EDTA is most often used with detergent, oxidizing agents, or weak acids, and it is noncorrosive and nontoxic. A very effective decontaminating agent for metal surfaces is a mixture of oxalic and citric acid. The metal ion preferences of the two complement each other, and the organic acids also act to dissolve the oxide film. EDTA is also used with oxalic/citric acid mixtures. When using the organic acids as complexing agents, the precautions described for organic and weak acids should be considered.

The advantages of using complexing agents are that they increase the DF of most decontaminating agents, can perform dual functions (in the case of the organic acids), and are relatively safe and nontoxic.

The disadvantages of EDTA and similar chelating agents are the cost, the limited range of applicability, and the effect on some radioactive waste processes like precipitation and ion exchange. Wastes containing EDTA may present a disposal problem. Site waste management should be consulted before using this chemical.

4.4.8 Oxidizing and Reducing (REDOX) Agents

An oxidizing agent increases the oxidation state of another chemical species, and a reducing agent lowers the oxidation state. A change in oxidation may be beneficial because some oxidation states are more soluble than others. Frequently, these two classes of chemicals are used jointly to maintain a specified oxidation level.

The following oxidizing agents are commonly used in decontamination:

- Potassium permanganate: KMnO_4
- Potassium dichromate: $\text{K}_2\text{Cr}_2\text{O}_7$
- Hydrogen peroxide: H_2O_2

Oxidizing agents find extensive application in decontamination by conditioning metal oxide films, dissolving fission product debris, dissolving various chemical species, and oxidizing the metal surface for either protection or corrosion.

Many metallic and other compounds either break down or are more soluble in higher oxidation states, and base metals must be oxidized to dissolve them. Most metal surfaces can be treated with oxidizing agents, but conditions must be adjusted to avoid excessive corrosion.

Solutions of alkaline permanganate (AP) are used extensively to condition metal oxide films, especially for stainless steel. Because the strong oxy-acids (HNO_3 , H_2SO_4 , and H_3PO_4) are also oxidizing agents, these are usually used alone, but hydrogen peroxide finds application in solutions with the other nonoxidizing acids and salts.

Solutions of organic acids and peroxides frequently get superior DFs to those of strong oxidizing acid, but without some of the corrosion and safety problems.

The advantages of using oxidizing agents are that they complement various acid decontamination solutions, allow less corrosive acids or salts to be used, and perform a unique function in the dissolution of many compounds.

The disadvantages include some metal corrosive action, violent reactions with some compounds, loose activity during storage, and the need to be neutralized before treating in the radioactive waste system.

Reducing agents alone have limited application for decontamination because metals plate-out when reduced, and this is usually undesirable. Under specific conditions, reducing agents could be used to protect a metal surface or reduce higher oxidation states for sequestering agents. Possible reducing agents are sodium hypophosphite (NaHPO_2) and hydrazine (N_2H_2).

Examples of the manner in which this class of chemicals can be used are described in the following sections.

Alkaline Permanganate

Alkaline permanganate (AP) is an oxidizing agent used to oxidize chromium in the corrosion film to Cr_2O_3 , which can subsequently be dissolved in an alkaline solution. It is used as a pre-treatment process in multi-step decontamination programs to expose the remaining corrosion film matrix to subsequent chemical dissolution.

Low Oxidation-State Metal Ion (LOMI)

The low oxidation-state metal ion (LOMI) process was developed by the UK Central Electricity Generating Board (CEGB) in the late 1970s. The process utilizes V^{+2} ions in the form of vanadium picolinate to reduce Fe^{+3} ions in the corrosion product scale to the more soluble Fe^{+2} state, with the V^{+2} ions being oxidized to V^{+3} . The oxidized V^{+3} ions are also formed by the reaction of V^{+2} with oxidizing species formed by the radiolysis of water. Therefore, formic acid is added to the reagent to scavenge these oxidizing radicals.

The LOMI decontamination process is applied in a manner similar to that used for the CAN-Decontamination process. The reactor coolant is first adjusted to neutral pH and a low dissolved-oxygen level and is then brought to a temperature of 80–90 °C. The chemical decontamination solution is then injected, and a side stream of circulation coolant is passed through filter and cation exchange resin columns to regenerate the solution on line.

Decontamination times are very short, typically of the order of 1–3 h. A prior pre-oxidizing AP or nitric acid permanganate (NP) step is required to remove the higher Cr films present on pressurized-water reactor (PWR) components. As with the CAN-Decontamination process, this pre-oxidization step oxidizes the insoluble Cr^{+3} ions to the soluble Cr^{+6} state, and these are dissolved in the subsequent LOMI treatment.

The first formulation of the LOMI reagent typically contained $2\text{--}4 \times 10^{-3}$ M V^{+2} , $1\text{--}2 \times 10^{-3}$ M each of picolinic acid and formate ions in thoroughly deoxygenated water, and sufficient NaOH to adjust the solution pH.

This first formulation generated a relatively large amount of radioactive waste from the ion-exchange process, which had to be disposed. Therefore, a second generation LOMI reagent, containing less formate and NaOH, has recently been introduced, resulting in a 50% reduction in the amount of ion-exchange resin required for waste cleanup.

The advantages of this process are that it has low corrosion without the use of inhibitor and it reacts rapidly. The disadvantages are that the reagent is somewhat expensive and it creates a relatively larger volume of waste.

The LOMI process is the established decontamination process for the Winfrith SGHWR (UK). In 1984, it was used in the decontamination of heat exchangers and recirculation pipe work in the Monticello BWR.

Experience to date indicates that this process is an effective method for routine decontamination of BWR piping and fuel. It can be applied to decontaminate the structural materials of carbon steel, SS304, SS316, SS321, SS410, Inconel 600, Inconel 800, Zircaloy 2, etc.

Electrochemical Low Oxidation-State Metal Ion Exchange (ELOMIX)

Electrochemical LOMI ion exchange (ELOMIX) is a modification of the LOMI process. The primary objective of ELOMIX is to reduce the volume of waste arising from the LOMI decontamination process.

Currently, the resin resulting from the application of the LOMI decontamination process is normally managed by solidification in cement-based matrices for shipment to an appropriate disposal location, but this is not desirable as a long-term solution because of the instability of organic media and the cost of long-term disposal.

The key element of the ELOMIX process is an electrochemical cell consisting of three compartments: anode, cathode, and resin. The following are the principal features of ELOMIX:

- Electrodeposition of metals
- Back-diffusion of nonplating ions
- Continual resin regeneration
- Compatible chemistry and regeneration of the LOMI solution

The concept of ELOMIX has been in development since May 1989. In October 1990, a small pilot-scale ELOMIX cell was operated at Commonwealth Edison's Dresden Unit 2 on a sidestream of actual decontamination solution. This pilot-scale cell operated successfully during three LOMI steps, processing a total of 33 l of decontamination solution through a resin volume of only 0.2 l.

DECOHA Process

The DECOHA process combines important chemical processes – metal dissolution and electrochemical recovery of dissolved metals from a chemical decontamination – into a single “closed loop” process.

Fluoroboric acid (HBF_4) is the heart of the DECOHA process. HBF_4 is a commercially available acid produced when gases are washed during aluminum production.

HBF_4 primary decontamination attribute are its electrolytic properties, which are effective over a wide range of chemical conditions. In general, the acid reacts with a metal to produce the corresponding metal-fluoroborate and hydrogen gas. The HBF_4 reacts similarly with metal oxides-generating water rather than hydrogen gas as a reaction end product.

The effectiveness of these reactions depends in large part upon the solubility of the various metals in HBF_4 .

Experience has confirmed HBF_4 as an extremely powerful solvent for metals. Iron and other important metals exhibit solubilities close to or greater than 200 g/l in 50% HBF_4 , and the pH

of the solution is maintained above 4–5 as a result of the formation of the salt of the acid rather than the formation of the free acid.

Using this process, thin layers of the contaminated metal can be removed from the surface of the contaminated object. Consequently, the level of damage to an object and the corresponding amount of waste produced can be minimized through process control, removing only the depth of metal required to achieve the specific objectives of the decontamination.

The DECOHA process is generally applied at temperatures between 30 and 98 °C. Some metals such as carbon steel, zircaloy, and aluminum may be treated at room temperature. However, the stainless steels and nickel alloys require elevated temperatures to allow realistic application times.

Basically, the speed of the DECOHA process follows a typical dependency on the temperature – for every 10 °C increase in temperature, the reaction requires half as much time to take place.

Typical removal rates range from 3 to 4 μm/h at 80 °C for nickel alloys in 50% solution of HBF₄ to 20–25 mm/h at 21 °C for aluminum in a 5% solution of HBF₄ solution.

Chemical Oxidation Reduction Decontamination (CORD)

In the first step of the chemical oxidation reduction decontamination (CORD) process, permanganic acid is added to the system to oxidate the chromium to the hexavalent state. The decontamination solvent, dicarboxylic acid is added directly without the fluid contents of the system having to be replaced. Permanganic ions are reduced to manganous ions by an equivalent concentration of the decontamination solvent. Dissolved metals may be removed by ion exchange in real-time application or by subsequent evaporation of the solvent.

This procedure is referred to as one cycle and can be applied several times. It may be applied to oxide films. The operating temperature is around 95 °C, and the concentration of chemical does not exceed 3 g/l. An adequate DF is normally achieved after two cycles.

Pressurized Water Reactor Oxidative Decontamination (POD)

The PWR oxidative decontamination (POD) process is applied as follows:

- Apply NP reagents (KMnO₄, at 1.0 g/l and HNO₃ at 0.25 g/l) for 5–24 h, typically 7 h for PWR oxide.
- Apply oxalic (at 1.4 g/l) and HNO₃ (1.5 g/l) for 0.5–1 h to destroy excess permanganate and manganese dioxide.
- Add oxalic (at 0.45 g/l) and citric acids (0.96 g/l) to dissolve the chromium-depleted oxide, and remove dissolved metals in solution using ion exchange.

In the first phase, the permanganate oxidizes chromium in the oxide to bichromate ions as it reduces to manganese dioxide. There is no pH change in this phase.

In the second phase, oxalic and HNO₃ are added to destroy the excess permanganate and manganese dioxide. The primary advantage in using oxalic acid is that it imposes no resin requirements and reacts rapidly.

In the final phase of the process, the chromium-depleted oxide, which can be represented by the formula for hematite or nickel ferrite, is dissolved by the addition of oxalic and citric acids. The former may act as either a chelating or a reduction agent towards Fe⁺³. The dissolved metal ions in all cases are held in solution as complexes of citrate and/or oxalate

The DFs on stainless steel range from 4 to 25, with 5–10 being typical values. On Inconel 600, DFs of approximately 2 were obtained.

Bleaching

The bleach solution is added in generous amounts to the contaminated surface. The surface is scrubbed for 15–60 s, allowed to stand for about 15 min, and then flushed thoroughly with water. The bleach application and wash can be repeated a second time if necessary.

Bleach is most effective against chemical agents and liquid pesticide spills. Bleach has been used on metal, wood, and concrete surfaces, but is most effective on metallic surfaces. Bleach formulations chemically degrade and detoxify many contaminants, especially pesticides. Chemical degradation rates can be affected by other pre- or post-bleach decontamination efforts.

Bleach formulations are normally used in conjunction with other decontamination techniques, most often as a follow-up for detoxifying pesticides on surfaces where a physical procedure did not produce satisfactory results (i.e., did not achieve the cleanup goals).

Solid bleach formulations are generally applied as a slurry, which can result in periodic clogging of application equipment. Depending on their concentration and composition, bleach slurries may cause corrosion of the application equipment and/or the surfaces being treated.

Various types of bleach formulations have been used as decontaminating agents. Traditionally, calcium hypochlorite has been used, although recently sodium-based bleach formulations have had some application.

The various bleaches used include:

- Grades I, II, and III, with >35%, 29–35%, and <29% available chlorine, respectively
- Supertropical bleach (STB), a British formula containing >30% available chlorine
- High test bleach (HTB), which has approximately 42% chlorine content
- Liquid household bleach (sodium hypochlorite and NaOH)

Work is needed to improve the technique for application to porous surfaces and to lessen the corrosive impact of bleach on equipment and building materials.

Detergents and Surfactants

Most commercial detergents involve some formulation of a detergent (sodium laurel sulfate, sodium oleate, alkyl aryl sulfonate) that also acts as a wetting agent or surfactant, a phosphorous or carbonate salt (Na_4PO_4 , Na_2CO_3), a thickening agent (carboxyl methyl cellulose), and other fillers. EDTA or other complexing agents may also be added.

The formulations are numerous and involve foaming or nonfoaming and phosphate or nonphosphate choices. Other surfactants that may be used with the detergent or separately include various sulfonic acid salts, quaternary ammonium salts, and nonionic alcohol, or amine polymers.

Detergents are used in decontamination to remove grease, dirt, and certain organic materials. Surfactants produce similar results by lowering liquid surface tension and providing better contact between the surface and the liquid.

Detergents are effective, mild, all-purpose cleaners for all facility surfaces, equipment, clothes, and glassware. Where applicable, they are preferable to harsher methods. They can be used to increase the effect of water, steam, solvents, and complexing agents. Effectiveness is increased by mechanical agitation. Detergents are not effective on metal corrosion and contamination.

Detergents are cheap, available, safe, and have few material-handling problems. The disadvantages of detergents are their limited effect and possible foaming or ammonia release in a radioactive waste system.

Surfactants are used as wetting agents, detergents, and emulsifiers. They typically consist of long carbon-to-carbon skeletons plus a polar group containing atoms of nitrogen, oxygen, or sulfur. Because the polar group is hydrophilic (water-loving) and the hydrocarbon part is hydrophobic (water-hating), these molecules (or ions) tend to migrate to water-oil interfaces where the polar group is attracted to the water phase and the hydrocarbon residue remains in the oil phase.

4.4.9 Organic Solvents

Solvents are used in decontamination for removing organic materials, grease, wax, oil, and paint from surfaces and for cleaning clothes (dry cleaning). Some typical organic solvents are the following:

- Kerosene
- 1,1,1-Trichloroethane
- Trichloroethylene
- Xylene
- Petroleum ethers
- Alcohols

Dry cleaning of personal protecting equipment (PPE) and rubberized articles have some advantage over detergents in that a much smaller volume of waste is produced. Moreover, dry cleaning in many cases is just as, or more, effective than water cleaning.

In general, the wastes produced include a sludge and a small amount of trichloroethane solvent.

The disadvantages of dry cleaning are that it is limited to certain materials (e.g., plastics must normally be avoided), it gives poor results with wet items or aqueous-soluble stains, and there can be some cross contamination as the solvent is reused.

For other applications, the solvents are used to dissolve certain organic materials from surfaces.

Because of their flammability and their potentially toxic vapors, they are best used on small areas or in contained systems. Some solvents contain chlorine, which is normally avoided in stainless steel systems.

Most radioactive waste systems cannot handle organic solvents. Where other solvents such as alkali or detergents can be used, organic solvents are normally avoided. Conversely, in situations where organic solvents can be properly handled, these solvents are most effective in the decontamination of many RCRA/CERCLA organic constituents.

4.4.10 Multiphase Treatment Processes

Alkaline Permanganate Processing

AP is normally used as the pretreatment in a multi-step process. The AP solution usually includes an inhibitor and a wetting agent to reduce surface tension. Permanganate is also

sometimes used in an acid form as NP for similar applications. Other examples of the manner in which AP is used in multiphase processing are described below.

Alkaline permanganate followed by ammonium citrate. Ammonium citrate (AC) has been successfully used with an AP pretreatment (referred to as APAC) to achieve significant decontamination results. This is a two-step process with intermediate water rinsing. In dilute form, the AC removes residual MnO_2 from the AP solution and neutralizes that solution. In concentrated form, the AC attacks the remaining corrosion film. However, redeposition has been a significant problem with this process.

This process is widely used to decontaminate stainless steel and carbon steel. A dilute APAC process was used to decontaminate the PWR at Shippingport.

A major disadvantage of the APAC procedure, which was discovered during its use at Shippingport, is the necessity of switching from alkaline to acid conditions between stages – a switch that led to a requirement for extensive rinses. An additional problem is that the AP solution degrades ion-exchange resins. Tests on various resins and AP concentrations at Brookhaven National Laboratory (BNL) showed that if the solutions were cooled from their normal operating temperature $> 80^\circ C$ to room temperature, the concentration of AP was reduced sufficiently by being removed in an ion-exchange resin unit. However, at these low concentrations, the reagent was less effective in removing chromium from PWR oxides.

The liquid waste can be deionized using mixed-bed demineralizers, and the resins are disposed as solid waste. The resin volume is of the same order of magnitude as the system volume to be decontaminated. The decontamination solution can be recycled for further use.

Alkaline permanganate ammonium citrate with EDTA. Ethylenediminetetraacetic acid (EDTA) can be added to the ammonium citrate in the APAC process to react with the ion oxides in solution and keep them in solution (referred to as APACE). This inhibits redeposition of the contamination on the treated surface as it permits the oxides to be removed in the waste-processing step via demineralization. Process usage parameters are the same as APAC, with the addition of about 1.0 g/l EDTA.

The liquid waste can be demonized using mixed-bed demineralizers, and the resins are disposed as solid waste.

The resin volume is the same order of magnitude as the system volume to be decontaminated. The decontamination solution can be recycled for further use.

Alkaline permanganate with citric acid. AP with citric acid is a mixture of oxalic acid, citric acid, and an inhibitor. It is an effective decontaminant for stainless steel as the second step after AP pretreatment. The citric acid neutralizes any component of the alkaline solution, dissolves any manganese oxide (MnO_2), and complexes the iron oxides to keep them in solution and retard redeposition.

This process is highly corrosive to carbon steel and 400-series stainless steels. Accordingly, in decontamination, its use is confined to 300-series stainless steels and Inconel.

The liquid waste can be deionized using mixed-bed demineralizers, and the resins are disposed as solid waste. The resin volume is of the same order of magnitude as the system volume to be decontaminated.

Alkaline permanganate with HSO_3NH_2 . This two-step process is similar to the AP with citric acid techniques. AP with $HSO_3NH_2(NH_2SO_3H)$ (APSul) is effective in removing the contaminated film from stainless steel piping without forming a precipitate or causing redeposition.

The liquid waste can be deionized using mixed-bed demineralizers, and the resins are disposed as solid waste. The resin volume is of the same order of magnitude as the system volume to be decontaminated.

Alkaline permanganate with oxalic acid. This two-step process has been successful in removing aged films on high-temperature stainless steel water piping, but it has the disadvantage of causing redeposition in the form of a tenacious oxalate film on the base metal, which has required further treatment with the APACE process.

Foam Decontamination

The cleaning agents use foam such as that produced by detergents and wetting agents as carriers of chemical decontamination agents. They can be applied in a thin layer to a surface in any orientation, even to overhead surfaces. The foam decontamination method can effectively decontaminate metallic walls and parts of complex components. By increasing dwell time, the foam better exploits the capability of the decontamination agent. Surfactants in the foam agent enhance the effect by increasing contact with the surface.

The advantages of this process are that it is effective for large components with complex shapes, it is a good process for internal in situ decontamination to eliminate smearable contamination before dismantlement, and it produces a small final waste volume. In addition, the process is readily applied using remote operations, it is a well-developed and widely used process, it can be operated by recirculation to improve its effectiveness, and it reduces operator exposure to a potential uptake of the acid.

The disadvantages are that it is difficult to obtain a good DF using a one-time application (batch process), difficult to recirculate when it is used to fill large cavities, and it is not appropriate for use on cracked surfaces or where there are deep or convoluted crevices.

This process is well developed and widely used in the nuclear industry. It has been developed at DOE's Savannah River Site (SRS) as a waste minimization tool. Previous experience with foam decontaminants has shown a significant waste reduction of up to 70%, which is higher than that achieved with current decontamination methods. This process has been tested to decontaminate a series of large valves with complex internal configurations. The foam decontamination process also has been applied to contaminated walls at the West Valley Demonstration Project. In this instance, results indicated that decontamination foams achieve better DFs on stainless steel surfaces than on carbon steel or painted concrete.

When using this technique with a closed system for making the foam, extreme caution should be taken. The closed system is pressurized to force a mixture of organic foam makers and decontaminating agent through a chamber where air is added to make the foam and to shoot the foam out through the nozzle.

One experience of this hazard occurred at SRS when a large amount of organic foam maker was added. This resulted in a chemical reaction between the chemical foam maker and the HNO_3 (i.e., decontamination agent) that had a constantly accelerating reaction rate. The volume of gas that was produced was more than the pressure relief setpoint. The system was overpressurized and ruptured. A DOE Class B investigation was conducted. It is worth noting that the equipment was not supplied with a pressure-relief valve and that one was added by the operators before equipment installation and operation.

In general, the collected process waste liquid can be treated by coprecipitation to remove radio-nuclides.

Chemical Gels

Chemical gels are used as carriers of chemical decontamination agents. Gels are sprayed onto a component wall, allowed to work and then scrubbed, wiped, rinsed, or peeled off. An airless compressor can be used for spraying the gel and, with a change in heads, for rinsing.

Typical reagent combinations are a nitric-hydrofluoric-oxalic acid mixture and a nonionic detergent mixed with a carboxymethylcellulose gelling agent, with aluminum nitrate used as a fluoride chelating agent. Steps include scraping and vacuuming solid waste material, using a hot-water rinse as pretreatment, and gel spraying throughout the cell.

The advantages of this process are that it is effective for removing smearable contamination from large components in situ, generates only a small volume of secondary wastes, can be readily applied using remote applications, and can achieve DFs as high as 100.

The disadvantages are that it is a complex that generally requires at least two applications and rinses and requires further treatability studies before the optimum compound composition and operating conditions are adapted to site-specific needs.

Chemical gels have been used to decontaminate cooling carbon dioxide pipes and pipes of ordinary ferritic steel. The following procedure has been used in this project:

- Soda gel spraying (3 M NaOH), 30-min contact time, rinsing
- Acid gel spraying (3 M H₃PO₄, 3 M H₂SO₄, and 16% silica), and rinsing for 30–60 min

The results have indicated that gel spraying is an effective process for beta gamma emitters on ferritic iron steel pipes with simple geometry. It generates a low volume of secondary wastes.

The waste generated from the chemical gel can be collected, neutralized, and treated using precipitation.

4.4.11 Selection of Chemical Decontamination Processes

When selecting a suitable decontamination process, several criteria must be considered in a detailed analysis based on site-specific conditions. Most of the criteria are related to the specific features of the nuclear installation, such as the following:

- Location of the contamination (e.g., inner vs. outer surfaces of closed fluid systems)
- Materials (e.g., steel, concrete)
- History of operation (to determine contamination strata profile)
- Nature of the contamination (e.g., oxide, crud, particulate, sludge)
- Effectiveness of previously used chemical decontamination processes
- Distribution of contamination (e.g., surface, cracks, homogeneous distribution in bulk material)
- Exposure to human health and the environment
- Safety, environmental, and social issues
- Exposure-level reduction requirements (e.g., recycling vs. disposal)
- Quantity and type of secondary waste from decontamination
- Conditioning
- Ultimate placement of decontaminated materials
- Time and cost

4.5 Mechanical Decontamination Techniques

4.5.1 Overview

Mechanical decontamination methods can be classified as either surface cleaning (e.g., sweeping, wiping, scrubbing, etc.) or surface removal (e.g., grit blasting, scarifying, drill, and spall). Mechanical decontamination can be used as an alternative to chemical decontamination, simultaneously with chemical decontamination, or in sequence with chemical decontamination.

Many surface-cleaning techniques can be used for both equipment and building decontamination, and some surface-cleaning techniques can be used as a secondary treatment following surface removal. Because these techniques are so versatile, it may be advantageous to locate a centralized decontamination facility on-site, in which one or more of these techniques may be used. Such a facility could then be used to decontaminate dismantled or segmented components (waste management facility, WMF).

The applications, advantages, and disadvantages of each decontamination technique are presented in  [Table 17](#).

4.5.2 Water Flushing

This technique involves flooding a surface with hot water. The hot water dissolves the contaminants, and the resulting wastewater is pushed to a central collection area. This technique is usually performed after scrubbing, especially on floors. Squeegees can be used to force the wastewater to the collection area. This technique may be used with detergents or other chemicals that enhance the effectiveness of the technique. The volume of the wastewater can be reduced by simply wetting the surface and flushing before drying occurs. The volume of wastewater can also be reduced by using a water treatment system to recycle the flush water.

The water flushing process can be used for areas that are too large for wiping or scrubbing. It is effective on loosely deposited particles (e.g., resins) and readily soluble contaminants, and it can be used as a first step to prepare a surface for a more aggressive decontamination. Obviously, it is not recommended for fixed, nonsoluble contamination.

4.5.3 Dusting/Vacuuming/Wiping/Scrubbing

These techniques refer to the physical removal of dust and particles from buildings and equipment surfaces by common cleaning methods. If dust and particles are contaminated, PPE may be required for workers as a health and safety control.

Vacuuming is performed using a commercial or industrial vacuum equipped with a HEPA filter. If a wet vacuum is used to pick up liquids, however, a replacement filter system has to be used because HEPA filters do not function properly with liquids (i.e., they clog).

Surfaces that cannot be reached with a vacuum can be wiped with a damp cloth or wipe (soaked with water or solvent) to remove dust. If required, the cloth or wipe is disposed as contaminated waste.

Scrubbing is similar to dusting/wiping except that pressure is applied to assist in removing of loosely adhering contamination.

Table 17 Applications, advantages and disadvantages of mechanical decontamination techniques (SOGIN-NIS)

	Flushing with water	Dusting/wiping/scrubbing	Vacuuming	Steam cleaning	CO ₂ blasting	Wet ice blasting	Hydroblasting	Ultra high pressure water	Shot blasting	Wet abrasive cleaning	Grit blasting	Grinding	Scarifier	Milling	Drill and spall	Paving breaker/chipping hammer	Expansive grout	Electropolish	Ultrasonic cleaning	Vibratory finishing

The dusting and vacuuming techniques are applicable to various types of contamination, including lead-based paint chips, PCBs, and asbestos. The techniques are applicable to facility surfaces, although scrubbing should not be used on porous or absorbent materials because loosely deposited materials may be pushed deeper into the surface and should not be used when contaminants are not soluble in water. Wastes are contained in vacuum-cleaner bags, wipe cloths, scrub brushes, or mops, and, depending on the nature of contamination, may need to be containerized or treated before they are disposed. All these techniques are best suited for smooth surfaces.

Several considerations must be addressed before these techniques are applied. The wiping technique can be used to remove dust generated from other operations. Fugitive dusts may be created by the dusting or vacuuming action and spread contamination. It is important to remember that if the source of the contaminated particulate is exterior to the work area, interior vacuuming, or dusting efforts may be ineffective until the external source is controlled. Thermal effects need to be considered when collecting fissile materials (i.e., Pu) while using these techniques.

4.5.4 Steam Cleaning

Steam cleaning physically extracts contaminants from building and equipment surfaces. The steam is applied using hand-held wands or automated systems, and the condensate is collected for treatment. This technique combines the solvent action of water with the kinetic-energy effect of blasting. As a result of the higher temperature, the solvent action is increased and the water volume requirements reduced, compared with hydroblasting.

Steam cleaning is applicable to a wide variety of contaminants and structural materials. This technique is recommended for use on complex shapes and large surfaces to remove surface contamination or to remove contaminated soil particles from earth-moving and drilling equipment. It can be used in conjunction with scrubbing, either as a preliminary step or as part of the scrubbing process.

Although a lesser volume of waste is generated using this technique than in hydroblasting, the installation of sumps and the use of wastewater storage containers may be necessary. As in hydroblasting, existing sumps or water collection systems may be used, but must be checked for leaks to ensure that contamination does not inadvertently migrate to another medium.

4.5.5 CO₂ Blasting

This technique is a variation of grit blasting in which CO₂ pellets are used as the cleaning medium. Small dry-ice pellets are accelerated through a nozzle using compressed air at 3–15 bar. The pellets shatter when they impact the surface, and the resulting kinetic energy causes them to penetrate the base material and shatter it, blasting fragments laterally and releasing the contaminant from the base material. The dry-ice fragments instantly sublime, which adds a lifting force that speeds the removal of the contaminant. Removed debris falls to the ground, and the CO₂ (now gas) returns to the atmosphere. Because the pellets vaporize, they do not pose a collection, treatment, or disposal problem; however, collection of the removed debris is required. Use of CO₂ is advantageous as regards radioactive contamination because it does not become radioactive and because no secondary waste is produced. The airborne contamination

potential is typical of blasting actions. A typical system consists of two major components: a pelletizer that converts liquid CO₂ into dry-ice snow and a cleaning station where the pellets are stored and blasted. The cleaning station is portable and may be used to clean equipment in place, but it may also be used to clean dismantled equipment that has been transported to a centralized cleaning area where the pelletizer is located.

Blasting with CO₂ has proven effective with plastics, ceramics, composites, and stainless steel. Wood and some soft plastics could be damaged, and brittle materials may shatter. Hard coatings that bond very firmly to the base material may not be removed effectively by this technique. Additionally, soft contaminants such as grease and oil tend to splatter and may require specialized application procedures and collection systems. If the object being cleaned is porous, soft contaminants may be pushed into the base material. However, this technique is very effective for hardened, baked-on grease.

Some cooling takes place in the base material, but the amount of cooling seldom exceeds 40 °F. In some applications, cooling makes a small contribution to the cleaning, principally with those contaminants that break up more easily as a result of thermal shock (i.e., those with high moisture content or a high freezing point). The likelihood of damage resulting from cooling is remote, but material analysis should be performed before using this technique on components that may potentially be reused.

In general, CO₂ blasting is best applied in a room or booth that is dedicated to contain the loosened debris and to isolate the noise of blasting, which can range from 75 to 125 dB. In a normal workspace, ventilation is usually sufficient to prevent undue CO₂ build-up; in a confined space, however, ventilation needs to be actively monitored. Because CO₂ is heavier than air, placement of exhaust vents is best at or near ground level. Static electricity may be generated during the blasting process, and, therefore, the component being cleaned should be grounded.

4.5.6 Wet-Ice Blasting

This technique is similar to other decontamination technologies that direct a high-velocity stream of fine particles such as steel pellets, plastic pellets, or glass beads onto a surface to remove contamination. This system employs low-pressure air and wet ice for cleaning and surface preparation. Typical air requirements range between 60 and 250 psig at 280 scfm. Because this system uses water in the form of ice as its medium, no other consumables are required. The contaminated water that is generated by the melting ice particles is the controlling medium for the displaced contamination. The process uses, and therefore generates, a maximum of a few tens of gal/h of water. The water must then be treated for discharge.

When using the wet-ice blasting technique, the ice-blasting cleaning head may be manually moved about on the surfaces being decontaminated. Decontamination efficiency depends on the applicator translation speed, cleaning head distance from the substrate, operating pressure, and geometric complexities of the substrate.

Ice blasting removes coatings and some fixed surface contamination, but will not take off concrete to a significant depth. The waste produced is contaminated water. The amount of water generated depends on the ice blasting rate. For example, a unit recently demonstrated at the ORNL site operated at 11 gal/h.

Because of the low volume of water generated during operation, evaporation, and not recycling, is likely more cost effective. Remote operation requires the adaptation of the ice-blasting and water-collection systems to a robotic control system.

4.5.7 Hydroblasting

In the hydroblasting technique, a high-pressure (several thousand pounds per square inch) water jet is used to remove contaminated debris from surfaces. The debris and water are then collected, treated, and disposed.

Use of the correct lance tip is critical to producing desired results. Configurations range from a jet tip, which produces a narrow stream, to a flat fan shape that produces a flow similar to a point scraper in form. The treated surface may require painting or other refinishing methods if the surface is to be reused. Many manufacturers produce a wide range of hydroblasting systems and high-pressure pumps.

This technique is recommended for surfaces that are inaccessible to scrubbing or that are too large for scrubbing. Hydroblasting can be used on contaminated concrete, brick, metal, and other materials. It is not applicable to wooden or fiberboard materials.

In general, the technique is very effective, completely removing surface contamination. On the average, hydroblasting removes 3/16–3/8 in. of concrete surface at the rate of 40 yd²/h. Hydroblasting may not effectively remove contaminants that have penetrated the surface layer. However, variations such as hot or cold water, abrasives, solvents, surfactants, and various pressures that may increase the effectiveness of decontamination can easily be incorporated into the technique.

Water lances have been successfully used to decontaminate pump internals, valves, cavity walls, spent-fuel pool racks, reactor vessel walls and heads, fuel-handling equipment, feedwater spargers, floor drains, sumps, interior surfaces of pipes, and storage tanks. DFs of up to several hundred have been obtained. Experience at one site indicated that DFs of 2–50 could be achieved using water only and that DFs of 40–50 could be achieved if a cleaning agent, (e.g., Radiac-Wash) is added. Personnel at the site recommend an initial treatment at lower pressures (500 psi) because the lower pressures perform just as well as higher pressures (3,000–5,000 psi).

To decontaminate pipe runs, a variation of the water lance – the pipe mole – is used. In this method, a high-pressure nozzle head is attached to a high-pressure flexible hose and inserted into pipe runs. The nozzle orifices are angled to provide forward thrust of the nozzle so that the hose can be dragged through the pipe.

Hydroblasting has also been used to decontaminate nuclear facilities, remove explosives from projectiles, and decontaminate military vehicles. Hydroblasting also has been employed commercially to clean bridges, buildings, heavy machinery, highways, ships, metal coatings, railroad cars, heat exchanger tubes, reactors, piping, etc.

Given the volume of water generated, installation of sumps and external wastewater storage tanks may be necessary. Existing sumps or water collection systems may be used, although they must be checked for leaks to ensure that contamination does not inadvertently migrate to another medium.

4.5.8 Ultra-High-Pressure Water

In this technique, water is pressurized up to 55,000 psi by an ultra-high-pressure intensifier pump. The water is then forced through a small-diameter nozzle that generates a high-velocity water jet at speeds of up to 3,000 ft./s. The same technique is used in abrasive water-jet cutting, except that for cleaning purposes the nozzle is mounted in a cleaning head.

With the cleaning head attached to a lance, it can be manually moved about the surface being decontaminated. Surface contaminants are first eroded and then removed by the water jet.

Deeper penetration of the surface is possible by adding abrasives to the water jet; however, care should be taken to not damage or cut through the material. The contaminant and wastewater require a processing system in which the contaminant is separated, containerized, and disposed and the wastewater treated and recycled.

Concrete, metallic components, structural steel, and ceramic tile are just a few of the materials that can be decontaminated with ultra high-pressure water. Water jets can remove paint, coatings, and hard-to-remove deposits without damaging the underlying surface. They can also remove galvanized layers from sheet metal.

The decontamination efficiency of the technique is dependent on a number of parameters: water pressure and flow rate, nozzle/cleaning-head configuration, distance of the cleaning head from the surface, and translation speed. These parameters must be evaluated, along with the geometric complexities of the substrate, to achieve optimum results.

Because water jets are omnidirectional and have very little thrust, they are readily adapted to robotics or remote operation. Moreover, the power unit is basically the same as that used for water-jet cutting. Therefore, with minor modifications, the unit can be used for either technique as long as the appropriate nozzle is used (i.e., a cleaning head or a cutting head).

4.5.9 Shot Blasting

Although the shot blasting technique was originally developed and marketed as a surface preparation technique to enhance coating adhesion, it can be used to remove contaminants from floors and walls.

Shot blasting is an airless method that strips, cleans, and etches the surface simultaneously. The technique is virtually dust free, so the potential for airborne contamination is very low. The surface is left dry and free from chemicals, so additional waste treatment is not required.

Portable shot blasting units move along the surface that is being treated as the abrasive is fed into the center of a completely enclosed centrifugal blast wheel. As the wheel spins, the abrasives are hurled from the blades, blasting the surface. The abrasive and removed debris are bounced back to a separation system that recycles the abrasive and sends the contaminants to a dust collector. Larger shot removes more concrete, and the etch depth can be controlled by varying the speed of the unit. Units are available that can remove up to 1/4-in.-thick surface in a single pass. Units are also available for vertical surfaces.

The contaminated debris and contaminated shot must be treated and disposed. The mobile unit must also be decontaminated.

Shot blasting is generally used for concrete surfaces, but it can also be applied to metallic components such as storage tanks. Shot blasting effectively cleans surfaces that have been exposed to acids, caustics, solvents, grease, and oil. It can also remove paint, coatings, and rust.

4.5.10 Wet Abrasive Cleaning

A wet abrasive cleaning system is a closed-loop, liquid abrasive (wet grit blasting) decontamination technique. The system uses a combination of water, abrasive media, and compressed air and is applied in a self-contained, watertight, stainless steel enclosure. There is no danger of airborne contamination because a self-contained HEPA air ventilation system maintains negative

pressure inside the cabinet. The radioactive waste is mechanically separated from the cleaning media, resulting in a very low waste volume. The water can be recycled and filtered, eliminating any access to wastewater drainage.

