of creating databases and getting creative at capturing customer information. Real-time analyses of customer behavior on the Web for better customer selection and targeting is already here (e.g., Net Perceptions), which permits companies to anticipate what customers are likely to buy. Companies will learn how to develop better communities around their brands, giving customers more incentives to identify themselves with those brands and exhibit higher levels of loyalty.

One way that some companies are developing an improved focus on CRM is through the establishment or consideration of splitting the marketing manager job into two parts: one for acquisition and one for retention. The kinds of skills that are needed for the two tasks are not the same. People skilled in acquisition have experience in the usual tactical aspects of marketing such as advertising and sales. The skills for retention are different because the job requires a better understanding of the underpinnings of satisfaction and loyalty for the particular product category. In addition, time being a critically scarce resource makes it difficult to do an excellent job on both acquisition and retention. As a result, some companies have appointed a chief customer officer (CCO), whose job focuses only on customer interactions.

A possible marketing organizational structure is shown in Figure 6. In this organization, the person overseeing the company's marketing activities, the vice president (VP) of marketing, has both product management and the CCO as direct reports. The CCO's job is to provide intelligence to the VP, from marketing research and from the customer database, for use by product managers in formulating marketing plans and making decisions. In addition, the CCO manages the customer service operation. Although it would perhaps seem more logical for the CCO to report to product management, the reporting arrangement to the VP of marketing is a signal to the company of the prominence of the position. The CCO also interacts with other company managers whose operations may have a direct impact on customer satisfaction.

The CCO at EqualFooting.com, a company offering streamlined purchasing, financing, and shipping services for small manufacturing and construction businesses, has the job of integrating marketing and operations to ensure that customers are satisfied (Manring, 2001). An

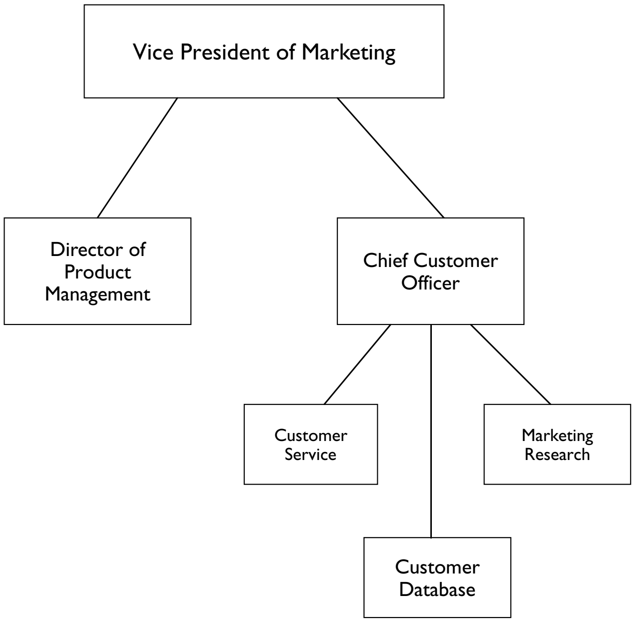

Figure 6: A future marketing organization.

alternative conceptualization is to create two jobs, a customer manager and a capability manager (Pine, Peppers, & Rogers, 2000). The former oversee the relationship with customers while the latter make sure that their requirements are fulfilled.

The notion of customer satisfaction is being expanded to change CRM to CEM—customer experience management. The idea behind this is that with the number of customer contact points increasing all the time, it is more critical than ever to measure the customer's reactions to these contacts and develop immediate responses to negative experiences. These responses could include timely apologies and special offers to compensate for unsatisfactory service. The idea is to expand the notion of a relationship from one that is transaction-based to one that is experiential and continuous.

As with any decision with substantial resource implications, a cost–benefit analysis of CRM investments must be performed. Marketing managers for frequently purchased products such as toothpaste are not as likely to find CRM investments paying out to the extent they will for computer servers, given the differences in difficulties of reaching customers and the profit margins of the respective products. As the Crest community-building effort described earlier shows, however, even toothpaste companies are using the Web to attempt to differentiate their brands from the myriad others appearing in supermarkets and discount stores. This is some evidence that many companies in diverse industries can benefit from the CRM structure.

GLOSSARY

Chief customer officer A manager who is charged with managing a product or company's relationships with its customers.

Churn rate The percentage of a customer base that switches brands in a period.

Clickstream data The data that customers generate from the clicks of the mouse when visiting Web sites.

Customer communities Networks of customers that interact with a company and each other.

A customer database A file of information containing transactions, descriptive information, company contacts, responses to marketing programs, and monetary value to the firm.

Customer experience management (CEM) The management of the experience that a customer has at all of the touch points.

Customer pyramid A hierarchy of groups of customers based on their profitability.

Customer relationship management (CRM) A set of marketing activities and investment in information technology designed to develop long-term relationships with customers.

Direct e-mails E-mails with an advertising message targeting individual customers.

Lifetime customer value (LCV) The present value of the stream of revenues and profits expected to be generated by each customer.

Loyalty and frequency programs Provide rewards to customers for repeat purchasing.

Margin multiple A factor that estimates the LCV when multiplied by the current profit margin that a customer generates.

Mass customization The creation of products and services for individuals or small groups of customers.

Metrics Measures by which the efficacy of marketing programs are judged.

One-to-one Marketing programs that target individual or small groups of customers.

Permission-based e-mails Targeted e-mails in which the customer has given the company permission for contact.

Proactive customer service When a company contacts the customer without a request to do so.

Reactive customer service When the company responds to a customer service request.

Spam Messages from organizations to which a customer has not given permission for e-mail contact.

Touch points All points of contact that a customer has with a firm and its products.

Cybercrime and Cyberfraud

Camille Chin, *West Virginia University*

INTRODUCTION

The phenomenal growth of the Internet continues into the 21st century. With that growth has come tremendous opportunity for education, culture, entertainment, and commerce at the "click of a mouse." However, as the benefits of the Internet increase, the risks have increased as well. We must face the reality that crime has found a home in cyberspace.

Electronic commerce is fast becoming the blueprint for global commerce. For example, 50 million people per day pass through the virtual storefront of eBay; eBay vendors sell goods valued at $12 million every day. The profit-making ability of Internet businesses such as eBay not only boosts the global economy, but also dramatically increases the range of opportunities for criminals to defraud consumers involved in online transactions. The speed and ease of sending e-mail not only facilitate personal and business communication, but also make it easier for computer savvy criminals to use e-mail or keyboard capture devices to obtain the credit card numbers of unwitting consumers.

Cybercriminals are now seizing the opportunity to capitalize on these new business models. While the Internet is a publishing medium that can be used to express our first amendment rights, it is also a medium that can be exploited by forgers and counterfeiters. The challenge that Internet users and lawmakers face is to maximize the commercial and individual benefits of the Internet while minimizing the increasing risk. To minimize risk, we must be educated about cybercrime as well as the resources currently available to protect us from fraudulent online activity. We need to be educated so that we become aware of the gaps that the law does not address with respect to criminal transactions on the Internet. What is cybercrime and cyberfraud? What recourse do we have if cybercriminals victimize us? What can we do to protect ourselves from this new type of crime?

CYBERCRIME

Definition

"Cybercrime" is an evolving concept. Cybercrime constitutes criminal acts, committed by way of computer networks (especially the Internet) that can be accomplished while sitting at a computer keyboard. Such acts include gaining unauthorized access to computer files, disrupting the operation of remote computers with viruses, worms, logic bombs, Trojan horses, and denial of service attacks; distributing and creating child pornography; stealing another's identity; selling contraband; and stalking victims. Cybercrime is a subset of computer crime.

There are many debates today among experts about what constitutes a computer-related crime or cybercrime. Cybercrime generally is understood to include traditional activities such as fraud, theft, or forgery whenever a computer is involved. It can also include a number of new crimes such as cyberstalking (see the online stalking chapter in this encyclopedia).

Cybercrime can also include activities not considered criminal in one jurisdiction, but punishable in another. Since a vast number of criminal acts may constitute cybercrime, this chapter will focus on highlighting the general concept of cybercrime and its classifications, and selected forms of cybersabotage and cyberfraud.

Committing cybercrime is inexpensive if one has the know-how to do it. It is hard to detect if one knows how to erase one's tracks and often is hard to locate in jurisdictional terms, given the geographical indeterminacy of the Internet.

Experts believe that most crimes in the future will involve computers. Recently, the Internet Fraud Complaint Center (IFCC), a public–private partnership among the FBI, the U.S. Department of Justice, and the National White Collar Crime Center, reported that it had received 1,000 complaints of fraud per week since opening in May of 2000. The IFCC anticipates receiving more than 1,000 Internet fraud complaints per day once it becomes fully automated. Cybercrime is growing rapidly across the country, and it is expected that most crimes within the next five years will be related to computers (Internet Fraud Complaint Center, December 2001).

In 1984, Congress enacted U.S. Code (U.S.C.) section 1030 of Title 18, the Computer Fraud and Abuse Act (CFAA), to address computer crimes. The CFAA protects classified information maintained on federal government computers and protects financial records and credit information on government and financial institution computers. Through two amendments in 1986 and 1996, Congress broadened the scope of the CFAA by first extending protection to "federal interest computers" and then by replacing the concept of "federal interest computer" with the phrase "protected computer." A "protected computer" includes any computer "used in interstate or foreign commerce or communication" (Burke, 2001).

Cybercrime Statistics

The most common types of cybercrime, according to statistics compiled by the IFCC, are online auction fraud (48.8%), followed by "nondelivered ordered products" (19.2%), and securities/commodities fraud (16.9%) (IFCC, 2001).

In the IFCC's 2000 Computer Crime and Security Survey, the majority of the respondents were large corporations and government agencies, and 90% of them detected computer security breaches within the last 12 months of the survey. Forty-two percent of the survey's respondents were willing and/or able to quantify their financial loss. The losses from these respondents totaled $265,589,940. Over the past three years, the average annual total was $120,240,180 (Computer Security Institute, 2000).

Of the 1,501 youths, ages 10 to 17, that were surveyed, 20% of them who use the Internet regularly received a sexual solicitation over the Internet in the last year, and 1 in 33 received an aggressive sexual solicitation. Twenty-five percent were unwillingly exposed to pictures of naked people or people having sex; 1 in 17 was threatened or harassed (Finkelhor, 2000).

The most common source of computer crime is a disgruntled employee or former employee. Employees with an average age of 29, holding managerial or professional positions, commit up to 75% of computer crimes (Finkelhor, 2000).

International estimates indicate that cybercrime costs approximately $50 billion annually. More specifically, cybercrime costs the United States more than $5 billion per year. In England, cybercrime is estimated to cost approximately 250 million pounds or $417.7 million annually. In fact, only about 10% of all cybercrimes committed are actually reported and less than 2% result in a conviction. This is primarily due to two reasons. First, businesses and financial institutions believe that they have more to lose by reporting computer security breaches. They argue that customers will lose confidence in the company if business and financial transactions are known to be insecure. Second, a majority of cybercrime victims do not report crimes against them, assuming that law enforcement will provide little or no assistance (Hale, 2002).

TYPES OF CYBERCRIME

Classification of Cybercrime and Cybercriminals

There are two ways to classify cybercrime. One system of classification of cybercrime is the computer as a target or the computer as a tool. The second classification system is to use a profiling approach that distinguishes between insiders and outsiders. The FBI uses the profiling system (FBI, 2000).

Classification 1

Computer as Target. This kind of activity is the wrongful taking of information or the causing of damage to information. A list of specific offenses in this category might include

- Arson (targeting a computer center for damage by fire),
- Extortion (threatening to damage a computer to obtain money),
- Burglary (break-ins to steal computer parts),
- Conspiracy (people agreeing to commit an illegal act on a computer),
- Espionage/sabotage (stealing secrets or destroying competitors' records),
- Forgery (issuing false documents or information via computer),
- Larceny/theft (theft of computer parts),
- Malicious destruction of property (destroying computer hardware or software),
- Murder (tampering with computerized life-sustaining equipment), and/or
- Receiving stolen property (accepting known stolen good or services via a computer).

Computer as Tool. This kind of activity involves modification of a traditional crime by using the Internet in some way. Laws governing fraud apply with equal force regardless if the activity is online or offline, but a few special regulations apply at the federal level:

- Internet fraud (false advertising, credit card fraud, wire fraud, and money laundering);
- Online child pornography, child luring (sexual exploitation, transportation for sexual activity);
- Internet sale of prescription drugs and controlled substances (smuggling, drug control laws);
- Internet sale of firearms (firearms control laws);
- Internet gambling (interstate wagering laws, lottery laws, illegal gambling businesses);
- Internet sale of alcohol (liquor trafficking);
- Online securities fraud (securities act violations);
- Software piracy and intellectual property theft (copyright infringement, trade secrets); and
- Counterfeiting (use of a computer to make duplicates or phonies).

Classification 2

The classification profiles are as follows:

Employees who steal money from the company or harm it some other way. The largest percentage of computer criminals is employees of the particular company being perpetrated. This is usually because they have the easiest access to the computers. Motives vary for employees; they may want to steal some company information and resources for themselves, or they may want to sabotage the company's progress for revenge.

Nonemployees or password crackers ("crackers") who steal or damage its infrastructure in some way. Clients, friends, or suppliers may have access to the company's building, computer system, and/or network. A perfect example of this is a supplier who may have legal access to alter inventory as part of his/her job but also who illegally gains access to suit his/her own needs. Crackers use their skills to gain unauthorized access into computer systems/networks for the fun and challenge of it. They can gain access on-site or can access the systems remotely from their own computers. They may alter files to cause malicious damage for fun and/or for personal profit.

Organized criminals who use a company's information technology for monetary gain (FBI, 2000).

Cybersabotage

Definition

A major subset of cybercrime is cybersabotage, which is the act of using the Internet to undermine the normal functioning of computer systems through the introduction of worms, viruses, or logic bombs. Cybersabotage can be used to promote illegal terrorist activities, to gain economic advantage over a competitor, or to steal programs or data for the purposes of extortion.

Trojan Horses, Viruses, and Worms

Trojan horses, viruses, and worms are all forms of malicious code, which is computer code designed to invade a computer system or to steal information.

Trojan Horses. Trojan horse attacks pose one of the most serious threats to computer security. The name derives from the Greek legend in which the Greeks won the Trojan War by hiding in a huge, hollow wooden horse to get into the fortified city of Troy. Similarly, a computer Trojan horse is a malicious, security-breaking program disguised as something benign such as a screen saver or game.

The most famous Trojan horse was the so-called "Love Bug" in May of 2000. It appeared to be a love letter, but once it was opened, it wreaked havoc by sending itself to everyone in an e-mail address book or Internet relay chat channel, deleting or altering files, and downloading other Trojan horse programs designed to steal passwords.

Many Trojan horses permit password crackers to control a person's computer remotely in order to, for example, use the computer to perform denial of service attacks.

Many people use terms such as Trojan horse, virus, and worm interchangeably, but these terms do not mean the same thing. Trojan horses can be designed to have many functions, such as destroying data, software, and hardware, or transferring a computer virus or a worm. However, a Trojan horse is just as dangerous as a virus or a worm and can easily replicate itself rapidly to harm others. Federal law provides remedies to individuals harmed by Trojan horse programs. Any impairment to the computer system, or data contained therein, is governed by several subsections of section 1030(a) in Title 18 of the United States Code (Colombell, 2002).

Viruses. A malevolent virus is a small piece of programming code usually disguised as benign files that are designed to penetrate and damage personal computers and their contents, operating systems, and computer networks. Programmers write viruses to execute certain functions by altering the original computer program.

Computer viruses are usually designed to spread to other computer users instantly. Viruses transmit themselves as e-mail attachments, as zipped files, or as downloaded files, or they attach themselves to a CD or diskette. Some viruses work instantly; other viruses are initially dormant until the host computer executes the virus' code. Viruses require human interaction to spread, so virus execution occurs when the recipient computer user is tricked into opening an e-mail attachment. Viruses can inflict serious damage, such as erasing hard drives or files, or they are designed to simply taunt the victim with pop-up windows (e.g., pop-up windows saying, "Ha Ha! You are infected!"). There are three main types of viruses:

File infectors: Some file infector viruses attach themselves to program files, .com or .exe files, or they infect programs or .sys, .ovl, .prg, and .mnu files. The virus loads itself when the program loads.

System or boot-record infectors: These viruses infect executable code found in certain areas on a system disk or boot disk. They attach to the DOS boot sector on diskettes or the master boot record on hard disks. A typical scenario is to receive a diskette from an innocent source that contains a boot disk virus. To prevent this type of attack, one should always have a bootable floppy disk.

Macro viruses: Macro viruses infect the Microsoft Word application and typically insert unwanted words or phrases. These are among the most common viruses, and they tend to do the least damage; however, some may argue that they can cause substantial damage (Lo, 2000).

In March of 1999, David Smith, a 28-year-old middle school teacher, authored and launched the Melissa Virus, which harmed over a million computers across the world and caused over $80 million in damages. The virus was hidden in Microsoft Word attachments that appeared to be from a person known to the victim, and once it was activated it e-mailed itself to the first 50 addresses in the victim's Microsoft Outlook e-mail program. Within 48 hours of Melissa's launch, both Intel and Microsoft were forced to shut down their servers.

The federal criminal statute provision that penalizes virus writers such as Smith is 18 U.S.C. section 1030(a)(2). This provision addresses viruses that invade computer systems and sends data from the computer. Another provision is section 1030(a)(5)(A), which prohibits the intentional transmission of viruses disguised as e-mail attachments that damage a computer system. Also, a number of states have adopted statutes criminalizing virus dissemination along with computer fraud and computer intrusions (see Cyber Crime Report at http://www.ifccfbi.gov).

Worms. Worms are special types of viruses that can replicate themselves and use memory but cannot attach themselves to other programs. Unlike viruses, however, worms do not require human interaction and can spread themselves automatically over the network from one computer to the next. Worms are designed to take advantage of automatic file sending and receiving features found on many computers. Malicious worm programs freeze computer monitors and keyboards, disable computers, slow down computers, and use up significant amounts of computer memory.

The Morris Worm, unleashed in November of 1988, was one of the most devastating worms in Internet history. Robert Morris released the worm into a Department of Defense network. It disabled more than 6,000 computers with repair damages per computer ranging from $200 to more than $53,000. In 1989, the Second Circuit Court of Appeals upheld Morris' conviction under the Computer Fraud and Abuse Act, 18 U.S.C. section1030(a)(5)(A) (Burke, 2001).

Computer users can protect themselves from malicious code by using antivirus programs to detect viruses and to prevent their spread. Trojan horses and worms are now more prevalent today than viruses, so antivirus programs are designed to combat rapidly spreading Trojan horses and worms more so than viruses.

The best steps for protection against viruses is to use antivirus software and know the origin of each program or file loaded into the computer or downloaded from e-mail attachments; also check all files periodically and remove any viruses that are found. Be wary of e-mail messages warning of new viruses. Unless the warning is from a recognized source, the warning could be a virus hoax.

Denial of Service Attacks

Denial of service (DoS) attacks, also known as "nukes," "hacking," or "cyberattacks," are incidents in which a user or organization is deprived of the services of a resource they would normally expect to have; in other words, a denial of service attack is an attempt by attackers to prevent legitimate users of a service from using that system. Denial-of-service attacks can essentially disable a computer or network. Usually, the loss of service is the breakdown of network services such as e-mail, or the temporary loss of all network connections and services. In the worst cases, for example, a Web site accessed by millions of people can occasionally be forced to temporarily shut down. Computer system files and programming can also be a casualty of a denial of service attack. DoS attacks are common. The attacks should not be confused with viruses, Trojan horses, worms, and cracking or "hacking."

There are two categories of DoS attacks—operating system attacks and network attacks. Operating system attacks target bugs in specific operating systems and can be fixed with patches. Network attacks exploit networking limitations and may require firewall protection. Denial of service attacks may be part of a larger invasion. Examples of DoS attacks include

attempts to "flood" a network, thereby preventing legitimate network traffic,

attempts to disrupt connections between two machines, thereby preventing access to a service,

attempts to prevent a particular individual from accessing a service, and

attempts to disrupt service to a specific system or person (Lo, 2002).

A denial of service attack can cost the targeted individual or organization considerable time and money. However, these attacks are a type of security breach to a computer system that does not usually result in the theft of information or other security loss. The recent DoS attack on 13 Internet servers around the world illustrates this point. At approximately 4:45 p.m. on Monday, October 21, 2002, these servers were bombarded with 30 to 40 times the normal amount of data. Seven of the 13 servers had periods of zero-response and Internet commerce sites such as eBay, Amazon.com, and Yahoo! also had periods of zero-response. Some have described this incident as the largest denial of service attack in Internet history.

Specific types of denial of service attacks are

a. *Buffer Overflow Attacks:* The most common kind of DoS attack is to overwhelm a network address with more traffic than what the programmers who planned its data buffers anticipated. The attacker may actually be aware of a weakness in the target system and may be trying to exploit it, or the attacker may be testing the system to see if an attack will succeed. Attacks based on the buffer characteristics of programs or systems include these:
   - Sending e-mail messages that have attachments with 256-character file names to Microsoft and Netscape mail programs.
   - Sending a message with a "From" address larger than 256 characters to a user of the certain e-mail programs (Carnegie Mellon Software Engineering Institute/CERT, 1997).

b. *Viruses:* Computer viruses can serve as denial-of-service attacks when there is no specific victim targeted just a host who is unfortunate enough to receive the virus.

c. *Zombies:* A zombie is a computer that has been implanted with a daemon that puts it under the control of a malicious hacker without the knowledge of the computer owner. Malicious hackers use zombies to launch DoS attacks. The hacker sends commands to the zombie through an open port. On command, the zombie computer sends an enormous amount of packets of useless information to a targeted Web site in order to clog the site's routers and keep legitimate users from gaining access to the site. The traffic sent to the Web site is confusing and therefore the computer receiving the data spends time and resources trying to understand the influx of data that has been transmitted by the zombies. Compared to programs such as viruses or worms that can eradicate or steal information, zombies are relatively benign as they temporarily cripple Web sites by flooding them with information and do not compromise the site's data. Such prominent sites as

> Yahoo!, Amazon.com, and CNN.com were shut down in 2000 by zombie DoS attacks. Zombies are also referred to as *zombie ants* (Colombell, 2002).

The Computer Fraud and Abuse Act has several provisions that regulate denial of service attacks. DoS attacks can be a serious federal crime under the National Information Infrastructure Protection Act of 1996, with penalties that include imprisonment. At a minimum, DoS offenders usually lose their Internet service provider accounts or are suspended if they used school resources to launch the attack. However, DoS attacks are not explicitly criminalized in many state codes (FBI, 2000).

Social Engineering

Social engineering is a password cracker's use of psychological tricks on legitimate users of a computer system/network to gain the information (user names and passwords) he/she needs to gain access to a computer system/network. Social engineering is basically a new way to commit fraud in the information age or to "pull a con job," hacker style. The object is to get information or access to systems that are normally only used by privileged users. The following excerpt illustrates examples of social engineering:

> A woman calls a company help desk and says she's forgotten her password. In a panic, she adds that if she misses the deadline on a big advertising project her boss might even fire her. The help desk worker feels sorry for her and quickly resets the password—unwittingly giving a hacker clear entrance into the corporate network.
>
> Meanwhile, a man is in back of the building loading the company's paper recycling bins into the back of a truck. Inside the bins are lists of employee titles and phone numbers, marketing plans and the latest company financials. All free for the taking. (Gaudin, 2002)

Hackers, and possibly even corporate competitors, are breaching companies' network security every day. The latest survey by the Computer Security Institute and the FBI shows that 90% of the 503 companies contacted reported break-ins within the last year.

What may come as a surprise, according to industry analysts and security experts, is that not every hacker is sitting alone with his/her computer hacking his/her way into a corporate VPN or running a program to crack executives' passwords. Sometimes all hackers have to do is call up and ask (Gaudin, 2002).

Social engineering has existed in some form or another since the beginning of time, primarily because most people are helpful and trusting. It is human nature. The Love Bug virus illustrates this; it was designed to exploit the psychological need and/or want of human beings to be loved. Other social engineering tools used by password crackers include the telephone, e-mail viruses, "dumpster diving," and the use of "snail mail"—mailing a fraudulent survey that asks delicate questions and offers a cash reward for completion.

So with the immeasurable security threat that social engineering brings to the computing community, why is very little ever said about it? In general, victims view social engineering as an attack on their intelligence, and apparently victims do not want to be considered "ignorant." The reality is that a large number of computer users are, and will continue to be, susceptible to social engineering attacks.

Although the methods used by social engineers rely on the same principle, the disguises of the password crackers may vary greatly, depending on the cracker's level of skill and the type of information he or she seeks. One common method used is for the attacker to pretend he/she is new to the system and needs assistance with gaining access. The role as a new person ("newbie") is easy for a potential password cracker to assimilate. The cracker can easily pretend not to know much about a system and still retrieve information. This ruse is commonly used when the attacker is unable to research enough about the company or finds enough information to undermine computer security. A simple method of this technique is for the cracker to call a secretary for the company and pretend that he or she is a new temporary agent having trouble gaining access into the system. The secretary (or other legitimate user) may be inclined and proud to be able to offer help to the new person on the job. The user may simply give out the guest account name and password or may even go into detailed instructions on log-in procedures for different departments. Once the intruder is in a guest account, however, he or she may be able to access other (more important) accounts from there.

Another guise used by social engineers is to pose as computer aides or helpers and try to gain information as the potential victim fixes the computer. This technique, however, relies on the assumption that there is something wrong with the computer system. When the social engineer poses as a helper, the legitimate user often is less suspicious and more willing to answer inquisitive questions. Another role for the attacker to assume is that of a system operator for the network itself. The potential password cracker will pretend that an error in all the accounts has been made and that he or she needs to reset the accounts. To do that, the attacker needs the old passwords of the users. If the employee is naive enough, he or she will divulge the information, thinking that they are doing their company a service (Nelson, 2000).

The most famous social engineer to date is Kevin Mitnick. Mitnick served almost five years in prison for breaking into computers, stealing data, and abusing electronic communication systems. Mitnick said in a speech, "You try to make an emotional connection with the person on the other side to create a sense of trust. That is the whole idea: to create a sense of trust and then exploit it. Through social engineering, I gained the ability to obtain any number, listed or unlisted. This really came easy to me—manipulating the Telephone Company" (Lemos, 2000).

What can be done to protect a person or business from social engineering? First, potential victims need to be aware that it exists. Individuals must be trained to avoid giving out any more information than necessary if anyone solicits sensitive information. In other words, if anyone asks for a password, one must avoid divulging one's password information or divulging anyone else's password to anyone for any reason.

If a person or business suspects a social engineering attack, or is the victim of a social engineering attack, the victim should immediately notify the person(s), or department(s) responsible for computer/network security. The only way that these criminals can be apprehended is if more victims quickly and accurately report these crimes as they occur.

Cyberfraud

Definition

Cyberfraud is any type of fraud that occurs on the Internet. The most common forms are online auction fraud, including nondelivery of paid products purchased through online auctions, identity theft, and credit card theft. Other common forms of cyberfraud include nondelivery of merchandise or software bought online from non-auction sites, data break-ins, and online securities fraud.

Internet Auction Fraud

What is an Internet auction? An Internet auction site is a virtual marketplace that requires sellers to register and create a user identification tag. The seller then lists the items they wish to sell on the Web site, usually including a digital picture of the item and a written description. Bidders are required to register and create user identification tags before they place bids on items they wish to purchase. Potential buyers bid against each other until the auction ends. The seller determines the time and date for the end of the auction. When the auction expires, the highest bidder wins (Federal Trade Commission, 2000b). The winner sends payment, including shipping and handling charges, to the seller, either through credit card payments, money orders, checks, or online payment methods such as Western Union BidPay, PayPal, and eBay's Billpoint. Once the payment is received, the seller ships the auctioned item(s) to the buyer to complete the transaction.

What is Internet auction fraud? There are seven types of Internet auction fraud, and most of them involve fraud on the part of the seller: nondelivery of goods, triangulation, misrepresentation, shill bidding, selling black market goods, fee stacking, and bid shielding or multiple bidding (IFCC, 2001).

The first category is nondelivery of goods. This occurs when the seller knowingly auctions off an item that does not exist. The seller places a description and digital picture of the nonexistent item on an auction Web page, receives payment from the highest bidder at the end of the auction, and never delivers anything to the buyer. In addition to duping the buyer out of the winning bid price, the seller also gets access to the buyer's credit card number and name, which can be used for identity theft crimes.