The system's design is based on field experience and is governed by ALARA concerns. The system uses no soluble or hazardous chemicals, only the abrasive media (e.g., glass beads, aluminum oxide, silicon carbide, and ceramics) and water.

Wet abrasive cleaning is being used by many nuclear facilities to remove smearable and fixed contamination from metal surfaces, such as structural steel, scaffolds, components, hand tools, and machine parts. The equipment can be used on close-tolerance parts such as turbine blades or valves where the removal of metal is not desired, or it can be adjusted to remove heavy-duty corrosion and paint by varying the amount of air pressure and media.

A basic 4 × 4 × 5-ft. or a larger 4 × 8 × 7-ft. system provides enough space to decontaminate small tools or heavy, large-scale parts. If a material cannot be cut down to a smaller size (e.g., long I-beams), it can be fed through small cabinets. Most booths are custom-designed to specific configurations and sizes.

4.5.11 Grit Blasting

The grit blasting technique, commonly called sand blasting and abrasive jetting, has been used since the late 1980s. This technique, which uses abrasive materials suspended in a medium that is projected onto the surface being treated, results in a uniform removal of surface contamination. Compressed air or water, or some combination of both, can be used to carry the abrasive. Removed surface material and the abrasive are collected and placed in appropriate containers for treatment and/or disposal.

Grit blasting is applicable to most surface materials, except those that might be shattered by the abrasive, such as glass, Transite, or Plexiglas. It is most effective on flat surfaces and, because the abrasive is sprayed, it is also applicable on hard-to-reach areas such as ceilings or areas behind equipment. Nonetheless, obstructions close to or bolted to walls must be removed before application, and precautions should be taken to stabilize, neutralize, or remove combustible contaminants because some abrasives can cause some materials to detonate. Static electricity may be generated during the blasting process; therefore, the component being cleaned should be grounded. Remotely operated units are available.

Abrasives may be applied under either wet or dry conditions. Under dry conditions, dust-control measures may be needed to control dusts and/or airborne contamination. This problem can be reduced by using filtered vacuum systems in the work area. When water is used to apply the abrasive, large volumes of waste are produced that include the wastewater, the abrasive, and the removed debris. These wastes must be properly treated and/or disposed. If the wastewater can be recycled, it may or may not need to be treated before it is reused. Depending on the application, the following variety of materials can be used as abrasive media:

- Minerals (e.g., magnetite or sand)
- Steel pellets
- Glass beads/glass frit
- Plastic pellets
- Natural products (e.g., rice hulls or ground nut shells)

Silica has also been used as an abrasive; however, its use is not recommended because silica is moderately toxic as a highly irritating dust and is the chief cause of pulmonary disease. Prolonged inhalation of dusts containing free silica may result in the development of a disabling pulmonary fibrosis known as silicosis.

A grit-blasting system consists of a blast gun, pressure lines, abrasives, and an air compressor. Several grit-blasting equipment manufacturers and contractors are available. Labor cost could be high because this is a relatively slow and labor-intensive technique. Large amounts of abrasive are required, so costs are necessarily dependent on the type of abrasive used.

4.5.12 Grinding

The grinding technique removes thin layers of surface contamination from concrete. In many cases, the contamination is limited to the paint coating or concrete sealer finish. The technique involves abrading the surface that is being treated using coarse-grained abrasives in the form of water-cooled diamond grinding wheels or multiple tungsten-carbide surfacing discs.

Machines to power these abrasives are floor-type grinders whose grinding heads rotate in a circular fashion parallel to the floor.

Water required for cooling is injected into the center of the grinding head, reducing the amount of dust. Supplementary contamination control can be accomplished using HEPA-filtered vacuum systems and wet vacuums attached to or held near the machine. The surface may be moistened before and during grinding to hold down dust.

In general, grinding is recommended for use where thin layers of contamination need to be removed. If the contamination is deep, the grind wheels or discs are quickly worn down, which decreases the overall effectiveness of the technique.

A typical diamond grinding wheel (used on a floor grinder) is capable of removing several thousand square feet of surface per day to an approximate depth of 1/2 in. In smaller areas, the wheel can remove up to 1 in. of surface per day. The machine can be operated by one operator. Floor and hand-held grinding machines have been successfully used at the San Onofre 1 Nuclear Plant to remove surface contamination.

4.5.13 Scarifiers

Scarifiers physically abrade both coated and uncoated concrete and steel surfaces. The scarification process removes the top layers of contaminated surfaces down to the depth of the sound, uncontaminated layers.

Concrete scarification was considered a radical approach to decontamination owing to poor performance of the tools and inability to provide a uniform surface profile upon removal of the contaminants. Today's refined scarifiers are not only very reliable tools, but also provide the desired profile for new coating systems in the event the facility is to be released for unrestricted use.

For steel surfaces, scarifiers can completely remove contaminated coating systems, including mill scale, leaving a surface profile to bare metal. To achieve the desired profile and results for contaminated concrete removal, a scabbling scarification process is implemented; for steel decontamination, a needle scaling scarification process is used.

Scabbling

Scabbling is a scarification process used to remove concrete surface layers. Manufacturers of scabblers typically incorporate several pneumatically operated piston heads to simultaneously strike (i.e., chip) a concrete surface. Today's scabblers range from hand-held scabblers to remotely operated scabblers, with the most common versions incorporating 3–5 scabbling pistons mounted on a wheeled chassis. Because scabbling can cause a cross-contamination hazard, vacuum attachments and shrouding configurations have been incorporated by a few scabbling equipment manufacturers. According to one manufacturer's claim, users can scabble with no detectable increase in airborne exposures above background levels.

One of three types of scabbling bits, which are mounted on the piston heads, can be used: a 6-point anvil bit for surface scabbling, a cross anvil bit for aggressive surface reduction, or a 9-point bit for aggressive removal, leaving a smooth, finished surface profile. All bits have tungsten-carbide cutters from 1 3/4 to 2 1/2 in. in diameter, depending on the manufacturer's configuration. The bits have an operating life of approximately 80 h under normal use.

Before scabbling, combustibles must be stabilized, neutralized, and/or removed. In practice, floor scabblers can only be moved to within 1/2 in. of a wall. Other hand-held scabbling tools are manufactured to remove the last 1/2 in. of concrete flooring next to a wall, as well as surface concrete on walls and ceilings. This technique is a dry decontamination method – no water, chemicals, or abrasives are required. The waste stream produced is only the removed debris.

The approximate removal rates for a scabblers vary, depending on the type of bit that is used. In general, the removal rate for a 6-point anvil bit is 30–40 ft.²/h based on the removal of a 1/6 in.-deep layer. The removal rate for a cross anvil bit varies inversely to the thickness removed: 14–24 ft.²/h for a 1/4-in.-deep layer, 7–12 ft.²/h for a 1/2-in.-deep layer, and 3–6 ft.²/h for a 1-in.-deep layer.

Needle Scaling

Needle scaling is a scarification process used in both concrete and steel surface removal. These tools are usually pneumatically driven and use uniform sets of 2-, 3-, or 4-mm needles to obtain the desired profile and performance. The needle sets use a reciprocating action to chip the contamination from the surface. Some manufacturers have added specialized shrouding and vacuum attachments to collect the removed dust and debris during needle scaling with the result of no detectable concentrations above background levels.

For removing surface contamination from steel surfaces where combustibles were once stored, copper beryllium needle sets can be used to reduce the risk of needle sparking. Needle scalars are an exceptional tool in tight, hard-to-access areas, as well as for wall and ceiling surface decontamination. This technique is a dry decontamination process and does not introduce water, chemicals, or abrasives into the waste stream. Only the removed debris is collected for treatment and disposal.

Production rates vary depending on the desired surface profile to be achieved. Nominal production rates range from 20 to 30 ft.²/h.

Applications

Scabblers are best suited for removing thin layers (up to 1 in. thick) of contaminated concrete (including concrete block) and cement. They are recommended for instances where no

airborne contamination can occur and the concrete surface is to be reused after decontamination, or for instances in which the demolished material is to be cleaned before disposal. The scabbled surface is generally leveled, although coarsely finished, depending on the bit used. If necessary, after release, the surface can be finished with a concrete cap and an epoxy, polymer, or similar finish. This technique is suitable for both large open areas and small areas.

Needle scaling is best suited for removing of surface contamination and coatings from steel surfaces, piping, and conduits. Needle scalers with vacuum attachments and shrouding are ideal for clean room surface removal operations, dustless decontamination operations, and the reduction of containment structures and ventilation schemes. They can also remove surface contamination from concrete surfaces (up to 1/2 in. thick). Needle scaling is generally more versatile than scabbling and is highly effective on concrete walls and ceilings.

A proprietary system integrates scabblers and scarifiers into a family of remotely and manually operated scarification equipment for dustless decontamination of concrete and steel. The system incorporates a high-performance vacuum/waste packaging unit in conjunction with pneumatically operated scabblers and needle scalers to safely remove contaminated material. Dust and debris are captured at the cutting-tool surface, which minimizes cross contamination. The HEPA filtration design incorporates a patented fill-seal drum change-out method that allows the operator to fill, seal, remove, and replace the waste under controlled vacuum conditions. The unit can accommodate 55- and 23-gal drums. It can also simultaneously support several drum sizes, including up to three scabblers/needle scalers from a 100-ft. distance. The remotely operated floor scabber has an on-board vacuum packaging unit. The smaller scabber and needle scaler have vacuum ports that can be attached to the vacuum waste packaging unit. Although the equipment is designed to work as an integrated system, the individual components can also be operated as stand-alone units that can be used with conventional air supplies and vacuum systems.

4.5.14 Milling

There are two milling techniques, one used for shaving metals and one for shaving concrete. Metal milling is the technique by which a machine shaves off a layer of material (up to 1/8 in.) from a surface using rotating cutters. The most commonly used method involves feeding the work piece past stationary cutters that are perpendicular to the cutter's axis. Other types of milling machines (i.e., where the work piece is stationary and the cutter or cutters move) are available. Waste consists of the machined-off chips and any cooling/lubricating fluids (which can be recycled if necessary).

Concrete milling is similar to concrete scabbling or scarifying, except that it may be applied to a much larger surface area. Large, paving-type equipment is generally used to shave the concrete surface. Approximately 2 1/2–10 in. can be removed in this manner.

Because of the set-up time per configuration (1/2–3/4 h), metal milling is most effective when there is a large number of similarly shaped items to be decontaminated. After the equipment is set up and loaded, about 2.5 ft.²/h can be milled. Concrete milling is most effective when used on large, open, horizontal surfaces. Metal milling has been used at the Oak Ridge K-25 site to decontaminate individual metal items.

4.5.15 Drill and Spall

The drill-and-spall technique was developed to remove contaminated concrete surfaces without demolishing the entire structure. All potential obstructions to the drill or spall rig should be removed and combustible sources stabilized, neutralized, or removed. The technique involves drilling 1 to 1 1/2-in.-diameter holes approximately 3 in. deep into which a hydraulically operated spalling tool is inserted. The spalling tool bit is an expandable tube of the same diameter as the hole. A tapered mandrel is hydraulically forced into the hole to spread the fingers and spall off the concrete. The holes are drilled on approximately 12-in. centers so that the spalled area for each hole overlaps the next. The removed concrete is collected, treated, and/or disposed. If the contamination is deeper than that which can be removed in one pass, a second pass may need to be performed.

The drill-and-spall technique is applicable to concrete only (not concrete block) and is recommended for removing surface contamination that penetrates 1–2 in. into the surface. Removal of the near-surface-contamination in this manner decreases the amount of contaminated material that needs to be disposed prior to demolition. This technique is effective for large scale, obstruction-free applications, the only limit being the interior building configuration. The treated surface may require a concrete cap if a smooth surface is desired, because any rebar is exposed and the surface is generally left in an overall rough condition.

A concrete spaller was used at Pacific Northwest Laboratories (PNL) to remove 1 in. of contaminated concrete from the surface of air lock cover blocks. The concrete spaller was first set up and tested on nonradioactive concrete to allow hands-on training of personnel. During these equipment tests, it was found that if the surface was first painted with a latex paint, it acted to keep the spalled aggregates together, somewhat in the same manner as a fixative. A nominal 8-in. spacing between drilled holes was found to be satisfactory. The interface between the push rod and bit was lubricated between each spalling operation rather than every four operations as recommended. This lubrication sequence may have helped prevent wear or galling-type failures. One spalling bit was replaced when the wedge portion broke away from one of the expanding prongs. During operation, workers were required to wear respirators. The spalling rate ranged from 2 to 10 ft.²/h, depending on worker experience.

4.5.16 Paving Breaker and Chipping Hammer

Although paving breakers and chipping hammers are primarily used in demolition activities, they can be used also to remove surface contamination up to 6 in. thick. In this case, surface is left very rough and resurfacing might be required.

4.5.17 Expansive Grout

Although expansive grout is primarily used as a demolition technique, it can also be used as decontamination method to remove a thick layer of contaminated concrete.

4.5.18 Asbestos Removal

There are four methods used to manage the abatement of asbestos contamination in buildings: removal, encapsulation, enclosure, and special operations. Only the first method, removal, permanently eliminates the asbestos from the area or building. The other three methods leave the asbestos in place in some form. For the purposes of decommissioning, removal is the preferred option and therefore is the only one described in detail in this section.

Building materials containing asbestos are removed to prevent the release of asbestos fibers in the air. To maximize worker protection, removal should be performed before any other segmenting or decontaminating activities in the area. Before removing or disturbing materials containing asbestos, the work area is isolated so that all asbestos fibers released by the removal activity will be confined to the work area. Accordingly, temporary partitions are constructed, and all exposed surfaces (other than those being removed) are covered with plastic sheeting. HEPA filtration of the air in the work area is required to minimize the risk of asbestos exposure of removal workers and/or building occupants (if the building remains occupied during removal).

After the work area has been enclosed and plastic sheeting placed over all exposed surfaces, the asbestos-containing material is wetted in place with conditioned water (i.e., water with surfactant added to increase wetting action) or encapsulant. The material is physically removed and placed in sealable bags or containers. When removal is complete, the work area is subjected to thorough cleaning. All surfaces are wet-wiped or mopped. Vacuums equipped with high efficiency filters may be used to vacuum up any visible debris deposited on building floors, ledges, other equipment, etc. Porous surfaces may require sealing with a chemical penetrate to prevent the release of any residual fibers.

To prevent the fibers from becoming airborne or otherwise transported and deposited, equipment and personnel leaving the work area must pass through a partitioned area designated as the decontamination room. In this room equipment is wet-wiped to remove asbestos fibers, and used personal protection equipment is discarded into sealable containers for proper disposal. A portable shower and a change area may be provided for the use of workers exiting the work area. Spent shower water is filtered with a disposable high-efficiency filter.

A visual inspection is conducted following removal of the asbestos-containing materials to detect incomplete work or inadequate cleanup. Following satisfactory visual inspection, the work area remains undisturbed for 24–72 h to allow fibers to settle. Air monitoring is then conducted to measure the level of residual asbestos fibers. Acceptable levels are based on state regulations. When air monitoring results indicate that the work area is adequately decontaminated, the isolation barriers are disassembled, placed in sealable containers, and disposed in regulated landfills.

Potential hazards to personnel include inhalation of asbestos fibers, known to be fibrogenic and carcinogenic; heat stress caused by high temperatures and humidity, minimal or no ventilation, and PPE; and electrical shock from the use of water (for wetting) in proximity to electrical equipment.

4.6 Other Decontamination Techniques

This section presents decontamination techniques in which the primary force is not the result of chemical or mechanical means. These techniques work to decontaminate a surface by inducing a chemical reaction or mechanical action that actually performs the decontamination.

4.6.1 Electropolishing

The electropolishing technique, a cleaning technology developed in the 1950s, has been widely used in the metal-finishing industry. It was not until the 1970s, however, that the nuclear industry recognized its potential for cleaning radiologically contaminated equipment.

Currently, the technology is gaining popularity in the nuclear industry for surface pre-treatment as well as for decontamination operations. The electropolishing technique should be considered for cleaning conductive materials. It has been shown to be particularly effective on conductive materials, reducing contamination to near background levels, and making the free-release option technically obtainable.

Several advantages are associated with electropolishing. Conductive surfaces can be decontaminated to a very low or even nondetectable level for free-release applications. A wide range of contamination and conductive surfaces can be effectively decontaminated (i.e., the technique is versatile).

Relatively complex components and shapes can be decontaminated using the electropolishing technique without disassembly. Fairly large items can be decontaminated without sectioning.

One disadvantage associated with the technique is that nonconductive components cannot be cleaned. Nonconductive coatings (e.g., paint, epoxy) must be removed from conducting components before cleaning can be performed. Exposure levels could be excessive, unless remote techniques are employed when cleaning highly contaminated parts. Components may need to be repeatedly cleaned if excessive amounts of contamination are allowed to build up in the electrolyte.

Description of Technique

Electropolishing is an anodic-dissolution technique. During electropolishing operations, a small, controlled amount of material is stripped from the surface of the object being cleaned. Contamination embedded in the stripped material is carried off into dissolution, resulting in a surface nearly free of contamination. The technique is considered a versatile technique that is equally effective for almost any combination of contamination and conductive surfaces, including corrosion layers.

There are three basic process technologies available: phosphoric-acid-based systems, nitric-acid-based systems, and organic-acid-based systems. Each of these systems is similar in arrangement to plating installations.

Direct current (dc) power is supplied to the system at low voltages. The object being cleaned is connected to the anode (+), and a series of metallic plates is connected to the cathode (-). Both the anode and the cathode are immersed in a chemical bath consisting primarily of one of the three electrolytes listed above. When current is applied, the electrolyte acts as a conductor, allowing metal ions to be removed from the part being treated. While the ions are drawn towards the cathode, the electrolyte maintains the dissolved metals in solution.

Electrolytes

The nature of the electrolyte constitutes the primary difference in each of the following three available systems.

H₃PO₄ Electrolytes

Representative operating conditions for phosphoric-acid-based electropolishing decontamination are as follows:

- Concentrations: 40–80% by volume
- Operating temperature: 40–80 °C
- Electrode potential: 8–12 V dc
- Current densities: 60–270 mA/cm²

The time involved for a typical decontamination ranges from 5 to 30 min, which corresponds to the removal of 0.3–2 mils of surface material at a current density of 160 mA/cm². It is usually necessary to move the anode contacts once during a cycle to decontaminate the area under the contacts.

PNL has demonstrated that phosphoric-acid-based systems are effective on steel, stainless steel, and a number of alloy systems. The electrolyte's hygroscopic nature helps to minimize airborne contamination. Phosphoric acid's good complexing characteristics may be a significant factor in minimizing recontamination from build-up in the electrolyte.

Studies performed at PNL, in cooperation with Rockwell Hanford Operations and United Nuclear Industries, show that components heavily contaminated with plutonium oxide were decontaminated from 1,000,000 dpm/100 cm² to background in less than 10 min.

Phosphoric-acid-based electrolytes are not effective in decontaminating welds. It is believed that metallurgical changes caused by welding make welded areas less soluble than the base materials. It has also been observed that low-current densities produce nonuniform metal removal and that high-current densities produce excessive oxygen evolution.

HNO₃ Electrolytes

Two sets of operating conditions are used in nitric-acid-based systems: high-density current and low-density current. Representative operating parameters for high-density, nitric-acid-based electropolishing decontamination are as follows:

- Electrolyte: HNO₃, 6–12 mole
- Operating temperature: 10–35 °C
- Electrode potential: 5–8 V dc
- Current densities: 400–2,000 mA/cm²

The time for a typical low-density decontamination ranges from 1 to 2 h, which removes 0.3 mils of surface material at a current density of 400 mA/cm².

Because of the low-density current, a basket-style anode can be used, thus eliminating the need to move the anode contacts during the decontamination cycle.

Studies performed at Harwell Laboratories, Oxfordshire, UK, show that low-density current HNO₃ electrolytes could achieve DFs of better than 10⁴ for components contaminated with colloidal plutonium and with PuO₂ in about 2.2–1.7 h, respectively.

Harwell Laboratories have demonstrated that nitric-acid-based systems are effective on steel, stainless steel, and a number of alloy systems. Dissolved substrate levels in the electrolyte of up to 20 g/l have only a minor effect on the recontamination of the object being cleaned.

Nitric-acid-based electrolytes, operated at low-density currents, provide good results on welded surfaces. The systems can generate hydrogen and nitrogen oxide gases, but these gases can be controlled or eliminated by using the proper electrode materials and electrolyte additives.

Organic Acid Electrolytes

Harwell Laboratories have performed research on the relationship between cathode materials and chemical additives and their effect on hydrogen and nitrogen oxide production in

nitric-acid-based electrolyte systems. Representative operating parameters for acetylacetonate-based electropolishing decontamination are as follows:

- Electrolyte: acetylacetonate + KBr + n-propanol
- Operating temperature: 20–40 °C
- Electrode potential: 15–24 V dc
- Current densities: 200 mA/cm²

The time of a typical decontamination ranges from 40 to 100 min, which corresponds to the removal of 1–2 mils of surface material at a current density of 200 mA/cm². It is usually necessary to move the anode contacts once during a cycle to decontaminate the area under the contacts.

There are three major advantages of using an acetylacetonate-based electrolyte:

- Acetylacetonate has good pH stability and can resist changes caused by the formation of hydroxides.
- The organic acid component can be destroyed, resulting in a nonacidic waste.
- The radioactive contents of the electrolyte reach a steady state, governed by the solubility of the acetylacetonate salts. This advantage is a benefit where criticality is a concern and where radiation control is essential. The large salt crystals formed in this process can be removed from the bottom of the electropolishing vessel and isolated in a safe storage condition.

Studies performed at Kraftanlagen Aktiengesellschaft, Heidelberg, Germany, show that an acetylacetonate electrolyte could achieve a DF of 36 for components with generalized contamination consisting largely of ¹³⁷Cs and ⁶⁰Co in about 60 min.

Applications

There are two major divisions in immersion electropolishing equipment:

- Equipment that accommodates total immersion of objects
- Equipment that accommodates partial immersion of objects

Total-immersion The literature reports that several sizes of immersion electropolishing systems have been designed and built. At PNL, a 400-gal system was designed, built, and used for decontamination studies. Mobile electropolishing decontaminating services are available.

Partial-immersion Large equipment can be electropolished in stages by using partial-immersion processes. One such technique makes use of a trough-shaped tank equipped with roller-base supports that provide easy rotation of cylindrical tanks during the polishing process. Some tank interiors can be electropolished using the partial-immersion process. The process involves filling the tank with electrolyte, making the appropriate electrical connections, and setting the power supply to the appropriate current density. After the process is complete, the tank is emptied and the electrodes are removed. The final step is rinsing the tank.

4.6.2 Ultrasonic Cleaning

This technique uses a generator to produce an ultrasonic frequency (above 20 kHz). A transducer then converts this high-frequency energy into low-amplitude mechanical energy (i.e., vibrations) of the same frequency. A vigorous scrubbing action is produced by a cleaning solution and imparted onto the object being cleaned. The scrubbing action is attributed to the

rapid formation and violent collapse of thousands of minute bubbles. The bubbles are created by cavitation, which is caused by the outward and inward movement of the transducer's surface, in the solution.

The most important parameters for ultrasonic cleaning are ultrasonic frequency, power intensity, cleaning-solution viscosity, temperature, and fluid recirculation rate. Additionally, the tank size and the geometry of the object being cleaned in relation to the transducer placement must be evaluated. These parameters must be properly controlled to obtain the best possible decontamination of an object. In addition to cavitation, ultrasonic streaming (induced liquid circulation) contributes to the decontamination of an object.

The cleaning action can be enhanced by heating the solution, performing mechanical stirring, and adding chemicals to the cleaning solution. Additives such as wetting agents and chelating agents can also have a profound effect, although the concentration of chemicals in the bath solution should be approximately 2–5% by weight.

An effective method that may be used for removing radioactive particles from solid surfaces using ultrasonics is the following. First, the parts to be cleaned are sprayed or sonicated with a dilute solution of a high molecular weight fluorocarbon surfactant in an inert perfluorinated liquid to effect particle removal. Second, the parts are then rinsed with the perfluorinated liquid to remove the fluorocarbon surfactant applied in the first step. Third, the residual rinse liquid is evaporated from the parts into an air or nitrogen stream from which it is subsequently recovered.

Objects with loosely deposited and loosely adherent contamination (i.e., not fixed) have been decontaminated successfully using ultrasonics. These objects include metallic hand tools, pump seals and pistons, valves, seal-injection filters and other filters, and control-drive mechanisms. Ultrasonic equipment for small items is commercially available. Ultrasonic equipment for large items can be designed and constructed, although it should be noted that immersion of large items results in less effective decontamination. This technique is not recommended for concrete components, nor should it be used on materials that adsorb ultrasonic energy (e.g., plastics, rubber).

4.6.3 Vibratory Finishing

Objects are placed in a basket filled with abrasive media that is vibrated at a high frequency in a cleaning solution. The vibrating media produces a scouring action that removes contamination as well as tape, paint, and corrosion products from the surfaces of almost any type of item. Commonly used abrasives are triangular ceramic or conical plastic material impregnated with aluminum oxide. Spent abrasives and removed contaminants are carried to a holding tank by the cleaning solution where they are collected and concentrated for disposal. The cleaning solution can be recycled, thus reducing the amount requiring disposal.

This technique is commonly used in manufacturing as a deburring technique. However, it is also applicable for decontaminating such items as hand tools (e.g., hammers, wrenches, screwdrivers, etc.) and large quantities of smaller objects. The size and weight of the objects are obviously limited by the size of the vibratory container. For example, a 4-ft.³ container can handle approximately 300 lb of components, the maximum size of each object being 8–12 in. in diameter. The time required to decontaminate a component is dependent on the component geometry and the amount and type of contaminant. Process times to decontaminate range from 4 to 10 h per batch. Units are commercially available with volumes up to 100 ft.³.

This technique is an effective pretreatment technique for chemical decontamination methods. It removes latex paint, enamel paint, grease, and oil, each of which can limit the effectiveness of chemical decontamination methods. Because an abrasive is used, excessive metal loss may occur as well as curvature of previously sharp corners; however, in decommissioning this is not a problem.

5 Cutting and Dismantling Techniques

5.1 Overview

The dismantling of a nuclear installation requires the cutting and segmenting of equipment and structures with varying sizes, dimensions, and materials.

The conditions under which the cutting operations are carried out depend on the location and space of the working area, on the qualification and experiences of the personnel, on the available tools and technologies as well as on the environmental conditions under which the operations are made: under water, in the air, under radioactive radiation, and under contaminated atmosphere.

There is great diversity in existing cutting tools, which are useful and available under industrial conditions or in the RTD phase, each tool having its own performances, conditions and field of application. The following techniques are available:

- Thermal cutting
- Hydraulic cutting
- Laser cutting
- Mechanical dismantling
- Microwave spalling
- Explosive cutting

When choosing cutting techniques the following factors should be taken into account:

- The technique (tool) should be used in practice, so that experience exists and supply security spare parts and handling are ensured
- The technique (tool) should only generate a minimum of secondary waste, e.g., dust, particles, fumes, aerosols with controlled dispersion, and liquid effluents
- The personnel on-site should be at low risk of contamination, easy to decontaminate
- The technique (tool) has to be compatible with the working-environment

5.2 Thermal Cutting Techniques

In thermal cutting techniques, the solid material is melted and then blown away. Since molten states of material are present, the net amount of force needed is much smaller than for the techniques, which use strain energy. Hence, the use of mechanical force is only a minor part of thermal cutting processes.

It is possible to classify the thermal cutting techniques according to the type of heat source:

- Gas processes
- Arc processes

- Plasma arc processes
- Combined cutting processes (a composition of the above mentioned processes)

The energy density of the heat source increases from the gas flame to the arc and the plasma arc to the laser beam.

5.2.1 Gas Processes

Thermal cutting techniques with gas flames are mainly used for flame-cuttable materials. Most of the process heat is released during the exothermal combustion of the work piece. The residual part is released by burning the heating gas in oxygen. The resulting flame heats the work piece to its ignition temperature and oxygen is then added, in which the work piece is burnt.

Two different kinds of fuel can be used to provide the heating flame:

- Fuel gases, such as hydrocarbon compounds and hydrogen
- Liquid fuels

For safety reasons, only hydrocarbon compounds should be used in nuclear facilities, since hydrogen involves the risk of explosions in connection with possible leaks.

Liquid fuels are more difficult to handle and less effective than hydrocarbons and should only be used for exceptional cases in underwater cutting.

The most important parameters for the selection of fuel gases are the maximum flame temperature, the primary flame efficiency, and the density of the gas in comparison with the density of air (► [Table 18](#)).

Powder Injection Flame Cutting

There are two different types of flame cutting that use additional powder injection:

- (Sand) powder cutting
- Metal-powder fusion cutting

In both cases, a heating flame and an oxygen cutting jet are present as in flame cutting. Different powders are added depending on the material to be cut.

Powder cutting was developed for cutting stainless steel, which cannot be cut by flame. A special sand is added as a powder. Due to its abrasive effect, this sand tears open the oxide skin and thus facilitates the blowing out of the high velocity molten steel. Nowadays, this method has been replaced to a large extent by plasma arc cutting.

In metal-powder fusion cutting, exothermally-burning metal powders are introduced into the oxygen cutting jet. The heat emitted during the oxidation causes the fusion of the work piece.

■ **Table 18**

Hydrocarbon compounds data

Type of fuel	Maximum flame temperature (°C)	Density (kg/m ³)
Acetylene (C ₂ H ₂)	3,150	1.17
Propane (C ₃ H ₈)	2,828	2.02
Methane (CH ₄)	2,786	0.72
Natural gas	Values depend on the composition	

In addition to the oxygen cutting jet, the kinetic energy is significantly increased by means of the developing oxides. In this way, it is easier to blow the molten products out of the kerf.

In most cases, the powder consists of iron or a mixture of iron and aluminum (85% Fe, 15% Al).

Since metal-powder fusion cutting is a pure fusion cutting process, it can be used for cutting stainless steel, non-ferrous metals, cast iron, and concrete. Nowadays, the cutting of concrete is the most important field of application for this technique. The emerging metal oxides convert the viscous slag into a more fluid one. This sort of slag, called lava in case of concrete, can easily be blown out of the kerf.

The latest development is a specially designed flat torch for cutting concrete walls more than 1 m thick. One meter represents the thickest cut that can be achieved with conventional torches, the large size of which normally prevent immersion of the torch into the kerf. Flat torches are smaller than the kerf they produce, and hence the cutting operation becomes a gouging process.

The underwater use does not produce satisfactory results.

Aerosol Emission A series of aerosol measurement tests were carried out during a CEC project carried out by AEA Windscale, UK, and CEA Saclay, France.

Cutting Speed The cutting speed for cutting concrete with metal powder ranges between approximately 15 mm/min for a 300-mm thickness and 5 mm/min for a 1,000-mm thickness. The cutting speed for cutting stainless steel ranges between 200 mm/min for a 10-mm thickness and 170 mm/min for a 30-mm thickness (► [Table 19](#)).

Cut Thickness The thickest cut in concrete by means of conventional torches is about 1,000 mm. This value can be exceeded by using flat torches, which are able to immerse themselves into the kerf. In this case, no limit for the maximal cut thickness exists. The thickest cut in metals should not exceed 500 mm.

Flame Cutting

Flame cutting is performed with an oxy-fuel gas flame and cutting oxygen. The heating flame heats the work piece locally to its ignition temperature. The flame then keeps the work piece at this temperature during the cutting process. In this way, it compensates for heat dissipation by conduction into the work piece and the environment. The cutting-oxygen jet is added after the ignition temperature has been reached. The cutting kerf is formed by the relative motion between the cutting jet and the work piece.

■ **Table 19**

Cut thickness and cutting speed using oxyacetylene torch (SOGIN-NIS)

Guide method	Cut thickness (mm)	Cutting speed (mm/min)
Mechanically guided oxyacetylene torch	10	700
	40	460
	110	250
Manually guided oxyacetylene torch	10	370
	65	115
	110	21

The use of flame cutting is limited to mild steel, titanium, and molybdenum. Stainless steel and the remaining non-ferrous metals are not suitable for flame cutting without additional powder injection. In the field of nuclear facility decommissioning, mainly conventional torches for flame cutting in atmosphere are currently in use.

Underwater Use Firstly, special protection of the heating flame is required so that burning underwater is possible. This can be provided by an additional protection cap or by a concentric water curtain of a conical shape. Under this curtain, combustion gases produce a cavity between nozzle and work piece. Other versions use compressed air instead of water to form the curtain.

Cutting Characteristics The cutting speed mainly depends on the handling technique (manual/mechanical), the type of cutting nozzle, i.e., the design of the cutting oxygen bore, and the applied hydrocarbon. For cut thickness > 100 mm propane is recommended compared to acetylene because of higher cutting speed (see [▶ Table 20](#)).

Cut Thickness In atmosphere, a maximum cut thickness of more than 2,000 mm can be achieved for mild steel. Underwater, the cut thickness obtained with flame cutting range between 3 and 450 mm for mild steel.

Flame Gouging

Flame gouging is a variation of the flame cutting process. The surface of the work piece to be cut is heated to its ignition temperature by means of a heating flame. In this process, the same fuel gases as in flame cutting are used, i.e., acetylene, propane, natural gas, and hydrogen.

Following this, the gouging oxygen is applied, which oxidizes the preheated material and blows it out of the kerf. The oxygen pressure should be 0.5–0.7 MPa. The velocity of the gouging oxygen jet is much slower compared to the velocity of a cutting oxygen jet for flame cutting, i.e., 60–300 m/s in case of gouging and 400–500 m/s in case of cutting.

The slag heats up the work piece in front of the torch. This process supports the effect of the heating flame and renders possible a continuous process with high gouging speeds. When the oxygen jet gets into direct contact with the work piece, without any layer of slag between them, the iron reacts immediately with the oxygen.

Underwater Use The heating flame must be shielded from the surrounding water by shielding gas caps, into which additional oxygen is inserted as a shielding. The tips of these caps must be as acute as possible, so that the required angle between torch and work piece can be achieved.

Compared to flame gouging in atmosphere, the slag cools much quicker, and solidifies directly in front of the heating flame. Because of this, the feed rate of the torch is much slower than that used for flame gouging in atmosphere.

Cutting Characteristics For flame gouging in atmosphere, the maximum feed rate ranges from 500 to 2,000 mm/min. The kerf is 3–10 mm deep and 5–18 mm wide. Deeper kerf can be produced by repeated application of the gouging process. Flame gouging underwater results in a slower gouging speed and a smaller kerf volume.

Oxygen Lance Cutting

Two different types of oxygen lances are available:

- Packed lances
- Powder lances

An oxygen lance consists of a tube into which a core wire is inserted. Both tube and wire are made of flame-cuttable mild steel.

The free-end of the oxygen lance is heated to its ignition temperature by means of an external heating flame and then burnt in the pressurized oxygen, which is fed through the lance. The temperature reaches values up to 2,500 °C and the emitted heat melts the metallic work pieces as well as the mineral materials. The molten material is then blown away by the oxygen jet.

In the case of oxygen powder lances, metal powder is blown through a hollow tube by means of compressed air. A mixture of iron and aluminum powder is normally used. Oxygen lance cutting with packed and powder lances is used for cutting high-melting metallic materials and mineral materials such as concrete. Mild steel is burnt in the oxygen jet. Concrete and stainless steel are fused and blown out of the hole by means of the oxygen jet and the combustion gases.

Oxygen lances are usually guided manually. Automation of the process would be difficult to maintain and control, and therefore extremely costly.

In the case of cutting concrete, only a single hole in the work piece is generated instead of a straight kerf. The so-called perforation cut, which consists of a sequence of several holes in a row, represents the first choice for the severance cutting of concrete. The remaining material must be removed mechanically.

Underwater Use The underwater use of oxygen lances is possible. This technique is not widely used underwater for cutting steel less than 40 mm thick. Following the penetration of the lance into the work piece, there is an atmosphere-like condition around the hole, since the intrusion of water into the hole is impeded by the emerging oxygen, the combustion gases, and the slag. For cutting in atmosphere the lance must point upwards, so that the molten metal can drain off. In contrast, for underwater use, the lance must be pointed downwards in order to enable the emerging gas bubbles to rise.

Cut Thickness The thickness of concrete suitable for drilling depends on the cutting position: horizontal approximately 2 m, vertical – top to bottom approximately 1.5 m (► [Table 21](#)).

Aerosol Emission Tests showed that by using aerosol filters, a filtration efficiency of 99.96% was obtained. The service life, however, was not satisfactory. For the cutting of concrete, there was a shift towards bigger particle sizes.

5.2.2 Arc Processes

Oxy-Arc Cutting

The principle of oxy-arc cutting is similar to that of flame cutting but, instead of using a flame, an arc preheats the work piece material. In oxy-arc cutting, the arc is ignited between a hollow

■ **Table 21**
Cutting data for oxygen lance cutting (SOGIN-NIS)

Environment	Material	(Feed rate mm/min)	(O ₂ consumption l/min)	Hole diameter (mm)	Lance consumption ($m_{\text{lance}}/m_{\text{hole}}$)
In atmosphere	Concrete	200	500	45	4.25
	Mild steel	225	550	40	7
Under water	Mild steel	200	400	45	4–6

electrode and the work piece, and heats the latter to its ignition temperature. A cutting oxygen jet is then introduced through the hollow electrode onto the work piece, where it burns the material to be removed and blows the slag out of the kerf. The oxygen jet, therefore, has two functions: first, to establish an exothermic reaction, and second, to form the kerf by blowing the molten slag away. The oxy-arc cutting technique is suited to the cutting of ferritic steel, and with some restrictions is also suitable for fusion cutting of stainless steel, cast iron and non-ferrous metals. The fusion of materials which are not flame cuttable is achieved by means of the arc energy and the combustion heat which is released during the exothermal reaction of the mild steel electrode.

In the case of flame-cuttable materials, the oxygen is required to blow the slag and to oxidize the work piece and the mild-steel pipe electrode.

Underwater Use This cutting technique is mainly used for underwater applications. In contrast to flame cutting underwater, no additional shielding gas is required for oxy-arc cutting. In addition to manual operation, this process can also be automated.

Cut Thickness The most common work-piece thickness is from 5 to 40 mm. If the electrode is moved up and down, so that the kerf is produced in a sawing motion, thicker walls of more than 100 mm can be cut. The quality of the cut obtained, however, is by far inferior than that achieved with continuous feed. For stainless steel, a maximum cut thickness of 10 mm can be achieved with continuous motion. Here, cut thicknesses of over 100 mm are also possible by means of a sawing motion and a lower cutting speed.

Cutting characteristics. Operating speed for underwater cutting of mild steel is shown in **▶ Table 22** (not including the time for electrode replacement).

Consumable Electrode Oxygen Jet Cutting

In this case, an arc burns between the melting wire electrode and the work piece. A wire feed mechanism continuously feeds the cutting wire electrode to the torch. The electrical energy is transmitted from the power source by means of the current contact tip to the electrode. Generally, a mild-steel cutting wire is used, which is connected to the negative pole of a dc power source. The cutting wire diameter for cutting in atmosphere ranges between 1.6 and 2.0 mm.

The short-circuit arc is ignited at the top edge of the work piece when cutting is commenced and then moves down to the bottom edge of the cut. The arc is pressed downward by the magnetic blow-out of the work piece and furthermore by the mechanical pressure exerted by the inner gas jet with a pressure of approx. 0.4 MPa for atmospheric use. The arc then ignites

■ Table 22
Cutting speed for oxy-arc cutting (SOGIN-NIS)

Handling method	Cut thickness (mm)	Cutting speed (mm/min)
Manual handling	9	800
	25	450
	40	350
Mechanized handling	12	950
	40	600
	100	250

again at the top edge of the work piece, thus the process becomes periodical. The oxygen jet blows the wire and work piece material, which are both either molten or burnt, out of the kerf.

In the case of flame cuttable materials, an exothermal combustion process may occur, in which – similar to the oxidation process of the cutting wire – additional heat is released. This technique can also be used for cutting any electrically conductive material, which is not flame-cuttable.

The shape of the torch resembles pistols designed for welding in atmosphere. It usually has two concentric oxygen jets for cutting tasks carried out in atmosphere. The inner jet blows out the molten products and thus forms the kerf. The outer envelopment of shielding gas has a lower flow rate and prevents environmental gases from reaching the inner jet.

Underwater Use The consumable electrode oxygen jet cutting technique has also been developed for underwater applications. The cutting current is higher than for cutting in atmosphere in order to compensate for the heat transfer to the surrounding water. However, the achieved cutting speed is lower. Compared to the consumable electrode water jet cutting technique, the water jet, which is used for blowing the molten material out of the kerf, is substituted by an oxygen jet. In order to prevent the wire from premature oxidation, the mild-steel cutting wire has to be shielded from oxygen.

Cut Thickness The maximum cut thickness for the manual cutting of stainless steel in atmosphere as well as for the automated cutting of mild steel underwater is 90–100 mm (see [▶ Table 23](#)).

Consumable Electrode Water Jet Cutting

The consumable electrode water jet cutting technique is a further development of the consumable electrode oxygen jet cutting technique in atmosphere. It is a pure fusion cutting process, by means of which any metallic, i.e., electrically conductive material, can be cut.

This technique has been used exclusively for automated handling underwater. In contrast to consumable electrode oxygen jet cutting, oxidation of the work piece can be omitted. Substantially higher electric power outputs are required, since greater heat losses occur due to the water jet. The process is much more reliable than consumable electrode oxygen jet cutting, because the cutting wire is not liable to premature oxidation in the torch.

The principal cutting process and the cutting torch resemble those used in mechanical consumable electrode oxygen jet cutting underwater. In both processes, a cutting wire is continuously fed to the torch. The wire feed rate can reach up to 30 m/min. Stainless and mild-steel wires, as well as aluminum wires, are used as consumable electrodes. The best cutting performance can be achieved with mild-steel wire, the best quality of cut with stainless steel wire. The

■ **Table 23**

Cutting speed for consumable electrode oxygen jet cutting (SOGIN-NIS)

Cut thickness (mm)	Cutting speed (mm/min)
30	200
50	95
90	40

water jet, which surrounds the cutting wire, has a pressure of up to 2 MPa and blows the molten products out of the kerf.

An advantage of this technique is the proved possibility of cutting single pipes, tubes or bundles of these. Cutting is achieved by moving the torch and the cutting wire in a slow transverse motion across the work piece. The arc ignites when the wire tangentially touches the pipe. As soon as the pipe's interior is reached, two parallel arcs occur, which cut the front wall and the rear wall when alternated simultaneously.

Cut Thickness The maximum cut thickness is 100 mm for stainless steel and 50 mm for mild steel.

Aerosol Emission Although no shielding gas is used in consumable electrode water jet cutting, hydrogen and oxygen are released during the process, due to the hydrolysis of water. The volume of gas generated is linearly proportional to the cutting current.

The emitted amount of dust ranges from 0.05 to 0.2 g/m, i.e., the emitted amount of dust is smaller than that for plasma arc cutting. A disadvantage is the formation of secondary waste, i.e., the additional wire material.

Cutting Characteristics Cutting speed for consumable electrode water jet cutting is shown in [▶ Table 24](#).

Contact Arc Metal Cutting

Contact-arc metal cutting is a material removing, electrothermal cutting process and belongs to the family of electro discharge processes. The principle is based on the thermal effect of irregularly occurring short-circuit arcs of high current intensity which act on the work piece. All metallic materials can be cut with this method, and, in addition, metallic composite materials, such as clad steel, and matrix composite materials containing nonmetals and minerals, e.g., fiber reinforced metals, can also be cut.

To an extent, reinforced concrete can also be cut. The equipment required for contact arc metal cutting is relatively simple, compared to other thermal cutting techniques, and this makes the process extremely robust and reliable.

The equipment consists of three main parts: the power supply, the electrode with a feed unit, and the flushing fluid supply. By means of a mechanical feed unit, the electrode is continuously moved towards the work piece, until they touch and a short-circuit occurs. The high energy

■ **Table 24**
Cutting speed for consumable electrode water jet cutting (SOGIN-NIS)

Material	Cut thickness (mm)	Cutting speed (mm/min)
Mild steel	10	2,700
	20	1,700
	40	300
Stainless steel	20	1,800
	40	1,000
	60	500
	100	135

density of the developing high-current arc leads to the rapid heating of the work piece. The material melts and evaporates, following a sudden expansion. In this way, the material is blown out of the developing kerf. The arc becomes longer and eventually breaks after having reached a critical voltage. Since the electrode is fed continuously, it touches the work piece again and the cutting process recommences, during the course of which the electrode is immersed into the kerf.

The process is supported by a permanently fed fluid, which in most cases is water, and which flushes the material out of the kerf. Additionally, this fluid functions as a cooling medium, which dissipates the heat of the electrode and thus increases its service life. Using this cutting technique, it is not only possible to cut plate-shaped work pieces, but also to traverse cavities such as those occurring in single pipes or bundles of pipes.

Underwater Use The contact arc metal cutting technique is used both in atmosphere and underwater. Because of the required cooling water and the considerable emission of gases and particles, underwater applications are preferred to atmospheric ones.

Cutting Speed The cutting speed depends on the melting temperature, the specific amount of heat and the latent fusion heat of the material to be cut. For cutting stainless steel and using a 100 kW power source, the maximum cutting speed ranges between 1,000 mm/min (20 mm cut thickness) and 30 mm/min (150 mm). Using two power sources in parallel, the cutting speed ranges between 400 mm/min (50 mm) and 25 mm/min (200 mm).

Cut Thickness The maximum cut thickness depends only on the design and the material of the electrode, since it is consumed during the process: 150 mm (stainless steel) and, with two power sources in parallel, 200 mm.

Aerosol Emission In contact-arc metal cutting underwater, secondary by-products are produced. Since pollution of the water is quite high, water filtration should be considered. Furthermore, aerosols are produced, which reach the atmosphere. In comparison to plasma-arc cutting, the particle concentration is less constant, but is higher if the duration of the cutting process is taken into account. For comparable sheet thickness, the particle concentration is comparable when cutting with contact-arc metal cutting, because the feed rate is essentially slower than in plasma arc cutting.

Electrical Discharge Machining

The basic principle of the electrical discharge machining technique (EDM) is similar to contact arc metal cutting. EDM is in widespread use in the tool manufacturing industry, e.g., for the production of forge tools. With simple modifications, this technique was further developed for the cutting of all electric conductive materials.

Instead of arc erosion as in contact arc metal cutting, EDM uses the spark erosion as its basic mechanism. In comparison to an arc, unsteadily and statistically distributed spark strikes somewhere between the electrode and work piece without generating a plasma column. This is why EDM, in fact, is not really an arc process.

For the initiation of the process, the electrode has to be positioned close to the work piece surface. The gap between the two parts has to be filled with an insulating fluid, i.e., the dielectric. Therefore, the process takes place under immersed conditions, e.g., under water or adequate such fluids as kerosene, less flammable hydrocarbons, alcohol, or glycol. Sometimes,

locally-sealed habitats have to be adapted to enclose the dielectric. This measure enables the dismantling of large structures in atmosphere. For underwater application, similar suction shrouds minimize the spread of contamination as well as the volume of the dielectric.

The cutting performance mainly depends on the cutting conditions in the gap, i.e., the quality of the dielectric, which itself is influenced by the removal of cutting by-products. Therefore, it is necessary to flush the dielectric in the area of the cutting process and, with this, to remove the debris from the gap. Therefore, hollow rod electrodes with internal jetting or thin electrode blades with external jetting, should be preferred.

Cutting Speed For cutting 76 mm stainless steel, a cutting speed of 0.6 mm/min can be achieved with a nonrotating electrode. The cutting speed may further be improved by means of additional motion, e.g., rotating, vibrating, or periodically withdrawing of the electrode.

Cut Thickness Similar to contact-arc metal cutting, the maximum cut thickness depends mainly on the design and the material of the electrodes.

Aerosol Emission The EDM technique produces particles with dimensions ranging from 0.4 to 1 μm . This requires fine mesh filters of up to 1 μm , implying a poor waste density.

Arc-Saw Cutting

The arc saw consists of a circular, toothless saw blade, which cuts any conductive metal. The actual cutting process resembles the contact arc metal cutting process. In contrast to the graphite electrodes of the contact arc metal cutting technique, the saw blade rotates much faster. The residues are not removed from the developing kerf by means of a water jet, but are taken away by the rotary motion of the blade.

Since the arc foot moves continuously, the quick rotation of the blade limits its wear and, furthermore, an even and constant wear over the complete circumference is achieved. The rotation also helps the cooling of the blade and hence increases its lifetime. The depth of cut is limited only by the blade diameter.

Underwater Use The arc-saw cutting technique is suited for applications underwater and in atmosphere. However, underwater cutting is preferred because of the reduced noise level, the effective saw blade cooling resulting in an extended blade life, the shorter arc and narrower kerf, and cutting debris retention in the water. As compared to cutting in atmosphere, the risk of additional arcs occurring at the two sides of the blade is reduced. Because of the restricted kerf size, however, the blade can get jammed when the edges of the cut cool down. The service life of the blade is longer, but the cutting speed is lower.

Cutting Speed The cutting speed decreases significantly with increasing thickness of the work piece from 150–480 mm/min at 80 mm steel to 20–100 mm/min for 250 mm steel.

Cut Thickness Up to now, a maximal cut thickness of 1,000 mm stainless steel was achieved with a 3,000 mm saw blade.

Consumable Electrode Water Jet Gouging

The consumable electrode water jet gouging technique is a further development of the consumable electrode water jet cutting technique. The equipment is similar and the actual erosive process generally corresponds to the basic cutting process.

In contrast to cutting, the torch is positioned at an angle of 30–45° to the work-piece surface. Currently, two possible techniques are available. Both have been developed exclusively for underwater use.

Initial tests on consumable electrode water jet gouging were carried out in Japan. These tests used mild steel with a 6–12 mm stainless steel coating and were carried out underwater.

A second possible application of the consumable electrode water jet gouging technique has been studied in Germany (IW, Hannover) since the late 1980s. Tests were carried out for the removal of material from activated surfaces. With this technique, layers up to 4 mm could be removed with a single operating cycle.

5.2.3 Plasma-Arc Processes

Thermal plasma is a highly heated gas or gaseous mixture which is conductive and consists of ions, electrons and neutral atoms or molecules. Mono-atomic gases such as argon and helium, poly-atomic gases such as nitrogen and hydrogen, and also mixtures of these or air can be used as plasma gases.

The plasma arc is constricted by means of a copper nozzle. The thermal and electric pinch effects are used to attain temperatures which are considerably higher than the temperatures obtained with the open arcs described in the section above. The maximum temperature in the inner plasma arc is approximately 20,000 K or more. There are two groups of plasma-arc processes:

- Those with a transferred arc (the arc strikes between the electrode and the work piece)
- Those with a nontransferred arc (the arc strikes between the electrode and the nozzle)

For practical applications, the transferred arc is used almost exclusively for cutting and eroding any conductive material. The nontransferred arc can cut any material, i.e., also nonconductive materials, but significantly less energy is transmitted to the work piece.

Plasma-Arc Cutting with Single Torch

Conventional plasma-arc cutting with a transferred arc is a pure fusion cutting process by means of which any conductive material can be cut. The plasma arc, with its high energy density, melts or partially evaporates the work piece. The high kinetic energy gas jet blows the molten material out of the kerf.

In cutting processes with direct current, the torch electrode forms the cathode and the work piece forms the anode. The amount of heat which is transferred to the work piece mainly consists of energy from the impacting electrons, the Joule effect and convection.

The following techniques can be grouped according to the plasma gas used:

- Argon-nitrogen-hydrogen technique. For this cutting technique, a mixture of argon, nitrogen and hydrogen is used as a plasma gas. Without an additional shielding gas, this variant is mainly used for cutting in atmosphere.
- Dual-flow technique. The dual-flow technique is a further development of the Ar/N₂/H₂ technique that is especially suited for underwater cutting. Here, the plasma arc is surrounded by a shielding gas, such as carbon dioxide or compressed air. As a result of this measure, the plasma arc is protected against the surrounding water, energy losses are decreased and the quality of cut for mild steel is increased.

- Compressed air technique. In this process, compressed air is used as a plasma gas. This technique is especially suited for cutting mild steel in atmosphere. For underwater use, an additional secondary gas, e.g., compressed air, will decrease energy losses.
- Water-injection-plasma-cutting (WIPC) technique. The special feature of this type of cutting torch is the nozzle, the upper part of which consists of copper. Between these two parts, a concentric water curtain with a low flow rate ($<21/\text{min}$) is sprinkled onto the plasma arc. This leads to a further contraction of the arc and thus to an increase in the energy density and in the temperature. In addition, a swirl ring at the cathode leads to a rotating motion of the plasma gas around the electrode, which stabilizes the plasma arc. For decommissioning purposes, modular cutting torches were developed for the remote-controlled replacement of worn parts by means of manipulators. Thus, those parts with the highest wear rate, i.e., the nozzle and the electrode, can be easily replaced and the torch can be adapted for individual cutting tasks. This also makes it possible to switch between straight and cranked cutting units. Such a unit must be as small as possible, since it is used for cutting confined, complex structures.

Cutting Characteristics The cutting speed and cut thickness which can be obtained mainly depend on the process variants being used (see  [Table 25](#)).

Cut Thickness Maximum cut obtainable in atmosphere is 170 mm deep for stainless steel, 150 mm for mild steel and 80 mm for aluminum. The cut obtainable underwater is 100 mm deep for mild steel and aluminum, and 100 mm for stainless steel.

Aerosol Emission Aerosol emissions can be reduced by a factor of up to 500 if the process is used underwater. For cutting processes in atmosphere, the formation of dust is greater for mild steel than for stainless steel due to the exothermal reaction. For the cutting process underwater, however, higher emission rates are produced for stainless steel sheets with thicknesses up to 60 mm. A greater water depth leads to a further reduction in the number of particles reaching the surface.

Plasma Compass Saw Cutting and Plasma Circular Saw Cutting

The plasma compass saw and the plasma circular saw have been developed for underwater cutting of work pieces with wall thickness of more than 100 mm, which cannot be flame cut. Both techniques are based on similar cutting principles.

The cutting process is based on miniature plasma torches, which are of such a small size that they can be immersed into the kerf.

With both techniques, kerf of any desired depth can be cut by repeated actions of the plasma-arc gouging process.

 **Table 25**
Cutting speed for plasma cutting (SOGIN-NIS)

Cut thickness (mm)	Cutting speed (mm/min)
10	3,500
20	1,800
40	1,100
80	600

This stands in contrast to the conventional plasma-arc cutting process, in which the plasma torch must be positioned outside of the kerf and in which the energy input in the direction of the work-piece thickness, i.e., in the direction of the plasma arc, is limited.

The torches are designed for use with argon as the plasma gas and are equipped with pointed tungsten electrodes. The cooling of the nozzles can be improved by circulating water, which escapes through bore holes in the nozzles. In addition, the water flushes the granulated material out of the kerf.

Plasma Compass Saw

The cutting process is started at the edge of the work piece or from a bore. A kerf is gouged over the whole cut thickness by moving the torch linearly in the direction of the sheet thickness. After turning the nozzle, the process is restarted in order to remove the material adjacent to the kerf. If a sufficiently wide kerf has been produced by repeated application of this process, the torch can be moved in the intended direction of cutting. The result is a discontinuous cutting process in the direction of cutting.

In order to avoid additional arcs, the torch is inserted into a shielding tube made of nonconductive ceramic. The nozzle bore is also inclined with regard to the torch/electrode axis.

Here, the entire torch is moved around its axis by means of an adjustment unit mounted on the head of the torch. Furthermore, oxygen or compressed air exiting from an additional bore directly adjacent to the nozzle bore with a pressure of 1 MPa can be introduced into the plasma arc.

Better erosion results are achieved with this method for both mild and stainless steel.

The rod torch can also be used for cutting pipes and tubes from the inside if they are inaccessible from the outside. The torch is inserted into the pipe, which is then cut while the torch makes a complete turn around its axis.

Cutting Characteristics For cutting thick work pieces, the cutting unit is elevated in the direction of the torch axis with a speed of 80–200 mm/min. With a single operation and the additional input of oxygen or compressed air, kerf depth of approximately 5 mm and kerf widths of approximately 10 mm can be achieved (mild steel as well as stainless steel).

Plasma Circular Saw

The plasma circular saw consists of several single torches which are arranged on the circumference of a circular saw disk. In contrast to plasma compass saw cutting, where the arc burns continuously, in plasma circular saw cutting each torch is ignited just before immersion into the work piece and ceases burning when it leaves the kerf.

Plasma cutting with an immersed torch offers the advantage of cutting single pipes and bundles of pipes, since the arc jumps over from one pipe wall to another.

Since the torches have to be continuously re-ignited, the service life of worn parts is reduced because the arc ignition process represents the highest stress.

Cutting Speed For cutting 300 mm stainless steel, the plasma circular saw reaches a cutting speed of 1.3 mm/min.

Cut Thickness For this technique, the maximum cut thickness only depends on the diameter of the disk. A recent circular saw has a disk diameter of 1,000 mm for maximal cut thickness of 300 mm.

Plasma-Arc Gouging

The plasma torch for gouging resembles the one used for plasma-arc cutting. After being pre-heated, the molten work piece material has to be blown out of the kerf by means of the kinetic energy of the plasma gas.

In principle, this can be achieved with a slanted nozzle orifice or an inclined torch. In the case of a slanted nozzle orifice, the erosive process corresponds to the one described for plasma compass saw cutting.

The obtained erosion rates, however, are relatively small, because the nozzle wear increases due to the highly-energetic plasma arc and because the reduced size leads to a limited cutting performance.

In the case of an inclined torch, the nozzle orifice must be moved as closely as possible to the surface of the work piece. For this reason, the torch tip should have a conical shape. The nozzle diameter can be larger than for plasma cutting, since there is negligible constriction of the arc. The flow rate of the plasma gases should be increased proportionally to the cut depth, so that large amounts of molten material can be blown out.

In the case of plasma-arc gouging flame-cuttable mild steel, additional oxygen can be introduced into the area where the plasma jet leaves the torch. The oxygen then has two functions: it increases the kinetic energy used to blow out the molten products and it initiates the exothermal combustion of the work-piece material, thus generating additional process heat.

Cutting Characteristics In atmosphere, the gouging speed is approximately 1,800 mm/min. At considerably lower speeds, more gas is needed for blowing out the molten products.

5.2.4 Laser Cutting

A more recent technique applied to decommissioning is cutting by CO laser. Some information about the method developed by NUPEC is reported in  [Figs. 10](#) and  [11](#).

5.2.5 Combined Cutting Processes

Combined cutting processes have been developed with the aim of cutting mild-steel work pieces with very thick walls and with stainless steel plating. In this case, the total wall thickness of the work piece to be cut may exceed the maximum cut thickness which can be achieved with single-torch plasma-arc cutting and consumable electrode water jet cutting.

Flame cutting is usually selected for cutting thick flame-cuttable structures. However, in many cases it is difficult to use flame cutting torches exclusively since only the stainless steel liners are accessible for cutting.

The cutting principle of combination cutting processes is as follows: a fusion cutting torch gouges a kerf through the stainless steel liner, followed by a flame cutting torch which cuts the mild-steel walls.

Consumable Electrode Water Jet Gouging/Flame Cutting

This technique has so far been developed for cutting underwater only. The combined cutting process uses the consumable electrode water jet gouging torch as described in the subsequent section.

The maximum gouging speed is approximately 1,000 mm/min, with which kerf depths of 2 mm can be obtained.

The flame cutting torch is an underwater torch with a concentric water curtain. In order to cut mild-steel thicknesses of 300 mm or more, large cutting nozzles can be used at oxygen pressure ranging from 0.8 to 1.2 MPa. The heating flame is a gas mixture of propane and methylacetylene plus the burning oxygen. The overall weight of this system, including an actuator and a supporting plate, is 13 kg.

Cutting Characteristics It is possible to cut mild steel plated with up to 12 mm of stainless steel, with thicknesses up to 450 mm.

Plasma Arc Gouging/Flame Cutting

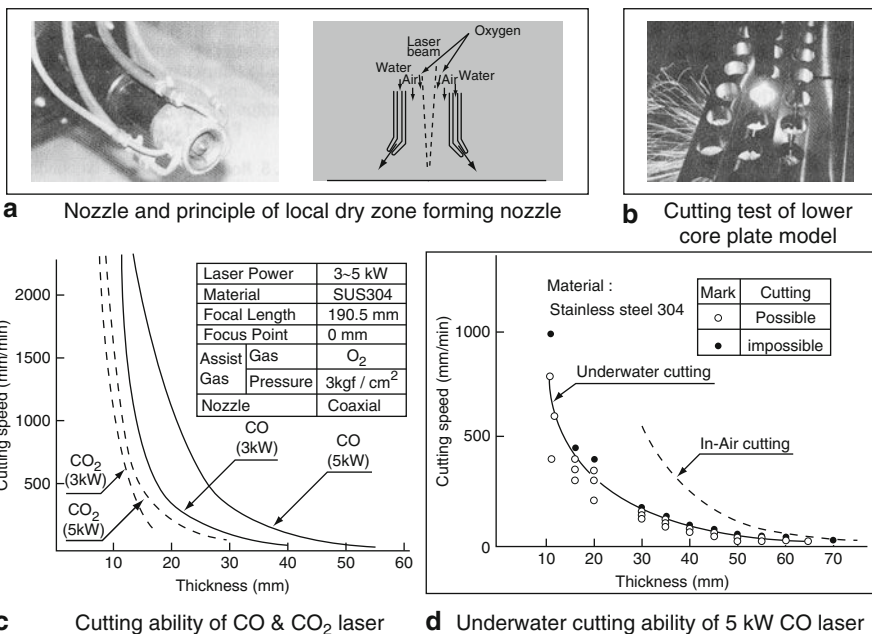

With this technique, the stainless steel cladding is gouged with a plasma-arc cutting torch, so that the following flame cutting torch can cut the uncovered mild steel. This combination cutting process has so far only been tested for atmospheric use. Nevertheless, cutting underwater may be possible, because single torches have already been tested for under-water use.

The arrangement of these two torches differs substantially from that used for consumable electrode water jet gouging/flame cutting. Here, the leading plasma torch produces molten material, the heat of which supports the preheating of the work piece for the flame cutting process. To achieve this, the torches are inclined in the direction of cutting. A commercial Ar/H₂ plasma torch is used for a successful ignition.

A specific characterization of this combined technique reported by NUPEC is shown in

► Fig. 12.

Cutting Characteristics The maximum cut thickness is 610 mm, with the exception of horizontal cutting, where only 310 mm can be achieved.

5.3 Hydraulic Cutting Techniques

Typical operations that can be carried out by water jets are cleaning, cutting, drilling, milling, marking and excavation. Plain water jets are typically used for nonmetallic and nonceramic materials, while abrasive water jets are used for materials of great hardness, strength or toughness. The main advantages of these water jet processes (with or without abrasives) are the following:

- Cutting can take place in atmosphere as well as underwater.
- Virtually any material can be machined.
- The process neither needs nor generates thermal energy, so that there are no thermal influences which could change the material properties by means of a heat-affected zone.
- Jet reaction forces are lower as compared to mechanical cutting techniques. Thus, manipulation by robots or mullet-axis handling devices is easier and more accurate.
- The jet is a precise noncontacting tool which can cut in all directions (omnidirectional) and does not deform the material during cutting.
- With a jet of a suitable diameter, small kerf widths can be achieved.
- The amounts of dust and aerosols emitted are negligible.

The main principle of both plain water jet and abrasive water jet cutting technology is to use a high-speed stream of water. The essential difference lies in the addition of an abrasive to the water jet. This addition increases the erosive action of the water jet, expanding the range of materials that can be cut. The jet cuts when its loading exceeds the strength of the material.

d Step of selecting combination cutting conditions

■ Figure 12

Arc gouging and gas cutting method (G&G method) adopted by NUPEC (Ishigure et al. 1992)

Depending on the properties of the material, the cutting is the result of erosion, shearing, or failure under rapidly changing, localized stress fields. The abrasive water jet has a more powerful compressive strength than the plain water jet.

For cutting purposes, the plain water jet or the abrasive water jet passes through the material and produces a complete cut. A special catcher is needed below the work piece, to receive the

high pressure stream. In the case of abrasive water jet cutting, it is also useful to collect the used abrasives in order to treat them as waste or to reprocess them for further use in cutting processes.

5.3.1 High Pressure Water Jet Cutting

Cutting with plain water jets is based on the erosion effect of high speed water droplets. For manufacturing processes, water jet cutting is used to cut different kinds of nonmetallic materials like plastics, paper, textiles or food. For these applications, high pressures (up to 400 MPa) are used, with small water flow rates.

Plain water jets are widely used for the cutting of concrete. For these jobs, moderate pressures (up to 100 MPa; some designs have been developed for 270 MPa operation) are normally used. In order to reach sufficient cleaning or cutting performances, the water flow rates are much higher than for high pressure water jets (50–100 l/min).

For plain water jets, the treatment of the waste is quite easy. After cutting, the suspended particles in the water (from the jet) and the removed material can be separated by sedimentation or filtration techniques. The water can be reused for cutting purposes: for moderate pressure systems (piston pumps), a simple filtration of particles up to a diameter of some μm is sufficient. When using an intensifier pump, deionization may be necessary.

Underwater Use In general, plain water jets can be used in atmosphere as well as underwater. Nevertheless, the maximum length of the jet underwater is much shorter than in atmosphere, because of the increased friction with the ambient medium.

Cutting Characteristics Both kinds of plain water jets are well established in the manufacturing industry and in civil engineering. They are used to cut nonmetallic materials, to remove debris, paint and surface layers and to clean concrete. The high pressure water jet is not able to machine metallic materials in an economical way: the cutting speed for 1 mm-thick aluminum plates is less than 100 mm/min, for 1 mm steel plates less than 10 mm/min. Much thicker plates are impossible to cut because of the instability of the jets.

5.3.2 Abrasive Water Jet Cutting

The abrasive water jet cutting technique is based on the application of plain water jets for cutting purposes. Abrasive particles are accelerated by the high speed water jet and cause the removal of the material. Instead of an erosion process as in the case of plain water jets, abrasive water jets cut by micro-chipping the material with the sharp-edged particles.

When using the correct abrasive material, which has to be harder than the work-piece material, any material can be cut, metals as well as ceramics, glass and concrete.

With abrasive water jets, severance cutting, as well as gouging, is possible.

To generate abrasive water jets, two different methods are currently available. The abrasive can be added to a plain water jet in a special mixing head (injection jet), or a premixed and pressurized abrasive water suspension can be released into the nozzle to form the abrasive jet (suspension jet). Sharp-edged mineral particles such as silicon sand, corundum or garnet sand are used as abrasives.

The increasing number of cutting applications has helped the abrasive water suspension jet (AWSJ) to become more important, despite the high consumption of water and abrasives.

■ **Table 26**
Cutting speed for abrasive water jet cutting (SOGIN-NIS)

Material	Cut thickness (mm)	Cutting speed (mm/min)	
		Injection jet	Suspension jet
Stainless steel	2	2,000	1,200
	10	350	250
	40	90	70
Concrete	100	30	25
	100	200	200
	300	–	25

Cutting Characteristics Cutting speed values for abrasive jet cutting are shown in ► [Table 26](#).

Aerosol Emission For underwater applications, the quantity of aerosols is reduced by a factor of about 200 as compared to applications in atmosphere. Gouging generates 3–4 times more aerosols than severance cutting, whether the operation takes place in atmosphere or underwater.

For both kinds of jets – suspension jets and injection jets – possible applications for decommissioning nuclear facilities have been investigated. ► [Table 27](#) presents a comparison between cutting parameters for aluminum and stainless steel with suspension and injection jets. The cutting performance for nonreinforced concrete is about six times higher than for steel.

5.4 Mechanical Dismantling Techniques

5.4.1 Grinder

This is an electrically, hydraulically or pneumatically powered disc made of resin-bonded particles of aluminum oxide or silicon carbide. Usually the wheel is reinforced with fiberglass matting for strength.

It cuts through the work piece by grinding the metal away, leaving a clear kerf. Grinding cutters can be used to segment all types of materials (e.g., metals and concrete or reinforced concrete) both in air and underwater.

The maximum thickness of the metallic components that can be cut with this method is limited to 150 mm, but the shape and diameter are not limiting factors. However, grinders used at dismantling sites are not suitable for cutting stainless or mild steel plates thicker than 30 mm.

The abrasive process generates a continuous stream of sparks. Contamination control is a significant problem, since the swarf comes off in very small particles. To limit the spread of contamination, grinders may be fitted with a swarf-containment system.

In most cases the operator would have to work within a contamination control envelope and would have to wear protective clothing and respiratory protection.

Experience in the use of such equipment is widespread both in conventional industry as well as in the nuclear industry.

Some useful information on the use of grinders is the following:

Table 27
Cutting data for injection and suspension jets (SOGIN-NIS)

Material	Abrasive water injection jet						Abrasive water suspension jet

Cutting efficiency ^a (mm ² /kW min)	610	45	308	58	169	263	429	260	137	

^a Cutting efficiency --- cutting performance/hydraulic jet power

- Disc wear increases in proportion to the thickness of the material being cut. For example, a thickness of 30 mm causes nine times as much disc wear as a 10-mm thickness
- For equal thickness of the work piece, disc wear is greater when cutting stainless steel than when cutting mild steel
- The quantity of aerosol produced reduces as the linear speed of the disc increases. This quantity is halved when the speed is increased by 3 and this applies to all types of steel (stainless, mild steel)
- In comparison to the total quantity of secondary emissions, the proportion of dross deposited increases proportionately the thickness being cut.

5.4.2 Hacksaw and Guillotine Saw

These tools are used to cut all types of metal pieces with a hardened reciprocating saw blade. Hundred millimeter is the maximum allowed thickness of metal when the running time is taken in account. The equipment can be used by remote operation, with the necessary adaptations, and it can also be used underwater.

Other characteristics are the following:

- These tools can be used as either portable or stationary units
- Portable power hacksaws weighing less than 10 kg and portable guillotine saws can be clamped with a chain to a pipe
- For both types of portable saw a pneumatic or electric motor may be used
- In general, blade lubrication is not necessary
- The control of the contamination produced by these types of tool is straightforward
- Set-up time for both types of portable saw is relatively short. Moreover, once in place the saws operate without any further action on the part of the operator, thus reducing occupational exposures
- These tools have low operating costs as well as a low initial price
- Reciprocating saws are also available and their use is widespread in both conventional and nuclear activities

Very large stationary hacksaws, weighing up to 5 mg, can be used effectively for large components, since they can cut metal up to 60 cm thick. Cutting speeds of about 100 cm²/min make these machines suitable for segmenting large quantities of material.

The provision of a large stationary hacksaw in decommissioning activities will reduce the costs and exposures associated with handling long sections of pipe, for instance. The decision on whether to use such a stationary facility depends on factors such as the cost of the equipment and labor, the amount of material to be cut, the activity levels on the pieces to be cut and the dose to operators.

Hacksaw The production of aerosols is relatively small compared to other mechanical cutting methods.

The swarf produced represents 99.9% of solid secondary waste. During pipe cutting, part of the swarf may be deposited inside the pipe and must be disposed accordingly. The hacksaw is unsuited to cutting more than 30-mm thick mild steel and is not recommended for cutting stainless steel at all.

Guillotine Saw The principle and characteristics of this saw are similar to those of the hacksaw, the difference being in the method of supporting the blade. Guillotine saws can cut pipes up to

more than 600 mm in diameter. For such large dimensions, the weight and bulk of the machine limit its use on-site.

5.4.3 Shears

Shears consist of a pair of blades arranged so as to exert a slicing force on the material to be cut. Both blades may be mounted on a common axis and operate like a pair of scissors or, alternatively, there may be one fixed blade with another parallel blade which approaches in a perpendicular movement, thus shearing the material to be cut. The latter type is more often used when the material thickness exceeds 1 mm.

Other characteristics are the following:

- Blade wear is not great in parallel-blade shears, where the blades have no direct contact
- Shears are used for cutting sheet steel, pipes, bars and concrete reinforcement bars
- The size of the shears and the power of the hydraulic or pneumatic motor working its jaws determine the cutting capacity
- In the case of a hydraulic motor, the command station can be at a distance from the shears
- Currently available shears can cut steel pipes up to 300 mm in diameter and with 30-mm wall thickness, and steel plates and bars of up to 6 mm thickness or diameter
- Shears are normally portable and can be easily adapted either for remote control or underwater use
- They produce very tiny amounts of dust or smoke

In cutting small-diameter pipes, the crushing effect of the cut closes the end of the tube in the form of two sealed lips. After the two ends of a tube have been cut by shears, the resulting length can be transported without dispersing any of the enclosed contamination into the surroundings. Easy to operate and involving little labor, they are suitable for cutting small-diameter pipes from reprocessing facilities and for use in hot cells.

When cutting highly contaminated materials, it is useful to have removable blades, as this part is generally the most contaminated part of the machine and must therefore be changed or effectively decontaminated.

5.4.4 Milling Cutters and Orbital Cutters

Both these types of tools cut by shaving the metal. The milling cutter consists of a wheel armed with blades which, in rotation, shave off metal particles and trace a continuous kerf in the material, until it is cut through. In orbital cutters a cutting tool is applied tangentially to the circumference of the piece being cut and, in rotating the tool and its holder around the piece, it shaves off the metal.

Such equipment can be used for cutting cylindrical objects, such as pipes, tanks, etc.

The cutting tool may need lubrication (related to cutting speed) and this requires a system for liquid recovery. In most cases, the tool holder is a saddle which moves around the surface of the piece being cut. The interior of the pipe being cut is only exposed on the last pass. The tool holder is guided either by rails or by a system of chains; its movement is achieved using either hydraulic, pneumatic or electric motors.