Triangulation schemes also combine identity theft with Internet auction fraud, and victimize online merchants and unwitting bidders. The perpetrator steals the credit card number and identity of another and uses that information to purchase goods from online merchants. The thief then offers the purchased goods for sale on an online auction site and sells the goods to the highest bidders.

Misrepresentation occurs when the seller places false or misleading information about the item offered for sale on the auction site to make the item appear to be more valuable than it actually is.

Shill bidding is when the seller or an accomplice of the seller uses another user identity to bid against potential buyers. The result is that the seller or the seller's accomplice purposely drives up the price of the item being auctioned, to the detriment of legitimate bidders.

Perpetrators who auction black market goods for sale usually place illegally obtained goods, such as pirated CDs, software, and videos, onto Internet auction Web sites without the appropriate packaging, instructions, or warranty information.

Another type of illegal auction fraud identified by the IFCC is fee stacking. Fee stacking occurs when the seller drives up the total price of the merchandise auctioned by adding separate fees for shipping containers, for handling, and for shipping instead of listing a flat rate for shipping and handling.

Bid shielding or multiple bidding is similar to shill bidding except that it involves fraud on the part of the buyer. The buyer creates several user identities and uses them to place multiple bids for the same item. By driving up the price with multiple aliases, the buyer drives other potential buyers away, and then the buyer retracts the high bids placed just before the end of the auction. The result is that the buyer wins the auction at a lower bid price.

What are examples of Internet auction fraud? In May of 2001, an eBay seller from Arlington, Virginia, was arrested for defrauding 20 victims out of approximately $6,000. The seller sold 20 first editions of the Harry Potter book series containing fraudulent autographs. The perpetrator placed digital pictures of the books along with a description in which he claimed that the books were worth $3,000 because they were legitimate first editions or first prints autographed by the author of the Harry Potter series (Duffy, 2001).

In February of 2002, three men of Seattle, Washington, were arrested and charged with wire fraud for running a shill-bidding ring on eBay. The seller and two coconspirators were accused of manufacturing over $1.3 million in high bids on highly collectable Rene Lalique glass (David Steiner, 2002).

In May 2002, an online auction seller was indicted for defrauding over 30 victims out of more than $25,000. Over a five-year period, the perpetrator offered computer laptops for sale and instructed the auction winners to send payment to a mailbox address. The seller never delivered goods to the victims (Ina Steiner, 2002).

What can be done to protect oneself from Internet auction fraud? Buyers should do the following: Get as much information as possible about the seller before bidding on any items the seller offers at auction. Buyers should also try to get the seller's name, physical address, and phone number. Potential victims should be particularly cautious if the seller only lists a post office box address instead of a physical address, if the seller is located outside of the United States, or if the seller only lists an e-mail address. Before engaging in these types of transactions, buyers should check the seller's feedback ratings posted on the auction site from prior buyers, but be wary of shill feedback posted by the seller or the seller's friends. Before bidding, buyers should determine what form of payment the seller will accept and be especially cautious if the seller accepts only money orders or cashier's checks and does not accept credit cards. It is safer to use credit cards, escrow services, or online payment services such as PayPal or use cash on delivery C.O.D. through the U.S. Postal Service (*Bidder beware,* 2002).

Buyers should also be sure to get information about the shipping and handling charges to be added to the price of the item before bidding. The more accurate information a potential buyer has prior to bidding, the more likely one is to protect oneself from this type of fraud; buyers should take time to learn exactly how the online auction works before bidding. Finally, buyers should never give out personal identifying information such as social security numbers or driver's license numbers to sellers.

What efforts have been made to protect buyers from Internet auction fraud? Presently, there is no regulation of Internet auction sites other than self-regulation.

Online auction sites usually place disclaimers throughout the site that are structured to minimize legal liability for any fraudulent activity occurring on the site. Internet auction sites are more similar to flea markets than to traditional auctions because these sites simply provide a venue for buyers and sellers to buy and sell their wares; unlike many traditional auctions, internet auction sites never possess title to any of the auctioned items.

Other than using the host site's feedback rating system, the only recourse that a victimized consumer has is to file a complaint with agencies such as the Federal Trade Commission, the Internet Fraud Initiative established by the Department of Justice, the IFCC, or the Better Business Bureau Online (Albert, 2002).

Internet Identity/Credit Card Theft

What is identity theft? Identity theft is the act of stealing the identifying information of others to access their financial resources through fraud and impersonation.

How does someone steal one's identity? First, the identity thief or impostor steals personal information such as one's name, birth date, social security number, driver's license number, credit card numbers, bank account numbers, mother's maiden name, and any other identifying information. Second, the identity thief uses the stolen personal information to commit fraudulent acts by assuming the victim's identity and withdrawing money from the victim's bank accounts, or submitting false applications for credit cards, auto loans, or bank loans. Sometimes the impostor uses the victim's personal information to open bank accounts, set up utility or cellular phone accounts, purchase homes, lease apartments and cars, or obtain driver's licenses and passports that contain the victim's name and personal information but with the perpetrator's picture in place of the victim's (Federal Trade Commission, 2002a).

How does the identity thief obtain a victim's personal information? Thieves watch victims as they enter credit card numbers, calling card numbers, and PINs ("shoulder surfing"). They listen as victims give their credit card information over the telephone. They steal a victim's mail and go through their garbage for bank or credit card statements or medical records. They break into a victim's home or automobile to steal personal information, and they "break in" or use password cracking skills or keystroke mirroring software to gain access to a victim's personal computer. Thieves use electronic devices to download the credit or debit card information of their victims ("skimming") (Hoar, 2001), or they use Internet databases to select their victims (Sabol, 1999).

What is the impact of identity theft on the victim? It may take months or even years before a victim realizes that their identity has been stolen. During that time, the perpetrator borrows and spends thousands of dollars using the victim's name and creditworthiness. Usually the defrauded creditor initiates collection action or even lawsuits against the victim, and the victim's credit rating and reputation is destroyed. Sometimes the victim is arrested for crimes committed by the impersonator. In some cases, victims have lost job opportunities or have even been fired.

What are examples of identity theft: In September 1997, the United States Secret Service brought an identity theft case against a couple from Maryland. They pled guilty to incurring $100,000 of debt under the stolen identities of victims that they selected from Internet databases (Saunders & Zucker, 1999).

In July and October of 2000, two members of an identity theft ring were prosecuted in the federal district court in Oregon. They hacked into personal computers and Web sites with keystroke mirroring software designed to capture credit card information, and they burglarized automobiles, stole mail, and searched the garbage of their victims to obtain identity information. The thieves used the stolen information to make approximately $400,000 in purchases on 400 fraudulently obtained credit card accounts (Hoar, 2001).

In August of 2000, two defendants were convicted in the federal district court in Delaware of obtaining the names and social security numbers of high-ranking military officers from an Internet Web site. They then used the information to incur approximately $300,000 in debt from fraudulently obtained bank and corporate lines of credit as well as credit cards (Hoar, 2001).

Last year, over 250,000 customers of an online bank were duped into providing bank account information to criminals. The thieves copied the bank's Web site and then manufactured a fraudulent e-mail message, purportedly sent from the bank, requesting that customers go to the link (to the copied Web site) and reregister account information that had been lost due to "technical problems." (Cronin & Weikers, 2002).

What laws exist to protect victims of identity theft? Congress enacted the Identity Theft and Assumption Deterrence Act on October 30, 1998. The Act mandates that the theft and misuse of personal information with the intent to commit an unlawful act be subject to a maximum fine of $250,000 and up to 25 years' imprisonment. As the agency primarily responsible for enforcing the Act, the Federal Trade Commission records and tracks complaints of identity theft, coordinates investigation of complaints with law enforcement agencies, and educates the public about identity theft (Saunders & Zucker, 1999). Several state legislatures have also enacted statutes designed to criminalize identity theft.

What can be done to protect oneself from identity theft? The victim(s) should contact the defrauded creditors, major credit bureaus, the social security administration, local police, and postal inspectors. The victim(s) should also follow up with a written correspondence via certified mail, return receipt requested. Victims may also want to contact the National Crime Information Center (Sabol, 1999).

Internet Investment Fraud

What constitutes Internet investment fraud? The most prevalent form of fraudulent activity related to investment activity on the Internet is market manipulation. In Ernst & Ernst v. Hochfelder, 425 U.S. 185, 195 (1976), the U.S. Supreme Court defined market manipulation as activity that "connotes intentional or willful conduct designed to deceive or defraud investors by controlling or artificially affecting the price of securities."

There are several types of market manipulation that occur over the Internet. These include, the posting of misleading information on message boards or "Web hoax" cases; the "accidental" delivery of private insider information via e-mail to "unintended recipients," and the posting of misleading investment information in chatrooms through "pump and dump" schemes or "stock guru" cases and/or "momentum trading" schemes, or "free stock offer" cases (Walker & Levine, 2001).

What are examples of Internet investment fraud? On August 25, 2000, misleading information about Emulex Corporation was posted in the form of a press release to an online news service. The fake press release indicated that the CEO and President of Emulex resigned, that the Securities Exchange Commission (SEC) was investigating accounting irregularities at the company, and that the company had sustained fourth quarter losses. For about an hour and a half, two different investment news services ran headlines based on the false press release. Even after the Web hoax was reported, Emulex stock was trading down 6 3/8 points.

On September 20, 2000, the SEC charged a 15-year old boy from New Jersey with civil fraud for making $272,826 of illegal profits based on a "stock guru" scheme. He created several aliases and brokerage accounts to purchase a large block of stock. He then sent misleading e-mail messages pumping up the value of the stock to several investment message boards. Within 24 hours, the perpetrator sold the large block of stock and gained profits between $11,000 and $74,000 on each trade (Walker & Levine, 2001).

On September 6, 2000, the SEC charged the creator of an e-mail list referred to as the "Unity List" with violations of section 17(a) of the Securities Act of 1933, and sections 10(b) and 10(b)(5) of the Securities Exchange Act of 1934. The perpetrator sent thousands of e-mails to the names on the e-mail list indicating that he intended to purchase large blocks of stock from certain companies and urging the e-mail recipients to buy stock in those same companies. The perpetrator owned shares in those companies beforehand and sold those shares as soon as the momentum he created in that stock caused the price per share to increase. He made over $12,000 in profits from this momentum trading scheme (Bell, 2002).

The SEC regulates the securities market and enforces the provisions of both the Securities Act of 1933 and the Securities Exchange Act of 1934. The Securities Exchange Act of 1934 applies to online market manipulation and regulates secondary trading. The 1934 Act contains antifraud provisions that make deceptive and manipulative conduct in connection with the purchase or sale of securities unlawful. Civil and criminal law suits may be initiated under the antifraud provisions. Each state also has securities enforcement agencies and state statutes designed to regulate securities fraud (Hittle, 2001). The SEC's Division of Enforcement (DOE) initiates investigations of securities law violations and files civil lawsuits against violators of the securities laws; the DOE also issues injunctions, and in some cases, initiates criminal prosecution. In addition, private individuals may initiate civil law suits.

In July 1998, the SEC established the Office of Internet Enforcement to investigate Internet investment fraud, and to oversee the online Enforcement Complaint Center and the Cyberforce, a team of investigators, lawyers, and accountants who surf the Internet looking for evidence of online securities fraud.

What steps can potential investors take to protect them from Internet investment fraud? Investors can educate themselves to recognize the warning signs of Internet investment fraud by taking advantage of the resources offered by educational agencies such as the SEC's Office of Investor Education and Assistance.

Potential investors can also access large amounts of information about companies by using the Internet. They can look for any evidence of insider trading and any evidence of inconsistencies between past company statements and current statements. Message boards can provide insight and additional information about companies. If an investor believes he or she has been defrauded then he or she may use the Internet to get information on any recently filed securities fraud cases against the company.

CONCLUSION

The advancement of Internet commerce has enabled many individuals around the world to become entrepreneurs. However, criminally minded individuals have used the Internet as a means to commit crime. Different variations of cybercrime and cyberfraud, Internet auction fraud and identity theft, for example, have increased dramatically in the past five years and will continue to increase.

Cybercriminals now have an arsenal of sophisticated tools to further their goals. Criminals can engage in corporate sabotage by planting Trojan horses, worms, and viruses in computer networks. Password crackers can use long established methods of fraud to extract delicate information from unwitting victims through social engineering. Cybercriminals can completely shut down businesses and potentially damage the Internet with denial of service attacks. In fact, the most destructive denial of service attack in Internet history occurred at the end of the business day on Monday, October 21, 2002. Thirteen computer servers around the world were attacked with 30 to 40 times the normal amount of data. Sites such as eBay, Amazon.com, and Yahoo! were temporarily inaccessible as a result of this attack. The incident highlighted the need for government and industry to stay ahead of those individuals who attempt to sabotage Internet security and Internet commerce.

The incidence of cyberfraud has also increased dramatically over the past five years. Online auctions present a myriad of opportunities for cybercriminals to engage in fraudulent transactions. The ease with which anyone can use the Internet to obtain personal information about consumers explains the sharp increase in identity theft and credit card fraud. White-collar criminals can now use the Internet, e-mail, chat rooms, and bulletin boards to manipulate markets on a much larger scale than ever before.

All Internet users should take advantage of the wealth of opportunities that the Internet affords us; however, Internet users should also take steps to prevent and stop the abuse and exploitation by cybercriminals. The only way to achieve this goal is to promote cybercrime prevention through wide-scale education and training of the participants of e-commerce.

GLOSSARY

Antivirus software A class of program that searches the computer hard drive and floppy disks for known or potential viruses.

Back door A vulnerability intentionally left in the security of a computer system or its software by the software programmers.

Black hat A term used to describe a "hacker" who has the intention of causing damage or stealing information.

Buffer A buffer is a data area shared by hardware devices or program processes that operate at different speeds or with different sets of priorities. The buffer allows each device or process to operate without being delayed by the other. For a buffer to be effective, the size of the buffer and the algorithms for moving data into and out of the buffer need to be considered by the buffer designer. Like a "cache," a buffer is a "midpoint holding place" but exists not so much to accelerate the speed of an activity as to support the coordination of separate activities. This term is used both in programming and in hardware. In programming, buffering sometimes implies the need to screen data from its final intended place so that it can be edited or otherwise processed before being moved to a regular file or database.

Cache (pronounced "cash") **1.** A storage area on the computer motherboard that keeps frequently accessed data or program instructions readily available. **2.** In a browser, a section of the hard drive that is set aside for storing recently accessed Web pages.

Cracker Password crackers—"crackers"—are often mistakenly called "hackers." Crackers are the so-called "bad guys" who seek to "crack" or gain unauthorized access to computers, typically to do malicious acts, e.g., to steal credit card information or destroy computer files. Crackers might accomplish this by writing a program called a "virus," "worm," or "Trojan horse." Alternatively, they may exploit weaknesses in the computer's operating system in order to gain entry. Many crackers will install a "backdoor" that allows the cracker to "remote control" the user's computer over the Internet, for example, to distribute child pornography or to perform a "denial of service attack" against somebody else.

Cracking The process used by "crackers" (see above) attempting to overcome a security measure.

Daemon (pronounced "demon" or "damon") A program, usually on a computer running the UNIX operating system, that serves some obscure function (such as routing e-mail to its recipients) and usually has a very limited user interface.

Denial of service attack An attack that causes the targeted computer system to be unable to fulfill its intended function.

Firewall A system designed to prevent unauthorized access to or from a private computer network. Firewalls can be implemented through both hardware and software, or a combination of both. Firewalls are frequently used to prevent unauthorized Internet users from accessing private networks connected to the Internet, especially intranets. All messages entering or leaving the intranet pass through the firewall, which examines each message and blocks or denies entry to those that do not meet the specified security criteria. A device designed to enforce the boundary between two or more networks, limiting access.

Hacker When used properly, this term refers to an elite breed of so-called "good guys," who are talented computer programmers. They enjoy solving challenging problems or exploring the capabilities of computers. True hackers subscribe to a code of ethics and decry the illegal and immoral activity of crackers (defined above). When the press uses "hackers" to describe authors of virus programs or criminals who use the Internet to commit theft or vandalism, it is not only inaccurate, but also interpreted as insulting to those who define themselves as true hackers.

Hacking The original term referred to the learning of programming languages and computer systems; now associated with the process of bypassing the security systems on a computer system or network.

Internet service provider A company that provides access to the Internet for individuals or other companies.

Internet relay chat (IRC) A "chat" system developed by Jarkko Oikarinen in Finland in the late 1980s. IRC has become very popular as more users connect to the Internet because it enables those connected at any location on the Internet to join in live typed discussions. Unlike older chat systems, IRC is not limited to two participants.

Logic bomb A delayed-action computer virus or Trojan horse. A logic bomb, when "exploded," may be designed to display or print a spurious message, delete or corrupt data, or have other undesirable effects.

Network In information technology, a network is a series of points or nodes interconnected by electronic communication paths. Networks can interconnect with other networks and contain subnetworks. The "Internet" is a network of networks, i.e., an internetwork.

Node In a computer network, a node is a connection point, usually a computer.

Password sniffing The process used by a program to examine data traffic for the purpose of finding passwords to use later in masquerading attacks.

Trojan horse An apparently innocuous program that contains code designed to surreptitiously access information or computer systems without the user's knowledge. For example, a harmless holiday greeting card delivered via e-mail, when opened, executes a program to copy the user's files and transmit them to the attacker through the Internet.

Virus A computer program designed to replicate or copy itself and spread the copies itself from one machine to another without the aid, and often without the knowledge, of the user.

Virus hoax A virus hoax is a false warning about a computer virus.

Worm A worm is a self-replicating virus that does not alter files but resides in active memory and duplicates itself. Worms use parts of a computer operating system that are automatic and usually invisible to the user. It is common for worms to be noticed only when their uncontrolled replication consumes system resources, slowing or halting other tasks.

Cyberlaw: The Major Areas, Development, and Provisions

Dennis M. Powers, *Southern Oregon University*

INTRODUCTION

As the number of Internet users, Web connections, and personal computers increased exponentially, controversies and legal problems also accelerated in cyberspace without any specific statutes or case law to govern conflicts. Despite solid preexisting legal foundation, no information medium ever had such an enormous appetite to leapfrog geographic territories and laws, in turn creating intense pressures on that system.

If somebody "ripped off" another's slogan or logo in "pre-Net" California, it was possible that a business located in Chicago would never know the difference. If one person wrote a defamatory article in a local Florida newspaper about someone in Oregon, the defamed person at that time could have died before reading that particular printed statement. Once the Internet came into existence, however, anyone with an Internet connection—whether living in Florida or in France—could stumble across that slogan or posting. Large organizations were caught napping when more nimble entrepreneurs registered their trademarks as domain names, and then offered to sell those registrations back for outrageous sums of money. And who could ever have predicted the rise of mass-copying technology such as Napster that bypassed the copyrights of the musicians, composers, and recording studios?

Then add in the wide differences among the laws of wide numbers of states and other countries. Whether entered into by e-mail or not, a contract under certain facts could be fine in Georgia but void in California, and a copyright claim upheld in Japan, but not in the United States with its differing laws and "fair use" exception. Over time, court decisions confirmed existing legal concepts as applicable to cyberspace, and specific statutes were enacted to fill in the gaps. These basic legal concepts with later refinements proved adaptable to the Internet technology of the new millennium, just as they had during the dawning of new technologies in the past century and as unfolds during the course of this chapter.

COPYRIGHT LAW

Your computer is a worldwide copying machine, and the Internet made it extraordinarily easy for nearly anything to be instantly copied, e-mailed, and printed out anywhere, regardless of the true copyright holder's rights. In response, the United States took the lead to enact legislation that complemented the basic law of copyrights and met this tension between strong competing interests.

The first major step taken was its enactment of the U.S. Digital Millennium Copyright Act of 1998 (DMCA). The online service provider section of the DMCA establishes the procedures for copyright owners to contact service providers with their complaints over a subscriber's improper online use of copyrighted material. This act mandates providers to remove materials used improperly once they reasonably determine there are, in fact, copyright infringements as alleged. If the subscriber files a counterprotest, however, then the provider must repost the material unless the complainant files a lawsuit against the infringer for copyright infringement over the offending use.

In effect, this legislation grants copyright owners an administrative tool to remove infringing material without having to litigate the problem, as well as a "safe harbor" against liability for U.S. online service providers. The definition of "service providers" is broad and includes not only Internet service providers (ISPs), Web hosting companies, wire and fiber transmission entities, and router services, but also corporations, universities, municipalities, governmental agencies, and other entities that "provide" online services. To receive the protection of this federal statute, an organization must register under the act with the U.S. Copyright Office and follow the DMCA' s removal provisions. Check out http://www.loc.gov/copyright for the details on the DMCA.

The United States was the first country to enact DMCA legislation, and this statute took it into compliance with an international copyright treaty (the WIPO Copyright Treaty). As other countries imitate this general approach, the ability to cause infringing material to be removed without using expensive litigation will begin to become globally codified. See Julia A. Gladstone's chapter in this encyclopedia, "International Cyberlaw," for more on these developments.

Another significant U.S. legislative enactment was the No Electronic Theft Act of 1997 (NET). Under the NET, criminal penalties can be imposed on people who exchange or barter unauthorized copies of software, videos, clips, or music, whether or not they receive money for it. The only requirement is that the value of the pirated material exceed $2,500 (for felonies) in a given 6-month period. Although enforcement of the NET Act has been limited to high-profile cases thus far, all users should be aware of its provisions.

Among other important copyright areas, cases have held that publishers must pay additional fees for pre-Net work by freelancers, including a U.S. Court of Appeals ruling that the National Geographic Society made an unauthorized use of pictures taken by a freelance photographer back in 1961 when it issued a CD-ROM years later of its back issues (*Greenberg v. National Geographic Society,* 2001). It was ordered to pay license fees for that use. The U.S. Supreme Court decided the issue when it later ruled that media companies must obtain the consent of their freelance writers and creators (as employees create "works for hire," their employers typically gain those copyrights) before any pre-Net text, picture, or creation could be posted or sold online, thus forcing royalties to be paid for that use (*New York Times v. Tasini,* 2001).

In addition to the above, other developments occurred pertaining to the online copyright infringement issue. The U.S. Supreme Court held in *Eldred v. Ashcroft* (2003) that Congress had acted constitutionally in 1998 when it extended copyright protection for most works through the Sonny Bono Copyright Term Extension Act (Supp. 1999), retroactively increasing the copyright protection term from 50 years after an author's life to 70 years. Various cases upheld the constitutionality of the DMCA, including its safe-harbor provisions for ISPs. An issue being court-answered is whether the DMCA mandates ISPs to turn over customer information to the recording industry of those suspected of illegally trading music files; in *Recording Industry Association of America v. Verizon Internet Services* (2003), a federal judge ordered the ISP to identify an Internet customer who used music-file-sharing services, and this case was promptly appealed.

Whether the situation concerns Napster imitators, video downloading, or copying overseas, the legal wrangling between the copyright holders and the public over "fair use" will continue unabated. As other countries have or enact their own cyber copyright and intellectual property laws, the likelihood of global jurisdictional disputes will also increase.

DOMAIN NAMES AND TRADEMARK LAW

Trademark Law and Domain Names

For decades before the emergence of the Internet, trademark law was relatively straightforward. Trademarks and service marks abound, simply arising from a company's use of marks identifying certain products or services as being theirs (e.g., Apple with its rainbow apple and eBay's stylized logo). The concept of trade and service marks came about to keep businesses from "passing off" their products as being those of their competitors or of rightful owners, and the ownership of marks is an important intangible property right, along with copyrights, patents, and trade secrets.

Then along came the Internet, domain names, and new Web sites that had registered the addresses of bona fide trademark and service-mark holders (i.e., Burger King versus the "burgerking.com" registered by an individual). They knew that the domain name used to access any site was an important asset of identification, just as an entity's mark was important in purchasing a product (or domain name selection). As domain names must be registered to have any validity and registrars don't conduct background checks over an applicant's representations as to who owns the legitimate trademark rights, registration even today can be a race to the swiftest on a "first come, first serve" basis.

In the early and mid-1990s, "entrepreneurs" recognized this grand opportunity. In a style reminiscent of the old Gold Rush days, they raced to tie up as many of those good corporate names as they could, whether it was "harvard.net" or "burgerking.com." Later, they would send a demand letter to those entities and offer to sell their domain names back—at a tidy profit. Or the new owners would sit on their names and wait for that interest, conjuring up the concepts of "cybersquatting" and "cyberpirating." When one adds to this equation the various classifications (i.e., from ".com" and ".org" to the later introduced ".biz" and ".info") with the different country designations that are possible, it is easy to see the large opportunities created to tie up good corporate names at a good profit.

A brisk market in the buying and selling of domain names began—just hit the key word "domain name" in your search engines and see what arises. The people who registered general names, such as "business.com" or "loans.com," made excellent business decisions. One Houston businessman paid $150,000 in 1997 for the rights to "business.com," then sold that to a California company for a cool $7.5 million 2 years later. In 2000, mortgage.com was sold for $1.8 million and loans.com for $3 million.

Without any statutory guidance, the courts handed down mixed decisions as to when a mark holder would prevail, if at all, over a cybersquatter and any given domain name. The reason: The law was clear at the time that domain-name registrations and trademarks and service marks, whether registered or not, were two different concepts. Because there was no right by itself to use a mark as a domain name, owning one didn't necessarily convey ownership rights to the other.

Anticybersquatting Consumer Protection Act

In response, the United States passed its Anticybersquatting Consumer Protection Act (ACPA) in late 1999. This act allows civil lawsuits to be brought for trademark and service mark violations against anyone, who with a "bad faith" intent to profit from a mark, registers, uses, or attempts to sell a domain name that's identical or confusingly similar to that protected mark. Factors indicating bad faith are whether the name owner actually diverted the trademark owner's customers, offered the registered name for sale without having used it, or registered multiple names. Under the Anticybersquatting Act, the courts can cancel a "pirated" domain name, assess attorney fees and costs, and levy penalties of up to $100,000 against an infringer (depending on the level of bad faith and the actual damages).

This legislation also made it illegal to register the name of any living person without that person's consent, while intending to profit by that action. Actors Brad Pitt and Kenny Rogers immediately filed suit on this provision alone, Kenny Rogers objecting to the "kennyrogers.com" registered to the Web site of a California wedding service. Both celebrities retrieved their "names" back.

Late in 1999, the Internet Corporation for Assigned Names and Numbers (ICANN) decided that domain name registrations had to be prepaid. Before this change, cybersquatters could "hold" names for speculation; if they didn't find a buyer, they let the unsold names expire for nonpayment of the registration fees. The amount of statutory damages for copyright infringements was increased. An amendment to existing trademark legislation was enacted, permitting trademark dilution grounds to be used as a cause of action in canceling domain-name registrations. In late 1999, ICANN then announced that more than 800 addresses of "dash dot" domain names had been revoked. A software glitch apparently had allowed these registrations to proceed, and the excesses of the past were being corrected.

ICANN's Dispute Resolution Process

ICANN next instituted a procedure for resolving domain-name disputes. Under an agreement called the Uniform Domain-Name Dispute-Resolution Policy (UDRP), those with a dispute over a registered domain name involving their trademark or service mark have the alternative to file a complaint with an ICANN approved dispute-resolution service. Pursuant to these procedures, the service provides an arbitration panel that then rules which party has the legitimate right to that name, and if either party disputes the ruling, then that party can litigate the matter further in court. The judge in the court case can review all of the facts and isn't necessarily bound by the review board's determination. Once a final decision is reached, the registrar transfers the domain name as the court or administrative panel decided.

Whether marks are registered or not, legitimate holders can take their case to different alternative dispute resolution centers under this process, and the United Nation's World Intellectual Property Organization (WIPO) hears most of these cases (http://www.wipo.org). Basically, the claimant must prove (a) that the domain name very closely resembles a trademark registered or owned by that entity, (b) that the party that registered the domain name has no rights or legitimate interest in that name, and (c) that the domain name was registered and used for illicit purposes or in bad faith. This is an inexpensive process (a one-person panel at the time of this publication costs a complainant $1,500, and a three-person panel costs $4,000); fast (the arbitrators' decision is rendered within 45 days); convenient (there is no hearing to attend; the arbitrator or panel reviews only the complaint, response, and supporting documents); and the decisions typically favor the trademark holder (some four fifths of the determinations favor the mark owner). For further details on ICANN or its UDRP procedure, see http://icann.org.