Of the two machines it is possible to observe that:

- They are widely used in conventional industry
- The initial price and running costs are low

- It is virtually not possible to use them in remote control, owing to their weight
- Large capacity machines are often automatic
- Both machines can work under water

Performances These machines can cut only metallic circular objects whose diameters are between 0.15 and 6 m. The orbital cutter can shave off up to 2 mm per pass in mild steel and can cut a thickness of several centimeters in a number of passes.

A complete cutting operation (setting up, cutting and removal) for a 1,600-mm diameter pipe with a 25-mm wall thickness takes about 1 h. In fact, the actual cutting time is a relatively small part of the total when setting up, removing, retrieval of secondary wastes, cleaning and decontamination are taken into account.

Both of these tools produce practically no aerosols and the resulting shavings are easy to retrieve. As the inside of the pipe or tank is open to the outside air only during the machine's last pass, dispersion of the internal contamination is easier to control.

Large-diameter, thick-walled pipes are particularly suited for cutting by these machines. Their use is made more complex when liquids are required to cool the kerf and it is necessary to recuperate the liquids. These machines are usable on-site, but handling equipment must be available and suitable for their weight and bulk, the larger machines weighing several hundred kilograms.

5.4.5 Knurl Tube Cutter

The knurl tube cutter (rotary disk knife, or cutting wheel, or plumber's pipe cutter) is a circular machine that consists of several wheels which turn whilst pressing against the internal or external surface of the cylindrical piece to be cut. One (or two) of these wheels, called the knurling wheel, has a triangular section and its outside knife edge presses strongly against the metal, penetrating it progressively at each rotation. This causes plastic deformation on each side of the kerf until the tube is finally ruptured. The other wheels, which are normally bearing rollers, have no effect on the cut, except to burr its edges.

Based on traditional plumber's hand tools, powerful, large-capacity machines have now been developed which can be operated by remote control. Rotation is normally powered by an electric motor, while the pressure on the knurl wheel is usually provided hydraulically. These tube cutters can cut a wall thickness of up to 40 mm in stainless steel pipes with an external diameter of 350 mm. Rotational speeds are between 20 and 50 revolutions per minute and the force applied to the knurl wheel is from 1.5 to 5 mg. The cutting takes a few minutes and it is the installation and withdrawal of the equipment that is the time-consuming part of the operation, especially when working inside elbowed pipework.

The use of this procedure enables the machine to be used by remote control and also limits spread of internal contamination, since the tube is ruptured only on the last pass. There is very little secondary waste produced by this method of cutting, as there is no removal of metal, either by abrasion or shaving, only creep by plastic deformation. In addition, no cooling system is needed. Taking account of the need for peripheral equipment (transmission tubes or flexible shafts to power the rotation, electric motor for rotation, hydraulic compressor, etc.) and the time needed for setting up the equipment, interior pipe-cutting tools are seldom used. The exception is where access to the pipe concerned is difficult, either owing to lack of space or to the level of ambient radioactivity.

5.4.6 Diamond Saws and Cables

This technique involves the progressive opening of the desired kerf by scratching diamond particles against the material to be cut. The diamond dust is encrusted or glued on the saw blade or around the cable.

Both these tools are well suited to cut concrete and reinforced concrete and they can also cut steels and alloys of various metals.

One of the problems that may be encountered is kerf clogging. This explains, for example, the difficulties encountered when cutting light alloys where the penetration rate of the blade is so high that the swarf cannot be removed fast enough.

When large cuts are being made, the tools have to be cooled and this is normally done with water. This liquid, injected at the cutting face, prevents the dispersal of dust into the surrounding area. The liquid has to be recuperated and, if there is a risk of contamination, it must be decanted.

Compared to other methods of concrete cutting, diamond cutters produce little or no aerosols or fine unstable particles, and the secondary wastes from cutting are minimal and easily controlled.

The use of diamond saws (circular and cable) is one of the most suitable solutions for making openings in reinforced concrete walls and floors, or for dismantling complete structures, particularly when dispersion of contamination and conservation of the immediate environment are important factors.

Diamond Saws

Only circular saws have been used on nuclear dismantling sites. The largest saw made was developed for cutting concrete biological shields in power reactors and has a diameter of 2.5 m and can cut a 1 m thickness of reinforced concrete. The blade advance of this saw is 180 mm/min, giving a cutting yield of 10 m²/h. The blade has to be changed about once every 200 m², that is about once every 20 h of operation. This tool weighs 2.5 tons, which involves the use of manipulation and guidance equipment which are adapted as necessary to the prevailing conditions in the work zone. Saws of all diameters can be purchased readily and may be portable or operated by remote control.

It is vital that the saw blade be kept aligned in its cutting plane at all times during a cut. Otherwise, the saw blade may become jammed, or break or, less seriously, the kerf may become enlarged, leading to excess production of secondary waste. Diamond saws produce little pollution and are well suited to cutting concrete. They are good for breaching concrete walls, floors and ceilings at competitive costs and with a minimum of harmful effects. Setting them up becomes more difficult when cutting a thickness of more than 30 cm, because the weight and bulk of the machines then require special adaptations to the manipulation and guidance equipment.

Diamond Cables

Diamond cables offer all the advantages of circular saws and enable greater thicknesses to be cut through. One of the disadvantages of using cables is that it is often necessary to bore holes in order to pass the cable in a loop around the piece to be cut. However, an advantage of cables is that the motor driving the loop and its tensioning devices can be placed outside the immediate work area. There are, thus, practically no difficulties which arise from manipulation or lack of space.

The technique of cable cutting is very widespread in conventional industry and is capable of cutting cleanly and precisely with minimal effects on the surroundings, e.g., shocks, vibrations, noise, sparks and dust, and with reduced production of secondary wastes.

5.5 Conclusions

In general, the techniques of thermal cutting are very efficient. They can cut very thick steel, are easy to use and can be carefully employed under water. On the other hand, their use generates gas, fumes and aerosols that require the installation of filtration and ventilation systems, which in turn increase the cost of cutting.

Mechanical means of cutting are particularly adapted to cut small-diameter pipes or thin sheet metals. They generate negligible aerosols. Most of them can be remotely operated, provided that the remote equipment can withstand the forces incurred in the cutting process.

Mechanical cutting under water often poses difficult problems. Many means and cutting tools are already available to meet the needs of nuclear facility decommissioning. It is necessary to compare the different tools used for underwater cutting, on the basis of several criteria such as speed, handling, kerf, and production of secondary wastes.

The main features, which are important for a comparison or judgment with regard to the special requirements of decommissioning tasks, are as follows:

- The cuttable material
- The maximal cut thickness
- The environment (whether applications in air and/or under water are feasible)
- The feasibility of remote controlled operation of the required cutting tools
- The relative cost, including the cost of equipment, consumable costs, and labor costs
- The state of development concerning the decommissioning of nuclear installations

In [Table 28](#) all the above-mentioned thermal and hydraulic cutting techniques are compared; “excellent relative cost” means low cost and “poor relative cost” stands for high cost.

■ **Table 28**

Tool comparison

	Hacksaw	Plasma torch	Grinder	Arc saw	Air saw
Required power	+++	+	+++	+	+
Cutting speed	+	+++	+	++	++
Kerf coefficient	+++	+++	+++	+	+
Wear coefficient	+++	+++	+	+	++
Secondary waste	+++	+++	+++	+	+
Aerosols	+++	+++	+	+	+

Concerning the state of development, “no application” means that currently no information regarding applications of this technique concerning the decommissioning of nuclear facilities is available. ➤ [Table 29](#) shows a comparison of mechanical dismantling tools. ➤ [Table 30](#) shows a comparison of the secondary waste quantities of different cutting techniques.

6 Remote Control Techniques

6.1 Basis of Remote Operation

6.1.1 Overview

In certain situations it is not acceptable for workers to perform a task. For example, when a work area contains a hazardous environment, such as a high radiation field or a mercury-contaminated atmosphere, human presence should be adequately limited to maintain safe operating conditions. For a manually operated system, limiting human presence means limiting operating time and productivity. Therefore, it is often desirable to provide equipment that can be operated from outside the hazardous environment to overcome these limits. This is the primary reason for using remotely operated equipment; some other reasons include further productivity improvement, utilization of facility resources, cost reduction, and access to hard-to-reach work areas.

In decommissioning projects where remote equipment would enter hazardous environments, it is important to remember that the equipment should be kept simple or be tried out under a variety of similar circumstances. This is done to ensure the success of the equipment and to prevent time, effort, and exposure to hazardous environments caused by retrieving and substituting a failed piece of remotely operated equipment.

This section describes the remote technologies that can be used in decommissioning in areas that are inaccessible or are unsafe for occupancy. ➤ [Section 6.1](#) explains why remote technology should be considered in a decommissioning project, and ➤ [Sect. 6.2](#) describes what can be operated remotely. The configurations of remote systems are detailed in ➤ [Sect. 6.3](#), and applications of remote techniques in decommissioning projects are discussed in ➤ [Sect. 6.4](#).

6.1.2 Safety Enhancement

Because the areas of the primary circuit are highly radioactive, workers who enter these fields can receive their legal quarterly dose limit in only a few minutes of work on the equipment, so more workers are required to complete each task. These labor- and exposure-intensive activities adversely affect the goals of reducing worker exposure and lowering operating and maintenance costs. Remote equipment that can tolerate these high radiation fields while performing the required tasks are beneficial to reducing both cost and operator exposure.

6.1.3 Cost Reduction

The use of remotely operated equipment can result in cost reduction as well. The first example of cost reduction is the same as for reduction of personnel exposure. To perform a manual task

Table 29
Comparison of mechanical dismantling tools (SOGIN-NIS)

Cutting technique	Material	Maximum cut thickness	Environment	Remote operation feasibility	Relative cost	State of development
Flame cutting	Mild steel	No limit (>2,000 mm)	Air/uw	+	+	+
Powder injection flame cutting	All metals concrete	ss: 500 mm c: 1,000 mm	Air	o	o	+
Flame gouging	Mild steel	–	Air/uw	o	+	–
Oxygen lance cutting	All metals concrete	c: 2,000 mm	Air/uw	–	+	+
Oxy arc cutting	Mild steel (stainless steel)	ms: 150 mm ss: 12 mm	Air/uw	–	+	No application
Consumable electrode oxygen jet	Mild steel	160 mm	Air/uw	+	+	No application
Consumable electrode water jet cutting	All metals	ms: 50 mm ss: 100 mm	uw	+	o	o
Contact arc metal cutting	All metals	1,000 mm	Air/uw	+	o	+
Electrical discharge machining	All metals	–	Air/uw	o	o	o
Arc saw cutting	All metals	1,000 mm	Air/uw	o	–	+

Table 29 (continued)

Cutting technique	Material	Maximum cut thickness	Environment	Remote operation feasibility	Relative cost	State of development
Consumable electrode water jet gouging	All metals	–	uw	o	o	–
Plasma arc cutting	All metals	ms: 150 mm ss: 170 mm	Air/uw	+	o	+
Plasma compass saw cutting	All metals	–	uw	o	o	–
Plasma circular saw cutting	All metals	ss: 300 mm	uw	o	–	–
Plasma arc gouging	All metals	–	Air/uw	o	o	–
Consumable electrode water jet gouging/flame cutting	Mild steel clad with stainless steel	300 mm ms +8 mm ss	uw	o	o	o

Abrasive water jet cutting	All metals concrete	ss: 100 mm c: 300 mm	Air/uw	+	–	o

uw under water; c concrete; ss stainless steel; ms mild steel; al Aluminum; + excellent; o average; – poor

Table 30
Comparison of secondary waste quantities of different cutting techniques

Reagents and processes	Treatment procedures	Metallic materials					Comments
		Stainless steel	Carbon steel	Cu alloys	Inconel	Al alloys	
AP	Alkaline	Non corrosive	Mildly corrosive				Used as a pre-treatment in multi-step process; AP includes inhibitor and wetting agent, oxides Cr ⁺³ to Cr ⁺⁶
APAC	AP then rinse then ammonium citrate	Non corrosive, removes remaining corrosion film after AP	Highly corrosive; attacks base metals				AC attacks the corrosion film remaining after AP; corrosion to carbon steel; redeposition can be a significant problem
APACE	AP then rinse then ammonium citrate plus EDTA	Non corrosive	Attacks base metals				Addition of EDTA improves the process and prevents redeposition of contamination
AP Citrox	AP then rinse then mixture of citric and oxalic acids	Non corrosive	Non corrosive		Citrox removes corrosion film		Citrox step used to remove remaining residual MnO ₂

Table 30 (continued)

Reagents and processes	Treatment procedures	Metallic materials					Comments
		Stainless steel	Carbon steel	Cu alloys	Inconel	Al alloys	
APSul	AP then rinse then sulfamic acid	Non corrosive	Non corrosive		Non corrosive		Sulfamic acid step prevents formation of precipitates, thus preventing redeposition
APOX	AP then oxalic acid	Non corrosive	Corrosive				Oxalic acid used to remove remaining MnO ₂ corrosive film; potentially forms insoluble precipitate that redeposits and reduces effectiveness
Hydrochloric acid	One step with 100 g/l concentration in water	Corrosive	Corrosive	Non corrosive			Very aggressive process; corrosive to stainless and carbon steels
Oxalic acid	Generally, one step with 100 g/l concentration	Non corrosive		Attacks base metals			Effective for removing rust; reacts with steel to form highly insoluble ferrous oxalate precipitate

Nitric acid	One step with 100 g/l concentration in water	Non corrosive	Attacks base metals	Attacks base metals	Attacks base metals		Non corrosive	Addition of 0.1% hydrofluoric acid improves the DF
Sulfuric acid	One step with 100 g/l concentration in water	Highly corrosive	Highly corrosive					Highly corrosive
Oxalic peroxide	One step with 2 g/l oxalic acid and 5 g/l H ₂ O ₂	Non corrosive	Non corrosive	Non corrosive	Attacks base metals	Non corrosive	Non corrosive	Mainly used to remove uranium, uranium oxide, and plutonium films
Phosphoric acid	One step with 100 g/l H ₃ PO ₄ in water		Corrosive	Non corrosive	Non corrosive			May cause redeposition if left in system too long
Sulfamic acid	One step with 90 g/l sulfamic acid in water		Non corrosive	Non corrosive	Non corrosive		Non corrosive	Not as active as phosphoric acid but redeposition does not occur

in a high radiation field, many workers are required to avoid overdosing. Therefore, there are additional expenses associated with the number of workers employed for the high radiation tasks. In other words, since the remote equipment operating in the high radiation field replaces many human workers, the employment costs of those human workers are saved.

Another aspect of remote operations for cost reduction is accessibility. Remotely operated detection devices can be inserted into piping, and areas in the nuclear facility that are too small for human entry and work. The survey of the pipes may show that the pipes are not contaminated and can remain in the facility after decommissioning. This reduces the cost for removal of potentially contaminated materials as well as reducing the amount of material requiring disposal in a properly designed disposal facility.

6.1.4 Productivity Improvement

Because of the cumbersome nature of some protective clothing, worker efficiency can be greatly reduced. In addition, workers may need to participate in multiple rehearsals to train for a task before it is performed. Thus, the overhead to accomplish a task in an area with a hazard such as a high radiation field is very large. When remotely operated equipment can be used to accomplish the task, fewer workers are required. Even though the operator of a remote system will require training to be able to perform a given task effectively, the overall work-hour requirement is lower.

6.1.5 Utilization of Facility Resources

A facility to be decommissioned often already contains remote equipment. Such equipment can be used again in the decommissioning effort. For instance, remote-operated manipulators such as master-slave manipulators or electromechanical manipulators may be used to aid the decommissioning of the areas in which they are installed. Remotely operated cranes, fuel handling machines, and other equipment can be used in decommissioning as they were used during operation. Such possibilities should be extensively researched, because using the existing equipment reduces the overall cost.

6.1.6 Accessibility

Remote equipment can provide access to work locations that operators cannot physically enter. For example, it is virtually impossible for a human to survey the inside of a 10-in. diameter pipe to validate it for free release, to remove a contaminated component from its perch 25 ft. above a hot cell floor, or to remove abandoned materials from the bottom of a quarry overlain by 50 ft. of water.

6.1.7 Disadvantages of Remote Operation

A major disadvantage of remote operation is the fact that the operator, located at a distance from the work being performed, cannot provide immediate response to the task or its problems. Also,

a worker needs rehearsals with mock-ups of the work area. In most cases, manual operation, no matter how complex, does not require training and rehearsals to prepare for the task. However, for manual operation in a hostile environment, prior training and rehearsals for the task are essential.

6.2 Remote Operation Technologies

6.2.1 Overview

Most of the technologies described could be successfully converted for remote operation. The conversion activity must account for each system function performed by the manual operation and provide for a suitable operator interface at some remote location, with visual and electronic feedback from the work location to that remote location. Other factors to be considered, when preparing remote activities, include tool set-up and change-out, operating clearance for remote equipment, terrain conditions for mobile equipment, and material handling operations. In some cases, basic manual tools can be modified to benefit the remote system. For example, modification may include changing the grip to something an effector can grasp, using remote alignment and pinning methods, and using self-standing bails. Successful remote operation requires the operator to see the area in which the work is being performed and manipulate the equipment well enough to accomplish the required tasks.

The following sections describe the six major categories of remotely operated equipment, including detection, segmenting, decontamination, materials handling, sampling, and hand-held remote equipment.

6.2.2 Detection Equipment

Detection equipment, such as cameras or measuring equipment can be used for surveys and data gathering activities or can be combined with other remote equipment for real-time operator monitoring. It is important to note that, besides real-time monitoring, remote detection equipment can perform the important functions of gathering data for subsequent analysis, data that may not be readily gathered by human observation.

Cameras and Lights

Most remote operations rely on real-time visual feedback to an operator. This information is the main link between the operator and the remote operation being performed. Use of cameras and lights is essential to the success of a remote operation. Signals are transmitted to a receiver and visually displayed on large monitors for the operator's use.

With the use of a stereo camera system, data can be fed to stereo monitors, providing the operator with limited depth perception. A stereo camera system can also permit mapping of the panned areas or creation of a computer model that can be used in self-guided robots or virtual-reality system displays.

For other remote operations, a self-guided robot can be equipped with recording equipment as well as cameras and lights. In this situation, no real-time visual data-are needed; so after

the robot returns from its pre-programmed mission, the tapes are removed and examined in an “off-line” mode.

Other Detectors

Other detection equipment may be required for specialized tasks (e.g., using a radiation detector to determine the most radioactive material in an area so it can be removed first and using an infrared detection system to monitor areas where heat-sensitive materials or equipment are required for decommissioning activities). There are many other techniques that can be used in a remote application.

These applications may include measuring alpha, beta, gamma, or neutron radiation; checking floors for volatile organics and mercury; using infrared cameras to detect heat; using microphones and radios to detect sound; or taking temperature and humidity measurements.

6.2.3 Segmenting and Demolishing Equipment

Almost all of the segmenting equipment (i.e., cutting tools) are applicable for remote use; and many have been converted for remote operations, including circular saws, nibblers, arc saws, plasma arc cutters, reciprocating saws, laser cutters, friction saws, grinders, and rotary hammers. Converting some equipment to remote application is relatively easy.

For example, plasma arc cutters already have remotely operated cutting heads, so extending these to hostile environments is simple. Other cutting tools are designed specifically for manual operation, so special fixtures, equipment, or custom-designed tools are required for remote operation.

Heavy equipment, which is usually used for handling materials, is now being converted for remote operation.

Some remotely operated heavy equipment is exclusively used for segmenting. An example is remotely operated backhoes with a ram implement attachment, which are used for breaking concrete.

Other remote equipment that falls into this category includes nut running tools and impact wrenches. These are standard tools that have long been used with remote systems and can be applied to decommissioning activities where applicable.

6.2.4 Decontamination Equipment

Some of the decontamination techniques are suitable for remote operation, including processes such as scabbling, vacuuming, steam cleaning, and spraying. However, some techniques may be more difficult to adapt to remote use.

For example, a remotely positioned, vacuum bell, in situ cleaning device can be used to apply electropolishing electrolyte or other surface cleaning chemicals, but the system may have to be coupled to a bridge-mounted, remote-operated manipulator if the task is to decontaminate cladding in a hot cell.

Although the adaptation is made more difficult by situational complexities, it is still feasible.

As required tasks become increasingly complex, the functions to be combined become more numerous, inputs to the remote system increase, and remote operations become more difficult and sometimes impossible.

6.2.5 Material-Handling Equipment

Lifting, packaging, and removing materials generated in the decommissioning effort are some of the most important parts of the operation. Most facilities have an established material-handling system, and if it is still functional at the time of decommissioning, operating costs and potential procurement delays can be reduced. It also minimizes frustration at the end of the project, when it comes time to survey clean subcontractor equipment. Where facility-based material-handling equipment is not available or usable, equipment should be carefully selected to minimize recontamination of clean areas.

Materials that are generated during decommissioning can be lifted using grapples, clamshells, or specially designed tools mounted on a remote manipulator. In general, the lifting capacity of a remote manipulator is limited. Another limiting factor is the physical clearance available in the material-handling corridor. Existing operating systems that can aid in handling operations include automatic guided vehicles, palletizing robots, cranes, hoists, elevators, and conveyors.

6.2.6 Sampling Equipment

Mobile robots can be designed to take air samples, water samples, and soil/debris samples. Some robots also have drilling capabilities, so they can bore through concrete walls and extract samples from inside a structure. This technology has been best applied in disaster management, when the situation renders process knowledge useless and alters structural configurations by scattering debris and blocking normal passageways.

6.2.7 Hand-Held Equipment

Hand-held remote equipment usually takes advantage of the distance rule in limiting radiation doses to operators. This class of equipment is utilized when dose rate limits to operators are exceeded in contact situations, but where dose rates are manageable. Examples include long-reach extensions to power wrenches and long-reach hand-triggered grapples. Using a long-reach power wrench, an operator can, for example, reach down into a vault and loosen remote bolts associated with a dismantlement task. A long-reach hand-triggered grapple might be used to remove hot elements from a mist eliminator or to retrieve equipment that has fallen into an inaccessible location.

6.3 Remote-System Configurations

6.3.1 Overview

Remote systems can be designed and procured in a number of useful configurations. However, already existing facility-based remote handling equipment may be useful in decommissioning. This is particularly true when equipment was specifically designed to be used in hostile environments. If this equipment is still functional, its use in the decommissioning project may be appropriate, efficient, and cost-effective.

Most existing remotely operated cranes or other existing moving equipment can also be useful in the decommissioning. All existing remote equipment should be carefully considered in decommissioning planning to maximize its use because of the potential project benefits.

Newly installed equipment for remote operations could be used in the hostile environments. This equipment could be designed specifically for the project, or produced commercially for a wide variety of similar work.

Newly installed remotely operated equipment can cut or otherwise disassemble the material being removed and lift and transport it to an area for removal and packaging by other equipment. Such equipment can be designed to be easily decontaminated.

Mobile remotely operated units can move about a facility and perform decommissioning tasks where necessary, and then transport the removed material to a staging area for further processing or packaging for disposal. These units do not have to be custom-designed, because a large number of mobile remote systems are now being built for use in hazardous environments.

Remotely operated equipment consists of five units:

- Control station, which controls all movements and actions of the remote equipment
- Communication and power link, through which control signals and power are transferred to the remote equipment
- Supporting platform, from which the arm is mounted and all work is managed
- Arm of the remote equipment, which provides orientation and fine positioning of the tools
- Operating tool at the end of the arm, which performs the actual work involved, such as cutting

These five units are described in the following sections.

6.3.2 Control Stations

The control station monitors and directs all actions associated with the remote equipment, including manipulating the operating tool. The control station is located in a nonhostile environment from which either radio or hard-wired signals are transmitted to the support platform, arm, and operating tool. In addition to the operating controls, the control station may provide displays of the work area provided by cameras and detectors mounted on the support platform. Some systems do not provide displays. For example, automated data-gathering systems record optical data for off-line playback.

Teleoperator Control Stations

A teleoperator control station is where an operator takes real-time control decisions. These decisions may be directed towards manipulating or navigating the system. Very few of the operations are directed by automated support functions. Currently, two types of teleoperator control stations are most common: traditional control stations and advanced control stations. Virtual-reality systems are quickly evolving in the research sector, however, and are expected to be useful for this kind of work.

The traditional control station was developed in the 1940s and 1950s at the time teleoperator manipulators were being developed. The system consists of two master-slave manipulators positioned in front of a viewing window. Operations are restricted by the reach of the manipulators and the field of view provided by the window.

In advanced control stations, the operations are even more isolated than those in the traditional control station, because operators are seated in front of a control console. Feedback is received through monitors for visual display of computer-generated graphics for data display. Controls include power switches and joysticks for control of the operating tool. The operator makes operational decisions, but the computer may aid in controlling the remote operations. Operations are restricted by camera coverage, length of cable and length of manipulator mast.

Virtual-reality control stations currently provide information to the operator using computer animation. This technology is rapidly developing. Other researchers are using helmet-mounted optical displays to enhance further the virtual-reality effect.

Teleoperator Managed Stations

Teleoperator managed stations are very similar to advanced control stations, except that the computer controls most of the operations of the robot, and the operator monitors the progress and only intervenes at critical points to perform specialized tasks, make navigational corrections, or recover the system from unexpected encounters.

Automated Stations

Automated control stations are used in situations where all functions are known and unexpected or unanticipated interference is very unlikely. All the functions are computer-controlled, and operator adjustments require reprogramming. This type of system has limited applications in decommissioning programs.

6.3.3 Communication and Power Links

Communication links may be of two types: radio-controlled or hard-wired. For multi-terrain robots, radio control makes sense, because hard-wired communication links limit the distance the robot can travel and may affect its overall performance, and unexpected field conditions may result in the robot becoming trapped by its own hard-wired umbilical.

When remote equipment travels a prescribed path only, hard-wire technology makes sense. These systems include cranes, hoists, bridge-mounted manipulators, and some inspection robots. Stationary systems like master-slave manipulators, wall- and pedestal-mounted electromechanical manipulators, and industrial robots are inherently hard-wired. The hard wiring can be one of several different methods or even a combination of methods. These methods include bus bar, festoon, umbilical, and flat cable systems.

The only control system that does not require a communication link is the automated station. The automated station can have all control functions located onboard. However, if the environment in which the robot operates is sufficiently hazardous, it may be wise to locate the controller in a safe environment and to establish a communication link to the robot.

Typically, radio-control units use onboard batteries, engines, or fuel cells as a power source. Hard-wired control systems usually use a hard-wire technology to provide power to the remote.

6.3.4 Support Platforms

The support platform is the base from which all remote activities are carried out. The platform includes all auxiliaries and housekeeping equipment required to keep the remote operation

functioning in a hazardous environment. Among the items required on the platform are the hardware (to transmit power from the source to the tool), monitoring devices (to control movements of the tool), and any onboard equipment for movement. There are two classes of support platforms: stationary and mobile.

Stationary platforms cannot move and must be placed in position by other equipment. Examples of this kind of remote equipment are platforms for cutting up a single component, from small tanks to large reactor internals. The platforms typically have the tools extending in only one direction from the platform, either completely above or completely below the platform.

Unlike stationary platforms, most of the equipment installed on a mobile platform is dedicated to performing the navigation and movement of the platform. Under the direction of the operator, the mobile platform moves from the vicinity of the control station into the hostile environment to perform the decommissioning task.

6.3.5 Arms

The arms of a remote system provide positioning and orientation of the end effector or tool in relationship to the work. Three different classes of arms include existing equipment, robots, and specially systems.

Existing Equipment

Existing equipment sometimes includes remotely operated cranes, master-slave manipulators, and electromechanical manipulators. They would only be used in facilities where this equipment is available and in operational order. Given the selection of current robotic and mobile equipment, there is very little reason to install this type of fixed equipment for a decommissioning project.

Robots

A robot can be defined as a re-programable, multifunctional manipulator designed to move materials, parts, tools, or specialized devices through variable program motions. Emphasis is placed on the reprogramable and program portions of the above definition. These types of robots pertinent to decommissioning include the following:

- Automated or flexible manufacturing robots: these “industrial” robots are employed in a wide range of manufacturing processes, including assembly and inspection, material handling, welding, and material painting
- Remote-exploration robots: this type of robot is designed to survive in environments that humans cannot tolerate (remote-exploration robots to examine tank interiors, cooling tower basins, larger service piping, and sewers)
- Hazardous material handling robots: robots of this type have been employed to remove bombs and handle hazardous materials and are similar to the other two, but usually incorporate a cargo hold in their configuration, which may be armored or have a criticality-safe geometry

The geometrical configuration of robot arms usually falls into one of the following categories:

- Cartesian (rectangular)
- Cylindrical
- Spherical (polar)
- Revolute (articulated)
- Tensor-arm (snakelike)

The cartesian-geometry arm consists of three linear motions that correspond to the cartesian coordinate system designation: X, Y, and Z. This geometry can provide extremely accurate motions, provide easy joint motion controls, and possess good obstacle-avoidance characteristics.

These robot arms require large structural frameworks and a large floor space in which to operate. They are usually more mechanically complex than other systems, because of the linear sliding motion of the joints.

The cylindrical-geometry arm consists of two linear motions and a rotary-type motion. The two-linear-axis design makes the mechanical system less complex than in the cartesian-geometry configuration. The arm has good joint motion control and collision-free movement. It is less accurate compared to the cartesian geometry, yet requires a large support structure.

The spherical-geometry arm consists of two rotary motions and a single sliding (telescopic) motion.

This geometry provides the lightest-weight construction and minimizes structural complexity. It also provides short joint travel for each motion.

However, the system has limited ability to avoid collisions with workplace obstacles. Because of the two rotary motions, position errors can be comparatively large, and the arm can have counterbalance problems created by large and variable torque on the second and third joints.

The revolute geometry arm is a humanoid-type arm with redundant degrees of freedom. The arm has the flexibility to reach over or under workplace objects, but has limited obstacle-avoidance ability. It also usually has poor resolution and accuracy relative to positioning and can have counterbalance problems. This geometry has a high moment of inertia and is subject to gravity effects. Dynamic instability can be a problem.

The tensor-arm can take any shape in three-dimensional space. It is constructed from many sub-elements that can move with respect to their adjacent elements.

Speciality Systems

Remote speciality systems form a separate class of remote equipment. Typically, these systems are designed to perform one task, like removing fuel pin assemblies from the reactor core or closing a 50 tons shield door. Material-handling speciality systems are usually amenable for use in a decommissioning effort. When these systems are available, their use should be considered in the overall decommissioning plan.

6.3.6 End Effectors and Tools

The objective of the remote operation is to perform some decommissioning task. This task is ultimately accomplished by the tool that is attached to the remote unit. Almost any tool identified in this book can be incorporated into the remote unit. Specifically, all demolition tools

and mechanical decontamination tools, most chemical decontamination tools, and some waste treatment techniques can be incorporated into the remote equipment.

In addition to the tools that have been previously described, manipulator systems can be designed with end effectors (grippers). Some systems allow these effectors to be “changed out” during the operation, to provide flexibility of use in the system.

6.4 Illustrative Experiences with Remote Applications

The following sections present examples of remote applications to decommissioning projects. The examples cover detection equipment, segmenting equipment, decontamination equipment, material-handling equipment, sampling equipment, hand-held equipment, and miscellaneous equipment.

6.4.1 Detection Equipment

Five projects that use remote detection equipment under circumstances that prohibit human entry are described in the following paragraphs. These projects are at the Idaho National Engineering Laboratory (INEL), SRS, French nuclear program, Nine Mile Point Nuclear Station, and Shoreham Nuclear Power Station.

INEL High-Level Waste Tank Farm Project The new high-level waste tank farm at INEL, which currently is under design, includes provisions for remote operations, including robotic inspection of the tanks’ interiors and exteriors.

The primary method of inspection is visual to detect slow seepage in the tanks. If seepage is detected during the visual inspection, additional inspections are performed remotely using an ultrasonic transducer.

Remote Radioactive Waste Drum Inspection (SRS) SRS is committed to reducing potential personnel exposure to radiation in its programs. Currently, large numbers of drums containing dry radioactively contaminated waste are stored at various sites awaiting final processing. These drums must be inspected as part of routine site operations and in compliance with federal regulations. An autonomous mobile robot is being developed to perform remote surveillance and inspection of these drums. The robot will be self-guided through narrow storage aisles and will record the visual image of each viewable drum for subsequent off-line analysis and filing.

Robotic Devices for Pipe Inspection Electricité de France has designed and developed remote devices that allow televisual inspection of the insides of water and steam lines. One of the systems developed is a small tracked vehicle, equipped with an onboard television camera, floodlights, and an umbilical data link and power system. The second system developed is a push-pull system that provides repair services to sections of the lines requiring maintenance.

Mobile Surveillance System The Surveyor Mobile Surveillance System, a remotely operated vehicle at Niagara Mohawk Power Corporation’s Nine Mile Point Nuclear Power Station, measures radiation, temperature, and relative humidity. It also provides optical inspection capabilities.

Shoreham nuclear power station termination survey The Shoreham Nuclear Power Station contains more than 8,000 ft. of embedded pipe ranging in diameter from 1 to 12 in. Some of the runs were in excess of 60 ft. in length.

The pipe was believed to meet the release criteria. A technique was developed to survey the lines in place to demonstrate compliance with the release criteria, rather than trying to cut the lines out of the concrete.

Two fixtures were made, one for lines with inside diameters of 3 in. or more and the other for 1.5- and 2-in. lines. The larger fixture consisted of six GM “pancake” probes and a television camera mounted onto a carriage to facilitate in-line transport. The detector for the smaller probe was a thin-end window GM tube. The television inspection and radiation measurements were done separately for the smaller lines, because doing them simultaneously was found to cause delays. The detector packages were pulled into and out of the lines by cable, since both ends of each piece of embedded pipe were made accessible. For the longer pipes the detector package was inserted once from each end, to enable it to measure the full embedded length.

6.4.2 Sampling Equipment

At the containment structure Sarcophagus at the fourth unit of the Chernobyl Nuclear Power Station, pairs of robots are used to gather sampling data. The first robot, equipped with a video camera, observes the motion of the second, which carries the main equipment. The first robot remains stationary until the second robot travels a certain distance, and at this time, the observation robot proceeds further. The robots continue in this way to the intended destination, while they are continuously observed and controlled by an operator. The second robot drills boreholes and collects samples under concrete and rubble up to 600 mm deep. This robot is equipped with a special electromechanical system that includes a drill bit, bore extensions, a servo mechanism for rotational or impact drilling, a bore extension feed mechanism with automatic drill pressure support, and a special plastic tube designed to accept and store core samples.

6.4.3 Hand-Held Equipment

Chernobyl’s Sarcophagus was completed in November 1986. An isolation and recovery program was commissioned a year later, and its emphasis was on locating and characterizing the site’s fuel. Bore holes were established to accommodate special inspection periscopes, photographic and video cameras, thermography equipment, and neutron and gamma detectors. These hand-held systems are of primary importance to cleanup at the Chernobyl plant.

6.4.4 Miscellaneous Equipment

The Shippingport Station Decommissioning Project provided access to the walls and superstructure of the Fuel Handling Building using a cherry-picker mounted on a bridge crane. The fuel handling canal occupied the main portion of the center of the building; and there was scarcely room to walk between the canal and the walls, so erecting scaffolding would have been difficult and time consuming. The fuel handling equipment was removed from the bridge and

a cherry-picker installed. In this configuration, workers were able to reach the entire inner surface of the building for the full length of the canal. Although the system was not entirely remotely operated, it provided an example of the variety of applications possible. Remotely operated systems, whether entirely or partially remote, help equipment to become more flexible for difficult tasks.

7 Spent-Fuel and Waste Management

7.1 Spent-Fuel Interim Storage

Depending on a number of conditions and considerations, two options are available for spent-fuel management: reprocessing and direct disposal; a third option (partitioning and transmutation, P&T) is today in an early R&D stage, and could be available in the future. A flow chart describing the two available strategies is shown in [▶ Fig. 13](#).

The disposal of spent fuel requires a first period of interim storage in the plant pool, a second period in interim dry storage and finally disposal in an adequate container.

Dry storage facilities were initially conceived as single-purpose facilities: buffer short-time (10–20 years) storage before transporting the spent fuel to reprocessing or final storage or interim centralized storage. Storage systems were not initially also qualified for transport off-site and, therefore, the spent fuel had to be transferred into transport casks at the time of off-site delivery.