The initial decisions on domain names reached conclusions in favor of companies with recognizable names, such as the World Wrestling Federation, Stella D'Oro Biscuits (a Nabisco affiliate), and Telstra (the Australian telecom company), ordering their domain names transferred back to them. WIPO arbitration panels handed back the Web addresses bearing the names of the Corinthians (Brazilian soccer team), Dan Marino, Julia Roberts, Kevin Spacey, Yahoo!, ESPN, and Wal-Mart. However, Sting, Bruce Springsteen, the Reverend Dr. Jerry Falwell, and Ted Turner failed to prove that their personal names had been used in a trademark sense as a label of particular goods or services and did not prevail in their UDRP proceedings. ICANN's dispute-resolution policy, however, does not apply to all registrars—only to the TLDs (top level domains of ".com," ".net," ".biz," etc.) and not to the "ccTLDs" (individual country domains, such as ".cn" for China), unless that country agrees or has established its own dispute resolution board.

The Legal Weapon Tradeoffs

Entities with U.S.-based domain name/trademark conflicts must decide whether to use the Anticybersquatting Act, an ICANN proceeding, or both. ICANN gives a fast resolution, whereas ACPA litigation can take up to 2 years or more for a decision. Although the federal statutory-authorized lawsuit allows for a preliminary injunction, the opportunity to be awarded good damages, and transfer back of the domain name (which is all that an ICANN-UDRP procedure can do), this alternative is highly expensive with much more downtime, complexity, and legal dollars required. The ACPA is a final determination, whereas the extent to which an ICANN decision can be litigated further is currently being determined.

A federal appeals court in *Sallen v. Corinthians Licenciamentos Ltda*. (2001), however, has ruled that the ACPA granted U.S. federal courts the jurisdiction to review and even override findings or decisions made by a dispute-resolution service provider under an ICANN proceeding. Lower U.S. District Court decisions have upheld ICANN-UDRP's validity and the right of courts to review and even overturn those decisions (see, for example, *Weber-Stephen v. Armitage,* 2000; *Parisi v. Netlearning,* 2001; and *Virtuality v. Bata,* 2001). One U.S. Court of Appeals decision in *Mattel v. Barbie-club.com* (2002) has held that in rem proceedings (deciding ownership rights to property, such as domain names) under ACPA may only be brought in the judicial district where the domain-name registrar is located—a large problem with international disputes or where multiple domain-name owners are involved. Owing to the negative aspects of the ACPA litigation alternative, the great majority of entities at this time do choose to employ only an ICANN proceeding.

The rest of the world is not as restrictive as the United States or other developed countries, and the game is still being played in some fashion. Countries in Asia, the former Soviet Union, Eastern Europe, and others have not yet tightened their laws, although over time, they likely will. It may still be possible in small nations such as Moldavia (until they change) for cybersquatters to purchase domain names that aren't already reserved, and the question of conflicting laws always seems to rear up when lawsuits are brought to challenge ICANN administrative rulings.

For international protection, entities need to register their mark with the U.S. Patent and Trademark Office (PTO), and U.S. concerns need to file that registration with the appropriate agency of the foreign countries in which they operate. Although the granting of a registration by the PTO is not conclusive on the issue of who owns a mark, it is prima facie evidence of that ownership (see the PTO at http://www.uspto.gov for the details).

Given the estimated numbers of domain names (more than doubling from present numbers to more than 100 million in 3 years by various estimates), the number of permutations, and various country designations, the volumes of conflicts, arguments, and opportunities for these disputes can only increase over time.

PATENTS

Through patents, the United States by its Patent and Trademark Office grants an inventor the exclusive right to make, use, or sell an invention for 14 years (design patents) or 20 years (inventions). To obtain a patent, the inventor must meet certain requirements, such as novelty, usefulness, and nonobviousness. Computer hardware (i.e., the design of electronic components, handwriting recognition systems, and so on) is patentable, but software typically isn't brought into the process, because of the time it takes for a patent to be granted and contrary regulations in a few cases. The number of patent applications for Internet applications increased in recent years owing to court decisions (beginning with *State Street Bank v. Signature Financial Group,* 1998) upholding patents issued for Web site business processes and operating methods. Amazon.com (its "one-click" online purchasing system), Onsale (operating auctions), Cybersettle (its "double-blind bid" dispute resolution procedure), Priceline.com (conducting an online "reverse" auction), Microsoft (online shopping and merchandising), Sun Microsystems (Internet bill processing), Tumbleweed Communications (online greeting card delivery), E-Data Corporation (online selling to any point of sale location), and other e-commerce entities have received patents on their specific business or operational models. As expected, the court challenges from competitors over these patents have also increased, as competing entities battle over controlling important operational methods. In this encyclopedia, Gerry Bluhm's chapter on patent law details this subject.

DEFAMATION

Cyberspace creates an inordinate ability to quickly post defamatory comments that injure another person's reputation and can be seen around the world. Those who post libelous comments, however, do not enjoy the anonymity in cyberspace that one might expect. A cyber-defamation lawsuit is typically filed in the city where the chatroom provider or ISP is located and lists various "John Does" or "Jane Does." This is legal jargon for naming unknown parties to the lawsuit, whose actual names will be added later on after discovering their true identities. The lawyer then files a subpoena (demanding that the desired information be released) against the provider to gain the identity of the particular John or Jane Doe who posted the inflammatory remarks.

Lawyers serve subpoenas daily on CompuServe, AOL, Yahoo, Microsoft, and others to retrieve some poster's identity. If the ISP doesn't turn over the demanded information, the attorney then goes to court to ask the judge to force the ISP into divulging the required data. The judge balances the right to protect someone's anonymity versus the injured party's right to be protected from harm. The plaintiff, or injured party, usually must prove that there's no other way to obtain relief without securing this specific information. If multiple servers are involved, the attorneys will follow the e-mail address back through that chain with multiple subpoenas.

One doctor at the Emory University School of Medicine in Atlanta, Georgia, came across a posting on a Yahoo message board. It falsely suggested that he had taken kickbacks from a urology company to give his department's pathology business to the company and had been forced to resign over this conflict of interest. The message was from "fbiinformant," who later was discovered to be a former employee at the urology company who disliked the doctor. In what was believed to be the first Internet defamation case to reach trial, a U.S. District Court judge awarded $675,000 to that doctor, all because of this one "anonymous" Internet message (see *Graham v. Oppenheimer,* 2000). Litigating defamatory e-mails, postings, and communications continued on unabated from there.

As to the online service providers, the court decisions have consistently upheld that there is no liability on their part for defamatory postings made by third parties. The Communications Decency Act of 1996 (CDA) bars tort-based claims or lawsuits against ISPs for defamatory, obscene, or other objectionable postings, provided there is no complicity by the ISP with that third party over those postings or other unreasonable behavior (the provider also must "actively" remove the objectionable material). Although portions of the CDA were later held to be unconstitutional (see *Reno v. American Civil Liberties Union,* 1997), these provisions continued in their legal validity and effect.

PRIVACY CONCERNS

At this time, there is no general, sweeping U.S. law regulating or requiring entities to disclose how they use sensitive financial and other personal information gained from their customers or users, nor how they gather that data. Notwithstanding recent U.S. Federal Trade Commission (FTC) high-profile proceedings against companies over their information practices, the FTC has had, in effect, a "self-policing" policy, promoting industry self-regulation in the fields of data collection and customer profiling. Congress did enact legislation as to the online privacy protection of children, however, when it enacted the Children's Online Privacy Protection Act (COPPA) in 1998. This statute requires that Web sites "earmarked" for children, or who knowingly collect data on users under age 13, need to (a) obtain verifiable parental consent for any collection or use of their children's information (i.e., "no consent, no collection") and (b) on request, provide the parent with the ability to review any personal information that has been so collected. The FTC has issued administrative rules on COPPA to guide these "kiddie" Web sites on their compliance with this legislation (see http://www.ftc.gov for more on this subject). Additionally, the FTC has charged entities with violating COPPA and reached settlement with several of those Web sites.

Congress also passed the Gramm–Leach–Bliley Act (GLBA), known also as the Financial Services Modernization Act of 1999. This legislation requires that financial institutions (a) inform consumers of their privacy policies and (b) notify consumers before acquiring, transferring, or selling their private data to third parties, giving them the opportunity to "opt out" of such data-transfer practices. Although the GLBA applies to the Internet and use of cookies, it remains to be seen how these basic provisions will be enforced as a whole.

Additionally, various states have passed privacy legislation both in the financial area and in preserving the confidentiality of sensitive medical records, including diagnosis, treatment, and prognosis. As with most state laws, these acts are not uniform—for example, depending on the subject area, some states require opt-in conditions before data can be collected or used, whereas others establish opt-out standards. Rules have also been enacted under the Health Insurance Portability and Accountability Act (HIPAA) of 1996 that deal in this area (see the U.S. Dept. of Health and Human Services at http://www.os.dhhs.gov for more information).

The differences between the United States and other countries, such as Canada and the European Union (EU), couldn't be more pronounced than in the rights of privacy area. Canada's Personal Information Protection and Electronic Documents Act (S.C., 2000) implements a wide array of data protection, including a phase-in of "opt-in" provisions for its citizens. The EU's Data Protection Act came into effect in 1998, also using a completely different approach from that of the U.S. Citizens there gained enhanced rights to prohibit their private data from being released, including requiring entities to secure "opt-in" permission in various situations before personal data can be acquired, sold, or shared. Although it remains to be seen how these provisions stand over time after later court reviews, statutory additions, and individual member country changes, these policies are more supportive of their citizens' privacy than those of the Unites States. Additionally, pursuant to the EU's Directive on Data Protection, EU countries may block the transfer of their citizens' personal data to countries that do not guarantee adequate privacy protection equal to theirs. Although the United States and EU negotiated "safe harbor" guidelines for U.S. subsidiaries that operate there (basically, the U.S. company must certify to the U.S. Department of Commerce that it is in compliance with the EU's tougher laws), global policy differences such as those of the EU and other countries place pressure on the United States to adopt generally more consumer-sensitive privacy policies. For further information, see the U.S. Department of Commerce Web site at http://www.doc.gov, as well as Pfaffenberger's treatment of these considerations in his chapter of this encyclopedia.

CENSORSHIP

The First Amendment places strong limitations on the government's ability to censor, or unduly regulate, the rights to basic freedoms such as those of speech and expression, and the Internet is no exception. For example, Congress passed the Communications Decency Act of 1996 (CDA) which, among various provisions, essentially made it a crime for anyone to knowingly distribute obscene material for sale in cyberspace. Later in 1997, the U.S. Supreme Court in *Reno v. American Civil Liberties Union* declared that most of the important provisions of the CDA dealing with obscenity were unconstitutional, holding that these provisions were so vague as to be void on their face. The fact that statutes applied to cyberspace didn't mean the constitutional tests applied were any less strict, and later legal battles over subsequent pornographic statutes have applied the same strict construction tests of the offline world.

For example, Congress in 1998 passed the Child Online Protection Act (COPA) as a successor to the struck-down CDA provisions in another attempt to stop children from gaining access to sexual materials on the Internet. In 2002, the U.S. Supreme Court reviewed COPA and partially upheld it, adding further legal uncertainty. In *Ashcroft v. ACLU* (2002), the court ruled that the act's reliance on community standards to identify "material that is harmful to minors" did not by itself render the statute unconstitutional. The divided court kept alive the fight over whether the measure was unconstitutional, however, by affirming the appellate court's ban on COPA's enforcement, then returning the issue to a lower court for further review or trial on free-speech questions the court felt were still unresolved. Legal experts feel that COPA runs into legal problems similar to those faced before by the CDA.

A three-judge panel ruled that the U.S. government cannot legally require public libraries, as a condition of receiving federal funds, to install mandatory filters on every computer to block online children's pornography. Accordingly, the panel struck down the Children's Internet Protection Act (CIPA, 2000), holding that the filter requirement blocked constitutionally protected speech and that there were less restrictive alternatives available (i.e., establishing "acceptable use" policies, requiring parental consent, and placing unfiltered machines away from public view). The two cases, *American Libraries Association v. U.S.* (2002) and *Multnomah County Public Library v. U.S.* (2002), were appealed to the U.S. Supreme Court.

The Supreme Court also granted review to the "Nuremberg Files" case, in which an 11-judge U.S. Court of Appeals panel voted 6–5 in *Planned Parenthood v. American Coalition of Life Activists* (2002) to uphold a 1999 trial verdict against an anti-abortion Web site that disclosed the names, addresses, and family information of physicians who performed abortions. The trial jury awarded punitive damages of $107 million against this coalition of activists, but the appellate panel remanded the damage amount back to the trial court to determine whether the award was excessive or not.

In a case in which the judge described was a dispute between the protection of trade secrets versus freedom of speech, a Federal judge ruled that a Web site operator could continue posting confidential Ford Motor Company documents on new car designs and other internal data (see *Ford Motor Co. v. Lane,* 1999). Lawsuits over employer Internet-use policies, however, provided the policies are reasonable with notice given to the employees, have generally been upheld in the employer's favor. An employer's use of Web filtering software (where worker e-mails are subject to scrutiny) also is under challenge, but most legal scholars believe that these challenges generally won't be sustained. Moreover, the courts so far have not been overly receptive to employee claims that work done on an employer's computer system is personal and entitled to constitutional protection.

Courts have generally upheld the right of "suck.com" Web sites to criticize the operations of major businesses (e.g., "http://www.ballysucks.net"; see *Bally v. Faber,* 1998), although the complaining companies have had more luck in challenging these sites under ICANN domain name proceedings. For example, the Salvation Army filed an ICANN-UDRP proceeding over the name "salvationarmysucks.com", and the arbitrators ruled in favor of it, when evidence of offers to sell the name back to the Salvation Army came to light. Generally, provided the posted allegations are basically true or represent protectable opinion rather than false facts, the cases hold these expressions to be protected by the First Amendment. If you use a search engine with the descriptive word "suck.com," surf to the site of "Sucks.com," or type your favorite company name with a "suck.com" after it, watch the complaint Web sites surface that already are in existence.

Another growing First Amendment consideration involves its use in controversies in which software sites collide with trade interests. For example, the DVD Copy Control Association (DVDCCA) attempted to shut down Norwegian teenager Andrew Bunner's Web site, which provided a link to software code that unscrambled encrypted DVDs. A California Court of Appeals court (*DVDCCA v. Bunner,* 2001) overturned the trial judge's temporary injunction against Bunner's site as an unconstitutional prior restraint, citing that the First Amendment protected his publication of the DeCSS software as an exercise of free speech, even given a continuing violation of DVDCCA's trade secret rights. The California Supreme Court currently is hearing the appeal; once this issue is decided, the main case on whether the defendant misappropriated trade secrets or committed copyright infringement by the DeCSS posting is to be decided, along with whether a permanent injunction or damages would be appropriate. For more on the subject of censorship, please see Julia A. Hersberger's chapter.

CYBERFRAUD

Cyberfraud is a major problem on the Internet, owing to its anonymity, commercial reach, and speed in exchanging credit card information. The ease of entry onto the Internet makes it even easier for "fly by night" firms to race in, skim off money, and quickly disappear without leaving a trace. No matter where you live, the Web has indeed become global in when and how the unwary are fleeced. In the United States, the FTC is the federal agency charged with prohibiting unfair or deceptive commercial acts, including misleading advertising (fraudulent investments are handled by the Securities and Exchange Commission, or SEC). The FTC's rules and regulations against unfair or deceptive business practices specifically cover Internet transactions, and its Web site (http://www.ftc.gov) has pages with information about Internet fraud, complaints, and its fight against this problem.

The FTC has brought countless numbers of fraud and misleading advertising complaints to stop such unfair practices, both online and offline. Sold ever increasingly over the Net, the first batch of the FTC's "Top 10" online scams centered in Internet auctions, ISP fee promotions, Web site design/promotions and cramming (being billed for services or products not authorized), Internet credit card cramming, multilevel marketing/pyramid schemes, business opportunities (i.e., software and sales motivational tapes) and work-at-home pitches, investment schemes (i.e., day trading, gold deals, and oil and gas leases) and get-rich-quick scams, travel/vacation fraud, telephone/pay-per-call solicitation, and healthcare scams. From year to year, identity fraud is the overall top consumer fraud complaint from all sources received by the FTC by a wide margin (over 40% of all complaints received on its Consumer Sentinel database), followed by Internet auctions and Internet services/computer complaints.

In 2001, the FTC opened up a Web site to the Net public with statistics and information on primarily U.S. Internet fraud and identity theft. The site is called "Consumer Sentinel" (see http://www.consumer.gov/sentinel), and it started with a database of more than 300,000 complaints lodged with the FTC over the last several years. The site provides data on fraudulent transaction trends, as well as the ability to submit online complaints (as does the FTC with its Web site). If you find Internet fraud problems involving different countries, then head to "econsumer" at http://econsumer.gov, which has in place direct links to consumer fraud agencies in numbers of countries and represents a coordinated world effort to work together on this global problem. This site also allows for the filing of international fraud complaints.

The Internet is both an excellent tool for investors with easy access to research sources, as well as for the shysters, hipsters, and con artists to that money. Because anyone with a computer and a modem can reach tens of thousands of potential investors simply by creating an attractive Web site and spamming, the U.S. SEC has had to become very active on the Internet. It established a national cyberforce of attorneys, accountants, and analysts specifically trained to watch out for fraudulent online security transactions (see http://www.sec.gov for more information, including its reported Internet fraud cases).

For example, one case involved a company that used spam e-mail to announce an initial public offering (nearly all of us have received junk e-mail of this type), stating that it had been approved by the SEC and would realize at least $1 billion in eyewear sales. In fact, it had never been approved by the SEC and didn't even own an office or inventory. The owner of the company used the "invested" money for restaurants (eating meals), casinos (gambling), and adult entertainment clubs. The investors lost everything that they had invested—the usual and unfortunate result with fraudulent investments, regardless of whether the FTC or SEC is able to intervene.

Regardless of the state or country, the law is clear with respect to cyberfraud: (a) any Web advertisement of illegal transactions under a particular country's or state's laws (e.g., gambling or usury) will be illegal there; (b) fraudulent, false, or misleading statements are illegal and unenforceable, no matter where you live; and (c) the regulatory agencies in different states and countries vary widely in their ability to crack down on misleading advertising, even when the customers or investors have lost all of their money. Remember: if the advertised "return" is too good to be true, then it usually is, and investors must be quite careful when reviewing potential investments of any kind, whether online or offline. (For more information, see Marc D. Goodman's chapter on cybercrime and fraud.)

E-COMMERCE LAW

Given the ease with which online contracts can be made, the tearing down of geographic barriers, and E-mail "proof" that lasts forever, basic contract law is even more important on the Net. From what is needed for a legitimate contract (i.e., mutual assent, consideration, capacity, and no legal defenses) to how duties are delegated and determining damages, all of the fundamental contract laws apply in cyberspace. (For an excellent discussion on this area, see *Cyberlaw, Text and Cases,* by Ferrera, Lichtenstein, Reder, August, & Schiano, 2001). As expected, however, e-contracts do have important aspects that stand out from offline contracts and as discussed in the next section.

"Click" Contracts

You can't sign an e-contract with your real name, as you could if you were in a face-to-face meeting with a sales rep. In place of this, the law basically allows that you can agree to the terms and conditions of an electronic agreement when you click the "I agree," "I'll buy," or "Subscribe" button. The mouse click on that agreement button sets the approval to the conditions of the e-contract.

The courts generally have upheld this as being as valid as if you signed a written contract on the dotted line. (See, for example, *Crispi v. The Microsoft Network,* 1999, and *Geoff v. AOL, Inc.,* 1998). Any on-screen click, no matter where it's located (but provided it's reasonably identified as the "click" agreement button), will do. The legal premise is that the medium in which a signature or contract is created shouldn't affect its validity, and the transaction is enforceable, whether that medium is paper or electronic. There are limitations on when click contracts will be enforced, however, and this is discussed at the end of this section.

E-signatures

The U.S. government and nearly all of the states have enacted some version of an electronic signature statute. The federal act (Electronic Signature in Global and National Commerce Act, 2000) ensures that electronic records, signatures, and contracts have the same legal effect as their ink-and-paper counterparts (including that electronic records satisfy statutes mandating that records be kept in writing), validating online commerce and allowing for the eventual recordation of documents such as deeds, mortgages, and bills of sale by accepting electronic notarization. This legislation (including state counterparts) mandates that an e-signature is enforceable if both parties agree to its technological format, and it provides that a signature may not be denied legal effect simply because it is in electronic form. Signature verification can be based on fingerprint scans, smart cards, encryption software, mouse-pad signatures, eye lasers, voice recognition, or whatever the parties agree to use in their contract. It is an enabling statute that sets down standards that can be followed and allows states to enact their own but generally consistent legislation within this umbrella, prohibiting laws that limit permissible electronic signatures to one single technology. The states differ widely in their authorizations because numbers are applicable to all electronic transactions, whereas others can be more limited in their scope and effect. Internationally, many countries (from Brazil and Taiwan to the individual members of the EU) have enacted e-signature and e-commerce laws, simply because it is in their best interests to do so.

Taxation

In 1998, the United States' Internet Tax Freedom Act capped taxes on online sales with a 3-year moratorium on any new state, local, or federal Internet taxes (as defined) to October 20, 2001; after an interim delay, the moratorium was extended for an additional 2-year period that expires on November 1, 2003. It is a misnomer, however, that this act generally ended taxation of the

Internet. Among other allowed taxes (including "grandfathered" Internet taxes and taxes on Internet access) when the "moratorium" expired, 45 states charged sales tax on tangible products brought online, given that the seller had some form of a physical presence or "nexus" (i.e., a warehouse, retail store, office, or sales representatives) in that state. Under existing tax law (see *National Bellas Hess v. State of Illinois,* 1976), mail-order houses and, in turn, Web sites can collect sales and excise taxes on the sales of goods when such a connection or nexus was present with the taxing state. What was held in abeyance was the legal ability to tax an online purchase from a resident in a state where no such nexus or connection to the selling site's state was present.

The position of the World Trade Organization and international agreements generally parallel the United States' tax moratorium and approach. The pressures not to follow this are strong, however; as one example, the EU already taxes certain online sales of goods such as books and CDs. As the Internet erodes into the base of revenues that governments receive from traditional "brick and mortar" stores and their sales, it is likely this taxation will increase over time—the only question is when and how. The first "opening" is after November 1, 2003. Although Congress could again extend the tax moratorium, it is expected that legislators will listen to the pleas from the states and non-Internet merchants to tax online sales as never before and the constant lobbying will continue well past that date. See William A. Duncan's detailed chapter on taxation for more.

Spam

As e-commerce expanded, huge increases in unwanted electronic solicitations (otherwise known as spam and junk e-mail) also occurred. Although more than 20 states in the United States have enacted laws now regulating the distribution of commercial bulk e-mail (including fines and jail time as penalties), these laws are rarely or difficult to be enforced. In some states, no one has yet to be prosecuted under those statutes. Part of the problem lies in the Net's anonymity, enforcement difficulties, and jurisdictional issues, not to mention that more serious crimes are usually in line for attorney generals and district attorneys to prosecute. Until a federal antispam law in support of the states becomes effective with a strong enforcement mechanism—not to mention such laws also being implemented in other major industrial countries—controlling spam legally will not be possible. For the latest on antispam legislation and developments, see http://www.spamlaws.com.

International Aspects

Although beyond the scope of this chapter, the global e-commerce aspects of cyberlaw are considerable. Whether the subject involves the EU's passage of e-signature, copyright, privacy, or e-contract laws, or the cyberlaws of major industrial countries such as Japan and Germany, these international aspects are continually evolving. Furthermore, the treaties that can affect cyberspace range from the General Agreement of Tariffs and Trade (GATT) to the United Nations Commission on International Trade Law (UNCITRAL) and beyond. Please see the treatment of these international areas throughout this encyclopedia.

E-COMMERCE "TERMS OF USE" PROVISIONS

Many Web sites separate out the necessary purchasing information from their legal Terms of Use and Privacy policies. Although the general areas treated are quite similar, each site's specific provisions are different, depending on whether a particular location sells products, provides services, gives information, or some combination. Nonetheless, the general concepts covered are basically the same.

Given that the basic contract business terms (e.g., quantity, price, time for delivery, delivery mode, and so on) are present, what was once "just legal boilerplate" has now become more important: disclaimers of liability, indemnity, handling of disputes, applicable law, and dispute resolution, among other areas—and this is especially true when distant localities become involved. The following "boilerplate" provisions are typically found in the "Legal Provisions" or "Terms of Use" sections:

Disclaimers of Liability

This section typically limits a seller's liability for injury or loss incurred by the buyer to exchanging the product or a refund of the purchase price, all at the seller's option. This refund policy is usually coupled with a disclaimer of liability, such as the following: "Seller disclaims all liabilities and warranties, express or implied, including the warranties of merchantability and fitness for a particular purpose, and this Web company shall not be liable for any damages, whether consequential or incidental."

The intent of these provisions is for the seller to "duck away" from liability, leaving the manufacturer on the hook. Although not unanimous in their decisions, the courts tend to uphold limitations on consequential damages (for example, loss of data that results in a further loss of customers or business) in commercial transactions. They usually are not upheld if a personal injury is involved, however, such as when a customer becomes injured when using a defective product that caused those injuries.

As a basic legal concept, no one can contract against the effects of strict product liability or their own negligence. If that were the case, there could never be any product liability, because every manufacturer and retailer in the world would be contractually providing, "Sorry, if there's a problem with our product, even if it's all our fault, we don't accept that liability—you do."

Depending on the circumstances, Web sites can be held completely responsible for a customer's damages, notwithstanding these one-sided contract provisions. For example, if a pharmacy Web site erroneously fills a prescription for high-blood pressure medication that severely worsens the problem, that Net retailer typically will have to compensate that injured person for his or her damages from those bad pills, regardless of any Terms of Use limitations to the contrary.

Indemnity

Standard Terms of Use agreements also provide "tight" indemnity provisions. These terms basically provide that the buyer or user indemnifies, or is responsible for, any damages that occur to the Web site by reason of how the buyer uses that product, but do not place the same indemnification responsibility on the Web site toward the buyer. Although courts tend to uphold these terms, they will look at how "fair" the provisions are, and some have been thrown out; this result does depend on the facts and applicable state law in any given case.

Handling of Disputes

Captions such as "Dispute Resolution," "Conflicts," or sometimes simply "Legal Fees" usually head this section. A growing trend is for Web sites to contractually require arbitration and mediation as the agreed methods to handle disputes—alternatives that are cheaper, faster, and more convenient than traditional litigation. (Cyberlaw Dispute Resolution is treated later in this chapter.) Should litigation flare up, the typical section also authorizes the payment of attorney fees and court costs to the "prevailing party," or the one that wins in court.

Applicable Law, Dispute Location, and Other Provisions

This is another important area, covering what law is to be applied and where disputes are to be heard, with Web sites generally choosing their hometown and those laws. If that law isn't entirely in the site's favor, it will always designate a place that is. Just because a site specifies that a certain state's or country's laws or situs applies doesn't necessarily mean that a court will uphold that designation (see "The Clash of Laws" for this discussion).

Terms of Use agreements contain various other provisions. For example, they may provide for copyright and trademark notice requirements, restrictions on chat-room conduct, forum rules, prohibitions on posting defamatory comments, linking conditions (e.g., "you need our permission to link here"), acquire the copyright to any postings made, rules for games or sweepstakes, address for sending notices, and how notification is to be made, among other provisions.

Web operators typically place a copyright notice on their sites (for notice purposes, even if it's not legally required) and limit what can or can't be done when you copy from their sites, whether this limitation is legally correct or not. For example, "You may not reproduce, post, transmit, or distribute in any way whatsoever any information or display from our site, regardless of its source, without our prior written permission." Regardless what is posted, Web sites cannot limit what the law already allows. For example, the United States provides for a "fair use" exception for copyrights, and the courts will not allow any such one-sided limiting or restrictive statements to erode this long-standing doctrine of "fair use."

Privacy Policies

The surveys conclude that to maximize customer "hits" and use, a Web site must provide reasonable, detailed, and understandable statements on how it protects a user's privacy and then follow these policies without fail. Net customers are skittish as to the sanctity of their sensitive data—and they should be, given the pace at which today's technological advancements are eroding their comfort zones.

Privacy policies do not necessarily have to be long-winded, detailed, or complex—and they shouldn't be. See the previous section, "Privacy," and other chapters in this encyclopedia for more on this topic.

Validity

Most courts uphold "take it or leave it," click e-agreements, provided (a) the terms are written in understandable English with readable print and not hidden from the user's view; (b) the user has the opportunity to read and understand these terms, all before having to make any purchase or use decision; (c) the provisions are reasonable; and (d) the user has to take some affirmative action to agree (such as clicking an "I agree" button). As courts tend to enforce software shrinkwrap agreements, they're doing the same with Web-site Terms of Use provisions, provided these elements are present.