Afterwards it became evident that it would be advantageous to avoid spent-fuel transfer from a storage system into a transport system at the time of its off-site delivery. This is because the transfer operation is always a complex operation, because there might not be enough space in the plant pool, or because the pool does not exist at all, since the plant has to undergo a decommissioning operation. Generally metallic casks are well suited for the double function (storage and transport), since they are mainly transport casks with additional design provisions

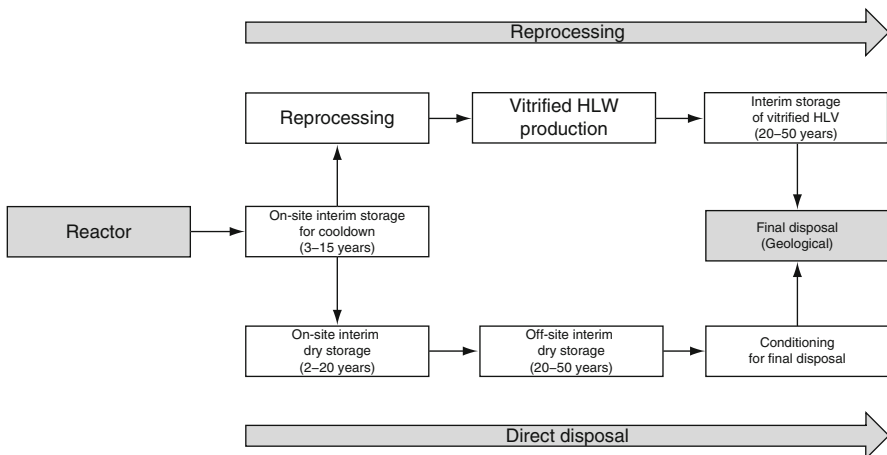

Figure 13
Spent fuel management alternative strategies

to enable them to remain in long-term storage. However, some other technologies have also developed special systems to allow off-site transport without transferring the spent fuel.

Recently in the USA, multipurpose systems have also been proposed, i.e., containers that would be qualified for on-site storage, transport, and final geological disposal. The qualification, of course, would require knowledge of the technical requirements of geological disposal and the acceptability of final disposal without spent-fuel conditioning. For these reasons, in Europe there is, at the moment, no container which is intended to be multipurpose.

At the same time, on-site storage periods became longer and longer, since both interim storage facilities and disposal sites were either not available or delayed (e.g., the case of the Yucca Mountain site for final disposal and the German case of Gorleben). Also for these reasons, the licenses have been requested for longer periods, up to 50 years. Moreover, there are research programs to check the limiting storage time for these systems, identifying the expected degradation in the storage components and in the spent fuel itself for up to 100 and even 300 years. The first results show that there are no strong indications of degradation for any components. It is therefore expected that in the future licensing for these systems can be extended.

7.1.1 Wet Interim Storage

For a long time, this was the only way to store the spent fuel of power reactors after their defueling. Each nuclear power plant with LWRs has a pool with different sizing criteria, but with at least enough space to store in adequate racks the spent fuel produced in 10 years of operation plus a full core in case of the need to completely defuel the reactor.

The water of the pool has both the function of removing the decay heat through cooling systems and of beta-gamma and neutron shielding. The shielding function requires a minimum depth of several meters.

In many cases, the need of spent fuel storing exceeds the former design values. This may happen mainly in relation to the difficulties experienced in most countries in sending the fuel to reprocessing or to a final disposal site. This need generally does not apply to a decommissioning phase, because at the time of the final shutdown, it is needed only to defuel an entire core and the lodgments in the racks that will always be available for an entire core. In addition, at an early stage of decommissioning, it is necessary to remove the spent fuel from the pool to proceed with dismantlement.

However, if an extension of wet storage capacity is needed, several alternatives are available, including:

- Recovery of spent-fuel pool capacity by removal of non-fuel items
- Re-racking (i.e., increasing the fuel-assembly density, with added poisons, in the racks)
- Rod consolidation
- Trans-shipping of spent fuel to another existing pool with free space available
- Construction of an additional spent-fuel storage pool

Pool Re-Racking

Subcriticality was originally maintained for LWR spent fuel (without credit to burnup) by spacing it in the storage racks or baskets. However, with the need to store greater quantities of fuel, higher storage density has been achieved by the introduction of neutron-absorbing materials in storage racks and baskets such as borated stainless steel or Boraflex. Re-racking has been often

considered the first choice and the least-cost alternative for expansion of at-reactor spent-fuel storage capacity. Some utilities have done so several times.

Adoption of neutron-absorbing materials increases rack costs and must be considered with care, taking account of existing operating experience. For example, some applications of Boraflex in existing racks have caused severe problems due to the contraction of such material under heavy irradiation and some consequential concerns have arisen about the maintenance of subcriticality calculated safety margins.

Long and very long wet storage is not really an issue for fuel and fuel cladding. Some zircaloy clad fuel has been wet-stored satisfactorily for over 40 years. In this case, care should be taken to maintain the required quality of the pool water.

Spent-Fuel Consolidation

Rod consolidation involves the disassembly of the intact fuel assembly (FA) by removing the fuel rods from the assembly hardware (shrouds, grids, etc.) and reconfiguring them in a metal storage container. Fuel-rod volume reduction of up to a factor of 2 has been achieved placing the rods from two FAs into a container not larger than a single assembly. After the fuel rods are removed, the non-fuel bearing components (i.e., end fittings and spacers) can be compacted and placed in a separate container. In the latter case, a volume reduction ratio of 6:1 can be accomplished.

Spent-fuel consolidation demonstration programs have been conducted in the US (Oconee, Main Yankee, West Valley, Battelle Columbus, Millstone 2, and Prairie Island), but no utility has yet proceeded with rod consolidation on a full-scale basis. Reasons for the lack of interest include:

- Need for license amendment to address criticality issues
- Seismic and structural analysis for the increased loads associated with storing consolidated fuel
- Thermal hydraulic analysis to demonstrate the capacity of the pool cooling system to provide adequate coolant flow to remove decay heat from the consolidated fuel canisters
- Increase of release of corrosion products (crud) during the consolidation operations, with consequent spent-fuel pool visibility problems and increase in duty and cost of pool water clean-up system
- Possible increase in worker exposure due to crud and failed fuel fission product release

Independent Wet Storage Pool

Independent, or away-from-reactor (AFR), pools are basically similar to at-reactor (AR) pools. They receive fuel from AR pools in either wet or dry transport canisters and store it in stationary racks or movable baskets.

A wet storage facility may have the following features:

- Cask reception, decontamination, unloading, maintenance, and dispatch
- Underwater spent-fuel storage (pool)
- Auxiliary services (radiation monitoring, water cooling and purification, solid radioactive waste handling, ventilation power supply, etc.)

Usually this solution is reasonable for large quantities of spent fuel (usually for many reactors) and in a situation where an intensive nuclear program is underway and will be maintained for

a long time. In addition, also in relation to the high operational costs, it is considered a rather short-term buffer system for more long-term solutions and/or for reprocessing. For example, there are AFR pools in all reprocessing plants.

7.1.2 Dry Interim Storage

Since the 1980s, the technologies of dry storing spent fuel, after an initial cool-down in a pool, have been gradually introduced for several applications.

This overview focuses on solutions already licensed and operated for storing spent nuclear fuel in an inert, dry environment. The feasibility of dry storage has been essentially demonstrated for all types of spent fuel. All types of storage concepts (metal casks, modular vaults, concrete casks, concrete silos and concrete canister-based storage systems) have exhibited good performances. The most significant concepts are outlined below.

Dry storage facilities can be AFR or at-reactor AR. Dry storage alternatives include:

- Metal casks
- Concrete casks
- Vaults
- Concrete modules

Metal Casks

Metal casks are massive containers used in the transport, storage and eventual disposal of spent fuel. The structural material for the metal casks may be forged steel, nodular cast iron, or a steel/lead sandwich structure. They are fitted with an internal basket or sealed metal canister, which provides structural strength and also assures subcriticality. Metal casks may have a single or a double lid, generally bolted. In any case, they have a double seal and the volume between the seals is monitored for leaks.

Metal casks are usually transferred directly from the fuel loading area to the storage site. Some metal casks are licensed for both storage and off-site transportation. Fuel is loaded vertically into the casks, which are usually stored in a vertical position. As an example, in [Fig. 14](#) and [Table 31](#) the main characteristics of the metal cask CASTOR 440/84 supplied by GNB are given.

In general, metal casks are expensive components. However, they provide the maximum flexibility, since, if they are licensed also for transport, they can be moved off-site without any further direct handling of the fuel and without leaving structures to be decommissioned. For limited quantities of fuel (e.g., up to 500 tons HM) they may also be economically advantageous. Another advantage is that they are highly modular and the supply may be adapted temporarily to the need. In the total cost, expenses for a storage building should be included.

Metal casks are used in a number of countries such as Germany, the USA, the Czech Republic, Switzerland, Spain and Italy. In Europe, most of the casks are licensed for both storage and transport. They are protected from all design accidents (air crash included), and can be stored indoors or outdoors. In the USA, casks are usually stored on a concrete pad in the open air. In most countries they are hosted in a dedicated building. A typical layout of these buildings is presented in [Fig. 15](#). Major functions of these buildings are to contribute to shielding and to enhance air circulation.

■ Figure 14
CASTOR 440/84 type metal cask (GNB)

Vaults

A vault (► Fig. 16) is an above- or below-ground reinforced concrete building containing arrays of storage cavities suitable for containment of a number of fuel units. Shielding is provided by the exterior structure. Heat removal is normally accomplished by forced or natural convection of air or gas over the exterior of the fuel-containing units or storage cavities, and subsequently exhausting this air directly to the outside atmosphere, or dissipating the heat via a secondary heat-removal system.

■ **Table 31**
CASTOR™-440/84 metal cask parameters

Max heat output	21 kW
Max enrichment	3.65%
Max burnup	42 GWd/tU
Typical cooling time	60 months
Cask length	4.080 mm
Cask diameter	2.660 mm
Wall thickness	370 mm
Cask body material	Ductile cast iron
Lid material	Stainless steel
Mass of transport configuration	131 tons

Typical features of the vaults are their modularity, which facilitates incremental capacity extension, separate shielding and containment functions, capability for containment monitoring, and a vertical fuel loading methodology.

Spent fuel is received (either dry or wet) at a vault facility using transfer or transportation casks. Spent fuel is removed from the cask, prepared for storage if needed, and placed in a metal storage tube (single fuel element) or a storage cylinder (single or multi-element canister) which is housed within a concrete storage cavity in the vault structure. The storage tubes or storage cylinders are sealed and may be backfilled with an inert gas to improve heat transfer from the fuel and prevent oxidation of spent fuel while in storage. They are usually fitted with connections to a continuous or periodic monitoring system.

In vaults using metal storage tubes, fuel assemblies are dried, as necessary, and transferred one by one directly into their storage locations. Typical components of this type of storage facility are the vault modules, the fuel handling machine operating in the charge hall, the cask receiving area and the auxiliary facilities (areas for plant control, maintenance, services, offices, etc.).

Single tube vaults are in place at Paks NPP in Hungary and at Wylfa NPP in the UK.

Storage-cylinder vaults receive the fuel already sealed in containers. They are used at Gentilly-2 in Canada (CANSTORE application of the MACSTORE system), the CASCAD facility in France, and Fort St. Vrain in the USA.

Generally, vault facilities are more advantageous for large inventories of spent fuel, since they require a number of auxiliary systems. They also need some efforts to be considered for decommissioning. One advantage is that they can be built in modules (all expenses for auxiliary systems are, however, upfront), and that the facility is completely independent of NPP facilities, since it can also provide necessary equipment for off-site transportation of the fuel in transport casks.

Concrete Casks

Concrete casks are movable structures with one storage cavity. They are used in the storage and, in some cases, transport of spent fuel. Structural strength and radiological shielding are provided by reinforced concrete or high-density concrete.

Spent fuel and vitrified waste section:

2. Reception zone
3. Testing and preparation zone
4. Storage hall
5. Hot cell input zone
6. Hot cell
7. Hot cell control hatch

Other radioactive waste section:

8. Loading and unloading zone
9. Reception zone
10. Testing zone
11. Out-of-standard storage hall
12. Laboratory
13. Storage hall no. 1
14. Storage hall no. 2
15. Storage hall no. 3
16. Workshop
17. Warehouse
18. Housing and offices

■ Figure 15

Combined waste and cask storage building (SOGIN-SRS)

■ **Figure 16**
Typical vault facility (NRC)

Concrete cask systems generally use sealed metal canisters housed inside the concrete storage cask to contain spent fuel. The metal canister may be cooled by natural convection of environment air and use a double-lid closure system.

Sealed metal canisters may be contained in an on-site transfer cask for loading spent fuel from the fuel loading station and for transfer to the concrete storage cask. Spent fuel may be loaded directly into a concrete cask in the fuel loading station and the concrete cask may be transferred directly to the storage site. Some sealed metal canisters may be licensed for transportation as part of an off-site transportation package.

Alternatively, concrete cask systems may use a metal liner in the cask cavity to contain spent fuel and a single lid closure system. Heat transfer may take place solely by conduction through the concrete structure.

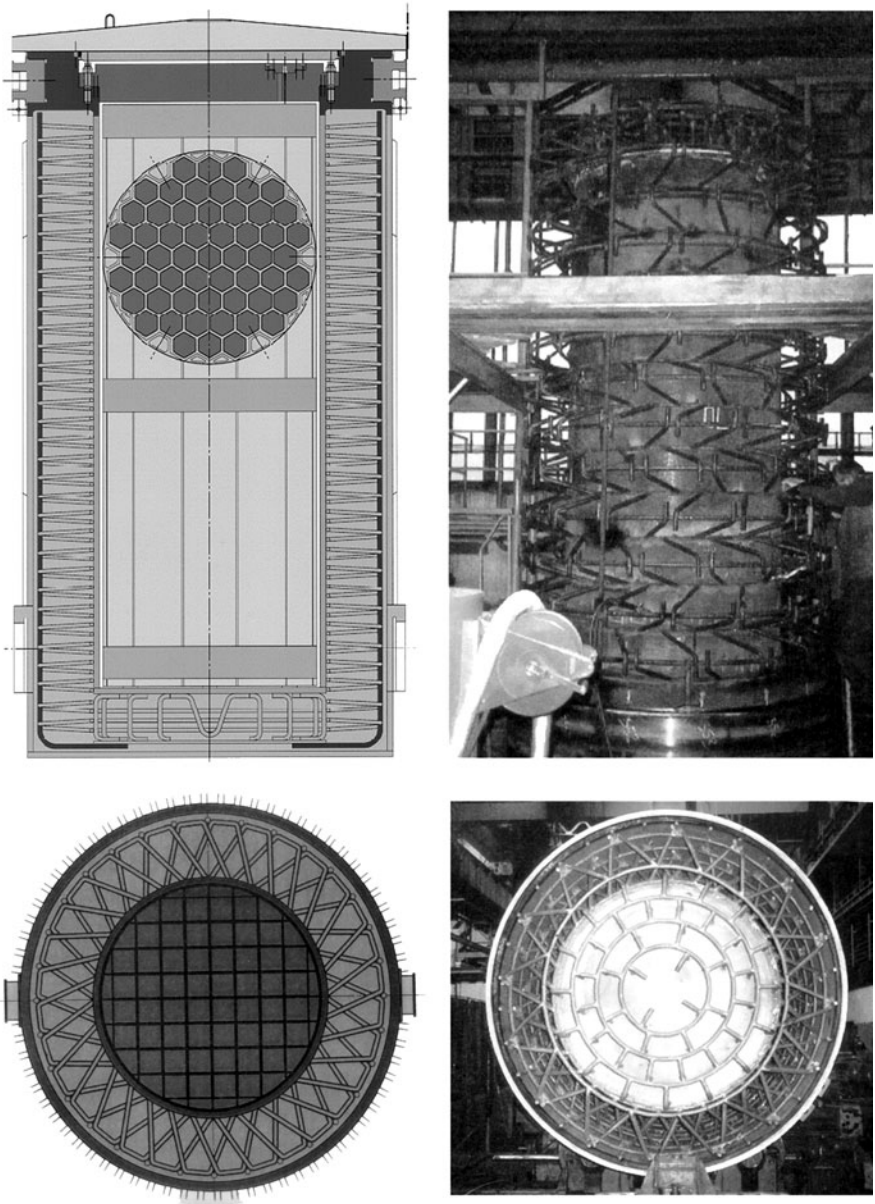

Concrete casks that rely on conductive heat transfer have more thermal limitations than those using natural convection air passages.

Fuel is loaded vertically into the concrete casks and the concrete cask systems are stored in a vertical orientation.

Concrete casks use single or double lid systems, are welded closed and tested for fuel tightness. Concrete cask systems may, or may not be monitored for fuel tightness.

Examples of vertical concrete casks include the Sierra Nuclear VSC cask and Ontario Hydro's Pickering concrete dry storage container, which is also designed for off-site transport.

GNB developed CONSTOR casks (● *Fig. 17*) for VVER and RBMK fuel, which are made of a material sandwich. It consists of an outer steel shell, a reinforced heavy concrete layer and an

■ Figure 17
Conceptual schemes and construction phases of a CONSTOR 440/54 concrete cask (GNB)

inner steel shell (40 mm/340 mm/40 mm). The aggregates for concrete are 40% barite and 60% steel balls. Inside the concrete, steel reinforcement is arranged to improve the strength and heat removal properties. The lid system is designed as a multi-barrier system. The bolted primary lid performs strength and shielding functions. The sealing plate and the secondary lid are welded to the forged steel ring after loading and servicing the cask.

The CONSTOR can contain 54 fuel assemblies because the allowable heat input is reduced and may be licensed also for transport. Since it can be manufactured by conventional methods with conventional materials, its cost is significantly lower than that of the CASTOR metal casks. The CONSTOR version for VVER 440 fuel requires 7 years of cooling time, at an average burnup of 42 GWd/tons of HM and a maximum enrichment of 3.8%. The total mass of the loaded cask is 95 tons.

Concrete Silos

Silo systems are monolithic or modular concrete reinforced structures. The concrete provides shielding, while containment is provided by either an integral inner metal vessel (liner), which can be sealed after fuel loading, or by a separate sealed metal canister. In silos, spent fuel may be stored in vertical or horizontal orientation. Fuel loading into silos always takes place at the storage site.

A typical example of a silo system is AECL's concrete canister, which is built on-site, using regular reinforced concrete, and is fitted with an inner steel liner. Spent fuel is transferred in increments in sealed baskets, using a shielded transfer cask, and loaded vertically. Once loading operations are complete, a closure shield plug is placed and welded to the inner liner, to provide additional containment.

NUHOMS Modular System

The NUHOMS (NUteck HOrizontal Modular Storage) is a family of dry storage facilities which are basically formed by a concrete structure into which metallic welded canisters are placed in horizontal position (► [Fig. 18](#)).

NUHOMS have been developed under the name of various companies (Nuteck, Pacific Nuclear, Vectra Technologies Inc.). Outside the USA, fabrication and commercial license have been granted to FRAMATOME. In 1998, Transnucleaire (a company 100% owned by the French COGEMA) purchased the NUHOMS system and created Transnuclear West, taking over all Vectra assets. So far, the NUHOMS system has been adopted only in the USA and in Armenia at the Medsamor plant. The main designs are known as NUHOMS-7P, NUHOMS-24P, and the standardized NUHOMS-24P/52B (where P stands for PWR fuel, B stands for BWR fuel, and the associated number stands for the quantity of fuel assemblies that can be stored in a single canister). Recently the Multi Purpose Canister (MPC) 187 has been approved by NRC, both for storage and for transport with the addition of an overpack.

The principal components of the NUHOMS are a stainless steel dry shielded canister (DSC) with an internal fuel basket, a concrete horizontal storage module (HSM) that protects the DSC and provides radiological shielding (overpack), a compatible transfer cask (TC) used to transfer the DSC from the spent fuel pool to the HSM, and a hydraulic ram system (HRS) used to insert the DSC into the HSM and TC (see ► [Table 32](#)).

Canister

Provides containment and structural support for the fuel assemblies

Storage module

Provides shielding, physical protection and cooling for the canister during long term storage

Transfer cask

Provides shielding and physical protection for the canister during transfer from the plant to the dry storage facility

Transporter

Transfers the cask and the canister from the plant to the dry storage facility

Main components of the NUHOMS system

7.2 Waste Management

7.2.1 Overview

Waste management in decommissioning activities concerns the treatment, conditioning, handling, storage, transport and disposal of the primary and consequential waste streams.

The wastes arising from decommissioning operations fall into categories that are defined principally by the methods employed to prepare the wastes for disposal.

Liquid waste encompasses contaminated liquids, usually dilute acidic or alkaline solutions, and materials bearing significant quantities of liquids such as sludges, ion-exchange media, and concentrates from evaporators and membrane separators.

Dry solid waste encompasses those wastes that do not contain any unbounded liquids, and includes both combustibles and noncombustibles. There may also be some gaseous effluents deriving from decommissioning, such as tritium and other aerosols.

The salient consideration in all waste management processes is that the applicable safety and radiological protection regulations must be complied with. The secondary objectives are to minimize the volume of material requiring disposal, to minimize the mobility of the radionuclides

■ Table 32

Design parameters for NUHOMS™ storage systems

	Site specific licenses		Standardized NUHOMS™	
	NUHOMS™ 7P	NUHOMS™ 24P	NUHOMS™ 24P	NUHOMS™ 52B
Initial enrichment ²³⁵ U	3.5	4	4	4
Burnup (MWd/tons HM)	35,000	40,000	40,000	35,000

Transfer cask diameter (m)	0.95	1.7	1.7	1.7

contained in the wastes, and to segregate the wastes by the type of radioactivity contained (alpha-bearing, non-alpha-bearing, low-, intermediate-, or high-activity-level). The purpose of minimizing waste volume and mobility and segregating wastes is to achieve an optimum combination of safety and economic disposal.

The likely sources of and the types of treatment and conditioning appropriate for liquid, solid, and gaseous radioactive wastes resulting from decommissioning are discussed in the following subsections. Also discussed are the factors involved in the selection of appropriate packaging, the methods of transport available, the factors involved in the selection of the proper disposal facility for the various waste types, and the possible release of decontaminated materials.

The wastes related to plant decommissioning derive only from the structures of the plant, which are irradiated or contaminated.

For irradiated materials, such as the reactor vessel, only a decrease of the natural radioactivity and appropriate shielding can reduce the irradiation. This explains the option of deferred decommissioning, by which the worker dose is reduced. Contaminated materials are first decontaminated before being dismantled.

These two solutions are recalled to highlight that the main goal of those responsible for plant decommissioning is to reduce as much as possible the impact on workers, the public at large, and the environment.

Another selection criterion for wastes related to nuclear plant decommissioning is to consider low- and intermediate-level waste and very-low-level waste.

For the first category, the final disposal process is similar to that of operational waste, for which disposal sites usually exist as they are built first. The capacity of the disposal site has, of course, to take into account this additional quantity of waste. There exists also another option, which is to dispose of these wastes on-site temporarily or definitively, for example in one of the not dismantled controlled buildings. This depends on the decommissioning strategy adopted according to the country-specific strategies and plant-specific conditions.

For the second category of waste, the very low-level waste (VLLW), the problem to be solved is related to the large volume, even after decontamination. The volume of such waste is a function of the clearance of such waste. Clearance is “the removal of material from a system of regulatory control provided that the radiological impact of these sources after removal from the system is sufficiently low as not to warrant any further control.” The definition of this clearance will of course have an important impact on the quantities of waste to be stored as VLLW or that can be considered as conventional waste.

Two main policies exist for this definition. One uses a criterion linked to the activity level to be considered as a threshold, while the other uses a criterion linked to the origin of the waste: a controlled-area structure or building of the plant. There are, of course, pros and cons for each solution and finally the decision rests with the country’s authority in the framework of its policy. But the impact is twofold: the amount of waste to be stored, which depends on the country’s policy, but also the released material, which may travel from one country to another and may pose a problem of harmonization of the clearance levels.

But in both cases the technologies necessary for processing the waste from dismantling are the same as those used during plant operation life. They vary from waste minimization at source, by means of optimized management, to concentration, sorting, packaging and finally, at specific waste-processing plants, nitrification, bitumization, polymerization, cementation, incineration, etc.

All these technologies are designed for safe conditioning of the waste in order to reduce to negligible values the risk of dispersion and radiation. The only real major difference between operation waste and dismantling waste is the quantity. This means that adequate large repository sites have to be made available, in one or more decades, to store these large amounts.

From the country-specific situations, the following overview of existing or planned repositories can be summarized. In all industrial countries, solutions exist at least for interim storage of all categories of waste (low level, intermediate level, high level, short lived and long lived). Final disposal is mainly under investigation and experimentation, with various lead times (years or decades).

There is no open, unanswered scientific question, which would cast doubt on the demonstration and implementation of disposal concepts. Thanks to the intermediate storage solutions, there is no critical urgency to speed up these final disposal solutions. But, from a public acceptance point of view, it would nevertheless be advisable to start the demonstration and implementation of radioactive waste disposal in underground repositories as soon as possible. This would be of paramount importance in confidence-building for society and would jointly provide the possibility for scientific and technical developments.

7.2.2 Clearance Levels

The concept of clearance is defined by the IAEA as the removal of radioactive materials or radioactive objects within authorized practices from any further regulatory control applied for

radiation protection purposes. Conceptually, clearance is closely linked to exemption, which means the determination by a regulatory body that a source or practice needs not to be subject to some or all aspects of regulatory control, on the basis that the exposure (including potential exposure) due to the source or practice is too small to warrant the application of those aspects. However, clearance can be seen as the process of relinquishing regulatory control, while exemption is the process of deciding that no regulatory control is necessary from the outset.

Clearance is based on the concept of triviality of exposure, generally taken to mean:

- The radiation risks to individuals caused by the practice or source be sufficiently low as to be considered trivial
- The collective radiological impact of the practice or source be sufficiently low as not to warrant regulatory control under the prevailing circumstances
- The practices and sources be inherently safe, with no appreciable likelihood of scenarios that could lead to doses above dose limit. In quantitative terms, this is generally related to the stipulation that the effective dose expected to be incurred by any member of the public due to cleared materials is of the order of 10 μ Sv or less in a year

It is implicit in the concept of clearance that materials, once cleared, are subjected to no further regulatory restriction or control. Consequently, cleared waste may be treated as normal waste; and materials cleared for reuse or recycling may be sold or transferred to any other party and used for any purpose without being considered to be radioactive.

This, however, does not preclude the concept of clearance for a specific purpose, often referred to as “conditional clearance,” i.e., the case where a certain condition has to be fulfilled before the act of clearance has been completed. Examples for “conditional clearance” are clearance of metal scrap for melting only (i.e., not for direct reuse), clearance of buildings for demolition only (i.e., not for reuse), or clearance of material for disposal on conventional landfill sites. After this condition has been fulfilled, the material is also subject to no further regulatory restriction or control.

Clearance levels that have been calculated with the radiological models presented in [▶ Sect. 3.2](#) are summarized in [▶ Table 33](#) for a set of radionuclides. These radionuclides are relevant in reactor and fuel cycle facilities and represent various groups of nuclides, such as weak beta emitters (^3H , ^{14}C , ^{63}Ni), strong beta/gamma emitters as activation and fission products (^{60}Co , ^{137}Cs), strong beta emitters (^{90}Sr), and alpha emitters of different origins (^{235}U , ^{241}Am , ^{239}Pu).

The first two rows of [▶ Table 33](#) relate to unconditional clearance from the two recommendations RP 122 part I of the European Commission (2000b) and RS-G-1.7 of the IAEA (2004j). Both documents contain a set of rounded clearance levels that are based on different scenarios and assumptions, but resulting in quite similar values. RS-G-1.7 has a slightly more conservative tendency, as these values are not merely meant as unconditional clearance levels, as is pointed out in the following: “The Safety Guide includes specific values of activity concentration for both radionuclides of natural origin and those of artificial origin that may be used for bulk amounts of material for the purpose of applying exclusion or exemption. It also elaborates on the possible application of these values to clearance.”

The third row in [▶ Table 33](#) provides the clearance levels from RP 89 (European Commission 1998a) for metal scrap for melting. In comparison with the values from RP 122/I, they are generally the same or larger, indicating that a smaller, and, therefore, less restrictive set of scenarios has been used.

■ **Table 33**

Clearance levels for some radionuclides

Purpose	³ H	¹⁴ C	⁶³ Ni	⁶⁰ Co	¹³⁷ Cs	⁹⁰ Sr	²³⁵ U	²⁴¹ Am	²³⁹ Pu	Unit
Unconditional clearance, RP 122/I	100	10	100	0.1	1	1	1	0.1	0.1	Bq/g
Unconditional clearance, RS-G-1.7	100	1	100	0.1	0.1	1	–	0.1	0.1	Bq/g
Metal scrap for recycling or reuse, RP 89	1,000	100	10,000	1	1	10	1	1	1	Bq/g
Building rubble, RP 113	100	10	1,000	0.1	1	1	1	0.1	0.1	Bq/g
Buildings for reuse, RP 113	10,000	1,000	10,000	1	1	100	1	1	0.1	Bq/cm ²
Buildings for demolition only, RP 113	10,000	10,000	100,000	1	10	100	10	1	1	Bq/cm ²

Recommendations European Commission RP 122 part I and IAEA RS-G-1.7

Similar observations apply to clearance levels for building rubble, shown in the fourth row in ► [Table 33](#). These values are closer to those of unconditional clearance, as they also apply to large quantities and therefore need to be more conservative in nature.

The last two rows in ► [Table 33](#) provide clearance levels for buildings from RP 113 (European Commission 2000b). As they are expressed in Bq/cm², no direct comparison with the other sets of values is possible or meaningful. It can be observed, however, that the values for clearance of buildings for demolition only (i.e., where any reuse would not be permitted) are generally higher or equal to those for clearance without restrictions (i.e., for reuse or demolition).

7.2.3 Waste-Management Strategy

The waste management strategy should ensure that the generation, conditioning, and disposal of wastes from the decommissioning process is conducted in a manner consistent with the project, waste minimization and the acceptance criteria. This strategy is based on national and regional waste management regulations and also takes into account government policy. It generally includes items such as

- An estimate of the sources and types of waste, their physical and chemical characteristics, and the volume of each waste category, including the rate at which waste is generated
- Criteria for the restricted/unrestricted reuse or recycling of equipment or materials from decommissioning
- Criteria for segregating waste into various categories
- The plans and procedures for handling, treating, conditioning, storing, and disposing of each category of radioactive, nonradioactive and hazardous wastes from decommissioning
- Procedures for monitoring and recording radioactivity, including the monitoring of cleared wastes before unrestricted release, as well as taking and analyzing samples
- Requirements for packaging and package design for transport and disposal

- Identification of adequate storage and disposal routes and sites (in some cases the waste streams may not have readily available routes for conditioning, treatment, storage, and/or disposal or reuse)
- A safety assessment of the waste-management strategy

The waste-management strategy considers aspects such as the possible reuse and minimization of waste, including secondary waste, through the use of waste-minimization and volume-reduction techniques. Techniques that may be employed include, among others, decontamination, size reduction, process optimization and volume reduction, e.g., evaporation of liquids or compaction of solids. It is expected that several different waste streams will be generated during the course of decommissioning; these may need to be considered based on each case in the development, modification, and application of appropriate waste-management techniques.

The waste-management strategy addresses how the applicable waste acceptance criteria for disposal will be met. If wastes from restricted areas are to be disposed by landfill or similar methods, the means of demonstrating that the release criteria are met have to be specified and documented. If some wastes are to be released for unrestricted use, special monitoring and analysis procedures capable of measuring the very low levels of radioactivity that are specified for unrestricted release are of concern. For this purpose, an area with low background radiation may be required, so that the necessary measurements can be made and/or extensive sampling and counting in the laboratory can be performed.

7.2.4 Waste-Management Arrangements

Decommissioning operations, which produce radioactive wastes can only be initiated when well-defined waste-management arrangements have been made. In some situations, the final disposal of waste will be transferred to an organization different from the facility licensee.

The conditioning, packaging, and recording arrangements are formally agreed with the repository organization before the recovery and conditioning of any waste is commenced.

In addition, many facilities generate both radioactive and other hazardous wastes. The development of a plan for hazardous material characterization provides an important insight into the impact of these materials on treatment, conditioning, packaging, storage, and final disposal.

The procedures, processes, and systems to be used for handling, treatment, conditioning, storage, and disposal of radioactive wastes are defined.

If radioactive wastes are to be temporarily stored on-site, the quantities of wastes, expected length of storage, location of storage areas, radiation levels at access points, and manner in which control is maintained are defined.

The methods of managing radioactive wastes from decommissioning are, in general, similar to those used in other parts of the nuclear industry during operation, maintenance, and refurbishment of facilities. However, the huge volumes and characterization of the waste streams may require some modifications to the methods used.

In  *Fig. 19* the conceptual decommissioning waste routes are presented.

7.2.5 Treatment and Conditioning of Liquid Wastes

Liquid wastes that consist of large volumes of dilute solutions containing dissolved and/or finely divided contaminated material are usually treated to extract the contaminated material from

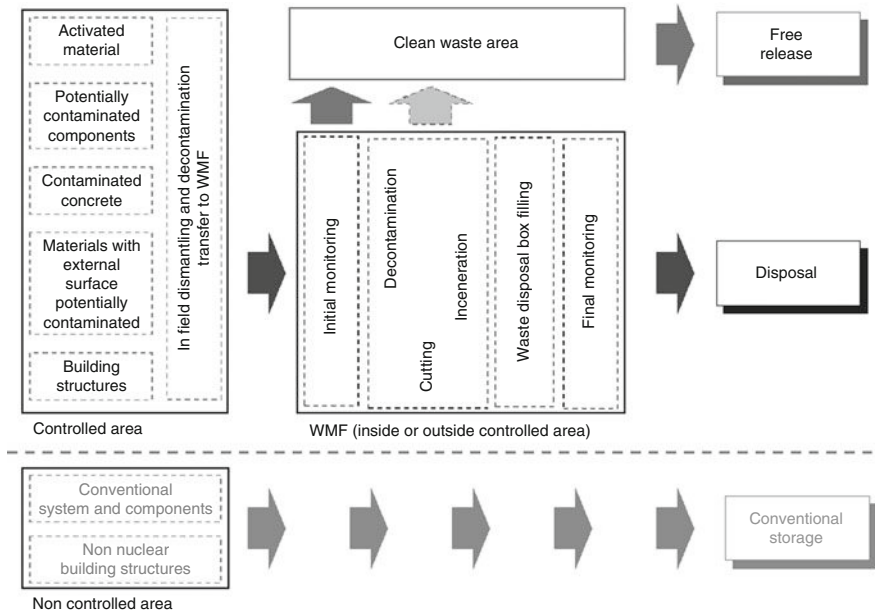

Figure 19
Decommissioning waste routes

the carrier solution, thus reducing the volume of material requiring further conditioning and disposal at a radioactive disposal facility.

The usual techniques for decontamination of liquid wastes are ion-exchange, filtration, membrane separation, and chemical treatment and evaporation. These techniques are used singly or in series combination, depending upon the characteristics of the solution being treated. The purified liquids resulting from these processes are usually decontaminated sufficiently so that discharge to the environment is possible after monitoring to ensure compliance with regulations.

Certain liquids used in some decontamination processes, such as phosphoric acid in electropolishing and organic solvents in surface cleaning, may require special treatment because of their specific chemistry.

The concentrated radioactive residues contained in the ion-exchange media, filters, or concentrator bottom liquids require conditioning to immobilize them. The immobilization required is accomplished by mixing the radioactive residues with a matrix material and subsequently solidifying the mixture within a suitable container. Matrix materials that have been and are being used include cement, bitumen, a variety of polymers (such as polystyrene, polyesters, epoxies, and urea-formaldehyde), glasses, and ceramics.

The choice of treatment and conditioning processes for a particular project will depend upon the following factors:

- Radiological and general safety considerations
- Technical requirements of the liquor streams
- Waste transport and disposal alternatives
- Economic considerations

The availability of appropriate liquid-waste treatment and conditioning processes at the facility may also be an important consideration in the selection of decontamination techniques for use on a specific project.

7.2.6 Treatment and Conditioning of Solid Wastes

Solid wastes arising from decommissioning operations consist principally of contaminated and activated structural materials and system components, including concrete, reinforcement and structural steels, graphite, stainless and carbon steels, and a miscellaneous assortment of other metals, rubber, plastics, and paper and other fibrous materials.

The principal objectives in the treatment and conditioning of solid wastes are:

- To minimize the waste volume in ways compatible with minimizing the mobility of the radioactive materials contained and the radiation dose associated with waste processing and handling
- To segregate the waste into groups according to the types of radioactive contaminants present to facilitate emplacement in the appropriate disposal facility
- To process and package the wastes in containers suitable for transport from the site and for disposal in the appropriate disposal facility
- To accomplish these actions in an economical manner

Treatment and conditioning of materials that are not combustible or compactable is generally limited to segmentation to facilitate packaging in standard types of disposal containers and to grouting within the containers when appropriate.

Treatment of combustible and compactable materials is usually accomplished using mechanical compaction and/or incineration. Compaction may be performed as the first step, followed by incineration, or it may be the only step, with the materials compacted within the shipping container. Numerous compacting devices are commercially available for compressing compactable wastes within steel drums or similar containers. Incineration of combustible wastes results in a concentrated waste form which requires further conditioning by immobilization in solidifying matrices, similar to those used with liquid waste concentrates.