If, however, the language used is hidden or not conspicuous, in small print, or wholly unreasonable in effect (e.g., "This Web site is not responsible for any of your damages, regardless of how much we are at fault"), then courts will generally not uphold them. There must be some knowledge (the terms are easily located and understood), prior decision making (the user can decide before having to order), and facts showing at least mutual assent or an implied agreement (e.g., clicking on an icon to show your assent).

A leading Second U.S. Circuit Court of Appeals case, *Specht v. Netscape Communications Corp*. (2002), reviewed the standard terms and provisions applied when a user downloaded software. The standard terms provided that all provisions came into legal effect when any user simply downloaded or installed the software. However, users could directly download this software before coming or scrolling down to the "I agree" icon and any inspection of the terms of use that bound their decision. Applying standard contract law on mutuality of assent, the court upheld a lower court's decision and refused to enforce an arbitration clause in the Web site's forum state, holding that the required mutuality for contract assent was not present.

When the requisite criteria is present, courts will uphold these terms on a general, conceptual basis, provided additionally there is no blatant unreasonableness in those provisions. Based upon the Uniform Commercial Code's Section 2-302 (basic to most states' laws) that codifies the traditional common law doctrine of unconscionability, courts still have the ability to set aside those standard terms. The intentional misuse of a Web site by a user, however, can negate provisions that don't meet these standards. For example, in *Register.Com, Inc. v. Verio* (2000), a court held that where Internet users intentionally misuse a site's content, there is an implicit agreement to any terms of the Web site's legal notice that prohibit such action.

THE CLASH OF LAWS

Given the numbers of cyberlaw conflicts, a key issue is whether a court in the plaintiff's geographical area can hear and decide the case. Simply put, if the problem is big enough, you want your understandable laws to apply, eat and sleep in your own home, work in your office when not in court, and not have to hire an expensive attorney in a different state or foreign country. People involved in a court case don't want jet lag, bad food, unfamiliar surroundings, a strange language, and separation from family for weeks on end—which is why jurisdiction and conflicts of law is such a large cyberlaw issue.

Jurisdiction over a nonresident Web site or Internet transaction in the United States is normally based on a local state's long-arm statute. These laws provide that a state can assert jurisdiction over a nonresident defendant who commits a tort, transacts business, or has some connection with that state. When a state court asserts jurisdiction over a particular controversy to render a binding decision, for the most part it will also be constitutionally permitted to apply its laws, given sufficient connections with that dispute. (Federal courts apply the appropriate state substantive law when relevant to their decisions).

The U.S. Supreme Court's landmark *International Shoe Company v. Washington State* (1945) decision established the law in this area. For a court to have proper jurisdiction, defendants must have purposely availed themselves of the privilege of doing business in that particular state (i.e., traveling in, selling there, advertising in, or other contacts in that state), and these "minimum contacts" must meet sufficient levels of due process so as not to offend our "traditional concepts of fair play and substantial justice."

For example, if a Wyoming rancher died and willed his ranch to his Wyoming son, it would offend our sense of "fair play" if a second son, who happened to live in Alabama, could sue and haul that Wyoming brother into an Alabama court. There are no connections with Alabama to this case, so the only court with jurisdiction should be Wyoming—and that court would apply Wyoming law (the property is there, the decedent and his heir lived in the state, the will was probated there, and so on).

When it comes to jurisdiction on the Net, U.S. courts generally look at a Web site's level of Internet activity, drawing distinctions between passive and active locations—and this distinction will be drawn more in foreign courts, although it is not yet a trend overseas. Called the "Zippo sliding scale," this test was set down in *Zippo Manufacturing Co. v. Zippo Dot Com, Inc.* (1997).

At one end of the spectrum, Web sites that enter into contracts with out-of-state residents involving repeated contacts, e-mails or other correspondence, and selling appreciable amounts of products or services into that state are held to be "active" Web sites. These active sites can be sued in the state of their customers, or in those out-of-state locations, as various U.S. cases have held. Given the existence of these sufficient contacts, a local court could (depending on the facts) disregard a contrary Terms of Use condition of the Web site that provided it could only be sued in its home state.

On the other side of the equation, sites that only advertise or post information about their business on the Internet—not taking any orders or conducting business through that Net site—are held to be "passive" Web sites. These Internet "informational" sites generally cannot be sued out of state and dragged from their home base into foreign courts, simply because they maintain a virtual presence. To hold differently would be to subject Net operators to being sued anywhere in the world that allowed an Internet connection to be made.

In between are Net sites that provide more connections between their state and out-of-state customers—and it usually takes more than having an e-mail capability and a toll-free number to confer that jurisdiction. E-mailing questions about a potential purchase (without more) doesn't suffice either, although some courts view this as borderline and "getting very close." If a defendant Web site displays a downloadable mail-in order form, toll-free telephone number, and e-mail address but no orders are ever made there, then these facts are not normally good enough. Given a finding that a passive site was involved, the upset user then must travel to the Web site's home state to sue. As indicated, a factual decision needs to be made in each case as to whether these minimum connections for due process reasons are present.

Some courts have developed an "effects"-based approach exception to the Zippo sliding scale. When using this approach, the court focuses its analysis on the actual effect that a Net site had in its state or the defendant's intent, not on how interactive the Internet location was. This test derives from the U.S. Supreme Court's *Calder v. Jones* decision (1984), where jurisdiction was found over a nonresident defendant newspaper, based on its intentional conduct outside the forum state that was deemed to cause defamatory injury to the plaintiff in that state—even though strong factual connections weren't otherwise present. Although courts tend to apply the "effects" test in cases involving intentional torts, such as defamation or trademark infringement cases, they do differ on what conduct constitutes the kind of "express" aiming or effect that's required to satisfy the test. Applying the "effects" test can find jurisdiction when there aren't sufficient contacts of the type called for under the *Zippo* sliding scale.

In a closely followed case, the California Supreme Court in *Pavlovich v. Superior Court* (2002) overruled a Court of Appeals decision involving the application of the effects test. Pavlovich had posted his programming adaptation of DeCSS software, a controversial technology allowing the scrambling system in DVDs to be rendered ineffective and their contents to be copied. The appellate court held that it had jurisdiction over Pavlovich, a Texas resident who was an engineering student at Purdue University in Indiana at the time of the alleged infringement. Although the defendant's actions didn't come close to meeting the *Zippo* test, the appeals court held that since there was an "effect" in California from Pavlovich's "intentional tortuous" actions, that California had jurisdiction, could apply its long-arm statute, and could force the defendant to come there and defend himself. The California Supreme Court, however, reversed this decision on a 4–3 vote. It held that under the *Zippo* test, the Web site was merely an informational one and there was no evidence that the defendant had expressly hurled his actions at California. It ruled that a defendant's knowledge or foreseeability alone of harmful effects ensuing in a specific state (California) is not sufficient to establish any "purposeful availment" of that state's law under the effects test. There must be more than that.

Keep in mind that the U.S. Supreme Court hasn't yet ruled on this area of virtual personal jurisdiction, nor what happens when a Web site's Terms of Use provisions are different from the reviewing court's laws—and courts, domestic and foreign alike, can and do give "wild" judgments that don't meet any tests or analysis. For example, Australia's highest court ruled in *Dow Jones v. Gutnick* (2002) that a publisher could be sued for defamation in whatever country an individual's reputation has allegedly been harmed. This case arose when an Australian businessman, Joseph Gutnick, sued U.S.-based Dow Jones & Co. for comments made about him in an article posted on the Internet in Barron's Online. This court found that since damage to the plaintiff's reputation had occurred in Victoria where the article was downloaded and read, it was appropriate for Gutnick to seek damages in that forum.

Because laws vary greatly from country to country, what's prohibited by one nation can be entirely permissible in another. Unless an international treaty applies (e.g., the United Nation's Contracts for the International Sale of Goods or CISG), countries are free to apply their own, quite different laws. The court that feels it has the greatest "connections", or the greatest interest in protecting its citizens, can and will take charge. It is very possible that the courts in two countries could reach two entirely different results–and this has happened numbers of times.

As one example, a French judge ordered U.S.-based portal Yahoo to block Web surfers in France from an auction where Nazi memorabilia were sold, including a fine of 100,000 francs ($13,700 U.S. dollars) for every day of noncompliance. Although Yahoo's offering sales of Nazi items was legally protected in the United States under the U.S. Constitution, it voluntarily banned the sale of these items in response. Arguing that the French court had no jurisdiction over it, however, Yahoo quickly countersued in a California Federal District Court to overturn that decision's effect in the United States.

In late 2001, the U.S. court ruled that Yahoo didn't have to comply with the French court's order (*Yahoo! v. La Ligue Contre le Racisme et L'Antisemitisme,* 2001). It held that a U.S. court may not enforce a foreign order that violates the U.S. Constitution by "chilling protected speech that occurs simultaneously within our borders."Thus, the U.S. court held that Yahoo didn't have to comply with all the laws in other countries that conflicted with those of the United States. Shortly afterwards, French civil rights groups appealed this decision to the Ninth Court of Appeals, and this case may very well journey all the way to the U.S. Supreme Court. The problem is, given other countries entering this fray, which court is right, when, and under or with what final authority?

Let's assume a Web site provides in its standard terms that U.S. law applies and all lawsuits must be brought at its U.S. headquarters. A German consumer feels that he's received a "lemon" and sues—of course—in Germany. Which law is Germany going to apply? You're right. German courts more than likely will apply German law in this case (by their own statutes). If the company sues in the United States, what law is that court going to apply? Probably U.S. law, because this country has a material interest in those proceedings. Because no international Supreme Court exists to adjudicate private disputes, there is no real way to settle this problem unless the parties later agree to those procedures. If the parties had negotiated the applicable law and forum before that dispute arose, then that agreement generally would control.

Fundamental differences among the various countries abound that affect basic principles, whether it's the United States and its First Amendment or EU countries with their basic consumer privacy protections. France mandates the use of the French language for numbers of documents in that country, while the EU and Japan have enacted strong antispam laws. Germany provides for a 2-week right of recession on online purchases, the U.S. to the contrary in this case, as well. One way to solve these questions is for countries to pass an International Jurisdiction treaty that binds the signatory states. Such legislation is in the works but will take years to finalize—and this state of affairs is another reason why alternative dispute resolution is growing in importance. For further treatment of international cyberlaw areas, see Julia Gladstone's chapter.

CYBERLAW DISPUTE RESOLUTION

One cyberlaw fact of life stands out: resolving disputes arising from the Internet's global reach through litigation is complex, expensive, and loaded with unclear results. In response, the Net community is actively pursuing alternative dispute resolution techniques (ADRs) such as mediation and arbitration—both offline and online. Given their low cost, confidentiality, limited negativity, and speed in resolving cyberdisputes, the use of ADRs is accelerating among users.

Web sites and online operators actively promote ADRs in their agreements and Terms of Use provisions. ADRs have been used to settle all types of Internet disputes, whether between Web partners, competing sites, domain name holders, ISPs and their subscribers, copyright holders and copiers, and many other Net matters. Credit card companies use an ADR form when they use "chargebacks" to end a customer's complaint with an online seller. As discussed before, ICANN has established a worldwide arbitration procedure to resolve domain name "cybersquatting" disputes. The U.S. Digital Copyright Act basically provides for an administrative procedure in resolving copyright disputes.

One of the striking ADR advances has been the rise of online cybermediators who work primarily online. For example, one party contacts the cybermediator about the problem and the parties' inability to solve it; the mediator then contacts the second party. If both parties agree to use a mediated approach and accept the ground rules, then the online mediation begins. Typically, each party e-mails the mediator with their position or an acceptable settlement amount. The mediator then intercedes, shuttling back and forth electronically to reach a settlement.

Although the experience has been that not having an actual physical presence between the mediator and parties (i.e., not experiencing body language and "real-time" emotions with words having a stronger unanticipated impact when made by e-mail) can be a drawback of online mediation, the 24/7 availability at any time, low cost, and no need to travel have proven to be advantageous.

Online resolution has particular advantages with lower monetary claims. In financial disputes, each party e-mails the amount at which they would settle their claim. In these "mediations," the agreed rules can provide for three rounds or more of settlement offers. Each party has also agreed to lower its demands by an agreed percentage—let's say 10%. By the third round, if the sides are close (let's say within 20%, or by some other formula), then that difference is halved and a deal struck. This is a brilliantly simple, mathematically oriented solution with special advantages for low-figure disputes.

The leading player in providing this "double-blind bid" procedure is Cybersettle.com, which was awarded a U.S. Patent for that process. Other ADR service providers in cyberspace are ClickNsettle (NAM), SquareTrade.com, InternetNeutral, American Arbitration Association (http://adr.org), and SettleOnline, to name a few. Rather than being caught up in establishing expensive legal precedents over simply the issue of which law applies, where, and when—and then the main legal case must be fought—more and more parties are settling their disputes on or off the Net by using ADRs.

THE LAW OF LINKING

The World Wide Web depends on linking for its existence, because this makes the Internet what it is. With the Net's maturity, however, the previous unconditional freedom to link has evolved into a framework of commonsense legal and netiquette rules that dictate limits on this freedom.

The general rule is that one doesn't need permission to link directly to another site, provided there is no commercial gain or some competitive informational advantage brought about by that linkage (even for a nonprofit institution). It is clear, moreover, that users should receive permission when they are "deep linking" or "framing," if only as a courtesy—and whether one should ask permission before any linking is a question of cyberethics, quite distinct from the law and any of its requirements. (See Jennifer Lagier's chapter on cyberethics for more on this area.)

Clearly, any stated or implied representation by linking that another's work is yours would be trademark infringement (e.g., using their logo), unfair competition and libel (e.g., saying something is yours when it's not), or a violation of the covenant of "good faith" that's implied in netiquette. Linking to illegal content by itself may also be illegal; in *Universal City Studios v. Reimerdes* (2000), the court enjoined the defendants from creating links from their court-prohibited site to a number of other "mirror" sites.

When links bypass homepages, connecting instead to a page deep within that site, additional considerations become present. Lawsuits have been filed and settled in the plaintiff's favor in which the plaintiff complained over "deep links" bypassing the advertising on their homepage, decreasing the "hit count" (users surf past the "count" page), diminishing their site's value, and allowing the defendant to "pass off" that information as its own.

The U.S. legal community, for example, watched closely when the owners of a newspaper, the *Shetland Times* in Scotland, brought a lawsuit against the *Shetland News,* a startup news service located in the same town. The *Shetland Times* published a daily online version of its newspaper, while the *News* was the first local daily to publish solely on the Web. It linked directly into the *Times* for news, and the *Shetland Times* went to court. The court granted the *Times* a temporary restraining order against the *News* and its linking practice (*Scottish Outer House,* 1996), and the case soon settled out of court.

One well-publicized framing case was the lawsuit brought by various media companies (CNN, Time Warner, *USA Today,* the *Washington Post,* etc.) against Total News for its framing strategy. The media argued that the use of those frames, whereby Total News showed news stories taken from the plaintiffs with only its advertising displayed, violated their copyright and trademark rights. Total News reached a settlement before trial, agreeing not to frame any content and paid to link to their sites in a separate window (*Washington Post Co., et al. v. Total News,* 1997).

An accelerating Net phenomenon has been the rise of linking agreements in which a linked site pays for the exposure. These situations occur in two ways: (a) the linkage is in reality an advertising contract or customer referral agreement (see Amazon.com's "Associate" program); (b) the linked site commercially profits or otherwise benefits from a deep link. In both cases, a written linking agreement is essential.

Commercially profiting by deep linking or sophisticated software without the other site's permission is another growing legal area. Known as "robots," "bots," "spiders," or "crawlers," these automated software systems steam past home pages deep into data banks, gathering information and transporting copies of whatever is desired back to the host site. If done frequently enough, these "hits" can create a near simultaneous look at whatever data is out there.

The largest Internet auction service, eBay, filed a lawsuit in late 1999 against Bidders Edge, one of several Net auction search services. It had been accessing eBay's site up to 125,000 times daily (as much as 1.53% of the total daily requests to eBay) in searching out what was going on specifically at eBay's auctions. EBay promptly sued after not being able to work out a license agreement with Bidders Edge to pay for this continuing access.

The judge granted an injunction, agreeing with eBay's contention that Bidder's Edge and its robots were trespassing on eBay's site by using and diminishing the resources of eBay's computer systems without permission (*eBay v. Bidder's Edge, 2000*). Bidder's Edge quickly appealed, but just before the appellate court issued its decision, the two companies agreed to settle their lawsuit. EBay reported that the settlement prohibited Bidder's Edge from sifting through its site for information and that Bidder's Edge agreed to pay an undisclosed sum of money.

Even search engines can be subject to linking conditions and exceptions. For example, in *Kelly v. Arriba Soft Corp.* (2002) a unanimous Ninth Circuit panel ruled that an Internet link to a full-sized copyrighted picture on a photographer's Web site did not qualify as "fair use" under U.S. copyright law and could be prohibited. In this case, Arriba's search engine, Ditto.com, displayed both full-sized and reduced-sized photographic images. The court found that the creation and use of the reduced-sized pictures, called "thumbnails," were fair use and could be continued. Internationally, a Danish court in *Danish Newspaper Publishers Association v. Newsbooster.com* (2002) ordered an online news site, Newsbooster.com, to remove links from its site to articles on the Web sites of various newspapers, on the ground that the links violated the EU Database Directory Act and bypassed the newspapers' homepages—following past precedent, both U.S. and international.

The directions of the law of linking are clear: (a) The general rule is that users do not need permission to link directly to the home page of another site, provided they don't disparage, misrepresent, or misappropriate; (b) given that these facts aren't present, framing and deep linking as opposed to linking will more likely constitute a violation; and (c) deep linking in commercial situations, as opposed to noncommercial or personel ones, are likely to be violations in which (1) direct competitors are involved, (2) there is an advantage being taken by that linkage, and (3) there is an element of "unfairness" or bad faith on the part of the linking party. Furthermore, if data is misappropriated, misused, or passed off by another as its own, even nonprofit or similar noncommercial sites may have valid causes of action.

CYBERCRIME

Cybercrime flourishes on the Internet, whether it is fraud, phony investments, pornography, rigged auctions, computer stalking, or prohibited gambling (see *http://www.cybercrime.gov* for more). The advantages of the Net for all users can quickly turn into disadvantages for law enforcement. The ease of entry and ability to disconnect from the Web allow criminals to appear and disappear within seconds with their ill-gotten gains. Arresting criminals is further complicated by the myriad jurisdictions that cybercriminals can cross so quickly, the protection of rogue nations, and differing state or national laws that can make extradition difficult. In turn, the authorities have had to add technology patrols to their arsenal of weapons, and users must be ever on the alert to not become victims.

Although nations add protective laws over time (e.g., the United States with its Access Device Fraud Act, 18 U.S.C. 1029 (1984); Computer Fraud and Abuse Act, 18 U.S.C. 1030 (1986); Trademark Counterfeit Act, 18 U.S.C. 2320 (1984); and the various ones previously mentioned), the question of jurisdiction and enforcement is always raised in this context. With criminal statutes, states and countries look at jurisdiction from the point of view of their laws and interest in protecting their citizens. For example, if gambling (or the Internet sale of wine) is illegal in State A but not State B, then a Web site in State B could be prosecuted by State A for its allowing the residents of State A to use that site. The reasoning is that every Web operator has the ability to be in compliance with State A's laws by simply refusing to allow A's residents to break their state's laws (i.e., by filtering out State A users).

Enforcement is always another question. Located in the Bahamas or other locations where activities such as gambling are legalized, just how do you enforce State A' s judgment penalizing another in a foreign state or country, not to mention the inherent conflict of laws question (i.e., the Yahoo Nazi memorabilia decisions)? Unless there's increased cooperation among the differing authorities and criminal justice treaties agreed to, the First Amendment legal considerations by themselves will be voluminous. When property rather than an individual's freedom is concerned, courts seem to have fewer problems determining rights, especially as to property that has already been seized. For example, *in U.S. v.* $*734,578.82 in U.S. Currency* (2002) the Third Circuit Court of Appeals affirmed a lower court's decision and upheld the forfeiture to the U.S. of funds seized from certain bank accounts. The funds were used in connection with an overseas gambling operation run out of England, where this type of gambling was legal. The court held that a New Jersey company—which had placed the funds in New Jersey bank accounts, then sent them to foreign institutions that in turn conducted the gambling activities—had violated U.S. law making it a crime to "conduct" an illegal gambling operation. The money under this decision could be lawfully seized.

The horrors of September 11 brought more aspects and another dimension of Internet crime to the forefront, given the ability of terrorists to communicate, raise money, and transfer assets over the Net. Among various legislative proposals, the enactment of the United States' International Money Laundering Abatement and Financial Anti-Terrorism Act of 2001, or the "USA Patriot Act," illustrates these new thrusts. Among other provisions, the USA Patriot Act requires key financial sectors to implement programs that prevent their services from being used to launder money or finance terrorism. Entire new industries, such as operators of credit card systems, money transfer companies, check cashiers, security firms, insurance companies, and even casinos—whether online or not—now are encompassed by strict regulations that once included only banks. This act also amended various provisions of the U.S. Code to allow broad interceptions of electronic communications and seizure of customer records. Other nations have or are enacting similar legislation. Their courts, including those of the United States, are currently being asked to rule on how legal these restraints are on individual privacy and constitutional rights. See Chuck Jaeger's chapter on cyberterrorism for more information.

CONCLUSION

Hold onto your hats, the Internet hurricane of change is still howling—but inside your office or study. Legally, as well as technologically, there are more vibrant areas of change coming. For example, professional associations these days face Web sites that give information out to potential patients, clients, and customers on a global basis.

From medicine and accounting to lawyering and filling drug prescriptions, state licensing boards are taking issue with this "practice without a required state license." This area will continue to be well litigated.

Another area involves the ability of the Internet to cut out the middleman. Because this medium allows consumers to contact suppliers directly, the old ways of conducting business are being seriously challenged in the courts. Travel agents are suing airlines, wine distributors are litigating with wineries that sell direct (in effect, suing their own customers or suppliers), and offline textbook distributors are suing online retailers, not to mention the ever-increasing numbers of other industries that are litigating these types of developments. Although the consumer has benefited, it's clear that the legal industry also has.

There's no question that the megasites and huge portals (such as AOL and Yahoo) dominate the Internet, and that the question of antitrust will rear its head even higher in the future. From AOL's acquisition of gigantic Time Warner to the Covisint cyber-venture between the world's six largest car manufacturers and their suppliers, the Web trend continues towards greater concentrations of power.

In addition to Covisint, various large virtual trading, exchange service Web sites abound: Altra Energy Technologies (utilities), ChemConnect (chemical and plastics), Converge (high-tech and electronics), Exostar (aerospace and defense), FuelQuest (independent oil and gas), PaperExchange (paper), and Transora (consumer packaged goods industry), among others. We will see over time more highly publicized Justice Department legal actions challenging these super offline and online combinations.

With the increase in cyberlaw actions over time, the rise and accepted use of cybercourts will also become a reality, along with more jurisdictions and courts converting to public accessible, electronic record keeping and filing. In this direction, Michigan became the first state to create a specific cybercourt (Mich. Pub. Acts, 2001). The new cybercourt under this legislation is expected to become operational in late 2003/2004. This court has concurrent jurisdiction over commercial litigation in disputes where the amount in controversy exceeds $25,000. All filings are made electronically, whereas all actions, depositions, and court appearances are to be by "electronic communications," such as streaming video, audio, and Internet conferencing; the intent is that there will be no paper transmitted or physical interface between judge, litigants, or witnesses. Appeals can be made either to a new cybercourt of appeals or through a normal appellate court. For the latest information and developments on Michigan's cybercourt, see http://www.michigancybercourt.net.

Regardless of the new Internet legal controversies that will rise up further in this new millennium, three realities exist: (a) The legal concepts already in place have proven to be quite adaptable to these challenges; (b) the concepts of fair play, common sense, and netiquette are filling in the gaps through court decisions and statutes; and (c) the use of ADRs on the Net will continue to grow over time because of the inappropriateness of litigation to solve the cyberdisputes among the citizens of the world.

The Internet has enhanced our lives and challenged our laws. The legal system is continuing to meet the challenge, but the world is never again going to be the same.

GLOSSARY

Anticybersquatting Consumer Protection Act (ACPA) The U.S. statute (15 U.S.C. 1125, 1999) that protects trademark or service-mark holders (including the names of famous people) from those who register a mark's domain name or its equivalent with a bad faith intent to profit from that act (e.g., cyberpirates). It allows the trademark or service-mark holder to sue for actual damages, statutory damages (when actual damages are difficult to prove), and/or force the domain name to be transferred back.

"Click" or "Clickwrap" contracts An agreement whereby a party agrees to the terms and conditions of an online agreement by clicking on a button reading "I agree," or some wording to that effect, to indicate the requisite mutual assent to those conditions and understanding.

Communications Decency Act Section 230 of this act (47 U.S.C. 223, 1996) provides that an online service provider is not to be treated as a publisher for purposes of liability for defamatory postings by third parties, nor liable for defamation in such cases.

Cyberlaw The emerging body of law that governs cyberspace transactions and disputes, otherwise known as the "Law of the Internet."

Cyberpirates Persons or entities who register a domain name that is the valid trademark or service mark of another, intending to sell that registered domain name back to the legitimate mark holder at a profit. This term is similar to "cybersquatters" who register domain names ahead of such interest but wait (or "squat") on those names until offers to buy back those names are received from others.

Dash-Dot Name A domain name registration that is off by one "dash dot" from another. For example, "www.microsoft.com" is registered as "www.microsoft-.com." ICANN regulations and case law have invalidated these registrations.

Defamation A false statement made by some person or entity about another, either orally or in writing, that is published to a third party and wrongfully harms the injured party's reputation.

Digital Millennium Copyright Act (DMCA) The 1998 act that amended U.S. copyright law and included (a) a section prohibiting circumvention of encryption or security protections on copyrighted software to violate its copyright (17 U.S.C. 1201–1204) and (b) a section on online service provider liability (17 U.S.C. 512). The online provider provisions set down an administrative proceeding that is used to resolve copyright disputes over third-party postings with online servers and establishes a "safe harbor" liability protection for those providers.

Fair Use The U.S. Copyright Act provides that the "fair use" of copyrighted works involving purposes such as criticism, comment, news reporting, teaching, scholarship, or research is not copyright infringement. Thus, some copying or copyright use is legally permissible in the United States that ordinarily would not be allowable in other countries.

Jurisdiction The power of a court or governmental agency to hear a case and decide the rights of the people or entities that appear before it. This jurisdiction can be *in personam* (determining the rights of people or entities, wherever they reside) or *in rem* (determining the ownership rights to property that is located within the court's territorial limits, regardless of where the disputing parties reside).

Internet Corporation for Assigned Names and Numbers (ICANN) The nonprofit organization that oversees a wide range of Internet functions (once the responsibility of the U.S. government) and now managed by an international board of directors. Among other functions, ICANN promulgates policy on the registration of domain names, accreditation of new registrars, and implementation of domain-name dispute resolution policies.

Long-Arm Statute U.S. state statutes authorizing a local court to assert personal jurisdiction over a nonresident defendant residing outside that state, given certain factual circumstances being present (for example, causing injury within that state by an act that takes place in part or wholly inside it).

Netiquette An informal, essentially noncodified doctrine of "Web manners," courtesy, and cyberethics aimed at creating a system establishing what is or isn't acceptable conduct on the Net, regardless of what the law provides.

No Electronic Theft Act (NET) The U.S. act (17 U.S.C. 506(a), 1997) that provides there is an illegal infringement when pirated copyrighted material over a 6-month period has a retail value of more than $1,000 (a misdemeanor) or more than $2,500 (a felony), even though there is no monetary gain or economic motivation with the infringer.

"Opt In" and "Opt Out" The two distinct privacy policies used by Internet firms and Web sites, which may or may not be codified. With "opt-out" provisions, the user must take the affirmative step to say "no" or refuse permission to a Web site's collection and transmission of financial and other sensitive consumer information. With "opt-in" policies, the Web site must take the steps to gain the positive approval of a user before it can collect, transmit, or sell such private information. Marketing firms prefer "opt-out" policies or laws, because these are less marketing restrictive and put the burden on the user, not the site.

Prima Facie Evidence Evidence presented that indicates a strong presumption the given fact or evidentiary assertion is factually true.

Service Mark A word, name, logo, mark, device, or some combination used by any person or entity to identify and distinguish services performed by it from those of another (e.g., eBay's name and logo).

Trademark A word, name, logo, mark, device, or some combination used by any person or entity to identify and distinguish its goods from those of another (e.g., McDonalds' golden arches or Nike's winged shoe).

Trademark Dilution When an entity uses a trademark (or service mark) of another in such a way as to cause that mark's value to diminish over a period of time. Although there is no immediate confusion as to whose product the mark applies, there is trademark infringement, given that the legitimate mark loses its value. For example, one William Nike starts up and operates "Nike's Ladies of the Night" striptease bar joints in cities where the legitimate Nike shoe and apparel manufacturer operates.

U.S. Copyright Office The U.S. agency that oversees the registration and regulation of copyrights (see www.loc.gov/copyright).

U.S. Patent and Trademark Office (PTO) The U.S. agency that oversees the registration and regulation of patents and trademarks/service marks (see www.uspto.gov for further information).

World Intellectual Property Organization (WIPO) The specialized United Nations agency and intergovernmental organization that is responsible for promulgating and administering major international intellectual property conventions.

Cyberterrorism

Charles W. Jaeger, *Southerrn Oregon University*

WHAT IS CYBERTERRORISM?

Incidents in Cyberspace

In November 1999, a Tampa, Florida man was charged in Federal court with using the Internet to threaten to destroy the reputations of six young women and girls unless they engaged in phone and cybersex. The incident was investigated by a task force that included the FBI (FBI, 1999).

In March 2001, a Canadian known as "Mafia Boy" answered charges related to large-scale "denial of service" (DOS) attacks causing $1.7 billion damage in which millions of e-mail messages brought down some of the Internet's largest e-commerce sites, including Amazon, Yahoo! and eBay. He pled guilty to 56 charges but boasted that he will commit other such acts in the future (Raines, 2001). Mafia Boy was a juvenile.

Perhaps the world's most notorious cybercriminal and the first to appear on the FBI's "Most Wanted" list, "the Condor" stole tens of thousands of credit card numbers and copied millions of dollars worth of computer software beginning in the 1980s. Kevin Mitnick eventually served five years in prison (Meriwether, 1995; Sargent, 2001).

The Terrorism Research Center's Information Warfare Database lists over 50 "incidents" dating back to 1982 of unauthorized entry, denial of service attacks, and similar cyberspace events. Targets include the North American Air Defense Command, NASA, U.S. military sites, the White House, the U.S. Department of Defense, and many others vital to U.S. and world security (IWDB, 2002).

People are becoming concerned that criminal behavior in cyberspace can affect them directly. A December 2001 survey reported that 74% of Americans expressed fear that their personal information on the Internet could be stolen or used for malicious purposes and are concerned that a cyberattack could target critical infrastructure assets like telephone networks or power plants. Harris Miller, President of the Information Technology Association of America (ITAA), said, "The attacks of Sept. 11 . . . destroyed peace of mind for many people using the Internet [and] is generating high anxiety in cyberspace" (Greenspan, 2002a).

While these are mostly "hacking" or "cybercrime" incidents, people increasingly recognize the potential for large-scale attacks that have the potential to create terror, and these prospects evoke fear. Yet, of the above cases, only the cybersex case resulted in charges of cyberterrorism. That incident included no unauthorized break-ins, affected relatively few people, and created virtually no property damage or other direct monetary losses. However, the FBI's Web site calls the attacks "large scale," and Frank Gallagher, Special Agent in Charge of the Tampa Division of the FBI, described them as "cyberterrorism" because of the fear created in the recipients.

Problems Defining Cyberterrorism

Acts such as these may or may not constitute cyberterrorism. It is important to differentiate acts of cyberterrorism from vandalism, common hacking, and criminal activity. Cyberspace is so new and rapidly changing that it is difficult to be precise. An overly broad definition will include so many acts that the term "terrorism" would become meaningless. Making a definition too detailed, in contrast, risks omitting acts that should qualify.

Fifty years ago, there was no mention of "cyber" in *Webster's Dictionary.* Today, it is used as a prefix for topics related to computers and/or networks, including acts of terror (http://www.dictionary.com). The term "cyberterrorism" is coming into common usage, and an evolving body of knowledge is moving toward defining it. Separate government departments and agencies have used this term, but none have formulated a definition of cyberterrorism that is binding outside their sphere of influence.

Definitions in common usage are seldom precise enough to be useful. A 1998 student paper written for a computer ethics class defined cyberterrorism as "the use of computing resources to intimidate or coerce others" (Sproles & Byars, 1998). At a conference early in 2002, Howard Schmidt, vice-chairman of the new Critical Infrastructure Protection Board and formerly chief security officer for Microsoft Corp., defined cyberterrorism as "anything that disrupts or causes mistrust about the security of computers and networks" (Moran, 2002). These two broad interpretations would include many forms of cybervandalism, hacking, and the like. While these activities might be annoying or damaging, they are probably not cyberterrorism.

The National Infrastructure Protection Center (NIPC) is a group of over 100 special agents, analysts, and others from the FBI, the Department of Defense, the CIA, the National Security Agency, and other federal departments (Vatis, 2001). It calls cyberterrorism an "evolving concept" and states, "the definition of terrorism must evolve to reflect the type of activity that goes beyond traditional physical violence" (NIPC, 2001b). The NIPC's Analysis and Information Sharing Unit has proposed the following definition:

> Cyber-terrorism is a criminal act perpetrated by *the use of* computers and telecommunications capabilities resulting in violence, destruction and/or disruption of services to create fear by causing confusion and uncertainty within a given population, with the goal of influencing a government or population to conform to a particular political, social, or ideological agenda. (NIPC, 2001b; emphasis added)

In congressional testimony, an official of the FBI's Counterterrorism and Counterintelligence unit defined cyberterrorism as "*the use of* cyber tools to shut down critical national infrastructures . . . for the purpose of coercing or intimidating a government or civilian population" (Greenspan, 2002b; emphasis added).

Mark Pollitt, of the FBI Laboratory in Washington, DC, in connection with his private academic studies at George Washington University, constructs a "working definition" as follows:

> Cyber-terrorism is the premeditated, politically motivated attack *against* information, computer systems, computer programs, and data which result in violence against noncombatant targets by sub national groups or clandestine agents. (Pollitt, 2002; emphasis added)

Dorothy Denning, Director of the Institute for Information Assurance, Georgetown University, expands the definitions by stating, "The attack should be sufficiently destructive or disruptive to generate fear comparable to that from physical acts of terrorism. Attacks that lead to death or bodily injury, extended power outages, plane crashes, water contamination, or major economic losses would be examples" (Denning, 2001).

Each of the definitions addresses a type of terrorism that goes beyond traditional physical violence and into cyberspace, but there are important differences. The NIPC emphasizes *the use of* computers in creating terror, emphasizing the act, itself. Pollitt emphasizes the *target* of the terror, or the victim(s). A logical definition of cyberterrorism would encompass three elements: the *use*, the *victim*, and the concept of *terror* itself in acts that may or may not include physical violence.

DIFFERENCES BETWEEN CYBERTERRORISM AND OTHER TERRORISM

Terrorism Definitions

Terrorism in the physical world has existed throughout history in one form or another. Since there is no consistent definition of cyberterrorism, it is reasonable to consider one by beginning with physical world acts of *terror*. Again, however, there is some inconsistency. The FBI and the CIA each have their own definitions of "terrorism."

The CIA's Counterterrorist Center refers to Title 22 of the U.S. Code, Section 2656f(d), in defining terrorism as "premeditated, politically motivated violence perpetrated against noncombatant targets by subnational groups or clandestine agents, usually intended to influence an audience" (DCI Counterterrorist Center, CIA, 2002).

The FBI defines domestic terrorism as "the unlawful use, or threatened use, of violence by a group or individual . . . to intimidate or coerce a government, the civilian population, or any segment thereof, in furtherance of political or social objectives" (Watson, 2002).

The two versions share common references to politics or politically motivated violence, but there are differences. One specifies actual *acts*, while the other could include *threats*. One mentions premeditation. The other specifies subnational groups or clandestine agents. These differences may seem trivial, but they become important when applied to specific cases of guilt or innocence.

Each of the acts cited at the beginning of this chapter concern some variation of fear, confusion, uncertainty, violence, intimidation, or coercion, and each at least implies a form of intent. None, however, including the one actually charged with cyberterrorism, is an ideal fit with the above definitions. The acts all lack overt political motives, none resulted in physical violence, and in most cases, there is a lack of intense fear, dread, and panic.

The Role of Fear, Panic, Violence, and Intent

Fifty years ago, *Webster's Dictionary* defined terrorism as the "use of terror and violence to intimidate, subjugate, etc., especially as a political weapon or policy." Terror was defined as "intense fear" or "the quality of causing dread;

terribleness." An example specified "political executions, as during revolution" (Webster, 1952). Recent versions of *Webster's* have changed very little. However, neither of the modern definitions used by our security agencies includes the elements of intense fear, dread, or panic, although they may be implied through intimidation. Both agencies specify violence or threatened violence.

All of the definitions of terrorism and cyberterrorism imply some variation of intent. These are not random or accidental acts and threats. The CIA definition specifies "premeditated" acts, while the FBI definition implies intention. Terrorism is usually considered to include some form of collective intent by a group or organization with an ideology intended to cause harm (FBI, 1999).

The Worldwide Perspective

Destructive acts can occur anywhere in the world. Indeed, terrorism and cyberterrorism have become worldwide concerns. Following the September 11, 2001, attack on the World Trade Center, the 56th regular session of the United Nations General Assembly unanimously passed a resolution condemning terrorism. More narrowly, the resolution includes cyberterrorism. One purpose of the UN is to maintain international peace and security. Clearly, terrorism threatens UN goals, and they recognize that cyberspace can be a weapon against them.

"The same Internet that has facilitated the spread of human rights and good governance norms has also been a conduit for propagating intolerance and has diffused information necessary for building weapons of terror" (Annan, 1999).

Although there are differences between the way individual nations and the world community view cyberterrorism, there is general agreement that it has the potential to create chaos and contribute to a lower standard of living on a global scale.

International agencies and other groups are beginning to work toward neutralizing cyberterror weapons. On November 23, 2001, the first-ever international treaty on criminal offences committed against or with the help of computer networks was signed in Budapest, Hungary, by 26 member states of the Convention on Cybercrime, a part of the Council of Europe. Four nonmembers who helped draft the document, Canada, Japan, South Africa, and the United States, also signed the treaty. The Convention deals with various cybercrimes and network security. Its main aim is to pursue "a common criminal policy aimed at the protection of society against cyber-crime" (Convention on Cybercrime, 2001a). Christian Kruger, Deputy Secretary General of the Council of Europe, announced that "the Convention would give national legal systems ways of reacting together to crimes committed against or through computer networks, especially those related to terrorism" (Convention on Cybercrime, 2001b).

WHO DECIDES WHETHER AN ACT IS TERRORISM?

Although there is no universal definition of terrorism or cyberterrorism, the terms are a basis for laws and regulations. In the United States, crimes and damages are usually defined beginning with legislation. To implement legislation in detail, government agencies enact specific regulations, and the regulations often define specific terms. Since cyberlaw is in its early stages, interpretation becomes more difficult.

Individuals, businesses, and other parties that disagree with the law or the agency implementations may challenge them in federal, state, or local courts. Courts consider definitions at every level in rendering their judgments. A trial court makes an interpretation based on the hermeneutics of the law and prior case law that has concerned the same or similar issues. Dissatisfied parties may appeal the ruling to a higher court for review. Ultimately, a federal or state supreme (or other highest) court makes a determination for a given situation that is binding on all parties and becomes a basis for future interpretations. Changes require new legislation or regulations, and the process begins anew. In the Florida cybersex case cited at the beginning of this chapter, the courts may ultimately determine whether cyberterrorism or simple criminal activity was involved.

Legislators, regulatory agencies, and the courts are all handicapped when interpreting potential cyberterrorism. Traditionally, laws have dealt with acts that occur in time and space. Crimes in cyberspace may have physical effects in time and place, but some of their causal factors reside in a virtual reality, mostly independent of a particular time and space. Laws and regulations are typically written by people who are more comfortable referencing time and space, and there is a scarcity of case law applying directly to causal factors residing outside of these parameters. Many other nations have similar systems—and interpretation problems.

This chapter cannot fully explore a precise definition of cyberterrorism. However, using terminology from the various agencies, it is reasonable to think that evolving cyberterrorism definitions will include acts designed to create fear, dread, or panic that may be directed at noncombatant targets by subnational groups or clandestine agents to intimidate or coerce a government or some segment of the civilian population in furtherance of political or social objectives. This chapter proceeds from this somewhat imprecise point.

HOW AND WHY WAS CYBERTERRORISM CREATED?

The Relationship to Cybervandalism, Hackers, and Other Cybercrimes

Using a broad definition, many ordinary crimes, vandalism, and hacking might be classified as terrorism. Even repeated "spam" might be cyberterrorism if it intimidates or coerces people into purchasing or otherwise acting on an offer. Pollitt's definition narrows the target to politically motivated attacks against digital devices. That would exclude threats against individuals or businesses such as the cybersex and Mafia Boy cases cited above, incidents that had a substantial fear or even panic component, but were not overtly political. The NIPC definition narrows it further, but it also excludes the cybersex case, the only case where actual charges of terrorism were brought, because the perpetrator did not have an overt political, social, or ideological agenda. The cyberterrorism term is widely misused.

Who Are Today's Cyberterrorists?

President Clinton, in a December 2000 address at the University of Nebraska, said, "One of the biggest threats to the future is going to be cyberterrorism—people fooling with your computer networks, trying to shut down your phones, erase bank records, mess up airline schedules, do things to interrupt the fabric of life" (Clinton, 2000). These kinds of incidents and many other activities in cyberspace are annoying and cause monetary or other damages. They include some degree of vandalism, mischief, unauthorized entry, or other destructive act(s), but only in a broad sense could they be construed to create fear, intimidation, or panic. There is considerable "gray area" when we consider actual cases.

In July 2002, CNN reported that Yale University complained to the FBI that it experienced 18 unauthorized log-ins to their Web site that were traced back to computers at Princeton, including computers in the admissions office (CNN.com, 2002c). In 1999, after the United States accidentally bombed the Chinese embassy in Belgrade, Yugoslavia, U.S. Web sites including the Department of Energy, the Department of the Interior, and the National Park Service were defaced in the name of China, and the White House Web site was shut down for three days after their servers were overloaded with massive amounts of e-mail. In August and September of that year, pro-Chinese hackers defaced or otherwise compromised 165 Taiwanese Web sites to protest the Taiwanese presidential elections (Jane's). In May 2001 some of the same activists attacked U.S. Web sites after a Chinese fighter jet was lost following a collision with a U.S. reconnaissance plane (Tang, 2001). In 2000, pro-Pakistani hackers defaced more than 500 Indian Web sites. In April 2001, pro-Korean hackers, primarily university students, attacked the computers and Web sites of various Japanese organizations following their approval of a new history textbook that the Koreans believed excluded atrocities committed by Japan in connection with World War II (NIPC, 2001a).

Each of these incidents created trouble or made a symbolic statement, and these kinds of people are widely referred to as cyberterrorists. Some are politically motivated, but they don't really create widespread fear, dread, or panic. While the target might be similar, and the same techniques can be used, this is not cyberterrorism. The objective, degree of violence, and reaction are different.

Conway describes a useful three-tiered schema for categorizing "fringe" activity on the Internet as "use, misuse, and offensive use" (Conway, 2002). Use is normal and legal Internet usage—the same for terrorists as for anyone else. Misuse includes acts that disrupt or otherwise compromise other sites, including vandalism and protests typically associated with hackers. Most of the above incidents fall into this category. Offensive use entails actual damage, theft, fraud, extortion, or commercial espionage, much of which is criminal. A subset of offensive use would be cybercrime, and a subset of cybercrime would be cyberterrorism. See Figure 1.

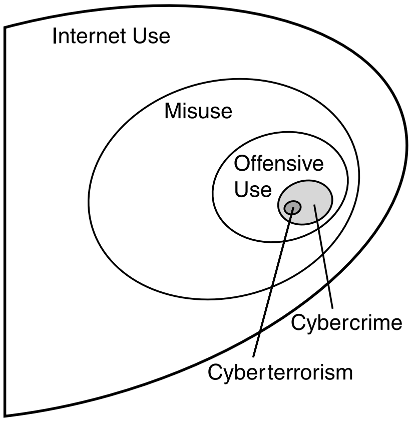

Figure 1: Categories of Internet usage.

Many misuse and offensive use "incidents" are tracked by the Carnegie Mellon CERT Coordination Center. The incidents counts have increased exponentially since 1988 (Carnegie Mellon CERT Coordination Center, 2002). See Table 1 and Figure 2.

Terrorists seldom engage in ordinary misuse or offensive use, as it is counterproductive to their larger goals through the potential risk of discovery. They engage in a small but potent subset of cybercrime. Today, the cyberterrorist threat that concerns the FBI, CIA, UN, and almost everyone else entails an end result including widespread death, destruction, fear and dread, chaos, or any of several other devastating consequences. Because of the magnitude of the potential effects, this small subset of Internet offensive use is a new and larger threat than the world has experienced.

Acts That May Be Cyberterrorism

Barry C. Collin, who takes credit for coining the term "cyberterrorism" in the mid-1980s, says, "This enemy does not attack us with truckloads of explosives, nor with briefcases of Sarin gas, nor with dynamite strapped to the bodies of fanatics. This enemy attacks us with ones and zeros" (Collin, 1996). The outcome can be deadly. He lists some possible acts of the cyberterrorist:

Table 1 Number of Incidents

Year	1988	1989	1990	1991	1992	1993	1994	1995	1996	1997	1998	1999	2000	2001	2002*
Incidents	6	132	252	406	773	1,334	2,340	2,412	2,573	2,134	3,734	9,859	21,756	52,658	102,706

*2002 estimated based on 73,359 incidents reported through Q3.
Note: Data from http://www.cert.org/stats/.

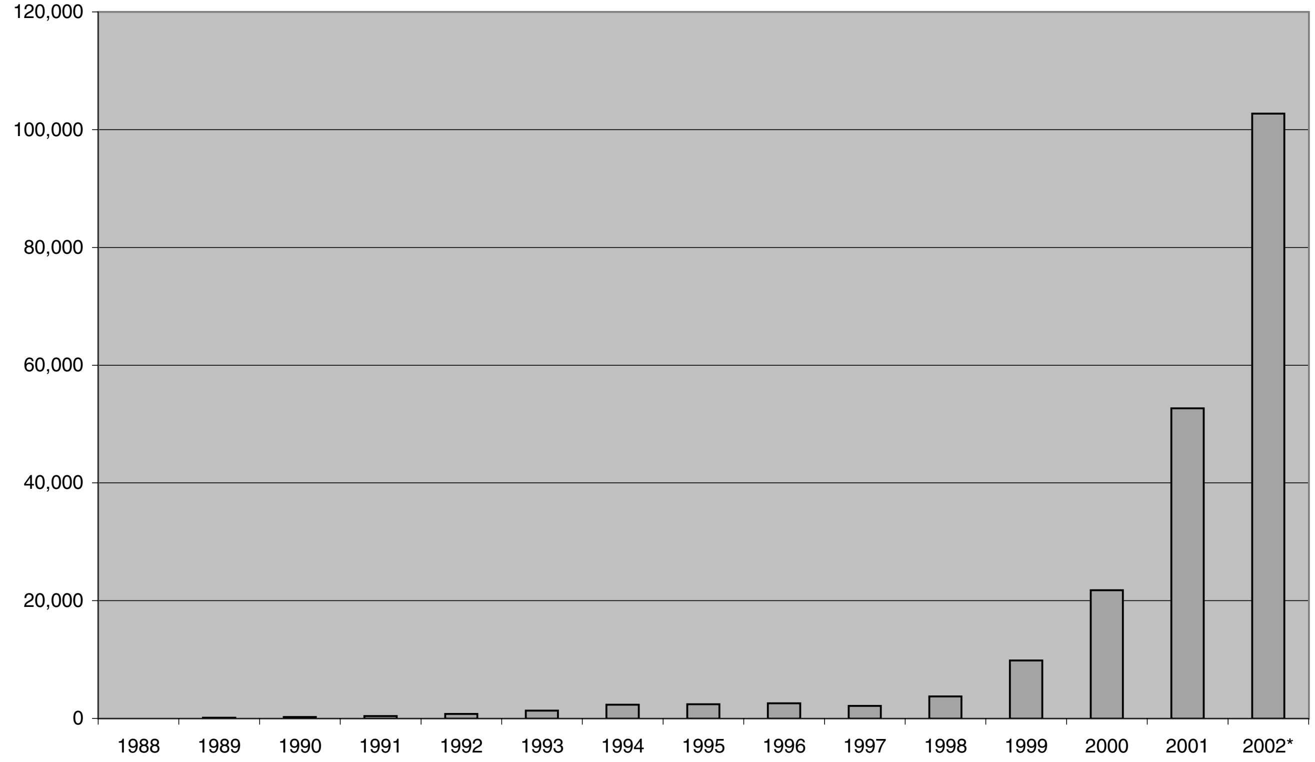

Figure 2: Number of incidents (graphical representation of Table 1).

Remotely changing the pressure in gas lines, causing valve failures, explosion, and fire.

Placing computerized bombs around a city, all simultaneously transmitting unique numeric patterns, each bomb receiving each other's pattern. If any of the set of bombs stops transmitting, all the others detonate simultaneously, which effectively prevents disarming any of the bombs.

Attacking future air traffic control systems to cause civilian jets to collide.

These "ones and zeros" attacks would have violent and fearful physical effects equally or more devastating than those caused by the truckloads of explosives, dynamite, or poison. Following the 9/11 attacks on the World Trade Center, it was reported that the government asked some of the film industry's most creative minds to come up with additional scenarios for potential attacks so that safeguards could be considered. Cyberterrorists might open a dam's spillway to inundate downstream communities or cause a meltdown of a nuclear power plant.

Collin also lists several acts in cyberspace that do *not* have devastating physical effects, but clearly have the potential to create widespread chaos, dread, or intimidation in offices, homes, and on the streets:

Remotely accessing the processing control systems of a cereal manufacturer to alter the formula and sicken children;

Disrupting banks and international financial institutions and stock exchanges, with resulting loss of confidence in the economic system;

Remotely altering formulas of medication at pharmaceutical manufacturers, resulting in ineffective or potentially harmful medications; and

Shutting down the electrical grid, causing wide-spread chaos.

Collin concludes, "In effect, the cyber-terrorist will make certain that the population of a nation will not be able to eat, to drink, to move, or to live. In addition, the people charged with the protection of their nation will not have warning, and will not be able to shut down the terrorist, since that cyber-terrorist is most likely on the other side of the world."

In November 2001, Richard Clarke, chairman of President Bush's Critical Infrastructure Protection Board, said cyberattacks on the nation's critical [information technology] infrastructure could potentially cause "catastrophic damage to the economy" akin to the "functional equivalent of 767's crashing into buildings" (Johnson & Radcliff, 2001).

What may make these acts even more dreadful is that most of them could be carried out from remote locations, and the perpetrators would be difficult to track down. "This is the new world of cyber-terrorism," says Tom Regan in an article for the *Christian Science Monitor*. "Cyber-terrorism allows terrorists—both foreign and domestic—to inflict damage with no harm to themselves and little chance of being caught" (Regan, 1999).

The Computer Emergency Response Team (CERT) Coordination Center, part of the Software Engineering Institute, is operated by Carnegie Mellon University for the

Department of Defense. Dr. Howard Lipson, in a November 2002 special report, says:

> The current state of the practice regarding the technical ability to track and trace Internet-based attacks is primitive at best. . . . Society continues to migrate increasingly critical applications and infrastructures onto the Internet, despite severe shortcomings in computer and network security and serious deficiencies in the design of the Internet itself. Internet protocols were designed for an environment of trustworthy academic and government users. . . . In this era of open, highly distributed complex systems, vulnerabilities abound [and] existing track and trace capabilities are primitive compared with the capabilities of attackers. (Lipson, 2002)

In 1998, Michael Vatis, director of the NIPC, was reported to have told a Senate subcommittee, "Tracing cyber-attacks is like 'tracking vapor' " (Christensen, 1999). Unknown and unseen, an enemy difficult to bring to justice connotes a lack of control that may make people more fearful.

Why Do They Do It?

Fun and Games, Attention and Peer Group Recognition, Profit

Some of the acts described by President Clinton and the Yale versus Princeton incidents may be nothing more than leisure activities by individuals that find them fun. Some of the incidents involve simple mischief, rather than offensive use. Many hackers engage in misuse activities to be recognized by their peers. Several accomplished hackers have been hired by business or government entities to prevent hacking, enhance network security, or edit magazines or newsletters that relate to these topics.

Revenge and Political Statements

In October 2001, the NIPC issued a report on rapidly growing worldwide activities designed to "expose government corruption or fundamental violation of human rights" or achieve similar goals. These include long-term attacks characterized as "hacktivism." "Cyber protests" are short periods of intense political activity. Both are used for revenge:

> In the last decade, with the explosion of the size of the Internet, protests and political activism have entered a new realm. . . . Cyber protests have become a worldwide phenomenon. . . . Unrestrained by geographic boundaries, protesters have an enormous forum in which to be heard. . . . It has only been since 1998 that cyber protests have skyrocketed in popularity and become commonplace in today's computerized world. (NIPC, 2001a)

Much as a delinquent child might act out to receive attention from a parent, teacher, or peer group, hackers can create havoc designed to make the world take notice of their opinions and belief. Defacing Web sites and interrupting e-commerce can highlight causes and attract the media spotlight, while it creates embarrassment and monetary costs for their adversaries.

Destruction, Fear, Dread, and Panic

Cyberterrorists usually have a political or societal agenda that is much more comprehensive and severe than a cyberprotester's. They may feel intense hatred for a business, society, government, way of life, or certain religions. They may seek to punish these targets—including individuals and entire populations not directly involved in the policy decisions with which they disagree. These acts almost always involve offensive use.

Terrorists typically believe strongly in their cause. They may attract a small following, and their methods may be condemned, or at least not widely supported. In this sense, they are extremists or fanatics. To communicate their point of view, they may create chaos through some horrific act, leaving fear, dread, and panic. In the vacuum that follows, they may hope to introduce their desired changes.

The Role of Asymmetric Response

Asymmetric response is a generic explanation. In free countries, those who do not approve of a government, business, or institution policy can disagree publicly. If their position is widely unpopular or repugnant, they would be considered "extreme." They may become frustrated, feel powerless, and believe that it is "them against the world." Convinced that they are right and unable to achieve their objectives through conventional means, they can strike against the "enemy" with an act of terror. This is the asymmetric (one-sided) response.

Asymmetric responses often are associated with conventional warfare. A rag-tag, poorly trained militia or even a neighborhood gang that is no match for a powerful state army may resort to guerilla tactics, sneak attacks, bombings, sniper attacks, or even rock throwing to harass and demoralize the superior force. This can be highly effective, as witnessed by Russia's withdrawal from Afghanistan and the United States' departure from Somalia.

The National Intelligence Council (NIC) has predicted asymmetric responses to an expected overwhelming military superiority brought about by a paradigm shift in the nature and conduct of warfare. This "revolution in military affairs" (RMA) will be "a small, information-intensive, professional armed force [as] the model for a 21st century military," largely based on strength in information technology and smart weaponry. As the balance tilts more and more toward the camp of the powerful adversary, asymmetric response becomes more likely, even between nations with broadly similar tools. "Iraq and Iran are examples of states that will likely explore the usefulness of information technology in pursuit of asymmetric conflict . . . including through the employment of information warfare and cyber-terrorism" (NIC, 1999).

Military analyst Tony Cordesman, former adjunct professor of national security studies at Georgetown

University and author of numerous books and articles dealing with asymmetric response predicts, "It is very likely that over the next few years, the [U.S. National] Guard will greatly expand its mission . . . [and] may well be reconfigured to perform more missions in asymmetric warfare" (ABC News, 2001).

Asymmetric cyberterrorism may be next. The Associated Press reported that White House Technology Advisor Richard Clarke, testifying before a Senate Judiciary subcommittee on cyberterrorism on February 13, 2002, said, "A serious cyber-attack is almost inevitable because it is cheaper and easier for a foreign country or a terrorist group than a physical attack" (Holland, 2002).

Denning notes that the Internet "may lessen the need for violence by making it easier for sub-state groups to get their message out," but concludes, "Unfortunately, this . . . does not seem to be supported by recent events. . . . Groups that foster hate and aggression thrive on the Internet alongside those that promote tolerance and peace" (Denning, 2001).