Because of the radiological detriment aspects and, therefore, the higher cost of disposal of alpha-bearing waste (perhaps ten times more costly than beta-gamma waste), for certain waste sources there may be an incentive to segregate waste streams during the processing and packaging phase.

7.2.7 Treatment and Conditioning of Gaseous and Aerosol Wastes

Small quantities of tritiated water vapor are the most likely gaseous radioactive wastes to result from decommissioning operations. If necessary, removal of the tritiated water vapor from the ventilation air can be accomplished using selected adsorber material that is contacted by the air streams.

Aerosols containing finely divided radioactive materials are likely to result from the various cutting methods used during decommissioning. Similarly, some of the cutting methods will produce large volumes of potentially toxic smoke and fumes. In all cases, the use of contamination-control envelopes coupled with appropriate filters in the ventilation streams should be adequate to collect and retain the particulate material.

Treatment of the resulting solid wastes (adsorbers and filters) is accomplished as described in the previous subsection.

7.2.8 Packaging and Storing Technologies

The selection of the waste-disposal boxes to be used for off-site transport and disposal should take into account:

- Existing regulations
- Technical requirements
- Infrastructure aspects
- Radiological conditions
- Economical aspects

Technical requirements can be derived from the Authority or Agency that operates the final national repository. If no explicit indication on the type of repository has been provided by the competent authorities, the only requirements to be met are those included in the international standards and code of practices such as, for example, IAEA documentation.

Based on the experience acquired from the repositories currently operated worldwide, including their acceptance criteria, the following assumptions may be considered for cost estimating purposes:

- Low- and intermediate-level waste produced during the safe enclosure phase (SEP) preparation phase and releasable as nonradioactive waste during the subsequent SEP phase, is packaged in 20-ft. containers without any filling or conditioning material.
- LLW produced during the SEP preparation phase and not free releasable during the subsequent SEP phase, will be packaged in one of the standard waste disposal boxes listed in [▶ Table 34](#). Packaged wastes are then stored on-site in dedicated buildings or inside plant buildings, until the national repository is available. To store waste inside the plant, some removal of equipment is necessary.
- Low- and intermediate-level waste produced during the site release phase is placed in one of the waste-disposal boxes listed in [▶ Table 35](#), and disposed.
- Already packed low- and intermediate-level waste is transported in 20-ft. containers (about 50 200-l drums per container). The drums qualify as an industrial package.
- Medium- and high-contaminated materials are conditioned and packed in 200- or 400-l drums. The drums qualify as an industrial package.
- Highly contaminated or activated material is packed in 200-l drums, which can be used with shielded overpacks or in shielded cast iron casks (for instance, German MOSAIK cast iron casks).

It should be noted, however, that the final decision on the proper packaging concept could be made only when the situation concerning the final repository is definitively assessed.

The waste drums, whose levels of radioactive contamination at the end of a 40-year SEP are expected to have decayed to levels satisfying the criteria for unrestricted use, will not be transported to the final repository, even if available.

It has been assumed that 4-m boxes will be used for the packaging of all LLW as well as of the ILW graphite. The filled box will be finally consigned for disposal as LLW or ILW, depending on the activity and therefore the origin of the contents.

■ Table 34

Waste disposal boxes to be used during safe enclosure phase (SEP) preparation phase

Container type	Closure	Contained waste	Waste treatment (example)
220 l metallic drum	Beaded with clamping-ring lid closure	Compacted DAW's	Baling
320 l metallic drum	Beaded with clamping-ring lid closure	Supercompacted DAW's	Supercompaction
220 l metallic drum	Welded with circumferential hoops and clamping ring lid closure	Conditioned ashes, liquids, resins, and sludge	Cementation
400 l metallic drum	Welded with clamping ring lid closure and internal mixer	Conditioned liquids, resins, and sludge	Cementation

■ Table 35

Waste disposal boxes to be used during the site release phase

Container type	Dimension	Wall thickness	Contained waste (example)
Steel plate container	1.7 m × 1.7 m × 1.6 m	4 mm steel	Dismantled components
Cast iron cylindrical cask	1.06 m diameter, 1.5 m high	160 mm cast iron, <80 mm lead	Activated components from reactor area
Cast iron cylindrical cask	1.06 m diameter, 1.5 m high	160 mm lead	Concentrates from liquid waste
200 l metallic drum	0.6 m diameter, 0.9 m high	1.5 mm	Metallic and concrete waste from small parts
400 l metallic drum	0.75 m diameter, 1.1 m high	1.5 mm	Metallic and concrete waste from small parts

The maximum gross weight of the box is limited to 65 tons. The box has provision for shielding, but this is not expected to be required, as the wastes do not exhibit high gamma dose rates. It has therefore been assumed that all waste using these boxes will be packaged without shielding.

The 3-m³ box is used for all ILW, except graphite. This box is unshielded and requires a shielded steel overpack for transportation. The design has been approved for transport and disposal in the UK. Each box is identified by a machine-readable identity plate which, when used in conjunction with the documentation prepared during waste processing and box filling and with repository details, allows a total record of the box, its contents, and repository location.

Re-usable concrete overpacks can be used for shielding these boxes during temporary storage.

The 3-m³ boxes are transported to the repository in a reusable steel shielded transport container. These are steel boxes with a hinged and/or removable lid. The small boxes have wheels, a 3-m³ socket and pin for linking together and can be moved on a pallet truck with lifting points for transfer via a crane. The boxes have provision for shielding if required. Two sizes are employed, a small box 1.05 × 1.2 × 0.9 m high (volume = 1.134 m³) and a large box 2 × 1.2 × 0.9 m high (volume = 2.268 m³). The boxes provide containment of active and potentially active materials during transfer. These boxes are re-usable.

7.2.9 Waste Transport

Transport of the conditioned and packaged wastes from the packaging facility to the disposal site is performed using conventional means via highways, railways or waterways. The mode of transport utilized is influenced by the type of transport access and handling equipment available at the packaging site and at the selected disposal site, and by the physical size of the packaged unit. Very large components can be transported intact most effectively by barge or ship.

For large-scale decommissioning projects, e.g., a nuclear power reactor, the logistic problems of moving many thousands of cubic meters of waste are likely to be significant and the total impact on existing systems should be assessed.

The sizes and weights permitted in shipments are governed by regulations issued by the appropriate national and local regulatory agencies. Protection of the public from harmful radiation is governed by the appropriate national regulations, which are based upon international recommendations.

7.2.10 Waste Characterization and Measurement Techniques

Estimation of the radiological inventory in a facility is required to define the operational decommissioning plan and estimate costs and radiological risks associated with the plan.

Once the decommissioning program is under way, wastes must be monitored and characterized for regulatory, safety, and waste disposal considerations. The objective of this characterization is to ensure that the wastes are handled and disposed in a safe and economic manner. Therefore, the characterization program should be able to:

- Segregate wastes into active and inactive (exempt from regulatory control) streams quickly and accurately, so that inactive materials and equipment can be released for unrestricted use or for conventional disposal
- Determine the radiological characteristics (major radionuclides present, quantities and chemical form of each radionuclide) for communication to the authorities responsible for waste disposal sites
- Characterize the site for final release

Characterization Methods

The methods and equipment used to characterize the radioactive wastes, which arise from decommissioning will vary considerably, depending upon the type and complexity of the facility and the radionuclide mix in the plant.

The simplest type of decommissioning waste arises from facilities containing only one type of radionuclide, for example a ^{60}Co processing plant. Similarly, decommissioning wastes arising from plants that processed materials with a fixed ratio of alpha, beta, and gamma activity would be relatively easy to characterize. Such plants could include:

- Certain fuel fabrication facilities
- Mining/milling buildings
- Spent fuel storage facilities

Also some types of components can be included in this type of wastes, such as pressure vessels and pressure tubes, which have been decontaminated, as well as concrete from biological shields, since the ratio of radionuclides should not vary even though the concentrations may change. In all the above cases, the quantity and quality of activity in unit packages of waste arising from the decommissioning of the facilities could be determined by gross gamma measurement and a suitable modeling protocol.

The waste streams arising from the decommissioning of reactors, reprocessing plants and fuel fabrication plants would be the most difficult to characterize, especially if the locations in the plant where the waste streams arise are not well defined. Complications arise because of the possible presence of streams having separated plutonium or variable mixes of alpha, beta, and gamma activity.

In the following sections, a review is made of the possible methods of measuring the activity in the waste, the instruments currently available and the means of establishing a waste characterization program.

Gross Gamma Measurement

The easiest and least expensive characterization of radioactive waste comes from measuring the gamma and X-ray intensity external to the package. This type of characterization requires that the waste arising from facilities have fixed ratios of alpha and beta to gamma activity, which can be predetermined by laboratory measurements. However, in many cases these ratios are not constant (particularly for alpha radiation) and other methods are required.

Measurements of total radiation fields due to gamma and X-rays from waste containers can provide an acceptable estimate of the activity if the relationship between activity content and radiation field has been well established. Because the characteristics of the bulk of the waste are measured, this method is more suitable than sample spectrum analysis for the examination of heterogeneous low-level wastes, but is not as indicative of activity content as bulk spectrum analysis. As with bulk spectrum analysis, the need for taking a sample is eliminated and the measurement time is short; so large volumes of waste can be processed relatively quickly.

A gross gamma reading alone will not indicate the nature and quantity of each of the major isotopes in a given waste package, unless a previous detailed analysis of the waste stream was done to derive isotope concentrations comparable with total gamma readings. Such relationships lose their validity if the ratios of radionuclides in the waste deviate from those of the initial quantification analysis.

The accuracy of this method, then, is dependent upon factors such as container geometry, relative isotope mixture, distribution of activity in the package, background radiation and actual measurement procedure (probe distance, measurement points, instrumentation used, etc.). The successful use of total gamma measurement as a waste characterization tool requires that all of these factors remain constant or be accounted for.

Gamma Spectrum Analysis

The most detailed analysis of the gamma emitting radionuclides can be obtained using gamma spectroscopy. This approach is required if the ratio of gamma emitters in the waste changes (e.g., if there are large variations in the ratio of ^{60}Co to ^{137}Cs).

In assaying wastes using gamma spectra, it is neither necessary nor desirable to measure all the gamma emitting radionuclides, and selection criteria must be established. In general, isotopes with half-lives of less than 1 year can be disregarded since they have little bearing on the potential detriment to people during most decommissioning operations and in waste disposal. The selection of the remaining radionuclides to be measured depends on the waste stream.

Accurate characterization requires that a small representative sample taken from the material stream or package be characterized. The spectrum of gamma radiation from the sample is measured and from it the constituents and their activities are deduced. Assuming that the sample is representative of the stream, the total activity per unit weight of the stream can be calculated.

To be effective, such analysis generally requires the use of sophisticated equipment such as Ge detectors and multi-channel analyzers. The necessity of qualified personnel and a suitable laboratory environment makes this method time-consuming and further increases the cost.

Although gamma spectroscopy gives an accurate determination of activity for gamma-emitting isotopes, this method cannot detect the presence of non-gamma emitters. The overall accuracy of this technique, when applied under decommissioning conditions, is further limited by the small sample size analyzed. The composition of low-level wastes, which constitute the major portion of total wastes, is known to vary considerably. Therefore, a small sample does not necessarily give a true indication of the radionuclide content of a package or component, unless supplemented by multiple sampling.

Gamma spectrum analysis based on measurements of the external radiation from a waste package or component is also possible. This method is generally much less accurate than the specific sampling method, but does benefit from the fact that the entire bulk of the waste is assayed. Its use requires that final results be corrected for factors such as the effects of package geometry, package shielding, and self-shielding of wastes. The capital investment in energy-sensitive, high-resolution gamma detectors, multichannel analyzers, and other analytical control hardware remains the same as that for sample analysis.

Energy-Sensitive Detectors

To some extent, the combined advantages of the spectrum analysis and gross gamma measurement systems can be achieved through measurement with an energy-sensitive detector and a single-channel analyzer. Gamma rays of one or more energies are externally counted at various positions on the waste container. Given the proper pre-established relationships, the activity content can then be derived. For example, if ^{60}Co and ^{137}Cs are known to be the major isotopes present, two counts would be taken on the waste, one with the single-channel analyzer set for 1.35 MeV (for ^{60}Co), the other with the analyzer set for 0.6–0.7 MeV (for ^{137}Cs). This procedure has the advantage of a bulk field count combined with the accuracy afforded by being able to count and integrate the photons from one or more specific isotopes in the waste. Measurement procedures and activity derivation factors must still be developed to account for the effects of package geometries, self-shielding and the presence of non-gamma-emitting isotopes. The major advantage of this method over externally measured full spectrum analysis is in the lower cost of equipment.

The methods described lend themselves to high-volume/production-scale automation. Such adaptation, however, requires that all influencing factors such as package characteristics, presence of non-gamma emitters and self-shielding be accounted for in the control analysis logic.

Instrumentation

Accurate characterization of radioactive waste requires that the detector be suited to the energy levels of the radiation emitted and that the resolution and accuracy of the detector be sufficient to meet the needs of the characterization program.

A wide variety of instruments have been developed for measuring the radiation emitted from waste material. Three general categories of instruments have been used to measure this radioactivity:

- Gas-filled detectors
- Scintillation detectors or phosphor detectors
- Solid-state detectors

In general, the energy emitted during the interaction of the radiation with the material in the instrument is converted into an electrical pulse that can be recorded. The total radioactivity can be measured by summing the pulses over a fixed interval of time or by converting them to a pulse rate. In spectrum analyses, the pulses are sorted out by energy level and the number of pulses at each level is stored separately using a pulse height analyzer.

Gas Filled Detectors

One widely used type of gas-filled detector is the Geiger-Muller (GM) detector, which consists of a sealed tube containing the counting gas, anode, cathode, and a secondary gas to quench the discharge and prevent secondary discharges.

The counter is inexpensive, trouble-free, and generally used to measure gross gamma or beta/gamma. Certain designs can be used to detect alpha, beta, and gamma radiation. The detectors can measure alpha above 3.5 MeV, beta above 35 keV, and gamma above 6 keV.

Since GM detectors are incapable of resolution, they cannot be used for spectrum analysis. However, such instruments can be used effectively to measure the quantity of radiation in waste having fixed ratios of alpha and/or beta to gamma radiation, provided that:

- Samples of the waste have been well characterized in the laboratory as to radionuclide mix and content
- The ratio of radionuclides in the stream does not change
- The operators are well trained and use the instruments in a consistent manner
- The total weight of material is known

The method is quite susceptible to error since it is subject to possible changes in the radionuclide mix, at least in some plants, and to operator inconsistency.

Another type of gas-filled detector that has been widely used is the gas-flow proportional detector. This type of detector can be made with a thin window, which increases the detection capability for alpha particles. A third type of gas-filled detector, the ionization chamber, can be made in a variety of shapes and sizes. It is extremely rugged and can operate over a wide range of temperature and gamma radiation levels.

Scintillation Detectors

A zinc sulfide scintillator may be used during decommissioning as an alpha survey meter. Plastic scintillators have been used as beta detectors and have a 100% efficiency for particles as low as 60 keV which pass through the protective foil window. The plastic is rugged and large detector sizes are possible; however, resolution for gamma rays is poorer than for sodium iodide (NaI).

Sodium iodide is the best scintillation detector material for high energy gamma detection and overall gamma ray resolution. The best resolution achievable is about 7% (for 662 keV ^{137}Cs gamma). NaI detectors are widely used in gamma spectrometers where portability and counting efficiency are the key parameters.

NaI detectors could best be used to segregate active/inactive waste since their detection ability and resolution are sufficient to define wastes above and below a minimum radiation level. Detailed characterization of active wastes is best left to the higher-resolution solid-state detectors.

Solid-State Detectors

These detectors are essentially solid-state ionization chambers, but with a higher efficiency owing to a solid, rather than a gas, detection medium. They are operated at liquid-nitrogen temperatures to reduce thermal noise.

The decision on which type of solid state detector to adopt for a particular program will depend on items such as which radioisotopes are to be quantified, which measurement method is to be implemented (gross gamma, gross alpha, single-channel analysis, multichannel analysis), throughput, degree of automation and cost. While the range and resolution of the instruments are prime considerations, the electronics (i.e., preamplifiers, amplifiers, analyzers, etc.) required with each of the different types must also be carefully evaluated since they affect both the cost and the flexibility of the final instrumentation set-up.

For decommissioning activities, completely portable high-resolution germanium diode spectrometer systems have been developed. These instruments are capable of measuring gamma and X-rays, and to detect transuranics (TRUs), activation products and fission products at very low levels. The data acquisition is accomplished using a multi-channel analyzer and a digital recording system for subsequent computer reduction and analysis.

Special Alpha Techniques

Wastes contaminated with TRU nuclides – for example, ^{239}Pu , ^{241}Pu and ^{241}Am – are difficult to detect, especially in the presence of certain fission products. The selection criteria for the measurement of TRU are not as clear-cut as for activation and fission products, especially if the waste is in packages. The only radiation that can be measured unequivocally from TRU wastes in the presence of other radionuclides which usually occur are the neutrons emitted spontaneously from the waste (passive) or those emitted following interrogation of the waste with pulsed neutron or photon sources (active).

Passive neutron techniques can be used to measure many of the TRU nuclides in low- or high-gamma-activity wastes. Such techniques are being developed for the verification of the TRU content of waste packages.

Waste Characterization Program

The essential steps of a waste characterization and verification program for a decommissioning project consist of:

- a) Conducting extensive sampling and laboratory analyses

- b) Dividing the intact facility into waste streams which are likely to have similar radionuclide mixes
- c) Obtaining suitable criteria which would permit inactive waste to be segregated from active waste and permit the active waste to be classified according to disposal facility
- d) Obtaining or developing instruments and equipment which would allow the waste to be segregated as in c) as quick, economical, and accurate as possible
- e) Developing a well-trained monitoring crew

The monitoring personnel should understand the equipment and criteria used for segregating the waste and should supervise and give directions to a team of operators who actually do the work.

The data required to divide the intact facility into discrete waste streams with similar radionuclide mixes could be obtained from the radiological inventory estimates and sampling procedures initially done in the facility to be decommissioned. The volumes of these streams can be calculated from the construction drawings. Depending on the type of facility, the radionuclides present and the thoroughness of the initial survey, samples of the waste streams from the dismantling may or may not have to be analyzed in detail to identify all the important radionuclides present using spectrographic and possibly chemical analyses. This type of confirmation would not be required for plants with fixed mixes of radionuclides, for example a natural-uranium-fed fabrication plant, but would be required for more complex plants such as reprocessing plants.

Once the streams have been defined, the type of instrumentation and sampling protocol required to verify the activity can be determined. Depending on the waste stream, monitors for gross gamma, beta and possibly alpha may be required as well as equipment for doing spectrum analyses on some or all of the waste. Depending on the form of the waste and the part of the plant or site being monitored, the physical design of the monitor could vary from hand-held types to a more advanced production-line monitoring assembly.

While for small samples the most accurate method of characterizing the radioactivity in waste is gamma spectrum analysis, this is not practical for large volumes of solid waste. For waste streams that require spectrum analysis, economies in time and labor can be achieved by combining several techniques. For example, in a specific waste stream having reasonably fixed mixes of gamma radionuclides, but variations in activity levels, the total activity content can be estimated fairly well using gross gamma measurements on most of the waste and spectrum analysis on selected samples from the wastes containing the highest activity levels.

Sources suspected of containing significant quantities of radioisotopes which are difficult to measure with gamma detection equipment, for example, weak or non-gamma emitters, would require further analysis to develop effective scaling factors to relate gamma levels to the content of the other radionuclides. Further analysis, enhanced by chemical separation of the relevant isotopes and combined with an isotope-behavior analysis, would yield relatively constant relationships between the hard-to-detect radioisotopes and those that can be readily measured. Scaling factors can be established from these relationships. Subsequent surveys of wastes being removed from specific source areas or systems can then be accomplished with more practical gamma measurement techniques. The concentrations of detectable isotopes would be used, with the scaling factors, to derive the concentrations of non-gamma isotopes.

Once specific waste streams are characterized in this manner, regular assaying of the waste packages by external gamma measurement, either with a multichannel or single-channel

analyzer, will be sufficient to ensure compliance with safety and regulatory criteria. The initial source characterization would show which radioisotopes are present and, hence the specific gamma energy regions to be surveyed if single-channel analysis is used. Periodic laboratory analysis of wastes would still be required to confirm the validity of the scaling factors and the assumed radioisotope mix. The frequency of both the regular waste surveys and the periodic confirmatory analysis should be high during the initial periods of waste generation and can be permitted to drop off as confidence in the methods grows.

The degree of reliability of these mixed survey methods, and the resultant time and cost savings, depend primarily on the consistency of the waste streams. This requires that the waste be sorted into streams as homogeneous as possible. The ability to effectively define general sources in such an economical manner varies from facility to facility. Any difficulty in establishing a suitable definitive source-base characterization can be compensated for by adopting more conservative scaling factors and/or more precise gamma measurement procedures. The latter applies to single-channel analysis and would be achieved by regularly surveying beyond the energy regions indicated by the detailed source-base analyses. Such a measure would result in more operator time being required, while the use of conservative scaling factors would ultimately result in less efficient use of disposal space.

In the special case of fissile material facilities, the requirements for criticality control may necessitate measurement of all the waste streams from selected areas.

7.3 The Waste Management Facility (WMF)

The removal from a nuclear plant of activated or contaminated materials, particularly during its decommissioning, requires a number of operations and precautions. Most of these operations are usually performed inside a special area, adequately confined and equipped, called a WMF. In  [Fig. 20](#) a simplified flow diagram is shown for a typical WMF.

7.3.1 WMF Design Criteria

The main design criteria for WMF are similar to the general radioprotection criteria, which could be summarized as follows:

- Minimizing the operational collective dose to the workers
- Confining contamination as much as possible to where it is generated
- Minimizing environmental impact by minimizing liquid and gaseous releases
- Minimizing risks to the environment and to the workers associated with accidents
- Radiologically classify all operational areas
- Preparing detailed procedures for operations in the radiologically affected areas
- Minimizing radioactive wastes generated during operation of the facility

A typical classification of a WMF identifies four levels:

- Clean areas where any ambient contamination can be excluded
- Clean areas where a limited contamination may occasionally be present
- Areas where only surface contamination may be expected

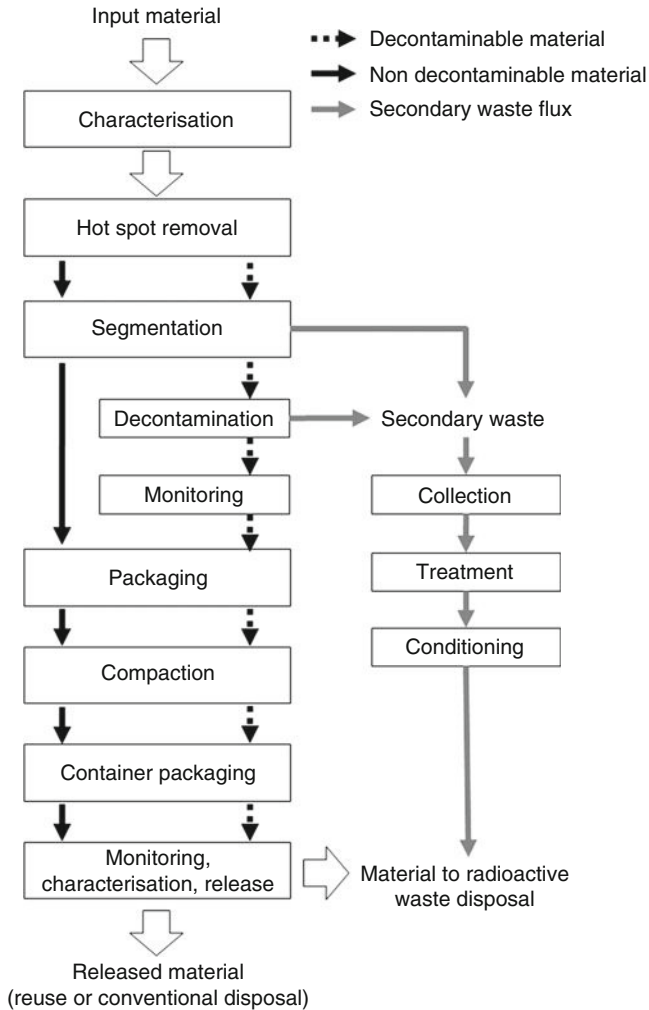

Figure 20
Typical waste management facility (WMF) material flow diagram

- Highly contaminated areas, where access is controlled and only personnel properly equipped with protection devices, including filtered masks, may be allowed

Minimization should be applied to primary wastes (those directly created by the dismantled materials), secondary wastes (those produced by the conditioning processes inside the WMF) and tertiary wastes (those consisting of equipment brought in from outside).

In addition, the WMF layout should optimize the logistics associated with material paths. These paths, called “waste routes,” can be grouped into four families:

- Entering-material waste routes
- Nondecontaminable-material (typically activated materials) waste routes

- Decontaminable-material waste routes
- Released-material waste routes

7.3.2 Description of the Areas and the Equipment

Specific WMF equipment may vary widely from one plant to the other and also from one NPP type to others. However, in general terms the following functional areas can be identified:

- Component segmentation (production of spools of predetermined size)
- Chemical or mechanical decontamination
- Volume reduction (compaction)
- Immobilization by grouting
- Monitoring, characterization and release
- Interim storage areas (“buffers”)

Segmentation

The main equipment of the segmentation area is that necessary to reduce large components into spools to be decontaminated that are compatible with the decontamination pools. This equipment is supplemented by static and dynamic confinement systems, usually associated ventilation systems for dust and smokes.

In this area, removal of hot spots (contamination concentration spots, such as piping elbows, drains, or highly oxidized areas) can be considered. This removal has the objective of facilitating subsequent decontamination and reducing secondary waste production.

Decontamination

Toward this area are forwarded the spools to be decontaminated for further release. This stream generally does not include small components, whose decontamination is complex and/or too expensive, and which are more advantageously directed to compaction and inclusion in waste barrels.

Typical equipment of the decontamination area consists of:

- Pool for pickling treatment
- Washing station with high-pressure pump
- Pools for acid treatment
- Pools for electric-chemical treatment

A dynamic containment is also foreseen for this area, in addition to a system of collection, filtering and treatment of liquid effluents.

The decontamination techniques of systems and components can be divided in two groups:

- “On-line” decontamination processes
- “Off-line” decontamination processes

“On-line” processes pertain to systems and components where they are installed, before dismantling. These processes, obviously, are performed outside the WMF. “Off-line” processes provide for the prior dismantling of systems and components to be treated and their transportation to instrumented areas for decontamination.

Volume Reduction

In this area waste volumes are reduced by filling standard drums with waste and then compacting them with a hydraulic press. This treatment is particularly advantageous for waste products that because of their size and shape would not allow a high filling factor of the containers.

Immobilization by Grouting

In this area, wastes may be immobilized by adding grout, or fluid cement, in standard containers compatible with the specifications of the final disposal site. The Safety Authority may provide special specifications, identifying two cases:

- Immobilization of the contamination only during handling and transport
- Full waste conditioning by inclusion

The grouting process must be qualified by the Safety Authority, and the cement should also be fully qualified and characterized in its composition to obtain the required performance of the final product (after maturation) in terms of mechanical resistance, leaching, etc.

Monitoring, Characterization and Release

In this area, the automatic volumetric contamination control equipment operates together with other equipment for surface contamination measurements.

In this area all data related to a specific waste package are prepared (as an ID of the package) and a Certificate for Disposal is issued, which, with the help of a database, will assure traceability of the package and its content at all times.

If contamination levels are below a threshold (generally between of 0.1 and 1 Bq/g) the material can be released as conventional waste. In particular, metallic wastes (the great majority in terms of weight and volume) can be recycled as metallic scraps in this case.

In many cases, this area is not fully integrated with the WMF, since the formed should be clean, not contaminated by proximity to contaminated areas and used only for controls and administrative operations.

Interim Storage Areas (Buffers)

It is difficult to control all waste routes and the material flow rate in a manner compatible with the processes occurring in each area, which are usually of the batch type. This creates the need for an interim storage area at the entrance and at the exit of the areas indicated above.

7.3.3 Staff Requirements

A typical WMF staff includes:

- One operator for spool acceptance from dismantling operations and their storage in buffer areas
- One or two operators for segmenting operations
- One or two operators for decontamination activities
- One operator for spool handling inside the WMF
- One specialist for preliminary and final monitoring
- One operator for waste-route management and treatment of each single spool

8 Safety, Health and Environmental Protection

8.1 Overview

There is a general feeling that decommissioning is an activity involving limited risks, compared to NPP operation, and in particular risks involving the general public. This is technically confirmed by licensing analysis and evaluations, where, once the spent fuel has been removed from the plant, the radioactivity inventory available to be released to the environment is very limited.

Decommissioning activities performed so far in the world have also confirmed the first assumptions and no specific issue has been identified in this field to justify a completely new approach. Commercial interest in international harmonization, which could drive an in-depth assessment about the bases of this approach, is weak at the moment.

However, there are several reasons why a discussion in an international framework about the safety case for decommissioning (and, in particular, about accident assessment) may be considered necessary and important, and why it may show some specific and peculiar aspects.

- Risk for workers could increase. The need for safety approach optimization, considering both radiological accidents and conventional industrial accidents, will be developed later. However, it is common experience from practical decommissioning work as well as feedback experience from annual outages and major refurbishment work at the power plants. Not only is it during these periods that most of the collective dose is absorbed, but many accidents also occur when people are testing or changing the systems of a plant. Handling of hazardous material (alkaline metal coolants, lead, asbestos, mercury, beryllium, etc.) requires special attention and the industrial safety issues are also of prime concern (high pressure, corrosive liquids, lasers, electrical hazards, falls, vibrations from jackhammers and scabblers).
- Regulations and technical guides are usually at an early stage in the development process. This is true in most countries. This is an additional reason why the approach to accident assessment in decommissioning is considered at a case-by-case level and, as a consequence, significant differences exist among different situations. Clearance levels for decommissioning material and rules for site release are still lacking.
- Peculiar issues exist. Accident assessment in decommissioning may be challenging, since a reference plant configuration practically does not exist and an accurate review of the decommissioning stages and activities should be considered in order to assure that the analysis is conservative and all-enveloping. Additional peculiarities are, as mentioned above, the combination of radiological and industrial risks and uncertainties about the quantification of releases.
- Harmonization advantages. A national and international harmonization process could imply a positive outcome in terms of the predictability of licensing processes, better public acceptance, reliable scheduling, and cost reductions.
- In some cases, the safety systems do not provide the same level of redundancy and protection as during plant operation.

- During the decommissioning process, the plant undergoes a number of mechanical and chemical stresses.
- Progressive dismantlement of systems and structures that may be degraded and not in a design configuration.
- Large quantities of liquid waste produced.
- Liquid pathways may become more important than in operation.
- Unusual source term may be present, which during plant operation may have been well confined inside systems and materials.

In  [Table 36](#) are summarized major differences in the approach between operation and decommissioning phases.

 **Table 36**

Major differences between operation and decommissioning phases

	Operation	Decommissioning
Hazard profile	Stable Well-characterized Radiological hazards dominant Potential for significant off-site effects	Frequently changing Often not well-characterized Industrial safety issues more significant Lower potential for off-site effects due to removal of inventory
Work planning	Frequently performing routine Focused on operation and maintenance Relatively short tasks	Task- or job-oriented New, first-of-a-kind tasks Work planning for workplace safety critical
Hazard analysis	Operation-oriented Generally stable focus on off-site consequences	Dynamic Mainly task-oriented Changeable Focus on-site
Workforce experience	Familiar with facility operation and routine work according to approved design	New mission Limited experience Subcontractors may not have process knowledge of facility operations Knowledge may need to be maintained for long periods
Contract management	Licensee managed and operated	More short-term subcontractor involvement, high level of Dependence on contractors performance Need for strong project management

8.2 Safety Culture

The issue of keeping an adequate level of safety culture during decommissioning has been brought to the attention of the safety authorities and decommissioning implementers in the last years.

The concept of safety culture became popular in the nuclear field after the Chernobyl accident in 1986, but in particular after the issue of the IAEA Report INSAG-4, where the group of safety experts assisting IAEA placed the basis for the application of the concept to nuclear activities.

Safety culture is not only knowledge and competence, it is mainly composed of a set and a mix of attitudes and explicit and implicit behaviors of individuals and of organizations as a whole. The concept would need a longer discussion, but here we would like to stress the key element related to decommissioning.

Loss of experienced personnel, unjustified sense of safety about radiological risks, the activities of a number of contractors not specialized to work in a nuclear environment, organizations more project oriented than safety oriented, lack of indication from the top of the organizations that safety is still a priority and other specific conditions may be cause of sharp reduction in safety levels and in an increased level of risks.

A number of initiatives help the organizations to keep and continuously improve the safety levels and the attitudes of all the personnel. Among the initiatives that may contribute to the above goal, the following is listed:

- Continuous indication by the top managers that safety is a Company priority
- Periodic review of the safety culture levels by means of KPI
- Periodic interview of the personnel by dedicated and experienced team
- Training program for all contractor personnel
- Review of operation experience and of specific incidents or near misses.

8.3 Safety Assessment

Experts involved in the safety analysis of operating plants might consider the same approach and rules (such as defense in depth, the single failure, the safety classification of equipment, prevention vs. mitigation, pervasive roles of quality assurance and safety culture), but it would be common sense to adapt these safety cornerstones to the real safety significance of decommissioning activities.

8.3.1 Accident Analysis

A number of data and assumptions are relevant to accident analysis. In several cases, the database and the assumptions used for operational safety analysis are not relevant or not applicable. Examples are:

- Source term for radiation fields and release calculations
- Statistical data on human errors and specific job conditions
- Computer codes for release and consequence calculations

- Approach to structural analysis for intermediate plant structural configuration
- Approach to fire protection
- Acceptance criteria in terms of plant damage and mechanical stresses

Once the list of accidents to be considered is complete, they must be classified in terms of expected frequency or probability, in order to associate appropriate acceptance criteria and their grouping in accidents of similar cause/evolution/effect, in order to be able to identify the most representative and consequently reduce the number of calculations to be performed.

An example of event grouping is presented in [Table 37](#). Events are grouped according to the type of challenge and activities involved.

Table 37
Some events to be considered in accident analysis

Events caused by the decommissioning activities	Decontamination activities	Leaks of pressurized fluids during decontamination activities (...)
	Dismantling activities	Metal components and piping cutting Concrete removal (...)
	Material handling	Drop of a contaminated component Drop of a concrete chunk Drop of a contaminated filter or of containers with radioactivity (...)
Loss of supporting systems	Loss of off-site power supply	Loss of ventilation and filtration lines (...)
	Loss of service water	Sudden interruption of decontamination, cutting and dismantling equipment (...)
	Loss of compressed air	Loss of dismantling equipment and loss of pneumatically operated valves (...)
Fires and explosions	Fires	Fire in the radioactive waste storage facility (...)
	Explosions	Explosion of a gas bottle used in the operations (...)

■ Table 37 (continued)

External events	Earthquakes	Integrity of structures and of systems and components during partial dismantling: generally the plant has been designed and verified for earthquakes according to regulations. In general, there is no reason to increase the seismic level during decommissioning. The only concern is the resistance of partially dismantled structures and the possible consequential release of radioactivity in the environment (...)
	Flooding	Internal flooding caused by water body exondation (...)
	Wind and tornados	(...)
	Volcanic activity	(...)
	Lightnings	(...)
	Toxic chemical releases	(...)
	Aircraft crashes	(...)
	Gas cloud explosions	(...)
	(...)	(...)

Some of the above events might not be applicable and some may fall below the credibility threshold. However, it could be of interest to fill out a comprehensive list of events, from which in each specific case one could identify those to be considered. It is estimated, for example, that at the beginning of dismantling activities there will be various potentially toxic or hazardous chemical products stored at the plant, such as those indicated in [▶ Table 38](#).

It is also of interest not to spend unnecessary resources on events of small probability and with small consequences, which could be difficult to quantify exactly. Therefore, experience and engineering judgment are of utmost importance in the selection process.

8.3.2 Human Factors and Organizational Considerations

The period before and after termination of operation could be one of stress and insecurity. Confidence in the management can deteriorate and motivation can decrease, a state of affairs, which

■ Table 38

Potentially toxic or hazardous chemical products stored in a nuclear power plant (SOGIN)

Substance	Estimated inventory (kg)
Acetylene	70
Carbon dioxide	12,000
Butane	70
Propane	110
Freons	500
Hydrogen	100
Nitrogen	10,000
Chlorine	200
Paints, varnishes and enamels	1,000
Solvents	1,000
Boric acid	500
Hydrazine	200
Ethanol	50
Acetone	300
Trichloroethylene	200
Gasoil	100,000
Lubricating oils	10,000
Ammonium	500
Sodium hypochlorite	10,000
Calcium hydroxide	10,000
Sulfuric acid	20,000
Halon	300

can affect safety and the decommissioning work. The process of decreasing the staff and the development of a decommissioning organization should be separated. Experience has shown that a special organization for re-education and job finding could be helpful.