The industrialized nations have highly developed electronic infrastructure that drives knowledge-based economies and gives them advantages in business, government, and military power. The virtual world of cyberspace increasingly leaves others behind, including some who consider technological progress in fundamental opposition to their belief systems or religions. More and more powerless, more extreme in their beliefs, they can neutralize their enemies' strength through asymmetric cyberattacks. Regan states, "Seemingly unconnected events may have a more sinister source: coordinated cyber-hacker attacks." He adds, "No other country or group can approach the US conventional-weapon superiority. This is why many terrorists find information terrorism an attractive alternative to traditional forms of terrorism . . . . It is a way for the 'weak' to attack the 'strong' " (Regan, 1999). The contradiction is that they may be using the very tools they condemn.

WHO SPONSORS CYBERTERRORISM?

When the world was simpler and more predictable, it was easier to determine who was pulling strings and causing consequences. Today's terrorists can pursue extreme agendas with more powerful tools than ever before. Many of these—especially those in cyberspace—are amazingly inexpensive, easy to get, and easily concealed.

In simpler times, terrorists required a sponsoring organization—often state sponsorship—to obtain sufficient funding and connections. Today, cyberterrorists acting alone or in small groups can pursue extreme agendas either through volunteer labor or by relatively small amounts of money disbursed from wealthy individuals, foundations, fund raising organizations, or almost any rogue country's intelligence unit. "Official" state sponsorship is less likely, and following a money trail is elusive in that physical currency need not be exchanged. Regan quotes Dr. Harvey Kushner, chairman of the criminal-justice department at Long Island University:

> We have moved away from state-sponsored terrorism. The old model of the hierarchical or "organized crime" group, no longer exists. These days, terrorists move in loose groups, constellations with free-flowing structures. So these days terrorism—both the traditional kind and cyberterrorism—is more the act of the freelancer or the individual. This is true both internationally and nationally. (Regan, 1999)

WHO ARE MOST VULNERABLE TO CYBERTERRORISM?

Cyberterrorism Vulnerabilities Today

It has been reported that "The U.S. Department of Defense logged 250,000 computer attacks on its sites in 1996 alone, 62 percent of them successful" (Thom, 1999).

In 1997, 35 hackers were hired by the National Security Agency to launch operation "Eligible Receiver," an exercise of simulated attacks on the U.S electronic infrastructure. They reportedly achieved "root level" access in 36 of the Department of Defense's 40,000 networks, "turned off" sections of the U.S. power grid, "shut down" parts of the 911 network in Washington, DC, and other cities, and broke into computer systems aboard a Navy cruiser at sea. Richard A. Clarke, White House terrorism czar, called this an "electronic Pearl Harbor" (Christensen, 1999).

On May 4, 2001, the White House Web site was the victim of a distributed denial of service (DDOS) attack lasting about three hours that effectively shut it down by overloading its servers with an automated barrage of service requests. This was symptomatic of similar attacks on commercial and other government sites, some of which may have included the Chinese hackers attacks (Weiss, 2001).

In late August, 2002, CNN published an Associated Press report about an FBI raid on the offices of a consulting firm in San Diego, CA, following a local newspaper story about the company's claim that it had found security loopholes in U.S. military computers, some of the country's most confidential data repositories. The company "identified 34 military sites where it said network security was easily compromised [using] 'free' software and relatively standard hacking procedures to identify vulnerable computers and then peruse hundreds of confidential files containing military procedures, e-mail, Social Security numbers and financial data." The company claimed they were simply trying to expose a need for better security. The FBI and Justice Department were not amused (CNN.com, 2002d).

On October 21, 2002, an estimated 6,000 computers worldwide swamped the Internet's 13 root servers that control most of the Net's traffic in a distributed denial of service attack. Eight were disabled to some degree in what was called "the biggest ever hacking attack on the Internet" (Naraine, 2002; Vickers, 2002).

On December 5, 2002, federal agents raided Ptech, a Quincy, MA, company "that provides critical software to major U.S. agencies and is suspected of having ties to Usama bin Laden and Al Qaeda terrorists . . . . Officials had suspected 'back doors' may have been built into Ptech software that could enable terrorists to access federal computers." Ptech's customers include the Department of Energy, the FBI, the U.S. Air Force, the Naval Air Systems

Table 2 Number of Vulnerabilities

Year	1995	1996	1997	1998	1999	2000	2001	2002*
Vulnerabilities	171	345	311	262	417	1,090	2,437	4,511

*2002 estimated based on 3,222 incidents reported through Q3.
Note: Data from http://www.certs.org/stats/.

Command, the Federal Aviation Administration, the House of Representatives, and NATO (Fox News, 2002b).

It is not comforting knowing that the White House had been compromised rather easily, especially when a security expert was quoted as saying that "such attacks have been common for years." Equally unsettling is that most private businesses probably do a better job of protecting their sites and vital data than do many government entities. "Most private business sites probably have Web servers equipped with firewalls that are capable of halting these types of attacks. Government sites, however, are usually more vulnerable because their staffs are paid less and don't have access to the latest software and hardware defenses" (Weiss, 2001).

The Carnegie Mellon CERT Coordination Center has been tracking "vulnerabilities reported" since 1995, and these have shown exponential growth (Carnegie Mellon CERT Coordination Center, 2002). See Table 2 and Figure 3.

The attacks may not have resulted in any direct or lasting damage, but they are unsettling. One expert maintains, "The [Internet router] attack itself was invisible and without effect on Internet users. The attack on the DNS system did not noticeably degrade Internet performance." At the same time, he says that "as nations and critical infrastructure become more dependent on computer networks for their operation, new vulnerabilities are created—a massive electronic Achilles' heel" (Lewis, 2002).

If the White House can't keep hackers from shutting down their servers and the Internet is vulnerable to its critical routers being shut down, can't cyberterrorists mount that same attack on other locations in our vital information technology infrastructure? Could they cause interruptions in air traffic control, banking, or stock trading systems to the point that people will experience widespread dread, fear, or panic? If our military can't protect vital data from hackers, aren't they vulnerable to an attack by cyberterrorists that could cripple their ability to defend the country? How can that happen?

HOW CYBERTERRORISM OCCURS: CONVERGENCE OF THE PHYSICAL AND VIRTUAL WORLDS

Cyberspace is a world of combinations of ones and zeros that can represent the physical world, but are not the physical object(s). This virtual world has no appreciable mass.

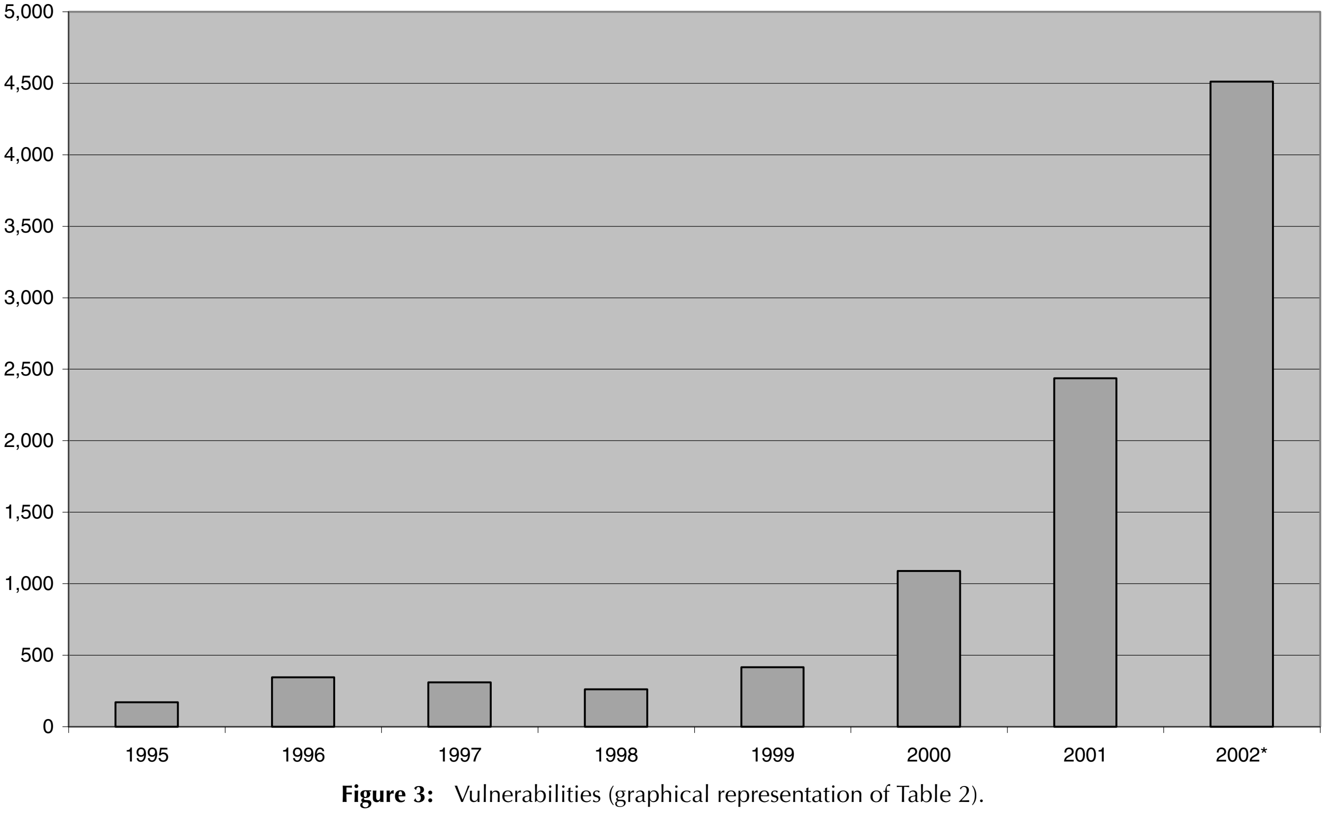

Figure 3: Vulnerabilities (graphical representation of Table 2).

It marginally exists in time and space. With the attachment of stimuli and sensory interface devices, the flow of ones and zeros can control physical objects that exist in time and space. Collin defines this interface as the convergence of the physical and virtual worlds. The physical world is matter and energy. The virtual world is symbolic, binary, and a representation of information, presumably from the physical world. "It is now the intersection, the convergence, of these two worlds that forms the vehicle of cyber-terrorism, the new weapon that we face" (Collin, 1996).

Any electronic signal can be attacked if its rule-based behavior of ones and zeros can be determined and accessed. Most of the previously cited misuse and offensive use acts use the Internet as a means to access target device points (some do not, e.g., the bombs transmitting signals leading to simultaneous detonation) through standardized Internet rules (Internet protocols, or IP, and transmission control protocols, TCP) that enable worldwide communication with devices. Each device has a unique IP address. Once terrorists have access to the IP address and the rules controlling the device itself, they have the potential to control it. Often, remote administration of the physical device is used, and control is through IP or other discoverable interfaces. These are vulnerable points.

Collin describes activities in the physical world that intersect with the cyber-based systems through these vulnerable points. His examples include food and pharmaceutical processing plants, electric and natural gas utilities, train crossings and traffic control systems, next generation air traffic control systems, virtually all modern military equipment, and military, public safety, and civilian communications. Using readily available digital tools and freely available information from Internet Web sites, the cyberterrorist exploits this "point of convergence" to achieve one or more of three goals: destruction, alteration, or acquisition and retransmission.

Denning poses several problems for the cyberterrorist, but ends up concluding that the threat is real:

> Although cyber terrorism is certainly a real possibility, for a terrorist, digital attacks have several drawbacks. Systems are complex, so controlling an attack and achieving a desired level of damage may be harder than using physical weapons. Unless people are killed or badly injured, there is also less drama and emotional appeal. . . . [Nevertheless,] some of these [computer hackers] are aligning themselves with terrorists like bin Laden. While the vast majority of hackers may be disinclined towards violence, it would only take a few to turn cyber terrorism into reality. Further, the next generation of terrorists will grow up in a digital world, with even more powerful and easy-to-use hacking tools. (Denning, 2001)

Collin might be an alarmist, but even with our best efforts at preventing cyberterrorism, some of his doomsday acts seem possible or likely.

The Tools of Cyberterrorists

Cyberterrorists are a special breed of hacker, and they use similar tools and techniques. Cyberterrorists need hardware, sophisticated software, and detailed knowledge of the technology, the targets, and the procedures used to maintain and control operations at the target sites. Much as a safecracker goes about business with torches and explosives, the cyberterrorist uses specialized cybertools to gain access and penetrate the barriers protecting targets. Hackers traditionally work alone, but that is changing. Today, hackers and cyberterrorists gain additional power by working together.

Knowledge

The cyberterrorist identifies targets and understands their intimate details. In cyberspace, it may not be necessary to know the physical location of the device, itself, but only the IP or other electronic address "where" it resides in cyberspace. Details include the physical structures in which the ones and zeros reside—usually a computer or system of computers with its associated network—and the processes used to maintain and control its action(s).

The technology to operate, control, and maintain the physical device normally has protective "firewall" barriers and is intentionally constructed to be difficult to discover and circumvent. In tracking "attack sophistication vs. intruder technical knowledge," Lipson points out that in 1980, attack sophistication was low, but it required high intruder knowledge. By 2000, attack sophistication had become high, but the required intruder knowledge was low, and there was "widespread availability of exploit tools" (Lipson, 2002).

In discussing "the democratization of hacking," John Christensen says, "The tools of mayhem are readily available. There are about 30,000 hacker-oriented sites on the Internet, bringing hacking—and terrorism—within the reach of even the technically challenged." He quotes a manager of technical security at a company that does business with the Pentagon: "It's about bragging rights for individuals and people with weird agendas . . . . You no longer have to have knowledge, you just have to have the time" (Christensen, 1999).

Software and Hardware—Cyberspace Resources

The Internet is a free-for-all. For a few thousand dollars at most, almost anyone can serve up images, information, and other content on the Web. There are no effective committees with official content authority or oversight. Government or other security agencies control information only minimally. Servers can reside in any country, sometimes in difficult to discover physical locations, and they can be moved easily.

The cost of computer hardware suitable for interacting in cyberspace is almost negligible. Better hardware enables hackers to carry out the millions of operations that may be required to discover access codes faster than they otherwise could, and may make following their trail more difficult, but almost any hardware will do.

Software is the set of instructions to control hardware. Hackers know where to find software and documentation posted on the Internet. If a hacker obtains a new tool, immediate action is needed to stop its dissemination and use. Meanwhile, new tools evolve. Such "cat and mouse" games have existed since police were organized.

Access

Operators and trustees of the target devices use increasingly sophisticated defenses, while hackers develop and share new tools and techniques to probe and defeat them. Hacking into secure sites may simply mean millions of iterations of new trial-and-error algorithms that ultimately discover the target device's secret passwords or defeat its other protective barriers. Even with low probability, the documented cases of unauthorized entry are common. An old saying is that "even a blind pig finds an acorn from time to time." In cyberterrorism, the odds of access are greater. A significant cyberterrorism incident can occur either by skill or through blind luck.

Power in Numbers

Obtaining the knowledge, hardware, software, and access to targets in cyberspace can be complex. Specialists can focus on a tiny problem that unlocks success in the broader venture. Acting together, even informally, hackers and cyberterrorists can defeat barriers that would be impossible for any single individual.

The Chinese, Pakistani, and Korean hackers were loosely associated individuals with common beliefs and an access to digital tools. Acting alone, they may have been limited to a lucky one or two successful acts. By communicating with each other on the Internet, they could exchange information about targets, hardware, software, access, timing, and target locations. They improved their probability of success by sharing. Networks of cyberterrorists working together, perhaps in widely separated parts of the world, may one day unlock the keys to making one or more of Collin's doomsday scenarios reality.

The Support Role of Cyberspace in Cyberterror

Just as businesses, governments, military forces, and other individuals use the Internet to communicate, so do cyberterrorists. It's fast, easy, cheap, and powerful. Just as the rest of us have gained power through file sharing, cyberterrorists transferred computer data to associates anywhere in the world. This is legitimate use.

They also use it for background work. Almost any computer can be accessed if left unprotected, and techniques to obtain passwords through algorithms and multiple iterations are available free on some 30,000 hacker sites (Christensen, 1999). Hackers and cyberterrorists alike use these resources to access homes, businesses, or institutions where they can plant spy devices and read the contents of computer hard drives and other data storage. The medium for cyberterror, itself, becomes the conduit for intelligence gathering. This can be use, misuse, or offensive use.

Attacks Occur through Different Countries and Different Systems

Hackers and cyberterrorists can operate out of almost any physical location on earth. Many nations have daunting problems such as hunger, disease, political unrest, or traditional war, often to the extent that they are unable to address security issues or exert control over cyberspace. This is not limited to the least developed countries. Many emerging nations have these problems and offer ample electronic infrastructure to facilitate cyberterrorism. In some cases, their political leadership is sympathetic to terrorists. In Richard Clarke's testimony before a Senate Judiciary subcommittee on cyberterrorism as cited earlier, he included Iran, Iraq, North Korea, China, Russia, and other countries as "already having people trained in Internet warfare" (Holland, 2002).

Even developed nations are vulnerable to cyberterrorism. A 1999 survey by the Victoria Police (Australia) found a third of the top 100 Australian companies had suffered from computer crime, and only 35% had a staff security awareness program. The head of the investigating squad remarked, "If a lot of [cyberterrorist] activity were to take place, Australia would be fertile ground." Some of these businesses control vital physical infrastructure or devices vulnerable to terrorism (Thom, 1999).

On October 25, 2002, the Associated Press reported that a special task force chaired by former Senators Gary Hart and Warren Rudman released a report saying that the United States remains "dangerously unprepared" to deal with another major terrorist attack, stating, "In all likelihood, the next attack will result in even greater casualties and widespread disruption to American lives and the economy" than the 9/11 attacks (AP 2002a). At about the same time, other headlines spoke of targeting railroads and voting machines (CNN, 2002b).

Vulnerabilities exist in network route traffic and in methods to keep track of users. Joel Snyder, a Canadian author, points out that the entire Internet depends on huge border gateway protocol (BGP) tables that detail the more than 100,000 routes information can travel. BGP4 is the protocol used to exchange routing information between providers and to propagate external routing information through autonomous networks. BGP-speaking routers "peer" with each other to exchange information about routes and improve data flow efficiency:

> In the early days, these tables were validated against routing registries that ensured bogus information could not be injected into the tables. Nowadays, that doesn't happen. Keeping those routing registries updated and synchronized is just too expensive and inconvenient. The lack of a global routing registry means that it's fairly easy to create routes to nowhere. . . . If a determined attacker were to start injecting routes into the BGP tables, the ripple effects could be enormous. . . . [It] could cripple routers around the world. (Snyder, 2002)

If the cyberterrorist could use BGP tables to redirect messages to random or unknown locations, it also might be possible to redirect them to specific destinations. This would be an example of acquisition and retransmission. If cyberterrorists could substitute the original path with routes to its own control station, alter the message contents, and redirect them, they may be able to take control of critical physical devices without discovering the secret passwords and other barriers to these devices! Some of Collin's dreadful cyberterror scenarios may come about through these means. While this probability is very low, vigilance is ongoing.

Groups such as the University of Oregon Route Views Project maintain servers that have regular BGP sessions with many routers spread throughout the world to study variations in core route table sizes and growth rates. Their findings are that the number of routes in the Internet increased from approximately 15,000 in 1994 to approximately 115,000 by mid-2002, magnifying their vulnerability (Meyer, 2002).

Internet domain name servers (DNS) track users, referencing millions of user names. It is common to "ping" these and other address nodes with a short query message that maintains communication with them and detects abnormalities. Normally, this traffic is minimal. The October 21, 2002, attack on 13 DNS nodes in Japan, Europe, and the United States consisted of a massive "ping flooding" denial of service attack (Naraine, 2002; Vickers, 2002). A creative terrorist might combine such an attack on the DNS servers with some form of extracting and redirecting messages through BGP routing intervention. Again, this is not likely, but it is among the many scenarios leading to potentially destructive effects.

Direct and Indirect Effects of Cyberterrorism on Vulnerable Parties

Some cyberterrorism effects—e.g., physical destruction—are obvious. Secondary results might include indirect damages to individuals, businesses, institutions, and government segments, including individual and mass dysfunction, job displacement, and other economic costs. Often, damage in one segment affects others.

Effects on Individuals

Terrifying scenes in action films, video games, novels, television shows, and other media are entertainment. Normally, they do not cause fear or dread for willing participants. H.G. Wells' famous Halloween Eve 1938 "War of the Worlds" radio broadcast created wide-spread panic, but that was not its intention (it was mistakenly believed to be real). Few people enjoy actual terror where they do not or cannot control the event.

People have experienced many instances of terror such as war; revolution; riots; bombings; the September 11, 2001, events (9/11); and the Bali bombings. Few or none have been created by cyberterrorism—yet. If disruptions of electric power, transportation, water control, or other public utilities occur through cyberterrorism, individuals are likely to react very much as they do in other terror situations, with varying degrees of fear, dysfunction, and wide-spread panic that would impact businesses, government, and society as a whole.

In the days and months following the World Trade Center attack, most individuals recovered their wits and returned to normal consumption patterns, albeit with additional caution. Consumer spending returned to near normal levels in the United States and continued to drive a recovering economy. Business activity, in contrast, was impacted, even though derived demand remained high.

Effects on Companies

Companies like stability and predictability. Spending in business markets slowed following the 9/11 attacks. Businesses were reluctant to risk economic resources in an uncertain environment. The same outcome would occur with a cyberterrorist attack. Cyberterrorism that directly disrupts plants, factories, distribution networks, or critical infrastructure lessens stability. It can drive companies out of business, with resulting economic dislocations and jobs losses.

Many businesses are aware of the potential for cyberterrorism and have taken steps to counteract it. However, an alarming number of companies are vulnerable. At a conference early in 2002, a cyberlaw expert stated, "People now have a real-world example of the issues that we discuss here. Sept. 11 has made people aware not just of the impact of loss of life, but also the impact of losing business infrastructure." Howard Schmidt, vice chairman of the Bush administration's new Critical Infrastructure Protection Board (CIP), added, "I don't think I've found anything anywhere that's free of vulnerabilities" (Moran, 2002).

Yet, many companies are not taking effective steps to protect themselves from cyberterrorists, and many are not sharing what they learn with other companies or the authorities charged with helping them. An April 2002 CNN.com article about the seventh annual Computer Crime and Security Survey, reported by the FBI and the Computer Security Institute (CSI), states, "About 90 percent of the respondents detected a security breach within the last 12 months. However, only 34 percent reported the intrusions to law enforcement officials." The CSI director added, "There is much more illegal and unauthorized activity going on in cyberspace than corporations admit to their clients, stockholders and business partners or report to law enforcement." Bruce Gebhardt, executive assistant director of the FBI said, "Now, more than ever, the government and private sector need to work together to share information and be more cognitive of information security so that our nation's critical infrastructures are protected from cyber-terrorists" (Sieberg, 2002). Why are companies reluctant to cooperate?

Companies want to avoid the bad publicity associated with having had their systems and facilities compromised by a cyberterrorist, and they want to protect their proprietary information from scrutiny by agencies that would turn such information into public record. In many cases, from a purely business point of view, it makes more sense to deal with the issue internally and not report it to police or other investigative agencies that might leak or subject it to the Freedom of Information Act. "Corporate leaders, in many instances, simply never tell the outside world they've been victimized, to avoid spooking investors or customers" (O'Connor, 2000).

Effects on Society

The general public has a limited understanding of cyberspace, the extent to which our infrastructure is interconnected by cyberspace, or the potential devastation that could occur by controlling air traffic, railroad switches, dam spillways, nuclear power, and other powerful devices. Although there is almost no research about cyberterrorism's effects on society, it is reasonable to assume that people will behave similarly to the way they react to conventional terrorism.

Society is composed of individuals and institutions. Many individuals become dysfunctional in the face of terror. They adopt negative attitudes and experience loss of morale. If society at a macro level becomes demoralized, traumatized, panicked, or filled with dread, as a successful cyberterrorist attack might accomplish, the collective synergy would have the potential to bring about a difficult-to-control negative spiral affecting financial institutions, securities markets, and individuals' financial conditions. Many individuals never fully recover from the psychological or financial effects of a terror attack.

However, if people perceive a terror source to be external and hostile to their way of life, it can bring society together with a common purpose. This occurred following the 9/11 attacks in the United States and the Bali attacks in Australia. The causes of traditional terrorist attacks are easily seen through on-the-spot media reporting, and many individuals throughout the world came together to condemn the terrorists. A cyberterror act might be more difficult to understand, and thus, the results are uncertain.

Effects on Government

Most governments ultimately govern through the support of their interrelated individuals, businesses, and societal entities. Successful cyberterrorism would weaken each supporting element, but the common purpose scenario might benefit a government and make it stronger, which occurred immediately following the 9/11 attacks. Much depends on how the government handles the crisis.

Effective government services include infrastructure development and maintenance, communication, defense, and other functions that could be directly affected by a successful cyberterrorist attack. If not brought under control, they could lead to a loss of confidence, ability to maintain order, and, potentially, anarchy and chaos.

Governments around the world have leveraged world terrorism and galvanized concern into support for strong antiterrorist measures. In the United States this has included aggressive new laws allowing an expansion of wiretapping and other surveillance activities. The USA Patriot Act of 2001 broadly expands law enforcement's surveillance and investigative powers. In December 2002, FBI Director Robert Mueller reported that since the World Trade Center attack, "tens of attacks, probably close to a hundred around the world" have been detected and stopped (AP, 2002c).

WHAT TO DO TO ELIMINATE OR MINIMIZE CYBERTERRORISM?

A long struggle with cyberterrorism may be just beginning. It could be a battle of minimization, not elimination. In the days following the 9/11 attacks, Secretary of Defense Donald Rumsfeld said,

> The cold war, it took 50 years, plus or minus. It did not involve major battles. It involved continuous pressure. It involved cooperation by a host of nations. And when it ended, it ended not with a bang, but through internal collapse. It strikes me that might be a more appropriate way to think about what we are up against here. (World Almanac, 2001)

In his appearance before the Senate judiciary committee previously mentioned, Richard Clarke said, "If I was a betting man, I'd bet that many of our key infrastructure systems already have been penetrated.... We reserve the right to respond in any way appropriate: through covert action, through military action, any one of the tools available to the president" (Holland, 2002). Most individuals have resigned themselves to some loss of freedoms to counteract the threats.

Individuals, businesses, institutions, and society are working to eliminate or minimize the effects of cyberterrorism. Individuals are turning off their computer at night and isolating their computers from networks, either through software or by physically disconnecting them. Each such defensive action carries its own trade-offs of individual freedom. Private organizations, higher education institutions, and conferences are contributing, often before the government is able to respond. Collectively, this helps mitigate the threat of cyberterrorism.

Addressing the Threat at Every Level

Government Branches and Entities

At Stanford University, on September 18, 2002, the United States released a draft of the National Strategy to Secure Cyberspace. It included 60 recommendations for government, companies, institutions, and individuals, including those in other nations, to help promote cybersecurity and prevent cyberterrorism. Six categories of defense included education, training, company procedures, new security technologies, federal modeling, and early warning and crisis management (Porteus, 2002b).

Critics on one side believe that the recommendations are not forceful enough and argue for more laws and regulations. Part of the strategy addresses "administration concerns that efforts to secure cyberspace are hampered by the lack of a single data-collection point to detect cybersecurity incidents and issue warnings" (Carlson & Fisher, 2002). Mark Rosh, formerly the Justice Department's top computer crimes prosecutor, said, "All of these are good recommendations, but none have the force of law. There is no carrot and there is no stick. You need to put some teeth into some of the proposals" (CNN.com, 2002a). Others believe that they are too invasive and infringe on civil liberties and privacy.

The federal government has a delicate balancing act in attacking terrorism and cyberterrorism, while maintaining personal liberties, freedoms, and business creativity and flexibility. It is probably impossible to satisfy both sides. Other nations have similar issues.

The U.S. government has established the Department of Homeland Security, centralizing many government agencies and branches into a more unified voice for establishing effective policies to help protect citizens and the government infrastructure against cyberterrorism. There have been ongoing disagreements about the specific implementation of this merged agency, but not the broad concept or belief that such an agency can help combat the threat.

Inside or outside the Department of Homeland Security, the federal government operates numerous intelligence gathering agencies, including the FBI, CIA, and supersecret units. For several years, they were constrained in what they could do with respect to human intelligence, actual agents on the street. In response, they implemented surveillance technologies that can monitor worldwide telephone conversations, e-mail, and other confidential correspondence. Such technologies can be very useful in intercepting and monitoring cyberterrorist threats, but they raise substantial privacy concerns. With the 9/11 attacks and increased terrorist activity worldwide, public opinion, balancing self-preservation with other needs, has swung to cautious support.

The National Strategy to Secure Cyberspace is intended to serve as a framework for federal action and as recommendations for companies, groups, and individuals. The strategy "strives to ensure that any interruptions will be infrequent, brief, manageable, geographically isolated, and minimally detrimental to the welfare of the United States" (Porteus, 2002a). Specific recommendations for government include improving federal cybersecurity so it can be a model for accountability, developing its own early warning and crisis management plans, and helping to promote science and industry in developing new security technologies.

Companies

The National Strategy to Secure Cyberspace business sector strategy calls for a heightened awareness and responsibility within companies. It promotes company-wide corporate security councils to integrate all aspects of security, including cybersecurity. Companies have much to lose through cyberattacks, but there is wide variation in how individual companies have taken action to protect themselves from various cyberspace attacks.

Some companies have been lax in applying even modest protective measures. In October 2002, the Associated Press reported on the W.32.Bugbear virus, calling it "the worst computer security outbreak in the world" (AP, 2002b). Once a computer is infected, the hacker can steal and delete information. The worm is expected to last well into 2003 because many users will not realize that their computer is infected. Incidents such as these, while destructive in the short term, will have a beneficial effect in prodding laggard businesses.

There is wide agreement that companies should do a better job of reporting cases of unauthorized access, cybercrimes, and potential cyberterrorism. The strategy is an attempt to raise awareness and spur them to action in both reporting and fixing security breeches. "The expectation is that shareholders will eventually hold boards accountable for security breaches, and, in turn, boards will hold security officials responsible" (Carlson, 2002).

Private "Pinkertons of Cyberspace" Firms

In the past several years, an entire service industry has grown up around the idea of helping companies with their cybersecurity needs. From a business point of view, creating an internal unit for this purpose may be costly, require the recruitment of specialized personnel, entail substantial start-up time, and risk becoming isolated from the latest developments. For many companies, it makes more sense to outsource their cybersecurity needs. Many service providers have highly trained people who are able to leverage their information and knowledge over several businesses.

Companies are investing in new security measures through software, private networks (only minimally connected to the Internet), and services. "Sales for firewalls and virtual private networks (VPNs) should hit $7.5 billion in 2005 and e-security services are expected to increase about 24 percent a year between 2001 and 2005. . . . Global investment in e-security services should total $14.5 billion by 2005. . . . North America will account for 58 percent of the global security product market this year" (McMahon, 2002). The world will follow.

Institutions

Nonprofits and private and quasi-private institutions typically do not have the same security needs as private companies. In many cases, they hold considerable financial and information resources that need protection, but it would be rare for them to have control over nuclear power plants, electrical grids, dams, or other vital infrastructure. Many of the techniques companies are using apply equally to institutions. However, institutions seldom have enough in-house expertise to combat potential cyberterrorism. They are good candidates for private security firms, but resource constraints make it more difficult to afford the needed services. This is an area that will benefit from closer attention.

Individuals and Society

In the past several years, the number of individuals engaged in cyberspace has skyrocketed in the developed world. E-mail is the most common application, but many users have become intensive participants in chat rooms, instant messaging, music and video swapping, and finding and contributing other text, graphic, and multimedia Web content. These societies have migrated to the information age. Many individuals and organized groups have become active in supporting new antispam laws, and many have taken measures to protect their computers from unauthorized access.

Most individuals become exposed to cybercriminals—not cyberterrorists—through credit card and identity theft or access confidential address books and other computer files involving property. Unscrupulous businesses send incessant e-mail (spam) and refuse to abide by good conduct norms. The "I Love You" virus caused an estimated $4 billion in damages to individuals and international systems (IWDB, 2000). Occasionally, individuals are

Table 3 Number of Security Notes

Year	1998	1999	2000	2001	2002*
Incident Notes	7	8	10	15	7
Vulnerability Notes	8	3	47	326	445

*2002 estimated based on 5 and 318 Notes reported through Q3.
Note: Data from http://www.cert.org/stats/.

exposed to bodily harm, as in the Florida cybersex case, but these are cyberterrorism only in the loosest sense. Disabling private computers likely would be a minor part of a cyberterrorist's plan.

The National Strategy to Secure Cyberspace makes recommendations to private users to regularly update antivirus systems, turn off computers at night, and install firewall software. The need for these measures has been a significant deterrent to expansion of broadband 24/7 connections. In addition, the strategy recommends that users apply caution in opening e-mail attachments that may contain viruses, worms, or other invasive components.

Organizations and Conferences

Many private and semiprivate groups combat cybercrime and cyberterrorism. For example, the Carnegie Mellon Software Engineering Institute's CERT Coordination Center, which tracks cyberspace "incidents" and "vulnerabilities," publishes a stream of security notes designed to help businesses, organizations, educational institutions, government, and technical individuals deal with incidents and vulnerabilities. Vulnerability notes rose dramatically beginning in 2001 (Carnegie Mellon CERT Coordination Center, 2002). See Table 3 and Figure 4.

The SANS Institute (SysAdmin, Audit, Network, Security) in conjunction with the FBI publishes a Top 20 list of security threats segmented by the two large and vulnerable operating systems used in corporate networks—Windows and UNIX. The list is "especially intended for those organizations that lack the resources to train, or those without technically advanced security administrators" (Wagner, 2002).

The National Intelligence Council publishes papers on global trends under the aegis of the National Foreign Intelligence Board and the Director of Central Intelligence, sometimes together with other government or private centers, and sponsors conferences such as the Future Threat Technologies Symposium and The Global Course of the Information Revolution: Technological Trends (NIC, 2000).

The National Infrastructure Protection Center (NIPC) and the National Association of State Chief Information Officers (NASCIO) have partnered to form an Interstate Information Sharing and Analysis Center (ISAC) "to disseminate intelligence quickly and prevent unauthorized and destructive infiltrations" (Greenspan, 2002b).

Some of these organizations are also in business providing services to commercial, nonprofit, government, and other entities. Many participate in, sponsor, or promote conferences calling attention to cyberterrorism issues and cybercrimes, and are working actively with the Bush administration on implementing the National Strategy to Secure Cyberspace. Many groups are working with the Department of Homeland Security.

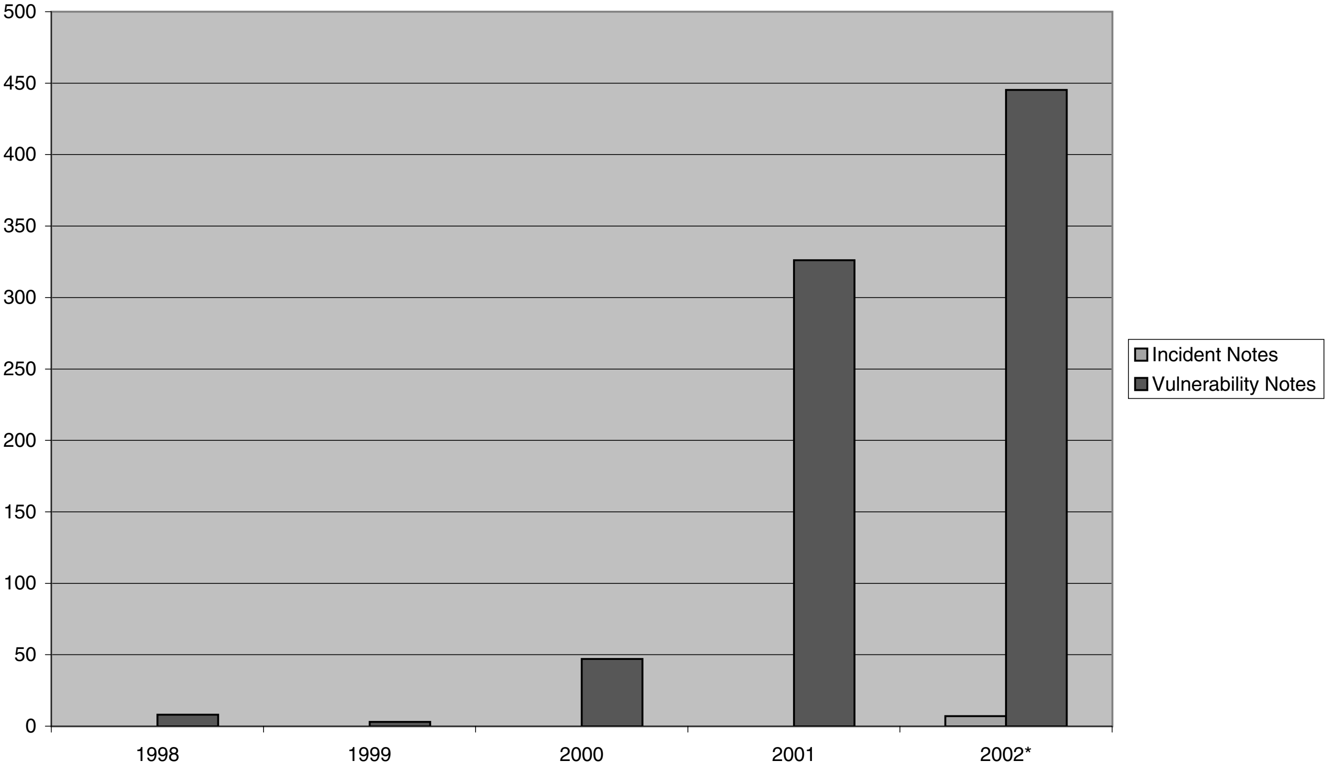

Figure 4: Security notes (graphical representation of Table 3).

Higher Education Institutions

In September 2002, it was reported that Congress approved National Science Foundation (NSF) grants for seven large projects and 240 smaller projects that will disburse between $500,000 and $13.5 million to each recipient organization, many of which are higher education institutions (Legon, 2002b).

Colleges, universities, and other higher education institutions were pioneers in using and promoting the Internet. Long before the graphical World Wide Web existed and before businesses were allowed to use the Internet for commercial purposes, the academic community was active in file sharing and facilitating other group research through the Internet. Many higher education institutions became leaders in developing security skills and experience with the UNIX operating system and its associated Internet protocols, TCP/IP. Vigilant individuals in higher education have a tradition of working long and hard—often with little or no extra compensation—in making UNIX and the Internet as robust as it is today.

Today, in community colleges, public and private universities, and specialized institutions such as the American Military University, innovative technologies are being developed and new courses are being created and taught about how to counteract terrorism in all its forms, including cyberterrorism. Many of these are overflowing. In a letter to alumni, John Hennessy, President of Stanford University, said, "Professor William Perry, former Secretary of Defense, was one of the many faculty members who made extraordinary efforts to accommodate students in oversubscribed classes. Bill's class on 'Technology in National Security' swelled from an enrollment of 145 in the fall of 2000 to 329 students this past year!" (Hennessy, 2002).

Legal and Privacy Concerns

With the rush to fight back against cyberterrorism and other cyberspace crimes and vandalism, a small but vocal group in the United States continues to maintain that these ends do not justify their means. They argue that the new laws giving law enforcement greater powers are acts of desperation and violate fundamental rights guaranteed by the Constitution and the Bill of Rights. In their view, the resulting loss of freedom is not worth the security benefits.

In January 1999, Ed Gillespie, Executive Director of Americans for Computer Privacy, attacked President Clinton's policies restricting the dissemination of encryption software. "This [protection of IT infrastructure] job can best be done by sophisticated encryption technology produced by U.S. high-tech companies. [It is] essential to fighting cyber-terrorism" (ACP Press Release, 1999).

Others argue that terrorists are helped by encryption products if the government is subsequently unable to monitor their communications. "Terrorists may be tech-savvy as well. They often use encryption programs when communicating over the Internet, scrambling the text of messages as they travel over the Web." The government fights terrorism with programs such as Carnivore and Magic Lantern, which "allow investigators to monitor personal e-mails and electronic communications." Other government agencies and private companies are making software to monitor file-trading activity, downloads, and message board notes with suspicious content. Strong encryption would hamper many of these efforts (Porteus, 2002a).

The new strategy, new laws, and new technology enable government agencies to seek out and identify terrorists. They also increase government and companies' ability (and perhaps willingness) to collect personal data. Fred Cohen, the keynote speaker at a three-day cyberterrorism conference in Connecticut, urged attendees to avoid many of the proposed security measures. He cited a potential national database on citizens and increased government surveillance: "We're doing the wrong stuff. It's not effective, and it's oppressive" (Moran, 2002).

Former Rep. Bob Barr, R-Ga., working with the American Civil Liberties Union, agrees:

> The only way that you can make this sort of system work, that they are talking about, is if you have access to all, virtually all the e-mail traffic, all credit card transactions, all medical records, all gun purchases. Otherwise the sort of system they are trying to develop here, where they can do cross-referencing and develop profiles, won't have any meaning. (Fox News, 2002a)

Cohen and Barr's concerns may be moot. In an interview with the *Boston Globe*, Richard Hunter discussed companies' data-collection policies and excerpts from his book, *World Without Secrets*: "Information is constantly recorded and made available to almost anyone who wants it, regardless of intent.... The amount of information that's out there, and readable, is already huge" (Denison, 2002). Companies already have most of the data, the government can get it, and in the wake of the 9/11 attacks and continuing terrorist threats, public opinion has become less sensitive to private data collection.

International Law Enforcement

What the United States and other developed nations are doing to protect their citizens can be applied on a global scale. However, the nations of the world are struggling to cooperate on international justice issues. So far at least, beyond prosecuting international war criminals charged with physical atrocities, such efforts have made only minimal progress.

International law and bilateral treaties rarely adjudicate actions directly concerning individuals. Entities such as the World Trade Organization set rules for engaging in trade and commerce and have a judicial branch to settle differences between nations in trade matters. They do not deal with conflicts between companies, individual entities, or public–private disputes. International law and treaties usually deal only with physical presence and events, but activities in cyberspace do not directly trespass.

Nations are reluctant to give up their sovereignty in prosecuting crimes or acts of terrorism to an international body. Many developed nations have set up their own international security agencies, many of which operate anywhere in the world—and often in the virtual world. Nations with such agencies generally work with each other through informal agreements. Since the mid-1990s, cooperation has been on the upswing, and the 9/11 attacks and other international terrorism incidents have added urgency. Although it is rarely discussed publicly, this is a very active area of international relations.

CONCLUSION

Terrorism, which has been a fact throughout human history in one form or another, has found a powerful new weapon. Operating in cyberspace and enabled with today's powerful technology, the cyberterrorist may strike from anywhere, anytime, and be very difficult to trace and bring to justice.

Cyberterrorism is in its early stages. Some experts argue that terrorists are just now beginning to learn the skills to turn cyberspace into perhaps the world's most effective weapon for asymmetric responses—and terror! Others say the threat is overblown, and governments, business, organizations, and other stakeholders will take effective measures to prevent its occurrence.

Very likely, the truth is somewhere in between. The battle with cyberterrorism is expected to be long, but it will not lead to doomsday scenarios. It is unlikely that the civilized world will be able to eliminate it, but it may be controlled. People will need to learn to live with cyberterrorism and minimize its impact.

This chapter overlaps with many others in this volume, including chapters about cyberlaw, legal issues, cybercrime, cyberstalking, privacy issues, and the organizational impact of the Internet and e-commerce. The reader should consult these other chapters for a fuller understanding of cyberterrorism.

GLOSSARY

9/11 The World Trade Center and Pentagon attacks, September 11, 2001.

24/7 An activity that can occur 24 hours per day 7 days per week, as do many broadband Internet connections.

Application software Software that allows a user to apply a hardware device to a task or series of tasks, such as word processing or Web browsing.

Asymmetric response A one-sided response and a generic explanation why cyberterrorists behave as they do. Unable to achieve their objectives through conventional means, an extremist may strike against the "enemy" with a one-sided act of terror.

Border gateway protocol (BGP) Tables that detail the more than 100,000 routes information can travel over the Internet. BGP routers exchange information about routes and improve data flow efficiency.

Cyber- A prefix for topics related to computers and/or networks, including acts of terror using computers and/or networks.

Cybercrime Activity in cyberspace usually associated with fraud, commercial espionage, or theft of intellectual property, identity, or private data, and can result in loss of data or corruption of computer files.

Cyberprotests Short periods of intense political activity in furtherance of political or social objectives.

Cyberspace, digital world, virtual world The world of discrete mathematical values, usually ones and zeros at its lowest level, that powers computers and networks and can be used to represent the physical world. It is generally outside time and space, unless it is applied to a physical object through an interface to the analog world.

Cyberterrorism An evolving body of activity that includes both acts *in* cyberspace and *using* cyberspace tools to create fear or panic, often done by subnational groups or clandestine agents and directed toward intimidating or coercing a government or some segment of the noncombatant civilian population, usually in furtherance of political or social objectives; differs from hacking and cybervandalism in its intent and the degree of severity of the attacks.

Denial of service A condition under which a Web site or other Internet resource is disabled by an attack from an overwhelming number of inbound messages.

Dysfunctional A state in which a person, object, or device has some degree of functional impairment, and can be caused by cyberterrorism.

Extremist or fanatic terrorist A terrorist that attracts a small following. Often, their methods are widely condemned, or at least not supported by other parties who may oppose the target of the terrorist.

Government Federal, state, local, military, police, justice, legislative, executive, and related entities.

Graphical user interface (GUI) Typically used to describe the graphical interface between a computer's display and the internal hardware workings, or the interface between a computer's display and images served up on the Web.

Hacker A person who gains unauthorized entry into computers or other digital devices through cyberspace, usually for the purpose of minor damage or annoyance, such as defacement of a Web site or observation of data.

Hacktivism Generally a long-term series of cyberattacks in furtherance of political or social objectives.

Hardware Physical devices that process mathematical ones and zeros. Hardware has an interface to the physical world, such as a keyboard or monitor display.

Internet The worldwide connection of computing nodes and its associated network that uses Internet protocols and transmission control protocols.

Information technology (IT) The general use of cyberspace for communicating and passing data.

Operating system Software that tells a hardware device how to operate, or run itself.

Physical world, analog world The world of physical objects and forces in time and space. The analog world is continuous. It can be represented in cyberspace by devices that use digital ones and zeros.

Software Programming code that, at its basic level, delivers ones and zeros that can be used to control the operation and function of hardware devices.

Transmission control protocols/Internet protocols (TCP/IP) The set of rules by which the Internet operates and communicates between devices.

Terrorist A person or group that usually believes strongly in their cause and is willing to engage in destructive acts that leave a trail of destruction, fear, dread, or panic to communicate their message.

Web browser Software that allows a computer to display graphical images that have been served up on the Web.

Web server Software that allows a computer to formulate, represent, and present graphical images on the Web such that they may be displayed by a Web browser.

World Wide Web (a.k.a. Web) The graphical overlay that resides on top of the Internet and allows graphics to be served and browsed.

Databases on the Web

A. Neil Yerkey, *University at Buffalo*

INTRODUCTION

Requisite technologies have converged sufficiently to allow dynamic access to databases using Web browsers. The Web has provided a global infrastructure, a set of standards, and a presentation format, while database technology has contributed storage techniques, query languages, efficient access to large bodies of highly structured data, and mechanisms for maintaining the integrity and consistency of data (Abitebol, Buneman, & Suciu, 2000).

Prior to the Web, Internet access to databases was hampered by low bandwidth, the lack of a standardized interface, and platform dependencies (Duncan, 1995). The emergence of the Web helped fix the interface and platform problems, and high-speed connections are helping to fix the bandwidth problem. Yet another problem to be solved was how to access databases dynamically, avoiding the problem of having to convert database data manually to text suitable for transmission using the hypertext transfer protocol (HTTP). This problem has been solved through the use of programs and scripts that convert relational data to hypertext markup language (HTML) for transmission over the Web.

DATABASE SUPPORTING ROLES

Not every database application is directed toward public outreach and public access, although the public side often works in conjunction with the private side. This section briefly discusses types of databases and the support they provide to organizations.

Reference databases support retrieval of literature citations, abstracts, and hard data from vast databases. Most are made available on a subscription basis. They are seldom used for transaction processing but can be useful as part of the informational services of an organization. They are of vital interest to libraries, information agencies, and information research units within organizations, and they make up an important component in corporate knowledge-management operations, digital libraries, and data mining. They are available over the Internet from companies such as Lexis/Nexis, Ovid, Ebsco, Dialog, and Dow Jones.

Back-office databases are part of an internal information system supporting the functioning of the organization. Some portions of the databases may be made available to Internet users, but they are less often used in transaction processing. Typically, back-office applications use small or medium capability database management systems such as Access (Microsoft), Paradox (Corel Corporation), FileMaker (Filemaker), and MySQL (MySQL AB).

Front-office databases support organizational functions that reach out to customers, constituents, or clients. They support customer or public information, selling and buying transactions, data warehousing, business intelligence, customer service, banking, securities, and a host of commercial and noncommercial applications. Typical front-office databases include DB2 (IBM), Oracle (Oracle), SQL Server (Microsoft), Informix (IBM), and Sybase (Sybase).

DATABASES IN E-COMMERCE

E-commerce (EC) databases support interactive catalogs of products and services, customer profiles, ordering, paying, transaction history, billing, shipping, and inventory management (Turban, 2002). EC is only one environment delivering database information and conducting transactions over the Internet. Others include nonprofit organizations such as libraries, universities, service organizations, government agencies, clubs, and other organizations that have a need to provide information and data interactions to customers, the public, constituents, students, members, and the like. These noncommercial applications are no less important than EC, and the principles of database access over the Internet are the same.

Database-driven Web sites run the gamut from huge, technically complex systems running on many servers to small sites using one or two servers. In addition to the usual functions of shopping, billing, payment services, and information dissemination, some sites maintain customer relationship management services, personalization features, and statistical analysis. Many are not so complex. Regardless of size and complexity, they all face the same problems of limited bandwidth, problems delivering images, and slow database connectivity (Shand, 2000), but these problems are being addressed as the Internet evolves and database vendors add features to make their databases more Web-compliant.

DATABASE EVOLUTION

Database technology has gone through several definable periods from early file systems to object-oriented databases.

File Systems

Before and during the1960s, data processing was mostly an attempt to computerize manual file systems. These early file systems had the following characteristics: data was separated and isolated across the enterprise, it had to be duplicated for different applications using the same data, data structures were dependent on programs written to exploit the structures, there was incompatibility between applications, and most systems depended on fixed (programmed) queries with little flexibility (Connolly & Begg, 2002).

Along the way, people began to use the term "database" to describe those file systems, but by whatever name, they did not usually have the defining characteristics of a database: data independence, controlled redundancy, interconnectedness, security protection, and real-time accessibility (Martin, 1975, p. 25).

Most file systems were single entity, flat files in which a single file contained all the data needed for an application. Multientity databases were introduced in the 1970s with relationships among data maintained through a complex network of linked records. Models included *hierarchical databases* in which pointers addressed subordinate records and *network databases* in which the pointers went both ways in a many-to-many relationship. These linkages become quite complex, and programmers had to write complex code to navigate the links.

The 1980s brought "nonprocedural languages" for creating, maintaining, and accessing databases. These were written and sold without regard to their ultimate application. As these products matured, it became easier for people to create their own custom database management systems using wizards and simple program expressions, instead of writing long and complex procedural code. The data and programs to manipulate the data were becoming separate. These small- and medium-scale systems are still being used, most often in "back-office" environments, but with a significant presence in "front-office" environments as databases for Web access.

Relational Databases

Codd (1970) introduced the idea of relational databases. Unlike files in a hierarchical or network database, tables in a relational database are not physically connected. This provides a separation of the physical aspects of data storage from the logical aspects of data access. Rather than using internal pointers to relate data, relational databases use common fields to pull things together.

Relational database systems separate what the user sees from what the designer sees, and may even separate what the designer sees from what the network administrator sees. The data are independent from the applications that use them. A database consists of an application structure (user level) and a physical structure (physical level) with a schema or logical description as intermediary (the logical level).

The user level consists of "views" of the data to meet specific application needs. On the Web, the user level most likely consists of HTML forms that present descriptive text, images, menu items, buttons, text boxes and drop-down lists for requesting information, and so on. The user's view of the database is a series of choices and opportunities.

The middle, or logical level, consists of descriptions (attributes) of data, data entities, and relationships. The physical level deals with such things as tables, fields, joins, indexes, files, storage devices, server paths, and so on. This multitiered scheme allows data independence, limited redundancy, multiple sharing, and unanticipated retrieval.

Object-Oriented and Hybrid Databases

A complex, interactive, public-access environment may place demands on databases that the relational model cannot handle. For example, an EC or digital library environment might include structured data such as customer names and addresses as well as unstructured data such as text, images, videos, graphics, sounds, maps, and animation. The unstructured and loosely structured data are objects to be manipulated, and the evolving object-oriented approach extends database capabilities to include such complex objects and data types.

The relational model is too rigid to handle such a variety of data, but an object-oriented database (OODB) will provide the necessary flexibility (Abiteboul, 1997). An object may encapsulate into one package the data, relationships among the data, and methods for manipulating the data (Burleson, 1999). An object may contain a mix of text, multimedia, and methods appropriate to the object. Its data types may be defined specifically for the object, instead of relying on the limited set typically provided as part of a relational system. OODB is changing the face of databases and database access. Nonetheless, Burleson (1999, pp. 26–27) outlines problems to consider: OODB databases work best in dynamic, interactive environments but are unproved in large corporate environments. In addition, they are not completely accepted by major vendors, and there is a lack of standardization.

Possibly for these reasons, and certainly because of the large investment that organizations already have in relational databases, vendors have extended their traditional relational products into what are called object/relational, or hybrid, databases. Database systems, such as Oracle, Informix, Sybase, and IBM have added support for object features, including user-defined data types, rules, and functions (Burleson, 1999, p. 27). For example, Oracle8i includes three database "flavors": traditional relational, traditional relational extended to include object concepts and structures, and object-oriented based solely on object-oriented analysis and design (Loney & Koch, 2000). OODB is a complex technology, and, although it has strong adherents, its emergence has been slow. Relational databases will remain in service for many years.

INTERNET-ENABLED AND TRANSACTION DATABASES

Internet accessibility places greater demands on databases. Cox (2000) lists the following requirements of Internet-enabled databases:

- **Security:** The Internet is an open network; data must travel across many networks and network components. Steps must be taken to ensure the data will be kept secure.
- **Scalability:** Databases must be able to handle larger amounts of data and supply it to a larger number of users. Some database systems will not scale up for Internet use.
- **Support for Internet standards:** Databases must support an array of new standards, such as XML and Java.
- **Integration:** In an EC environment, public databases must work with other databases, legacy systems, third-party software, application servers (such as financial servers, banking), Web servers, messaging, and other middleware.

A typical EC data application will contain a mix of informational and transactional processes. Transactional databases support such things as ordering, bill paying, registration, inventory control, banking transactions, airline reservations, and stock trading. In the Internet environment, the demands placed on transaction databases are greater than those placed on informational or decision support databases because data changes more rapidly, sometimes involving near simultaneous changes to the data. The special requirements for transaction processing go by the acronym ACID, and these requirements apply to databases that support transactions:

- **Atomic:** There should be no incomplete transactions. For example, a sold item must both be added to a shipping order and removed from inventory. Furthermore, if any part of the transaction fails, the entire transaction should fail.
- **Consistent:** The output of the transaction should reflect the current data. Transactions cannot work with incomplete, out-of-date data, in keeping with the idea that transaction databases are usually more dynamic and rapidly changing than informational databases.
- **Isolation:** Transactions cannot reveal their results to other users, and they should not "collide." It is important that data being accessed are not, at the same time, being updated by another transaction. Most database systems provide some lockout method when two transactions occur nearly simultaneously. The system may lock out the field, record, or even the entire database, until the first transaction is complete.
- **Durable:** Changes made must be permanent, and there must be a way to recover from transaction failures. Either the transaction must be completed, or the database must be "rolled back" to a state before the transaction started. Log files are used to account for changes to the information, including information on when the change occurred.

Not every component of EC is transaction based, and not all EC activities demand ACID requirements. Advertising, browsing, and general information supply may not require ACID properties, whereas purchasing and payment processing may require them all (Umar, 1997).