The persons who will carry out the decommissioning activities should be given the possibility to develop their knowledge and improve their competence. Instead of detailed central planning, it is better to work in a participative way and to have staff involved in the preparations of the decommissioning work from the beginning.

An open question is how to consider human factors in accident assessment, i.e., what type of mistakes might be made, how many, for how long and their probability.

Unlike plant supervisors and plant operators, in decommissioning personnel with less education and shorter experience in the plant may be utilized, probably increasing the risk

of radiological and conventional accidents. This is also the experience with operating plant maintenance work.

8.3.3 Emergency Planning

Related to accident assessment is the question of the importance of one of the mitigation features available, i.e., the emergency plan.

The role (if any) of an emergency plan in decommissioning is a subject for discussion. In some countries, there is confidence in the fact that, after the spent fuel has been removed from the site, there is no need for a special emergency preparedness plan. Six months after a reactor has closed the content of iodine-131 in the fuel is so low so that iodine prophylaxis is no longer justified. But, for reasons of public confidence and psychology, a strategy for the downsizing of the emergency plan should be carefully planned and each step should be well thought-out.

Information to the public about the activities at the site is needed at all stages in the decommissioning process.

The IAEA report Preparedness and Response for a Nuclear or Radiological Emergency, Draft Safety Requirements No. GS-R-2, DS43 addresses this issue. In this report five different categories of nuclear or radiation threat are identified.

- Installations for which events that can give rise to severe deterministic health effects off-site are postulated or have occurred in similar installations, including very low probability events.
- Installations for which events that can give rise to off-site doses warranting urgent protective actions consistent with international standards are postulated or have occurred in similar installations. This category (as opposed to category I threats) has no credible events postulated that could give rise to off-site doses resulting in severe deterministic health effects.
- Installations for which events that could give rise to doses on-site resulting in severe deterministic health effects are postulated or have occurred within similar installations. This category (as opposed to category II threats) has no credible events postulated for which urgent off-site protective actions are warranted.
- Minimum level of threat assumed for all countries and jurisdictions. This category includes events involving: facilities for which events could give rise to doses warranting urgent actions consistent with international standards on-site, but for which no credible events are postulated that could result in severe deterministic effect; mobile practices using dangerous sources; medical misadministration; transportation; and other events that could occur virtually anywhere (the public finding a source resulting in exposure and contamination, loss or theft of or damage to a dangerous source, reentry of a satellite, and illicit trafficking) that may warrant emergency intervention.
- Areas that could be contaminated to levels necessitating food restrictions consistent with international standards as a result of events at installations in threat categories I or II, including installations in nearby countries.

8.4 Environmental Impact Assessment (EIA)

The role of EIA as a tool for pollution prevention and minimization has gained wide acceptance since the late 1960s. EIA definition generally incorporates the following key principles:

- EIA identifies and assesses a project's likely significant environmental effects to inform decision-making
- EIA allows consideration of the environment early in the decision-making process on a proposed project
- EIA enables proposals to be modified, in light of potential impacts, in order to eliminate or mitigate them

The EIA process outlined in this guidance document is shown in  Fig. 21. This process can be divided into various phases, which are described in the following sections.

 Figure 21

Block diagram of environmental impact assessment (EIA) process (EU 2001)

8.4.1 Scoping

The scoping stage is the phase when, among other things, the terms of reference (ToR) for the EIA are defined.

At this stage, stakeholders (including competent authorities and the developer) should have an opportunity to express their opinions and concerns over the proposed decommissioning project, integrating them into the definition of the ToR. The decision-making procedures and criteria should be described at this stage and feasible alternative(s) selected.

In spite of not being formally required by the EIA Directive, the introduction of a formal scoping stage with stakeholder involvement has gained wide support for its advantages and is generally considered to represent best practice. Formal scoping ensures that stakeholders learn of the proposed development at an early stage, that key concerns are reflected in the ToR, and that resource use is optimized in further stages by focusing on the (previously agreed) fundamental elements for evaluation. In addition, it has been found (EC 1996b) that one of the principal causes of significant costs and time delays in the decision-making process is the lack of a proper scoping exercise and the subsequent failure to undertake systematic studies, resulting in need for supplementary information.

Scoping corresponds to Steps 1–10 of the proposed process. The technically feasible alternatives to be subjected to EIA are selected in this phase, firstly by rejecting alternatives that do not meet agreed decision-making criteria.

These criteria are likely to include considerations such as unacceptable environmental risks or excessive cost. Reducing the number of alternatives in this way makes the scoping phase more efficient in terms of the use of resources.

- Steps 1, 3: Identification and list of stakeholders. The input of stakeholders is vital to the success of the scoping stage and thereby to the entire EIA process, thus it is important to start by identifying all stakeholders and listing them in a single document. The list of stakeholders should include all contact details and be made publicly available.
- Step 2: Outline of feasible engineering alternatives. At the start of the process, and in parallel with the identification of stakeholders, an initial outline of feasible alternatives should be prepared. These alternatives are later screened, based on agreed criteria, to obtain a list of the alternative(s) to be assessed in more detail.
- Step 4: Definition of decision-making procedures and criteria. This is the core of the scoping stage. The agreed decision-making procedures and criteria are used throughout the EIA process and thus the widest support from stakeholders should be sought. Public participation plays a key role in integrating the public's concerns in the EIA and in the decision-making process in general. Another aspect to be considered at this point is the definition of the project baseline, specifying the existing situation against which comparisons of potential environmental impacts should be made.

It is expected that Steps 1–4 would take from 3 to 6 months to be completed. The amount of time required depends to a large extent on the degree of support for the decommissioning project. If there are disagreements between stakeholders, repeated meetings may be necessary before reaching an agreement on the scope.

- Step 5: Alternatives screened according to agreed decision-making criteria. A first screening of the proposed (technically feasible) alternatives should be undertaken as part of the public

participation procedure at this stage. The aim of this step is to concentrate resources on the investigation of realistic decommissioning options.

- Step 6: Public information on agreed decision-making criteria and remaining alternatives. The public should be informed about the results of this first part of the scoping stage, i.e., the decision-making procedures and criteria, as well as the alternatives selected for further examination.
- Step 7: Scoping for impacts of remaining alternatives. The remaining alternatives must then be scoped for impacts, in order to select the final alternative(s) for the remainder of the EIA process. This ensures that only alternatives that are technically feasible, socially acceptable and with potentially low environmental impacts are subjected to a detailed assessment.
- Step 8: Draft scoping report. A draft scoping report is produced at this stage, establishing the scope of the EIA for the decommissioning project. This document is made publicly available. The process, including the rejection of alternatives not meeting decision-making criteria (Step 5) through to the production of the draft scoping report (Step 8), is expected to take approximately 3–6 months.
- Steps 9, 10: Discussion and agreement of draft and final scoping reports. As scoping is the key to efficient EIA, helping to focus all resources on the significant issues of concern, all stakeholders must have the opportunity to discuss the draft scoping report, and outstanding issues or inaccuracies are pointed out at this stage (Step 9). The public review of the draft scoping report should take place according to the guidance on public participation provided in [▶ Sect. 3](#) and is expected to last approximately 3 months. A final scoping report (Step 10) is then produced and made publicly available. This report incorporates all the changes to the draft report agreed at the stakeholder meeting, and this document then forms the basis of the EIA to be undertaken.

8.4.2 Environmental Impact Evaluation

Once the scope for the EIA has been defined, the developer may proceed with it. In order to make an assessment of the potential environmental impacts and define ways to mitigate or eliminate them, as well as how to ensure their proper monitoring, a series of steps needs to be undertaken.

- Step 11: Determination of the environmental baseline. In order to predict the potential environmental impacts of the proposed project, the initial environmental conditions must be known. Environmental damage varies according to the initial conditions: for example, a given level of emissions may be more damaging in ecologically-sensitive zones or may surpass the ecosystem's tolerance level if the area is already polluted; tall structures may be tolerable in industrial areas but not within a site of outstanding natural beauty. The definition of the baseline conditions (e.g., meteorological conditions, geological formations, and groundwater flow direction) also provides data necessary to make impact predictions.

Because the same baseline conditions apply to all of the options, this step can be started before the full scope of the EIA has been agreed. There may be some unnecessary expenditure incurred, but this would be small compared to the wider project ones and are likely to be more than offset by the benefits of completing this stage early in the process.

- Step 12: Impact identification. Potential environmental impacts are identified at this stage, based on parameters related to the degree of physical and social-economic impact, as well as according to the public's perceptions and values. For each alternative being evaluated, a separate analysis needs to be carried out to determine the likelihood of environmental impacts.
- Step 13: Assessment of the significance of impacts. This step considers the implications of the impacts identified previously and assesses their significance. Significance can be gauged relative to environmental standards or against public perception for some more subjective impacts. Therefore, frequent dialogue with stakeholders throughout the Environmental Impact Evaluation can be very helpful.
- Step 14: Development of mitigation measures. One aim of EIA is to remove or reduce to acceptable levels all the impacts that may occur. The identification of possible mitigation measures must have the agreement of the developer, if they are to be included in the EIS.
- Step 15: Listing of residual impacts. Mitigation can rarely remove all the identified impacts and a clear statement has to be made about the impacts, which would still occur even after the implementation of the mitigation measures.
- Step 16: Development of monitoring plan. In recognition of the fact that the evaluation of impacts is subject to uncertainties, it is appropriate to develop a monitoring plan, which would be able to check that the residual impacts identified are the only ones which occur. This would ensure that no unexpected impacts arise and that the proposed mitigation measures are working adequately. If unexpected impacts do arise, these would provide an opportunity to take remedial actions. The study to evaluate the impacts of the alternatives under investigation (Steps 11–16) is expected to last up to 12 months. This timing depends on the information that is already available and that must be specifically collected (e.g., local meteorological and ecological data). The developer may have ongoing communication with stakeholders during this phase, in order to ensure that their concerns are being properly addressed and that local and expert knowledge has been used effectively.

8.4.3 EIA Regulations

The requirements of the EIA Directives and of the relevant guidance on EIA methodology provided by the European Commission are reviewed. Although the existing guidance is necessarily of a general nature, the advice given (e.g., advice on the assessment of indirect and cumulative impacts, European Commission 1999a) has been taken into account in developing the guidelines.

The report also examines the potential implications of two UNO Conventions, the Espoo Convention on EIA in a transboundary context (adopted in 1997) and the Aarhus Convention on access to information, public participation in decision making and access to justice in environmental matters.

The provisions of the Espoo Convention were largely taken into account in the 1997 EIA Directive, the main difference being that the Directive refers only to Member States, whereas the Convention has no such limitation.

Some modifications of the EIA Directive will be required when the Aarhus Convention comes into force, which will be when it receives its 16th ratification. The European Union is already a signatory, together with all of the Member States and most of the Applicant Countries participating in this study. The Aarhus Convention stipulates that public participation should

occur early in the EIA process, but at present the Directive requires only that the concerned public be given an opportunity to express an opinion before development consent is granted. In general, the Directive presently allows Member States more discretion than will be allowed by the Aarhus Convention on the issues about which views should be sought and on the timing of such public involvement.

8.4.4 Consent Processes for Decommissioning in EU Member States

Although a permit must be obtained before decommissioning can begin, there is some diversity of views about what operations signal the start of decommissioning. In particular, the removal of spent fuel (defueling) is a normal part of reactor operations as well as part of decommissioning operations. Since the decision to shut down a reactor permanently may be made on quite short notice – perhaps for economic or technical reasons, or prompted by a major outage – some countries (such as the UK, Spain, Sweden, and Germany) regulate the final defueling under the existing procedures for reactor operation. This avoids the need to keep spent fuel on-site if a decommissioning plan has not yet been fully developed and consent obtained.

There is general acceptance in all the countries that the EIA should include the selection of the strategy for decommissioning, i.e., the process of choosing between different possible decommissioning strategies. There is also a general acceptance that the process should address a wide range of impacts, including social impacts, land use and transport considerations, and both radiological and nonradiological impacts. All countries agree that the report should consider impact minimization.

The roles of the competent authority for decommissioning and for the EIA vary between countries, in accordance with the differences in national legislation already noted. There are different mechanisms for ensuring that all technological, safety and environmental aspects are covered, and that the permit is only granted with the consent of all the relevant authorities.

8.4.5 Consultation and Public Participation

There is a range of approaches being taken in all the countries to the question of what the EIA process comprises. A key distinction is the extent to which there is a formal scoping procedure to establish the issues that should be addressed by the EIA, including consideration of alternatives.

The definition of a public participation strategy for the EIA of proposals to decommission a NPP will depend on various factors, including the stage of the EIA in question and the specific context in which the EIA takes place.

An important aspect of undertaking an EIA for a nuclear decommissioning project is that the decision to undertake the project has been taken.

Therefore the focus of the assessment would normally be on how and when, rather than if, the project should be carried out. The comparison and selection of alternative decommissioning strategies will form the basis of the assessment. Another key feature of nuclear decommissioning projects is their high public profile: there is likely to be broader public support for the project if information on alternative decommissioning strategies is available and the public is consulted on them.

The responsibility for facilitating public participation depends on the stage of the EIA process and the country-specific legislation. Thus, some countries may require the developer to

organize the participation, including any mandatory public meetings or inquiries, whilst in other countries it may be the responsibility of the competent authority. These guidelines do not specify who should be responsible for defining the public participation strategy throughout the EIA process, but are applicable to whichever party holds such responsibilities. However, some opportunities for participation are more appropriate for the developer to organize, such as the ongoing consultations during the impact evaluation studies and the EIS preparation stage. Other roles are equally appropriate for the competent authorities, such as preparation of the ToR (scoping).

There are certain key issues in the definition of a public participation strategy which are common to all stages of the EIA process; guidance on these is defined first. Following this, guidance is provided on public participation for each stage of the EIA process.

8.4.6 Definition of Preferred Options

Once the decision to terminate the operation of a nuclear power plant has been made, preparation for the decommissioning phase begins. The end of the operational phase of a nuclear plant is characterized by the complete removal of the fuel from the reactor core and by the conditioning of operating wastes.

The central element of NPP decommissioning is made up of the activities of dismantling, decontamination and restoration. One result of these activities is the production of wastes of various types, including radioactive wastes. The dismantling option, and the particular methods and techniques selected for any particular project, is partly determined by the possibilities for management of these wastes.

The dismantling alternatives analyzed will imply the possible achievement of one of the three levels of decommissioning described by the UNO-IAEA (1983a):

- No action, implying maintenance of the shutdown situation.
- Long-term or “safe” storage, which entails modifying the installation to establish a structure that safely contains the radioactive material for a prolonged period. This allows radioactive decay to reduce the quantity of radionuclides in the former NPP, with a view to the eventual dismantling and unconditional release of the site. This period may cover from 10 to up to 100 years or more, depending upon the detailed decommissioning strategy adopted and the availability of radioactive waste storage or disposal facilities.
- Immediate dismantling, consisting of the dismantling of the facility in the short term, leaving the site free for unconditional use after a short waiting period (3–10 years), during which it is subject to surveillance.

The components to be analyzed in choosing the preferred alternative are summarized below:

- Requirements of the regulatory bodies
- Characteristics of the installation, including design, operation, and the radiological inventory existing after the definitive shutdown
- Evaluation of the radiological and nonradiological risks
- Physical status of the installation and its evolution; this analysis should include a study of the integrity of the buildings, structures, and systems
- Alternatives for management of the radioactive wastes (including spent fuel)
- Environmental impact of the decommissioning options

- Availability of funds for carrying out the various decommissioning alternatives
- Availability of qualified personnel and suitable techniques for dismantling tasks (including decontamination and waste volume reduction techniques)
- Experience of similar projects
- The possible end land-use for the installation site

As well as providing a tool for assessing impacts and for developing mitigation measures, the EIA process will also result in the development of information needed in due course to facilitate monitoring the environmental situation as the project proceeds.

In the particular context of the emission of effluents that contain radioactivity, the ongoing objective is to demonstrate that these emissions remain within the requirements of the applicable nuclear or radiological protection standards. The radiological impacts of emissions are assessed as individual and collective doses both for the workers engaged in the project and for the general public.

8.4.7 Baseline Description

The description of the environmental baseline must be as complete as possible about the environment as it exists prior to performance of the decommissioning project, so that it can serve as a basis for assessment of the project's potential impacts. The interaction between the environmental factors defined by the baseline description and the actions occurring as a result of the decommissioning project is described as well.

As regards the scope and depth of the baseline description, and for economic reasons, the greatest use possible should be made of existing information, ensuring that it is accurate. The competent authorities and organizations in the affected area should be consulted to obtain the maximum amount of existing data, thereby reducing the overall costs. The scoping exercise carried out as part of the EIA has identified those environmental factors that need the most attention at this stage and for the impact prediction stage which comes later. The main environmental factors that would be expected to be included in any baseline description are outlined below.

Impact Factors Relating to the Natural Environment

Air. The quality of the air should be characterized in terms of the pollutants known to have potentially harmful effects on either human beings or the environment, particularly concentrating on those which may be released from the installation. A study should be made of the potential sources and quantities of emissions. The meteorological characteristics of the region should be investigated including temperature, rainfall, humidity, wind speed and direction and climate classification. This information is used to assess the capacity for contaminant dispersion in the atmosphere and may be a factor in the design of structures, for example if waste stores are to be built.

Water. The hydrology and hydrogeology of the land and the quality of surface water and groundwater should be characterized in relation to both human activity and the environment in general. In this respect, any alteration in water quantity, quality, spatial location and availability will have a major repercussion on both mankind and on plant and animal communities. Furthermore, water may act as a receiver of contaminants and information on the pollutant capacity and response should be collected, taking account of the likely use of the water. Information on the ecological value of the water should be included, as should economic

factors and other issues such as the role of the NPP in controlling water flow, including possible flood risks.

Land and Soil Factors to be investigated include land use (in terms of physical, chemical and biological parameters), soil type and quality, terrain morphology, erosion potential, ecological risk, and agricultural capacity. The contamination status of the soil should be clarified before the dismantling tasks begin. The soil studies should focus on the soils on the site and in the adjacent areas, which may be affected by release and dispersion of effluents.

Flora and Fauna The baseline description should include a study of the plant and animal species existing in the area surrounding the plant site, as well as of their habitats and distribution. Rare and protected species should be identified along with analysis of the nature of the habitats and ecosystems in the area. Studies should be carried out at appropriate times during the year to ensure that flowering plants are properly identified and that migratory species, present only for short time periods, are also considered.

The Landscape An assessment must be made of the quality of the landscape. This includes both objective and subjective assessment criteria in areas such as:

- Visibility, including the extent of the domain from which the installation is visible
- The quality of the landscape, characterized by its morphology, vegetation, plant formations, lithology, and presence of large bodies of water
- Human presence, including the nature and extent of man-made structures and other influences (e.g., agriculture) on the landscape

Noise and Vibrations The background noise level prior to dismantling should be ascertained, either from existing monitoring reports or through direct measurement. This information is critical in the determination of noise impacts which might require mitigation or compensation to be paid.

Of equal importance to noise, in terms of future predictions, are vibration levels expected to be associated with decommissioning works. It is necessary to investigate buildings and other structures likely to be at risk, to determine their likely resilience to vibration damage.

Identification of Potential Impacts

This work must be carried out in a structured manner, in order to ensure that all actions having the potential to cause an impact are identified and considered. Various methodologies allowing such actions to be identified are listed.

The actions relating to the decommissioning of a NPP that might cause impacts are defined on the basis of the project activities.

Each of these activities is made up of a set of actions that may potentially have an impact on the environment. The actions, or their scope, will vary depending on each dismantling alternative, this being deduced from the data specific to the projects to be assessed.

Included below is a generic list of the main actions to be considered. As indicated above, these actions should be identified in the EIA and their alternatives considered:

- Modification of the level of occupation or manpower
- Modification of the industrial site
- Modification of industrial buildings
- Modification of property limits
- Demolition of buildings
- Construction of new buildings

- Landfill and earth movements
- Siting and drainage
- Recycling of waste materials
- Transport of materials
- Handling of hazardous materials (radioactive and toxic)
- Work in monitored and controlled zones
- Treatment of liquid and gaseous effluents (radioactive and nonradioactive)
- Use of rubble tips or tips for inert solid wastes on or off site
- Storage or disposal of radioactive wastes
- Risks of dismantling (potential accidents and actions)
- Fires of various types (involving radioactive and/or toxic materials)
- Releases and leakage of contaminating liquids and gases
- Maintenance failures (e.g., leading to dropping of loads)
- Personnel accidents (e.g., falling from heights and impact by falling objects)
- Structural failures due to the action of external agents (e.g., earthquakes, flooding and sabotage)

The environmental factors that might be affected by impacts belong to the physical, chemical and biological media or to the social-economic media. The description of the environmental baseline to be included in the study characterizes these factors in the situation prior to decommissioning, so that the subsequent impact can be assessed.

In the following, a list is presented of environmental factors that may be affected by a decommissioning project, with a brief description of the impacts. It is important to emphasize the fact that this list may serve as a guide when applying the guidelines to a specific project. The EIA should develop a specific list drawn up from the environmental baseline of the particular installation being studied.

Air The dismantling works include the demolition of buildings, crushing of rubble, disassembly of plant and machinery, and movement of vehicles and machinery. All these activities lead to the emission of radioactive and nonradioactive gases, particulates, and aerosols, and affect the quality of the air.

Alterations to the local or regional climate would not be expected, since the dismantling activities will not lead to the release of significant quantities of material or energy that might result in such impacts. Consequently, the environmental factor that may primarily be affected is the air quality.

Land and Soil The importance of the factors included in this category varies considerably depending on the dismantling alternative selected. Any parts of the site to be released for unconditional use must be decontaminated, and the buildings demolished if no further use is foreseen for them. The rubble and wastes generated may be stored on-site or removed from it. If materials are stored on-site, the project has to include a design for safe storage facilities. The potential modifications of the land will be caused by the refilling of gaps, leveling operations, the compacting and re-profiling of the terrain and, in certain cases, the removal of underground structures. The deposition on the surface of the soil of contaminated particles emitted during the dismantling operations might affect soil quality, although the contaminated areas would be strictly localized and would normally be within the site boundary. In view of the above, the main environmental elements likely to be affected are natural materials used for construction, soil replacement, compacting and settling, and the topography.

Water The environmental factors vary depending on the hydrological and hydro-geological characteristics of the site. Consideration should be given to the possible contamination of surface water and groundwater as a result of releases and to contamination by leaches. Among the positive effects associated with decommissioning, common to all the alternatives analyzed, special mention might be made of the elimination of thermal contamination caused by the need to dissipate the surplus thermal energy arising during plant operation. The inclusion of such a benefit in the EIA is dependent upon the definition of the project baseline. The removal of artificial surfaces (occupied by buildings and roads) modify surface water runoff, the drainage of the plot and infiltration to the groundwater. Consequently, the aquatic environmental factors that might be affected are fundamentally water quality, water resources, the hydrological regime, aquifers and marine contamination.

Flora The effects on flora are due fundamentally to the emission of particles during the work with the potential to cause indirect effects by their deposit on land and leaf surfaces. The environmental factors that may be affected include species diversity, positive or negative effects on rare or endangered species, productivity, stability, and plant communities.

Fauna Effects on the habitats and/or behavior of certain species may arise as a result of increased noise levels and also changes in flora (e.g., food plants), as noted above.

Factors which may be affected include diversity, positive or negative effects on rare or endangered species (including fecundity), the stability of the ecosystem, food chains, and animal communities.

Landscape The landscape should be considered an integral part of natural resources. The scope of the modifications of this environmental factor varies considerably from one dismantling alternative to the next. In general, the demolition of buildings and structures decreases the visual impact associated with a NPP.

Noise and Vibrations Nuclear power plants are large structures, made of reinforced materials. There will necessarily be a lot of noise associated with dismantling works, and the transport from the site of dismantled materials will lead to heavy traffic noise and associated vibrations.

Land Use The factors encompassed depend heavily on the specific project and on the dismantling alternatives, as a result of which no general patterns can be established. All of the alternatives analyzed imply a total removal or partial reduction in classified land on-site (land which will be subject to restrictions on use). As a result, the net effect is of restoration of land for other uses.

This affects leisure and recreation, the development of tourism, the availability of land for industrial, commercial or residential development, changes in the use of industrial land, surplus areas, and rights of way.

Cultural Factors The factors included depend on the site location. The factors considered may include cultural heritage and archeological remains.

Infrastructures Factors which may be considered under this heading include transport and communications networks and services, water supply, electricity supply, commercial and industrial equipment, and sewerage.

Generally, the dismantling activities cause an increase in vehicle traffic, which may be more or less significant, depending on the geographical location of the plant, the dismantling

alternative selected and the specific project. Dismantling activities do not require additional public services, such as sewers, etc., since the number of dismantling personnel is expected to be somewhat fewer than those previously involved in plant operation. As regards water supply, electricity supply and sanitary networks, the subsequent use of the site affects the permanence, or otherwise, of the installations.

Human Factors In general, consideration may be given to the following factors under this heading: the quality of life, nuisance, health and safety, well-being, and lifestyle. As regards health and safety, the decommissioning project implies certain activities that give rise to radiation exposure of the workers and to a series of other occupational risks. The project and its associated documentation will have to identify such risks and will need to identify methods to prevent or minimize risks. The most important of these risks are associated with the following:

- Exposure to ionizing radiation
- Exposure to toxic products (e.g., aerosols containing lead, asbestos)
- Exposure to high concentrations of dust
- Falls, contact with electricity and other risks typical of construction work
- Exposure to high noise levels

Risks to the public should be established and documented, though these are considerably lower than those existing during the operational phase of the plant.

Population and the Economy In general, consideration may be given to the following factors under this heading: levels of employment, population density, migratory movements, population centers, economic benefits, the appearance of auxiliary industries, investment and expenses, the local, provincial and national economies, and energy consumption. In some cases, a significant social-economic effect may result from the ending of plant operations, which may result in lower employment, a reduction in revenue from taxes in the area and problems associated with a downturn in the industries supplying the installation. The number of workers at the installation is smaller than during the operational phase, although for some options there may be a short-term increase in employment associated with construction activities.

Impact Identification Matrix

A commonly used methodology for identifying of the impacts of a project on the environment consists of drawing up an identification matrix. This relates the project actions that might cause impacts on the components of the physical, chemical, biological, and social-economic environments affected. When there is an interaction, the intersection box of the matrix is marked with a symbol and the interaction is subsequently analyzed.

These matrices make it possible only to identify impacts, after which it is necessary to evaluate each cell marked in the matrix. Care should be taken to ensure that additional approaches are used in order to identify indirect and cumulative impacts, such as, network approaches.

► *Table 39* shows an example of a matrix applied to the decommissioning of a nuclear power plant, with consideration given to the options of “long-term storage” or “immediate dismantling.” These are more illustrative than the “no action” option because of their greater complexity. The intersection symbols used are only illustrative in this example; they must be identified for each particular project. This matrix should be used as a starting point in future studies and should not be regarded as a definitive indicator of likely impacts.

8.4.8 Impact Assessment

This phase includes evaluation of the effects that the project has on the environment. The qualitative evaluation of impact requires the application of assessment criteria similar to those previously indicated. For each factor, an assessment of the impact is obtained on the basis of the indicated classification. For the quantitative assessment of impacts, comparisons can be made with detailed impact indicators, where they are sufficiently well developed.

Impact Indicators

As more environmental research is carried out, environmental indicators begin to play a more important role in the assessment of impacts. Impact indicators constitute a particularly useful tool when they reflect the value of a parameter that measures an impact whose limits are regulated, or when there are guideline values. For this reason, the use of indicators is recommended for those impacts that may be quantified by means of internationally agreed methodologies.

The impacts obtained in this way can be easily transformed into qualitative values.

Specific indicators can be developed for each particular project. As an example, some of the indicators, which can be used for certain factors previously indicated, are given below:

- Air: concentrations of radioactivity in the air, concentration of dust particles in the air, effluent flow, level of acoustic intensity or pressure, and affected population (human, animal, and plant).
- Land and soils: concentration of contaminants in the soil, contaminated surface, volume affected, and surface to be restored.
- Water: concentrations of contaminants in surface waters, volume of releases, water consumption, priority routes for infiltration, and changes in temperature gradient.
- Flora: number and identity of species (especially protected species that might be damaged), areas in danger of contamination and areas with increased potential for fires.
- Fauna: number and identity of species, especially protected species that might be affected, and migration routes.
- Landscape: visual quality, changes in and/or destruction of existing structures, volume of earth movements, type and location of embankments, and cleared areas.
- Noise and vibration: noise levels adjacent to inhabited properties, location of inhabited properties, location of susceptible (to vibration damage) structures, etc.
- Land use: surface area of site to be reclassified for free use, following decommissioning.
- Infrastructure: energy supply, changes in the transport network, and levels of use.
- Human factors: doses due to levels of radiation in the area and from radioactive effluents; areas with high levels of noise and inputs of atmospheric contaminants, etc.
- Population and economy: changes in local revenue from taxes and special levies.
- Level of employment, population required to change the activity performed to date, etc.

The following sections describe major issues regarding the assessment of impacts for a nuclear power plant decommissioning project.

Radiological Impacts

The radiological impacts of the different dismantling alternatives result in different doses occurring, at different times, to different groups of people. The doses are due to changes in the

installation, as a result both of the activities involved in decontamination and dismantling themselves and of the duration of each phase.

The health effects, expressed in terms of radiation dose, correspond firstly to the normal execution of the different alternatives, and secondly to the effects of possible accidents for each alternative considered.

In assessing the radiological safety of dismantling, consideration needs to be given to three important routes of exposure: inhalation, ingestion, and external irradiation from radioactive materials. The most important route of exposure for the workers involved in dismantling is probably the external irradiation. The ingestion and inhalation routes must be minimized through application of the protection techniques normally used in these activities (surveillance and control of radiological conditions, filtration, containment, use of confined areas with controlled ventilation, and protective clothing and breathing apparatus).

Inhalation is likely to be the dominant route of exposure for the public, since external irradiation due to radioactive materials deposited on surfaces and ingestion should both be minimized as exposure routes during dismantling.

In the transport of radioactive materials, application of the IAEA Transport Regulations (IAEA 1996d), as enacted in the particular country, will ensure that inhalation and ingestion are eliminated as routes of exposure for the public and workers in normal transport operations, leaving external irradiation as the dominant route.

Noise and Vibrations

Another important and significant indicator for a nuclear power plant decommissioning project is the noise level. It is important to determine the characteristics of the noise produced: a continuous noise is one whose level is constant with time or has only minor variations; intermittent noise varies continually over time.

It should be determined whether during the dismantling work the operation of fixed or moving machinery and the performance of activities will cause noise levels in excess of the permissible limits for those affected, the human population and biological communities in the natural protected spaces located close to the plant.

The environment receiving the impact and its characteristics has been defined in the Environmental Inventory; as a result, the study focuses on the potential sources of noise.

The main machinery that causes an increase in noise levels during a dismantling project is constituted by concrete crushers, cranes, pneumatic drills, compressors, diggers, bulldozers, dumpers, concreting plant, radial cutting machines, concrete mixers, ventilation and suction equipment, demolition hammers, electrical generators, conveyor belts, vibrating rollers, and motor-driven levelers.

In addition to the machinery, consideration should be given to the noise caused by the activities themselves, especially those relating to the transport, handling, and treatment of waste materials.

Account should be taken of the possibility of multiple noise sources emitting simultaneously. Some of the activities on-site that create noise are also likely to cause vibrations which may lead to off-site noise.

Of particular importance for vibration are heavy goods vehicles, and their routes should be carefully planned and controlled.

Air Quality

The dismantling activities cause an increase in the concentration of dust particles both in the atmosphere and on the surrounding land as a result of their deposition. The main activities that produce dust are those relating to the demolition of structures, walls, and floors and to rubble-handling work (e.g., transport and refilling).

The concentrations will be determined taking the following into account: the quantity and nature of the material, the size of the particles produced, the meteorological conditions of the area (mainly the distribution of wind frequencies and intensities), the EIA radius, and the duration of the work.

Mathematical models can be used to calculate the factors of dispersion and deposition. These factors, along with the rate of emission, give rise to the concentrations of particles in the air and deposition on the surrounding land.

Land Use

Land use is strongly conditioned by the possibility of storing off site the radioactive and nonradioactive wastes produced during operation and during the dismantling tasks themselves.

The alternatives of “Immediate Dismantling” and “Long-Term Storage” imply a total or partial reduction of the land area that will continue to be subject to restrictions on use, consequently leading to partial restoration of the site.

Results of Assessment

The results of the assessment are discussed not only in terms of comparison of the predicted impacts with the impact indicators, but also with the significance of the impacts.

If environmental indices have been calculated for groups of impacts or for the total impact, these will be discussed in the light of the weighting factors used and also, if information is available, in the light of sensitivity testing of alternative weighting schemes.

8.4.9 Mitigation Measures

An important step in the EIA process is the definition of measures to be applied to prevent, mitigate or correct the environmental impact of the decommissioning project.

Identification of Mitigation Measures

Each dismantling alternative implies the implementation of a series of measures on the negative effects of the project, the scope and duration of which depend on both the project itself and on the characteristics of the site and the installation to be decommissioned.

These measures may be preventive, if they remove the impact by modifying the project activity causing it, or mitigatory, if they cancel, attenuate, or modify the impact once it has been caused. Listed below is a generic set of measures designed to correct possible negative impacts. These are applicable to the alternatives analyzed, although the scope and duration will differ, depending on the dismantling project:

- Minimization of exposure to radiation (the ALARA principle) and to contaminants through the effective implementation of the programs required by the radiological protection and occupational safety standards in force, which will have to be sufficiently rigorous and detailed, and through the use of remote handling and/or robot-based techniques

- Minimization of atmospheric emissions of contaminants by means of the best and most cost-effective techniques available. These techniques should include the use of emission-capturing systems, high-efficiency filters, dust-emission control systems such as moving covers, confined enclosures, spraying with coagulant and fixing solutions, and the careful planning of operations for the handling, and transfer of dust-producing materials
- Minimization of releases to surface waters and of concentrations of contaminants through the recycling and re-use of waste waters, the conditioning of solid radioactive wastes and/or their treatment using the best and most economic techniques available
- Control of leachates in collecting areas and rubble tips
- On-line control and tracking of the production and location of waste materials, associated with methods promoting their recycling or reuse
- Control of landfills and clearing of areas
- Safe arrangement of the main areas used for the handling and storage of radioactive, toxic and other waste materials. Those areas, in which the quantities of materials and the risk are highest, will need to incorporate construction characteristics and equipment preventing flooding, leakage, spillage and uncontrolled or inadvertent releases, and to achieve confinement and control if such events were to occur. The design of such areas should include measures preventing uncontrolled access and consideration of the risk of fires
- Minimization of the extent of land required for the storage of radioactive wastes and installations during the latency period. This requires the intensive use of waste-production minimization techniques such as the following:
 - Detailed identification and characterization of materials prior to dismantling
 - Classification at the point of origin, elimination of intermediate stages, and decontamination prior to dismantling
 - Minimum secondary waste treatment
 - Prevention of cross-contamination and recontamination through the control of contaminated materials and of transport vehicles
 - Reduction of the number of potential sources of risk, preventing the dispersion of storage facilities and intermediate collecting areas, and consequently reducing transport operations
 - Reuse of materials from demolition and excavation operations for refilling and topographic restoration activities
- Application of a flexible fire protection system. Flexibility is an essential element, given the changing nature of the situation of the plant during dismantling
- General use of silencers on vehicles and machinery, and minimization or elimination of blasting operations
- Adequate personnel training, for all levels and areas of the organization
- Truck-washing station to prevent problems of mud on the roads
- Periodic overhaul of obligatory safety elements, e.g., fire extinguishers and alarms
- Maintenance of hygienic conditions in the toilets for the operation personnel and other users, as well as in the cafeteria and canteen areas if they exist
- Modification of buildings (e.g., size, shape, and color) to minimize the visual impact
- Restoration of the natural morphology and replanting with native species if the site is not to be re-used
- Measures to promote employment, including use of the available operation personnel and promotion of sub-contracting in areas around the plant

- Adherence to strict working hours and transport routes for movement of materials off-site and on-site

Although these measures, and others that might be specified for a particular project, are usually incorporated into the project, it is necessary for them to be defined to a degree of detail sufficient to demonstrate not only that attempts have been made to carry them out, but also that further improvements would not be justified.

Final Impact

Once the preventive and mitigative measures have been defined, the impact generated by the project may be re-assessed.