KEYS AND RELATIONSHIPS

Relationships among data are expressed through the use of common fields among tables. Most often this is done through the use of keys. There are two types of keys. A *primary key* is a field or combination of fields that uniquely identifies each record—an item number in a sales catalog, for example. There can be no two products in the table with the same item number. A *foreign key* is a field in one table that is a primary key in another table. For example, a table about books may have a field showing the publisher's name. Another table, about publishers, will have a primary key field of publisher's name. The name is not the primary key in the book table, but it is a primary key in the publisher table. The linking of common fields

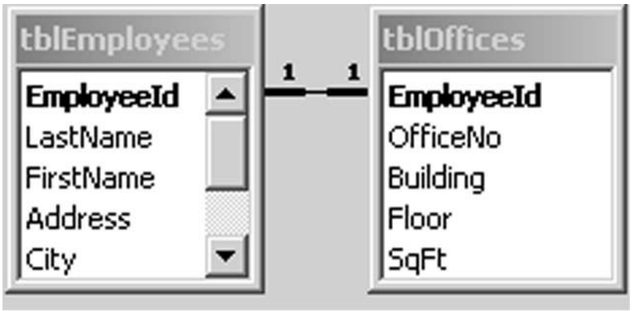

Figure 1: One-to-one entity.

among tables sets up relationships among the tables. The following relationships may exist.

One-to-None

This is not really a relationship. It is called a "single entity." All of the data are in a single table (in actuality, the database may consist of several tables, but they are all independent with no connections between them). The data has one "view": that which one application requires. Single entity databases are simple but inflexible. They work well for simple data management tasks but cannot meet the requirements of more sophisticated applications.

One-to-One

A record in one table relates to a maximum of one record in another table. This may be considered a single entity but with the data scattered across more than one table. For example, consider tables about managers and their offices. There would be a one-to-one relationship between *manager → office number*. This relationship is usually evident when a single-field primary key relates to a single-field primary key in another table, or when a foreign key in one table relates to a single-field primary key in another. Figure 1 illustrates the relationship. There may be good reasons to scatter the data across separate tables in a one-to-one relationship (security being one of the reasons), but often such data can be combined into a single table.

One-to-Many

A record in one table relates to zero, one, or many records in another table. This relationship is evident when a single-field primary key relates to part of a multiple-field primary key in another table. Figure 2 shows a customer table and an orders table. For any one customer there may be none, one, or many orders.

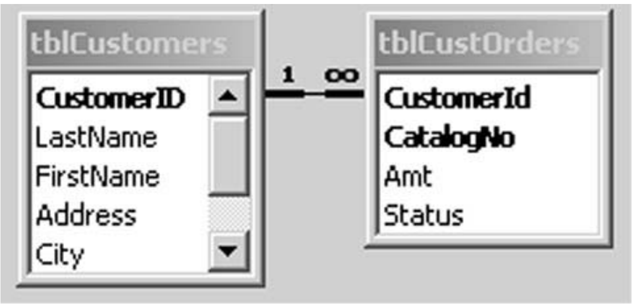

Figure 2: One-to-many relationship.

Many-to-Many

A record in one table relates to many records in another table,while, at the same time, a record in the second table relates to many records in the first table. An example is *customers ↔ products*. A customer may order many products and several customers may order the same product. This relationship usually requires setting up three tables with two one-to-many relationships. Figure 3 shows a table of customers, a table of products, and a table of customer orders. The relationships would be *customers ↠ orders* and *products ↠ orders*.

Recursive

A recursive relationship exists when a foreign key relates to the primary key *in the same table.* For example, a personnel table might include a field that shows the employee's supervisor. Both employee and supervisor records are in the same table because supervisors are also employees.

REFERENTIAL INTEGRITY

Database systems include a set of rules to ensure valid relationships between records in related tables. Specifically, they ensure that parent–child relationships match up. These rules, sometimes called "foreign key integrity rules," prevent adding a child record if there is no corresponding parent record, deleting a parent record when a child exists, and changing a parent's primary key if there are related child records.

An implementation of referential integrity rules may prevent such things from happening altogether, or it may allow "cascading" changes. For example, a cascading update automatically changes the matching value in all related records when the primary key of the parent record is changed. A cascading delete deletes related records when the parent is deleted.

NORMALIZATION

Codd (1970) introduced the idea of normalization when he introduced the idea of relational databases. These are practical rules of database design that we call "normal forms." Normalization has two functions: (a) to eliminate unwanted dependencies (see the discussion of Normal Forms), and (b) to reduce redundancy. A database designed in a helter-skelter fashion might work for a while, but problems will begin to crop up; simple additions, changes, and deletions become complex, requiring adding, changing, or deleting more data than intended. In addition, there may be unnecessary redundancy, adding complexity and wasting space.

Needless to say, these rules must be followed before a database can be made Web accessible. The slickest browser and the fastest server are of no value if the database is not organized properly. I briefly discuss the topic but leave the details for the reader to pursue in one of many textbooks on relational databases.

First Normal Form (1NF)

1NF states that the data must be cast into a table with one row for each record and one column for each field, with a primary key established that uniquely identifies

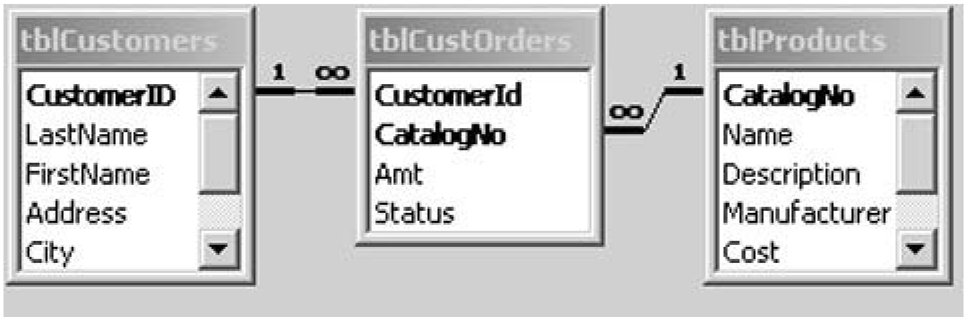

Figure 3: Many-to-many relationship.

each record. In addition, no field can have more than one value per record. A customer may have one last name, one address, and one telephone number, but the table that stores the customer information cannot also store more than one order for that customer.

To store the order information requires two tables: one for customers and one for orders. The customer table, with a primary key (PK) of CustomerID, contains information about customers but nothing about orders. Order data are stored in the order table with PK = CustomerID + OrderNo. The relationship, one-to-many, is made through the common CustomerID keys.

Second Normal Form (2NF)

A table satisfies 2NF when it satisfies 1NF and the entire primary key, not just part of it, identifies all fields. Violation of this rule, called partial dependency, occurs only with multiple-field keys. As an example, consider an order table that contains customers' names, addresses, and phone numbers along with ordered part name, part description, order status, and so on (PK = PartNo + CustomerID). This violates 2NF because the customer's address and telephone have nothing to do with PartNo, and the PartName field is dependent only on PartNo, not on CustomerID. It doesn't make sense to mix these fields, and doing so will cause update and deletion problems. The solution is to create three tables, one for Customers (PK = CustomerID), one for Parts (PK = PartNo), and one for Orders (PK = CustomerID + PartNo).

Third Normal Form (3NF)

A table meets 3NF when it is meets 1NF and 2NF and no field is dependent on another field that is not a key. This avoids a situation called transitive dependency. It is not always clear whether a particular design violates this rule, and it is easily (and sometimes deliberately) violated.

A typical example is when a table of catalog items has PK = CatalogNo, but the record also includes the manufacturer's address and telephone number. The manufacturer's name is correctly dependent on the primary key, but the address and telephone number are really dependent on the manufacturer's name. The solution? Remove the manufacturer's address and telephone number and put them in a separate table—a manufacturer's information table, keyed to the manufacturer's name. An important caveat: It may be worth violating this rule if you need to keep a "snapshot" of the conditions that existed at the time the item was put into the database. This is workable for archival files but not for active and volatile databases.

Fourth Normal Form (4NF)

2NF and 3NF have to do with the relationship between key fields and non–key fields. 4NF comes into play when parts of a key are dependent on other parts of the same key. This is called a "multivalued dependency" (Pascal, 2000). Because no part of a key may be blank, data must be entered in all parts of the key simultaneously, and all must be removed simultaneously. This is not always possible or desirable. The solution is complex and may require many related tables.

WEB DATABASE CONNECTIVITY

A Web browser usually should not connect directly to a database. The Web is based on HTML text files, but databases are structured and not easily handled directly by HTML. When it comes to moving data from the database to the user's browser, the alternatives are to convert database data into a series of text and HTML files and placing the files on the Web server (static access) or to run a Web page through a program that retrieves data from the database and creates HTML pages "on the fly" for return to the browser (dynamic access). These options are discussed in the sections that follow.

Static Database Access

Before 1995 the main strategy for providing relational database data over the Internet was to anticipate the kinds of queries users would want and then pre-create "views" of the data representing those queries. These queries were then marked up as HTML files and placed on a server. Pages created in this way represented a snapshot in time; they did not change as the database changed. They had to be re-created each time changes were made to the data. Worse, users could not search the database or choose particular items of data; they could only see what was previously saved in HTML format.

Databases with even minimal complexity are not easily converted into text files, and if they are, their dynamic characteristics are lost. The views available are dependent on what the database administrator decides to provide in the form of text files. The necessary step of creating text files from database tables is time-consuming and likely not done as often as it should be.

The development of HTML has been responsible for the success of the web. HTML is a markup language, however, and as such, it has little processing power. Web pages consisting only of HTML cannot search databases, make decisions based on conditions, do mathematical calculations, create animations, customize output for different users, respond to information entered on forms, and so on. These things require the addition of other languages to do the processing.

Dynamic Database Access

Dynamic database access means using Web pages to connect to databases in such a way that when users view the page, they are viewing the current state of the database. This method allows the user to connect to up-to-the-minute data, search it, and display it in different ways. This makes full use of an important characteristic of relational databases—the ability to reuse information in a variety of situations with multiple purposes.

I discuss several methods for creating dynamic database-driven Web pages, but first it is necessary to decide where the processing is to be done: on the user's computer (client-side) or on the server (server-side).

Client-Side Processing

Client-side processing is a method of having the server send back to the client a page containing both code and data. It is characterized by programs, or scripts, written in languages such as Java, JavaScript, or Visual Basic Scripting Edition (VBScript). The Web page calls programs on the user's computer to process the data. The user's computer does all the work; the server simply supplies the code and data.

Although this is less work for the server, there are problems with this approach:

- Not all browsers are guaranteed to support a particular language or its features.
- Debugging is difficult because the code must be designed for, and tested on, various browsers.
- The code is available to the user, a situation that may not be desirable in business environments.

Client-side processing is rarely used for database access, although there are a few systems that use it. One such is Microsoft Access, which includes a way to create what are called "Data Access Pages" (not to be confused with "Active Server Pages," discussed later). Database tables are converted into Extensible Markup Language (XML), which is sent to the user's browser for processing. The user must have the correct software to make use of it.

The use of XML to provide both data structure and data display shows promise. It provides many of the things found in databases: storage (XML documents), schemas (DTDs, XML schema languages), query languages (XQuery, XPath, XQL, XML-QL, QUILT, etc.), programming interfaces (SAX, DOM, JDOM), and so on. On the other hand, it lacks some of the things found in real databases: efficient storage, indexes, security, transactions with data integrity, multiuser access, triggers, queries across multiple documents, and so on. It is a powerful technology for many database applications, but Bourret (2002) argues that it may not work so well in production environments with many users, strict data integrity requirements, and the need for good performance.

Server-Side Processing

This method uses resources on the server, instead of the client, to process database data. After the server has retrieved and processed the data, it sends it back to the client as HTML for display on the browser. The server does all the work, and the client only needs to have a Web browser.

Server-side processing provides universal readability because the output is HTML. Browsers do not need special add-ons, and debugging is easier because it is not necessary to test and debug pages on the multitude of browsers that may be encountered. The server, not the client, works on the code and sends back the results, so the source code is not available to the user, an important consideration for EC (Kauffman, 1999).

Browsers connect to databases through a three-tier architecture (Watson, 2002, p. 452). The first tier is the browser, which sends Web page requests to the Web server. The second tier is the Web server that services the request and passes data request to an extension program. Extension programs are the workhorses of database access. They provide the connection to the database and translate Web data requests to database language. The third tier consists of the database server.

The second tier extension program accepts requests, converts them to a database-compliant form (such as OBDC SQL), and sends them to the database server (Lang & Chow, 1996). The database server processes the request against the database and sends the results back to the extension program, where it is converted to HTML and then sent to the Web server and browser.

Drivers

Because different databases organize data in different ways, the program to access a database must go through another program, called a driver, to give the database a more generic look. In essence, a driver has two faces (or interfaces). One face is proprietary and communicates with a specific database management system, and one face is standards-based and communicates with the application. Database management systems come with a set of drivers (sometimes called "native drivers") that interface with the particular database. Other drivers work with a variety of databases. For example, Open Database Connectivity (ODBC) is a standard developed by Microsoft but used by many vendors. Use of the standard makes it possible to access data from any database, regardless of which database management or query system is being used.

Another universal approach is Java Database Connectivity (JDBC) which was developed by Sun Microsystems. It allows Java programs to interact with any Structured Query Language (SQL)—compliant database. JDBC is designed specifically for Java programs. It is widely used but is not as language-independent as ODBC.

Identifying the Database

Web-based access requires some method of supplying information to allow the second tier to make a physical connection to the database. The necessary information might include the database name, the server path to the database, and driver name, user ID, and password. There are two methods of supplying the necessary information: Data Source Name (DSN) Connections and DSN-less Connections.

Data Source Name (DSN) Connections

In this approach, the database and driver are installed on the server, and the administrator assigns a DSN to the database. The DSN includes information about where the database is physically located, what kind of database it is, and what its name is. The Web page connects to the database by "calling" the DSN. Here is a typical DSN call to a database using VBScript:

```
Set conn = Server.CreateObject("ADODB.
  Connection")
conn.open "DSN=products"
```

The first line creates an object called "conn" and the second line opens the DSN identified as "products." Because the DSN is set up beforehand, the server knows to which database "products" refers and where it is located.

DSN-less Connection

This method does not require a DSN. Instead, the Web page contains all necessary information for the server to make a connection. Here is an example of a DSN-less call, again using VBScript:

```
Set conn = Server.CreateObject("ADODB.
  Connection")
conn.open "driver={microsoft access
  driver(*.mdb)}; dbq="& server.mappath
  ("serials")
```

Notice that this approach supplies the name of the driver, the type of database, the path to it, and the actual database name. All identifying information is contained within the call. This is a simple approach and does not require an administrator to set up a DSN.

Structured Query Language

SQL is a universal language to query, retrieve, add, and change database data. Most HTML-to-database connections make use of SQL. This chapter includes a few examples, but I do not attempt to describe the language here. The examples given use PHP as the underlying script (for more information about PHP, see the discussion about Embedded Programs).

SQL statements perform the following functions:

- SELECT receives a subset of data from one or more tables. It may be a subset of fields, a subset of records, or both. The following example selects a subset of fields and a subset of records from one table. The first line makes the connection, the second places the SQL statement in a variable, and the third executes the statement (subsequent examples will only show the middle line). This particular SQL statement retrieves the name, address, and telephone from the publisher table for those records where the city is Orlando:

```
$conn_id = odbc_connect('books','','') or
  die("Failure to connect");
$sqltext = ("Select pname, paddress, pphone
  from publisher where pcity = "Orlando"");
$result = odbc_exec($conn_id, $sqltext)
```

- JOINcombines data from more than one table, and there are several versions of this function: INNER JOIN combines data from two tables in which the keys match, LEFT JOIN combines all records from the "one" table and only matching records from the "many" table, RIGHT JOIN combines all from the "many" table and only matching records from the "one" table, THETA JOIN combines only records in which there is no common field match, and SELF JOIN combines a table with itself. Here is an example of an INNER JOIN:

```
$sqltext = ("SELECT m.manid, m.manaddress,
  p.cost FROM tblmanu INNER JOIN tblpart
  WHERE tblmanu.manid = tblpart.manid");
```

- This example retrieves the manufacturer's ID and address, from the many table and joins it with the cost from the part table for those records that have matching IDs.
- ACTION QUERIES are a class of queries that perform actions such as DELETE, INSERT, UPDATE. Here is a statement that decreases the price of all parts by 5%:

```
$sqltext = ("UPDATE tblparts SET price =
  price *.95");
```

The next issue is deciding where to put SQL statements. There are two approaches: Embedded SQL and Stored Procedures. The embedded SQL method embeds the SQL statement directly in the requesting Web page. Following is a search for publisher data in an ASP page, using VBScript (line numbers are given for reference; they are not used in actual pages):

```
1 <html> <head> <title>Publisher Name
  Search Response</title>
2 </head> <body>
3 <%
4 PName=request.form("PublisherName")
5 Set pub=server.createobject("ADODB.
  recordset")
6 sqltext="Select * from publisher  WHERE
  ppub like "&"'%" &  PName &  "%'" &  ";"
7 pub.open sqltext, "driver={microsoft
  access driver (*.mdb)}; dbq="&
  server.mappath("serials.mdb")
8 response.write "<p>The Publisher Data is
  as follows:<br>"
9 response.write "<p>Publisher Name: <b>" &
  pub("ppub") &  "</b><br>"
  ...other response.write statements...
10 %>
11 </body> </html>
```

Line 4 picks up the requested publisher's name from an HTML request form. Line 5 creates a record set object and names it "pub." Line 6 embeds the requested publisher's name in an SQL statement and stores the statement in a variable called sqltext. Line 7 opens the pub object and executes the SQL statement. An engine on the Web server (in this case, an ASP engine) sends the request to the database, which returns the correct publisher information. The rest of the page creates HTML statements out of the data and returns the page to the user's browser.

Queries based on SQL may be created ahead of time and stored as an object within the database using the stored procedures method. Instead of including the query in the requesting page, it asks the database system to run the stored procedure and return the resulting data for display. Here is portion of an ASP requesting page designed to run a stored procedure:

```
1 <html> <head> <Title>Items and
  Styles</title> </head>
2 <body>
3 <%
4 Set conn = Server.CreateObject("ADODB.
  Connection")
5 conn.open "driver={microsoft access
  driver (*.mdb)}; dbq="& server.mappath
  ("serials")
6 Set rs = Server.CreateObject("ADODB.
  Recordset")
7 rs.Open "qryitemstyles",conn
  ... other statements...
```

Line 7 opens and executes a stored procedure that has been created ahead of time to combine related data from two tables. The rest of the page takes the resulting data and creates HTML statements for sending to the browser.

TYPICAL SERVER-SIDE APPROACHES

Following are brief descriptions of typical approaches used to connect a Web browser to a live database. There are many other examples, each with variations, but they are similar to one of the approaches described here. They use different languages, such as Visual Basic, PHP, and Java to request user-entered information through a form, test for errors, display the results, and so on. Although they may be based on different *processing* languages, the common *retrieval* language is SQL.

These approaches divide into three methods of processing data: (a) using a separate program to do the processing (common gateway interface, or CGI), (b) using Application Program Interfaces (API), or (c) embedding the necessary programming language within the Web page and using a combination of CGI and a partner program (ASP, PHP, JSP, and so on).

Separate Programs: CGI

An early method of server-side processing, still widely used, is CGI. It is not a programming or scripting language but a standard against which to write programs for Web access. CGI programs may be written in almost any language that can be compiled, so long as the programmer follows the CGI standard.

Programs written according to the CGI standard take requests from a Web page, retrieve and process data from a database, and place the processed data into a file to be picked up by the user's browser (Khurana & Khurana, 1966).

One line of the requesting HTML page includes a call to a compiled CGI program residing on the server. Another line creates a Submit button. Following is an example (line numbers are for reference only):

```
1 <html> <head> </head> <body>
2 <form method="post" action="/cgi-bin/
  orders.exe/ksearch">
3 <p> Search Word: <input type="text"
  name="words"> [other html statements]
4 <input type="submit" value="ksearch">
5 </form> </body> </html>
```

Line 2 includes a call to a compiled CGI program called "orders.exe" residing in the cgi-bin folder of the server. When the user enters a keyword (line 3) and clicks the Submit button (line 4), the server executes the ksearch procedure of that program and returns a stream of text to be embedded in HTML for transmission and display on the user's browser.

CGI programs are platform-, software-, and database-independent, but they are not applicant-independent. Separate programs must be written, compiled, and loaded on the server for each application. CGI is widely used, and there are many free programs available for download.

It is slow because it must be loaded and run for each request. A more serious problem is that a CGI program might provide holes for mischief making. Hackers have used CGI programs to gain access to critical files on the server. As a minimum, any free, downloaded CGI programs must be examined for possible security problems, and the programs should reside on a server that contains no other critical files or information. Some network administrators simply will not allow CGI programs at all.

Application Program Interfaces

An API is a group of library routines that are called by the Web server as if they were part of its core program (Lang & Chow, 1996). The libraries are implemented as dynamic link library (DLL) modules or shared objects. Vendors can write programs that interact with the server operating system by calling these routines. The developer works with reusable blocks, making application development faster. DLLs serve much the same function as CGI programs, but instead of calling a separate CGI program, Web server software with an API extension intervenes and processes the request. This method is faster and takes up fewer server resources than CGI because APIs are part of the operating system. On the other hand, poorly written API extensions can bring down a server.

Embedded Programs

Another approach is to embed the programming language within the HTML page. In truth, these Web pages also interact with a “CGI-like” program, called an engine or a partner program, but those engines are part of, or added to, the operating system and are more general-purpose than CGI programs. The idea is to use a small CGI program partnered with a large server service that does much of the work (Lang & Chow, 1996). Application specifics reside in the Web page, and variations are brought about not by rewriting the engine but by writing different pages.

Typically, the browser requests the page containing the embedded script, either by URL or through the use of a menu or Web form. The server sends the page to the engine that reads the file and executes the script. The script contains calls to a database, and SQL statements seek out the data. The final product is an HTML page containing formatted data from the database.

All of the methods described in the following sections use this approach, and they are all similar in the way they work with databases. Of course, the devil is in the details.

Java Sever Pages

Developed by Sun Microsystems, Java Server Pages (JSP) use a combination of Java tags to retrieve data and HTML and XML tags to format and display it. A JSP engine receives requests from a client and generates responses for the client’s browser.

The JSP specification was developed through cooperation between e-commerce firms, vendors, and system designers. Tools were developed to integrate with and leverage existing expertise within the Java programming environment (Sun Microsystems, 2002). As a result of the cooperative effort, JSP will work on any Web or application server, any platform, and most any database product. The native scripting language is based on the widely used Java programming language, and the pages are compiled into what are called Java Servlets.

ColdFusion

ColdFusion was created by Allaire Corporation of Cambridge, Massachusetts, which later merged with Macromedia. Like most server-side products, it uses a CGI-like program partnered with an engine to access the database and build an HTML page incorporating both data content and data display. The resulting HTML is readable by any browser, but the server must be equipped with ColdFusion server software. The software can run on multiple platforms. It uses a scripting language called ColdFusion Markup Language (CFML).

PHP

PHP is a server-side scripting language that is becoming increasingly popular. It, too, embeds statements into HTML pages to build data content and data display. It derives its syntax largely from the C language and is cross-platform (although it is not supported by Macintosh). It is server and browser independent and provides native support for the most popular databases plus ODBC. It supports a large number of protocols such POP3, IMAP, and LDAP (Converse & Park, 2000).

Here is a sample program using PHP scripting language to connect to, and display data from, a Microsoft Access database though ODBC (line numbers are included for reference only):

```
1 <html> <head> <title>Publisher Name
  Search Response</title> </head>
2 <body>
3 <?php
4 $conn_id = odbc_connect('books','','')
  or die("Failure to connect");
5 $bibquery = ("Select * from publisher
  where ppub like '%$PublisherName%'");
6 $result = odbc_exec($conn_id, $bibquery)
  or die("Unable to search database");
7 $publisher = odbc_result($result, "ppub");
8 if (strlen($publisher) > 0)
9. {
10 $tel = odbc_result($result, "ptel");
11 $tel = "(".substr($tel,0,3).")
  ".substr($tel,3,3)."-".substr($tel,6,4);
12 print "<p>The Publisher Data is as
  follows:<br>";
13 print "<p>Publisher Name: <b>. "
  $publisher. "</b><br>";
  ... other statements...
?>
</body> </html>
```

This page has received a request from a Web form in which the requested publisher’s name is stored in PublisherName (line 5). The database call is to a DSN named “books” (line 4) and the SQL searches the table for PublisherName (lines 5–6). The rest of the program creates HTML out of the retrieved data.

Although a popular language, PHP is not widely used in the corporate setting. It is less object-oriented than some other languages, making it less suitable for large-scale, multiteam projects. It is a newer language and sometimes considered not mature enough for enterprise applications. Its heritage as a C language makes it easy for C programmers, but the language is not as intuitive or natural as other scripting languages. It is free and “open source,” which makes for dynamic evolution but at the cost of stability. For example, the online documentation includes “user comments” that describe problems (e.g., glitches, “won’t works,” and “work-arounds”), probably not something the enterprise data manager wishes to cope with.

Active Server Pages

Active Server Pages (ASP) are Microsoft’s method of providing server-side processing. Like the others, ASP imbeds scripting statements directly into the Web page. These statements may be written in Visual Basic Script or Jscript (Microsoft’s version of JavaScript).

ASP uses ActiveX Data Objects (ADO), a Microsoft-developed technology for working with databases on the Internet. ADO are prepackaged programming libraries that are built into Microsoft Web servers and called on to do some work when it needs to be done.

The example shown in the section on Stored Procedures is an ASP script. It uses a DSN-less connection to an Access database. See Yerkey (2001) for details about ASP technology. A demonstration and source code examples are also available (ASP Demo, 2001).

One serious limitation with ASP is that it works best in a complete Microsoft environment. The server must be running a Microsoft product. Combining Microsoft and other products is problematic. One way around this limitation is to use third-party software, such as Sun Microsystem's Chili!Soft ASP, which allows ASP pages to run under a variety of operating systems and platforms.

CONCLUSION

Many of the informational and transactional activities used by EC and other public-oriented organizations are supported by databases with the Web supplying the user interface and connections to them. Internet connections to dynamic databases place extra demands on the databases, and vendors are trying to satisfy those demands. Most of the connections use HTML over transmission control protocol/Internet protocol (TCP/IP) and rely on server-side processing. Systems use either CGI programs or an embedded mix of HTML and a scripting language to access databases and return information to the user.

The Web provides a global infrastructure, standards, and a presentation format, whereas database technology contributes storage techniques, query languages, structured data, and mechanisms for maintaining data integrity and consistency. Newcomers on the scene—object-oriented databases and semistructured data using XML—may change the rules of database design and provide more efficient access to complex data.

GLOSSARY

ACID An acronym to describe special requirements of computer transactions: atomic, consistent, isolated, and durable.

Application Program Interface (API) A group of routines called by a program to provide linkage to the operating system; APIs extend the capabilities of operating system software to allow a program to communicate with a database.

Common Gateway Interface (CGI) A standard for writing programs to access database data through Web pages.

Client-side processing A method of sending data and programs to the user's computer for processing.

Data source name The method of identifying and locating a database on a server.

Dynamic database access Using Web pages to connect to databases in such a way that when users view the page, they are viewing the current state of the database; The technology provides live, interactive access to databases, such that changes to the databases are immediately reflected in the Web page.

E-commerce In a narrow context, using computer systems and networks to conduct business. In a broader context, all transactional activities over the Internet.

Embedded programs Scripting language statements embedded in Web pages to access databases.

Internet-enabled databases Databases designed to meet the special demands of Web access.

Hybrid object/relational databases A traditional relational database that has been extended to include support of objects.

Keys Primary keys are fields in a table that uniquely identify each record; Foreign keys are fields in one table that are primary keys in another.

Normalization Rules for getting data ready for a relational database that are used to eliminate unwanted dependencies and to reduce redundancy.

Object-oriented databases A database system in which "data and instructions are combined into objects or modules that perform specific tasks when sent appropriate messages" (Watson, 2002, p. 581).

Referential integrity Rules for ensuring that parent–child relationships in databases remain synchronized.

Relational databases A collection of related data stored in multiple tables that are linked as required by comparing common columns.

Relationships Description of how data in tables relate to each other; Includes one-to-many, many-to-many, and recursive.

Server-side processing A method in which the processing is done on the server, which sends Hypertext Markup Language (HTML) statements back to the user's browser.

Structured Query Language (SQL) A universal language used to access and manipulate databases on a server.

Static access The method of providing preprocessed database data over the Web. The data is converted to HTML before use, and the resulting pages have no continuing relationship to the database.

Transaction A series of actions taken or operations processed as one unit of work in such a way that they must be entirely completed or aborted.

Transaction-based databases Databases used to support transactions such as ordering, bill paying, registration, inventory control, banking transactions, airline reservations, and stock trading.