8.4.10 Environmental Surveillance Program

The general objective of the Environmental Surveillance Program is to establish a system that guarantees compliance with environmental, health and safety standards and ensures implementation of the prevention and mitigation measures contained in the EIS. As such, reference will be made to the monitoring plan developed as part of the EIA (see step 16 of  Fig. 21). This control should be accomplished in such a way as to allow:

- Determination of real effects
- Direct tracking of work
- Monitoring of compliance with the environmental protection prescriptions (mitigation measures)
- Provision of data for the preparation or calibration of models predicting the existing and/or residual contamination

In a decommissioning project, the radioactive inventory will have been considerably reduced when compared with the plant's former operational phase. The parameters to be controlled will be:

- Concentrations of contaminants in the air, including gases and particles of dust, at the site itself (work areas), at its boundaries and in the closest inhabited areas, as well as at other points where the highest concentrations have been forecast
- Noise and vibration levels
- Control of possible leaches from waste-storage areas (if appropriate)
- Levels of contamination in water, soils and sediments
- Levels of contamination in the flora and fauna of the areas closest to the site
- Phenomena of settling and erosion of landfills and embankments
- Efficiency of replanting operations, where applicable
- Surveillance of the use of authorized tips
- Surveillance of the cleanliness of roadsides
- Other surveillance operations required by the standards governing fires at industrial establishments and by civil protection standards

In order to control these parameters, it will be necessary to define the measuring points and the frequency and methodologies used for such measurements, as well as the values that are to be expected, in order to be able to detect differences between the actual situation and that predicted by the EIA.

The environmental surveillance program should include a chronological flowchart indicating the frequency of the tracking work to be performed and the effectiveness of that work. The environmental surveillance program will involve the following phases:

- Installation of a surveillance network
- Data acquisition, storage and classification
- Analysis of the information acquired and of the causes of deviations from the expected levels

Finally, periodic reports are required indicating: the levels of impact generated by the project, the effectiveness of the mitigation measures, the degree of accuracy of the EIS forecasts and the required modifications: enhancement of the environmental protection system and adaptive changes in the surveillance plan itself.

9 Decommissioning Cost Evaluation

9.1 Cost Evaluation Methodologies

The methods of evaluating and presenting decommissioning costs differ from one country to another and even from one operator to another within the same country. In all countries, total expenditures are estimated based either on costs resulting from the experience in similar situations or on particulars related to each installation. For example, the cost of dismantling a power plant is generally estimated at 15–20% of the initial cost of construction. Dismantling represents less than 1% of the production cost of each kWh in actualized figures, or 2–3% without discounting.

According to current accounting standards, two methods are used by companies to evaluate expenses which will occur in the future, but for which a precise date cannot be attributed:

- The method of current value consists of evaluating future expenses by their present cost. The result is corrected every year for inflation and is revised periodically for technical and legal changes. In this way, the value of future expenses does not depend on when the expenditure is made. This is the method generally used in France and Germany.
- The method of net present value consists of calculating the current value by discounting future costs. This method is used in Belgium, the United Kingdom, Italy, and Sweden.

When choosing the method of calculation, the various companies are largely influenced by the legal requirements and accounting practices used in their respective countries, as well as by contractual considerations:

- The net-present-value method is very sensitive to the precise calendar of the forecast expenditures and to the real yield (above inflation) expected in the long run of accumulated capital.
- The current-value method accelerates the making of the necessary provisions, which are made gradually during the operation of the installations, according to their estimated duration and pace of activity (economic and technical). The net-present-value method provides an annuity to cover future costs by comparing the difference with the previous year's calculations.

9.2 Account Presentation

Regarding the account presentation, in some countries (Germany, Belgium, France, the United Kingdom, and Switzerland) assessments must normally show the provisions necessary to cover future costs. Costs must be justified to controlling bodies such as boards of directors, independent inspectors, and official authorities. Consequently, the estimated total cost is checked at the time of the audit of the responsible entities. This system is the most widespread.

On the other hand, in countries where responsibilities for the end of cycle and dismantling have been transferred to agencies funded by taxpayers, these costs no longer appear in the producers' financial statements, but in those of the agencies. A wide variety of situations exists, covering both these cases and all situations in between.

Once future costs are recognized in the accounts of the organizations that will have to bear these charges, it is then appropriate to secure the availability of the necessary funds at the appropriate time. The operator either pays into an external fund controlled by the competent authorities or makes provisions in his accounts whether associated or not with a mechanism of internal funds managed inside the company.

9.3 Responsibilities and Financing

An organization ensuring the availability of funds is usually created by governments, which can take responsibility for final waste storage and/or dismantling (in Belgium and France, in particular, the government created public establishments responsible for the storage of waste). Based on the final usage of sites, the government is often directly involved in dismantling the installations and managing the waste.

In most European countries, the government is not responsible technically or financially for dismantling operations except when managing historical waste. Operators in Germany, Belgium, France, the United Kingdom, Sweden, and Switzerland take responsibility for both activities.

In certain countries, like Germany, Belgium, Sweden, and Switzerland, laws stipulate operator financing. In other countries, where the companies involved have been privatized, part of the future charges is subject to special agreements (e.g., USEC in the USA, Magnox Electric/BNFL in the United Kingdom).

The various existing practices concerning technical responsibility and financing have been analyzed by the NEA of the OECD and split into four categories:

- Control of funds and responsibility in a centralized account, with operations and their financing transferred to a central governmental organization; examples are ENRESA (Spain), ONDRAF/NIRAS (Belgium).
- Control of centralized funds accompanied by decentralized responsibilities. The companies remain responsible for operations and financing (e.g., Sweden and Finland).
- Decentralization of responsibility for operations with legal or contractual guarantee mechanisms (e.g., USA and Canada for the mining industry).
- Complete decentralization of technical and financial responsibilities, with companies remaining responsible for operations and their financing. This category includes the most situations in the Netherlands, Switzerland, the United Kingdom, and France, with various degrees of control of the financial responsibilities.

It is often the case that in the same country, the solutions adopted for dismantling and the management of waste differ.

9.4 Standard Criteria for Cost Evaluation

Decommissioning projects for various types of nuclear facilities have also demonstrated that decommissioning costs may show relatively large variations. Studies attempting to understand the reasons for these differences have been somewhat hampered by the fact that different types of costing methods are used, with different data requirements. Although some uncertainty is inevitable in any costing method, an understanding of the costing methods used in particular projects is useful to avoid key uncertainties. Difficulties of understanding can be encountered and invalid conclusions drawn in making cost comparisons without regard to the context in which the various cost estimates were made.

The basis of the cost estimates for decommissioning projects derives from the world-wide experience acquired either in decommissioning projects or in maintenance and repair work at operating nuclear facilities where conditions are similar to some extent. This experience was utilized in the past either directly as an analogue for estimating the costs of similar tasks in decommissioning projects or indirectly for the assessment of unit costs for basic decontamination and dismantling activities.

Different costing methods have different data requirements, however, and consequently their reliability depends on the extent to which the various data are available and applicable to the specific case being considered. Regardless of the assessment method, some uncertainty is inevitable in all estimates of future costs, and no costing method is generally superior to others in this respect. However, analysis of the costing method may be useful in order to locate the key uncertainties in each specific estimate. It has been shown, indeed, that there is a potential for making errors, and that difficulties can be encountered in performing quick international cost comparisons. Numbers taken at face value, without regard to their context, are easily misunderstood and misinterpreted. This is due, among other things, to the fact that no standardized listing of cost items has been established specifically for decommissioning projects. Such a standardization would not only be useful for making cost comparisons more straightforward and meaningful, but would also provide a good tool for cost-effective project management.

The European Commission (EC), the IAEA, and the OECD-NEA agreed to start a coordinated action in order to produce a standardized listing of cost items and related cost-item definitions for decommissioning projects. Such a standardized list, as described previously, would facilitate communication, promote uniformity and avoid inconsistency or contradiction in the results or conclusions of cost evaluations for decommissioning projects carried out for specific purposes by different groups. The resulting list represents a uniform and more complete approach to decommissioning costs, and is hoped that the standardized list will be widely accepted and used.

9.5 Cost Evaluations

9.5.1 Overview

The total cost of decommissioning is dependent on the sequence and timing of the various stages of the program. Deferment of a stage tends to reduce its cost, because of decreasing radioactivity, but this may be offset by increased storage and surveillance costs.

The cost of decommissioning nuclear power plants is based on the following factors:

- The sequence of decommissioning stages chosen
- The timing of each decommissioning stage
- The decommissioning activities accomplished in each stage

In addition, costs depend on such country- and site-specific factors as the type of reactor, waste management and disposal practices, and labor costs.

Total decommissioning costs include all costs from the start of decommissioning until the site is released for unrestricted use. It is assumed that each facility will eventually be decommissioned to Stage 3, because some radioactivity will continue to exceed the limits for unrestricted access to the site for a much longer period than provided for in Stage 2. Hence, the total cost will either be that of an immediate Stage 3 decommissioning or that of a delayed Stage 3 plus the intermediate stages.

The cost estimates are based on previous decommissioning and decontamination experience, on the cost of maintenance, surveillance and component replacements, and on the cost of similar nonnuclear work. They are also based on a minimum storage period of 30 years after Stage 1, to allow for significant decay of radioactivity, and a period of 100 years after Stage 2, to allow worker access, generally without the need for shielding or remote operations. Estimates have been made by several European countries as well as Japan, Canada, and the United States.

Several methods of financing the decommissioning costs can be used, depending on the circumstances of each utility and the country in which it operates. In several countries, a fund of some type has been established or proposed to assure the availability of financing. This is usually done by estimating the cost of decommissioning at the end of the normal plant lifetime and requiring payments, either annually or on a charge per kilowatt-hour basis, to ensure that this sum is in place. This estimate is updated regularly and the charge adjusted accordingly.

The drawback to this system is that the amount estimated would not be in place if the plant were to be shut down before the end of its normal lifetime. To avoid this, a fund could be established at the start of the plant's operation which would cover the cost of decommissioning whenever it became necessary. However, this represents a heavy burden for the utility as construction and start-up costs are already high, and thus, although it may be imposed by law, this solution is not favored by many utilities.

The total cost of decommissioning is dependent on the sequence and timing of the various stages of the program. Deferment of a stage tends to reduce its cost, due to decreasing radioactivity, but this may be offset by increased storage and surveillance costs.

Financing methods vary from country to country. Among the most common ones are:

- External sinking fund (Nuclear Power Levy): This is built up over the years from a percentage of the electricity rates charged to consumers. Proceeds are placed in a trust fund outside the utility's control. This is the main US system, where sufficient funds are set aside during the reactor's operating lifetime to cover the cost of decommissioning.
- Prepayment, where money is deposited in a separate account to cover decommissioning costs even before the plant begins operation. This may be done in a number of ways, but the funds cannot be withdrawn other than for decommissioning purposes.
- Surety fund, letter of credit, or insurance purchased by the utility to guarantee that decommissioning costs will be covered even if the utility defaults.

In the USA, utilities are collecting 0.1–0.2 cents/kWh to fund decommissioning. They must then report regularly to the NRC on the status of their decommissioning funds.

9.5.2 Cost-Assessment Methods

Various methodologies are available for the calculation of decommissioning costs. The methodologies present different level of reliability and precision and are used according to the different objectives of the evaluations.

The major reasons that usually lead to the need of a cost evaluation are the following:

- To provide an input for the decommissioning funding during plant operational life
- To compare costs associated with different strategies for the decision-making process
- To prepare long-term budgeting and cash flow
- To provide a tool for project control

According to the above objectives, the methods include:

- Scaling up or down similar plant evaluations or experiences according to plant power, total plant activity, waste masses, or other criteria
- Simple calculations based on unit costs for a number of overall parameters like mass of activated metals, mass of contaminated concrete and mass of contaminated metals. This method can also be used for a generic power plant (not site-specific)
- Detailed site-specific calculations based on a very detailed bottom-up approach, separating each elementary work package

In the last case, a detailed database and a computer code treating a large amount of information are needed. The procedure for the calculation is generally the following:

Input data:

- Mass, activation and contamination analysis
- Strategy
- Organizational structure, work organization and personnel costs
- Boundary conditions (e.g., laws, standards and regulations, clearance levels, waste-disposal costs)
- Decommissioning technologies
- Operational practices and personnel performances

Output data:

- Actualized costs
- Overnight costs
- Cash flow
- Time schedule of the activities and their logical structure
- Manpower
- Waste characteristics and streams
- Worker doses

9.6 Cost Calculation Model Example

The procedure for the collection of the needed input data and evaluation of the specific plant data covers the following working tasks:

- Cost structure: definition of a list of all necessary decommissioning activities.

- Mass analysis: calculation of the decommissioning masses, radioactive waste, and radioactive reusable material based on the existing inventory of the plant.
- Calculation of the decommissioning activities: estimation of the cost, personnel capacity, and expected radiation exposure for every decommissioning activity.
- Elaboration of a time schedule: definition of the sequence of the decommissioning activities.

The key elements of the STILLKO 2 cost estimating process are described in the following sections.

9.6.1 Cost-Breakdown Structure

The cost breakdown structure (CBS) includes all decommissioning activities that are necessary for the successful completion of the decommissioning project, beginning with the licensing procedure up to green field status at the end. The CBS is organized into different levels in a hierarchical structure.  *Figure 22* shows this organization.

On the first level, the division of a decommissioning project is effected according to decommissioning phases, which are separated according to time and necessary permits.

On the second level, the decommissioning phases are divided into the following cost categories:

- Project management and project administration
- Planning and licensing
- Plant operation and security
- Plant technical activities for safe enclosure
- Preparations for dismantling

Phases	Subdivide the decommissioning effort into independent sections which usually require separate licenses. Operation (Ph 1A), SEP preparation (Ph 1B), SEP (Ph 2), Site release (Ph 3), Site restoration (Ph 4).
Cost categories	Subdivide the phases into sections which are important for the planning and implementation General planning and licensing, dismantling, decontamination, waste management, project management and administration, plant operation and security, etc.
Areas	Allocate cost categories to building areas. Plant, controlled area, ER, EA, ET and AT, support building for SEP, storage facilities, safe enclosure area, conventional area.
Tasks	Subdivide the cost categories within the areas into sections which allow a time and personnel oriented planning. About 200 tasks conditioning of primary waste, packaging of primary waste, release measurements, etc.
Activities	Subdivide the tasks into sections which allow a clear cost calculation. Ex: work permission, preparation of working area, restoration and cleaning of working area, etc.

 **Figure 22**

Decommissioning cost breakdown structure (CBS) organization

- Dismantling activated and contaminated components
- Decontamination
- Conventional dismantling
- Waste management
- Radiological and conventional worker protection

These cost categories have been created according to functional points of view and represent the volume of the decommissioning activities. The cost categories may occur in every decommissioning phase, with suitable contents of the cost categories regarding the respective decommissioning phase.

The third level is used to allocate the decommissioning activities to the buildings and areas on-site.

Using this level in the cost structure, it is possible to assign the work directly to the place where it arises, but also to determine the sequence of the activities and their schedule in relation to the building.

On the fourth level, individual tasks are defined that allow room-by-room or system-by-system planning regarding the situation on-site.

The execution of the tasks may be done at the same in different buildings, building levels or rooms.

On the fifth, the lowest level, the decommissioning tasks are divided into decommissioning activities. These activities are formed in such a way that each of them can be individually calculated. The bases of the calculation are illustrated in the following sections.

9.6.2 Mass Analysis

The components that are to be dismantled during decommissioning are partially activated by neutron radiation and partially contaminated through their contact with radioactive media. Taking into account technical and economical aspects, these components will be safely recovered as residuals or, if this is not possible for technical or economical reasons, properly disposed as radioactive waste.

The masses arising with such decommissioning are divided into three groups, according to their origin:

- Primary masses are all equipment, components and buildings of the controlled area as well as of the nonnuclear part of the plant existing in the nuclear power plant at the beginning of the decommissioning work and which have to be removed
- Secondary masses are articles of consumption which are necessary for the dismantling, crushing and treatment of the existing primary masses
- Tertiary masses, or additional masses, are tools and equipment which are necessary for the execution of the decommissioning work and which are placed in the controlled area

For each of these mass types a plan will be made out concerning how and at what time they occur, which possibilities are available for their treatment, or how to pack the radioactive wastes.

Primary Masses

Knowledge of the primary masses, including the pertinent radioactivity inventory, the geometry of the parts and the place of the installation, is a fundamental condition for the calculation of the costs.

As the decommissioning of radioactive waste and the unrestricted use of residuals also include external costs, the handling and whereabouts of the primary masses are to be defined in order to calculate the costs. These definitions are called “Mass Distribution.”

► *Figure 23* shows the different possible ways of handling and disposal.

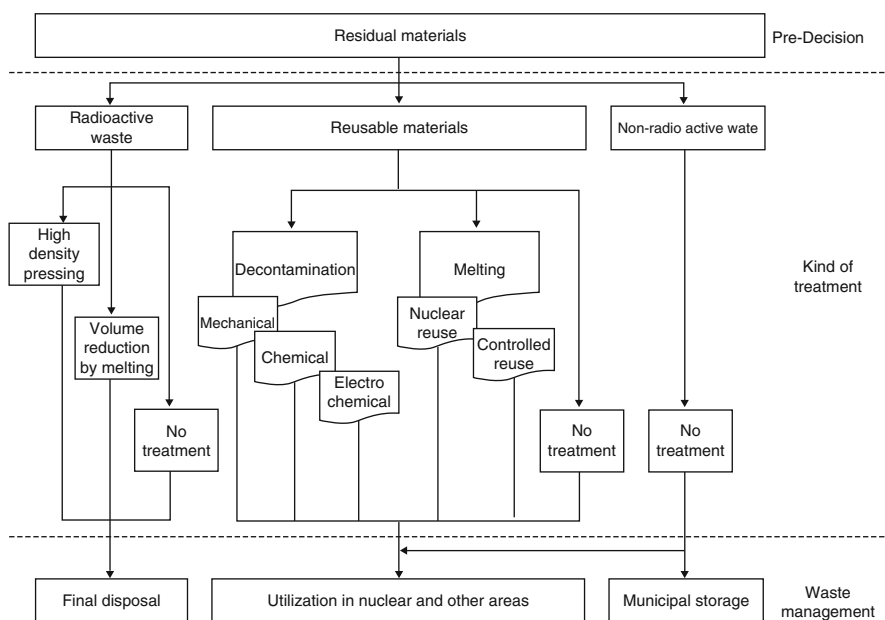

It is supposed that the prefixed result aimed at for each method of treatment will be achieved. After having executed all steps of sorting, attributing and calculating, it reveals which masses have to be treated with which method, which masses have to be disposed as radioactive waste, and which masses can be unrestrictedly used.

Secondary Masses

The determination of the arising secondary masses is important for the calculation of the costs for two reasons:

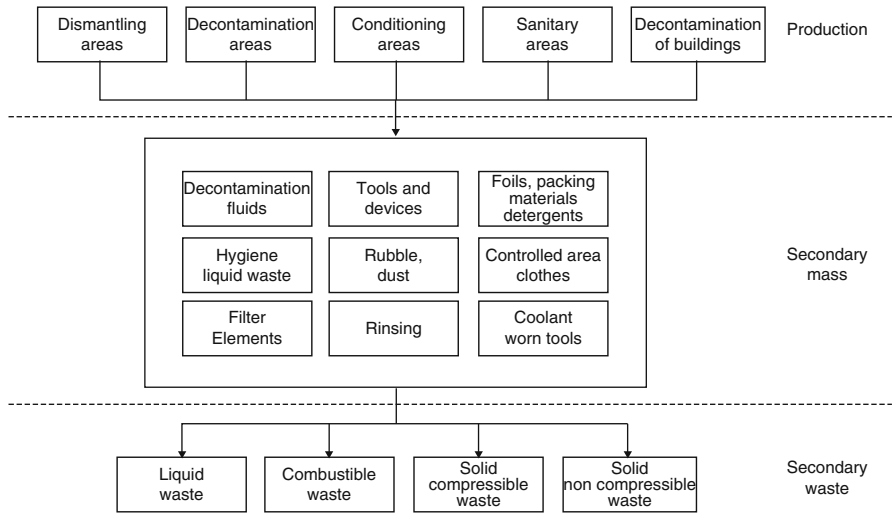

- In general, the activity inventory of the secondary masses is very high, as, for example, contamination is extensively removed from the primary masses during the decontamination process and concentrated on a possibly small secondary mass
- During chemical and/or electro-chemical decontamination, aggressive media are produced, which demand quite costly reprocessing

In the course of the decommissioning work, the secondary masses will be treated and reprocessed on-site to the greatest possible extent, so that a form will be achieved that can be disposed. The secondary masses cannot be recycled and have to be added 100% to the radioactive wastes. In the following, we will therefore talk about secondary waste. ► *Figure 24* shows the basic interrelations in the production of secondary waste.

■ **Figure 23**

Mass distribution model for primary and additional waste

■ **Figure 24**

Secondary mass and secondary waste

The main sources of secondary waste are dismantling and the activities for treatment of primary masses, especially the decontamination process. During decommissioning the following types of secondary wastes are produced:

- Solid, combustible secondary wastes. The most frequent ones are:
 - Work clothes worn in the controlled area
 - Cleaning wool
 - Paper

These waste materials are collected in plastic bags, pressed, packed into containers, and transported to an external incineration plant. The ashes are disposed as radioactive waste.

- Solid, noncombustible secondary wastes:
 - Contaminated tools or tool accessories
 - All kinds of plastic foils, adhesive tapes, etc.
 - Jointing material, chips and slags resulting from the dismantling of the components
 - Contaminated shielding material
 - Concrete rubble produced during the decontamination of building surfaces by removal of the surface layers

The noncombustible secondary waste is treated like contaminated components. Part of these secondary wastes can be pressed by high pressure to reduce the volume to be disposed.

- Filter materials

When dismantling contaminated or active parts by means of thermal separation methods, an additional exhaust system will be provided directly at the separation line in order to keep the exposure to aerosol of the air in the building to a minimum. The exhausted air will be cleaned by means of mobile filtering units. By doing so, filter media, including dusts separated from the air, are produced. The filter waste will be packed into barrels and disposed as radioactive waste.

Liquid secondary wastes are produced in the following areas:

- During the decontamination. In order to pre-decontaminate, an oxidic method will be employed, for example, for removing the oxide films and cleaning surfaces
- For chemical decontamination, an acid mixture consisting of HNO₃ and hydrofluoric acid will be used
- After treatment with the acids, the parts will be rinsed with water
- During the mechanical decontamination of metallic parts by means of high pressure water or steam jet appliances, which may contain abrasive additives, radioactive liquid waste polluted with suspended solids is produced
- During the decontamination of building surfaces, radioactive liquid waste polluted with suspended solids is produced
- In the hygiene area, i.e., in the hot-laundry area and decontamination of personnel, low-radioactive liquid waste polluted with suspended solids is produced

In order to estimate the quantities of secondary waste arising in these areas, it is necessary to execute different model assumption experiments. In detail, the needed quantities of the different acids and decontamination solutions have to be found out. On the basis of a calculation model, which takes into account the quantity of the parts to be decontaminated, the assumed thickness to be removed as well as the time available for the decontamination, the size and equipment of the decontamination area is determined. In this calculation model, the consumption of decontamination solutions resulting from the production of iron salts and the washing out losses, is also taken into consideration.

The liquids will be prepared for disposal by performing the following procedures and/or combinations of procedures:

- Neutralization
- Precipitation
- Evaporation
- Centrifugation
- Immobilization of the concentrates

Tertiary Masses

The dismantling and treatment of the primary masses as well as the reprocessing of the secondary masses demand the employment of equipment and tools, which will be especially installed for the decommissioning of the controlled area. After having served their purpose, the tertiary masses will be treated like primary masses. If possible, they will also be decontaminated and unrestrictedly used.

9.6.3 Calculation of Decommissioning Activities

Decommissioning Cost

For each activity of the cost structure, the following decisions have to be made and/or the related quantities estimated:

- Employable technology
- Necessary tools and equipment
- Other articles of consumption

- Required manpower, amount of labor, and duration of an activity
- Expected personnel radiation exposure

After determination of these data, it is possible to calculate the costs of each activity. The following types of costs are distinguished:

- Personnel costs as the product of the resulting amount of labor and payroll costs
- Costs for facilities, machines, special tools, and devices (expenses or rent)
- Costs for articles of consumption such as saw blades, drilling devices, clothes for the controlled area, acids for the decontamination and others
- Fees for the license and the disposal of radioactive wastes
- External costs for all activities which may not be carried out on the decommissioning site, for example incineration or super-compaction of radioactive wastes, melting for unrestricted use, etc.
- All other costs, e.g., insurance

Employable Technology

The technology and procedures employed for decommissioning are selected according to the following criteria:

- Radiation exposure of working personnel (ALARA)
- Production of secondary waste
- Safety
- Economic efficiency

The selection depends on the respective state of technology. The most important and especially required techniques for decommissioning are the following:

- Dismantling and size-reduction techniques
- Decontamination techniques
- Techniques for the safe and harmless recovery of residuals
- Techniques for radioactive waste disposal
- Measuring techniques for radiological protection

Necessary Tools and Equipment

During the decommissioning of a nuclear power plant a large number of marketable equipment will be employed. After recognizing the necessity of a certain device in an activity, it will be selected and the costs will be calculated.

Furthermore, special equipment and tools will also come into use during decommissioning. In the last few years, various research projects have been carried out in order to develop such special equipment. Many of them have passed their test phase and are ready for use. The selection of such special equipment is based on previous decommissioning experiences as well as on research results that are taken into consideration and analyzed. If necessary, special devices will be developed for single cases and the respective costs are considered as well.

Other Articles of Consumption

Other articles of consumption are, for example:

- Cutting gases
- Coolants

- Clothes for the controlled area
- Cover foils, one-way packages, adhesive tapes
- Decontamination agents

What aids are necessary and in what quantity depends on the technology employed and from the masses to be dismantled or treated.

Required Manpower and Duration

The execution of decommissioning requires qualified personnel who are accustomed to work in the controlled area. The personnel organization will be structured in a way that all requirements of decommissioning are met. The number of personnel required for each activity will be estimated. The criteria and boundary conditions for these estimates are the following:

- Amount of labor to be expected
- Room conditions
- Local radiation levels
- Use capability of tools and devices
- Already available equipment, e.g., lifting devices

The number and qualifications of the personnel are determined. The duration of one activity results then from the following formulations:

- The duration will be estimated
- The duration of an activity is a function of other activities
- The amount of labor is calculated using specific cost values (e.g., man-h/kg) in connection with the masses and other ratings regarding the plant

If the number of personnel is established at the same time, it is then possible to find out the duration of an activity.

The product of the duration and the personnel in the amount of labor.

Expected Personnel Radiation Exposure

The decommissioning activities will be carried out according to applicable radiological protection regulations, so that radiation exposure is as low as possible (ALARA principle). Determining the radiation exposure to be expected prior to carrying out the measure is an important criterion.

For this reason, the decommissioning plan includes a calculation model for the determination of the collective dose which is based on the activities as defined in the cost structure. An average dose rate will be assigned to every activity. Multiplying by the amount of labor, gives the overall activity dose (man-Sievert).

9.7 International Comparisons

9.7.1 Overview

Decommissioning cost evaluation comparisons carried out at the international level have always shown a large spread in relation to a number of factors, i.e., the specific conditions of the plant,

the national regulatory framework and local social-economic factors. Among the first, staff organization, on-site infrastructure, plant radiological characterization and the duration of the entire project can be mentioned as examples. Among other boundary conditions, the availability of a national waste disposal site with fixed prices and criteria for package acceptance and standards for unconditional release of radioactive materials with associated demonstration procedures are the most important.

In particular, it should be noted that most cost evaluations have been ordered by utilities from specialized companies with the main objective of assuring the adequacy of the decommissioning funding accumulation scheme during plant operation.

More recently, with many NPPs decommissioned, in decommissioning or close to decommissioning, and with the privatization process also involving the need for clear accounting of future decommissioning costs at the time of selling shares, cost evaluations became more important and subject to closer scrutiny by various organizations.

Various companies have specialized in decommissioning cost evaluations. Two important examples are TLG Services Inc. in the US and NIS in Europe, the latter recently extending its interest from the German to the entire European market. Other companies are in the market with increasing expertise but in the following we focus on the studies performed by the above companies, which are the most important in the international field.

9.7.2 Variations in Cost Estimates

Cost estimates are more and more based on the accumulated world-wide decommissioning experience. They are internationally evaluated as being 15% of the total investment, but from one country to another there may be differences due to national licensing policies, requirements and practices.

The factors affecting decommissioning costs can be grouped into the following categories:

- Scope of calculation
- Decommissioning timing
- Technical factors
- Waste-management system
- Administrative factors (labor costs and legal systems)
- Financial factors

The scope of the calculation turns out to be the single most important factor. The smallest scope considered comprises only the radioactive parts, while the largest scope includes some spent-fuel management. Normally the scope should include all the activities needed from the cessation of power production in the reactor until all the radioactive material has been removed off-site as radioactive waste and the site has been released for other use. The cost of the spent-fuel management should not be included. The differences in costs due to differences in scope could be a factor of two or more.

The timing of decommissioning, i.e., immediate compared to delayed decommissioning, will also have a great influence, particularly if undercounted costs are used. The costs of surveillance during the dormancy period will be important. The result could be quite different if discounted costs are used.

The most important technical factor is of course the type and size of the reactor, but this was not considered specifically in the study. On the basis of the literature, however, it can be

concluded that the cost of decommissioning a gas-cooled reactor would normally be larger than for a light-water reactor of similar electricity output.

During decommissioning, a large volume of radioactive waste has to be managed. The cost of decommissioning will therefore be affected in different ways by the specific waste-management system in the country. The influence will be both direct (e.g., fees for transport and disposal) and indirect (e.g., optimum cutting sizes, need of waste treatment and decontamination). In the study it was shown that this single factor could account for differences of more than 30% of the total decommissioning costs.

Decommissioning will be quite labor-intensive and thus the cost of labor in different countries will have a substantial effect. In the study a difference of up to 30% of the total cost was been found.

Finally, when comparing different cost calculations, caution is recommended with regard to the presentation of decommissioning costs from the financial point of view. Factors such as currency exchange rates, year of cost levelization, and the financing system considered should be kept in mind. The factor which could greatly change the global cost figures is, however, whether discounted or undiscounted costs are used. In cases where decommissioning extends over many decades, even a moderately low discounting rate makes the present value of the total cost substantially smaller than the basic undiscounted costs. Discounted cost 30 years ahead will, for instance, be only 25% (at a 5% discount rate) of the undercounted costs. Discounted cost estimates are useful for financing considerations and for comparison of different decommissioning strategies for the same facility, but for understanding the differences between estimates for different plants, undiscounted cost estimates are more appropriate.

In conclusion, the study shows that great care must be exercised when comparing different decommissioning cost estimates, as the boundary conditions may vary substantially. Only some of the different boundary conditions reflect real differences, while others reflect differences in scope and planning. It is thus not possible to define a universally applicable decommissioning cost.

Cost estimates are usually established by the company responsible for the plant operation, but they are reviewed and approved independently by regulators or ministries. This means that there is a regular adaptation of the amount of the fund and the national energy policy. Should this policy lead to an early shut-down of the plant (with respect to its economical life time), the fund would have to be reassessed accordingly.

The resulting funds are either set aside in a special fund in the company accounts or managed by an organization in charge of radioactive-waste management or by specific government funds.

In any case, the distribution of responsibilities is usually clearly defined in the national regulation establishing the national policy (responsibility for plant decommissioning, cost establishment and review, collection and management of the necessary funds). It is important to link responsibility for decommissioning activities and management of the provision funds, to make sure that the latter will be available in due time. The availability of funds is also dependant upon long-term economic stability.

It is unfair for decommissioning funds to be taxed differently from other types of provision funds (pension funds, etc.) because it would mean an increase of the money to be collected in order to make sure that the necessary amount is available in due time and thus indirect taxation of the customer. In addition, this special taxation would be an additional penalization of nuclear energy, which is the only electricity-production source whose costs include external costs.

It may nevertheless happen that a NPP is shut down before its useful life-time is over, before enough funds for its decommissioning have been set aside. This happened, for instance, in Italy where all NPPs were shut down by a political decision. Funds necessary for decommissioning, considering the adopted strategy and local conditions, shall be provided both by the owner of the plant (on the basis of the set-aside fund) and by the “electricity system,” on the basis of a limited charge per kWh.

9.7.3 Cost Estimates in the USA

In the USA in recent years, discussions have been held on the most appropriate methodologies and principles to be used in decommissioning cost evaluations. The most important issues are presented below to provide a proper perspective on various available estimations.

As discussed before, one of the reasons to assess decommissioning costs even well before final plant shutdown is to demonstrate to the authorities (in the US system to the NRC) the adequacy of the funds accumulated. The NRC has defined a minimum value, i.e., a lower threshold for the funds to be accumulated, respectively for BWR and PWR plants. However, as far as the NRC is concerned, these funds should cover only activities necessary for site release from any radiological restraints (license termination) and not for the remaining dismantlement activities to return the site to “green field” regardless of the Decon or Safstor strategy to be adopted. On these bases, the NRC adopts simplified methodologies, average plant features and conditions without considering project duration. In the last revision of their evaluation, in 1999, the NRC defined this lower threshold as 290 M\$ for a generic PWR and 370 M\$ for a generic BWR.

On the other hand, the Nuclear Energy Institute (NEI), on the basis of independent analyses, has proved that the above thresholds are underestimated because the methodology is not adequate the cost of the final disposal of the radioactive waste is not properly taken into account. In addition, the NEI is trying to include in US legislation the requirement to also include in the total cost evaluation the costs associated with the final plant dismantling, i.e., with the dismantlement of the noncontaminated buildings as well as the decontaminated buildings and structures, as already required in some US states.

In 1999, TLG Services Inc. (USA) presented a decommissioning cost assessment for 30 BWRs and 60 PWRs carried out between 1990 and 1997 (see [▶ Tables 40](#) and [▶ 41](#)). Costs are evaluated for DECON strategy and include spent fuel disposal, radioactive waste disposal, final site restoration and contingencies associated with the uncertainties of the process. In the tables costs associated with the site radiological release (or license termination) are identified, since they are the basis of the NRC evaluation, as discussed above. As usually accepted internationally, costs associated with spent fuel disposal are not included in the total costs. All costs are presented in 1998 dollars. It can be easily verified that costs associated with license termination present a wide spread, but they are above the minimum NRC thresholds.

A separate source of data is provided by the official assessments that each US NRC licensee has to present, i.e.:

- Post Shutdown Decommissioning Activity Report (PSDAR), to be presented to the NRC within 2 years from the final shutdown and before initiating any significant decommissioning activity.
- License termination plan (LTP), to be presented 2 years before receiving the License Termination Approval.

Turkey Point 4	666	1994	8,383	38,422	316,884	17.67	355,306
V.C. Summer	885	1990	n/a	n/a	338,039	25.00	338,039

These documents are not currently available for all US plants. However, as an example, the license termination cost for Haddam Neck (PWR, 590 MWe) PSDAR (1997) is 344.4 M\$ (1996 currency). The corresponding value calculated in 1992 is 290 M\$ (1998 currency) and, finally, the LTP value is 410 M\$ (2000 currency). Adjusting all values to 2000 values the above values are:

- 1992 : 352 M\$
- 1997 : 405 M\$
- 2000 : 410 M\$

This shows that, calculating costs on the same bases, there is a cost increase trend due to increased costs of waste disposal and for activities not well evaluated in the past, such as, for example, the cost of the final site characterization.

It is worth mentioning that the cost associated with the final site restoration, as evaluated in the most recent study, is 19.3 M\$ (2000 currency).

SOGIN (Italy) performed in 2006 a study on decommissioning costs taking into account all available information. The result for USA plants (under decommissioning or operating) is shown in  [Table 42](#).

9.7.4 Cost Estimates in Europe

In addition to the OECD-NEA study mentioned above, and mainly based on related to European data, the organization of European electrical utilities (UNIPED) has published in recent years studies on how local boundary conditions may influence decommissioning costs. The most complete study was carried out for UNIPED by the NIS (Nuklear Ingenieur Gesellschaft, Germany) in 1997 (Comparison of European decommissioning costs, June 1997). The study covers 12 countries (10 European countries plus Canada and South Africa), whose utilities contributed with data, assumptions (including unitary costs) and methodologies. The exercise was to apply different assumptions and approaches to a single NPP, Biblis-A (PWR, Germany). The methodology used by the NIS was the same as used in Germany by the company for the periodic re-evaluation of decommissioning funds adequacy.

In this way, all differences could be traced to assumptions and boundary conditions. The result is that spreads as large as a factor of 6 were identified between the lowest cost and highest cost. One of the major factors in these differences was the different items included in the cost evaluations in different countries, such as the cost for spent fuel disposal. Once the items included were standardized the spread factor was reduced to two.

In  [Table 43](#) all details discussed above are presented except for contingencies. It should be emphasized that the purpose of the exercise was not to calculate the real decommissioning cost for the plant, but only, to identify the source of the cost spread.

The following data were not provided by some participants in the exercise, and, therefore, standard Germany data were used by the NIS:

- Some parameters of the group “Operation on-site, Project management” were not provided by Canada and France
- Some parameters of the group “Waste treatment, container” were not provided by the Netherlands and South Africa
- No parameters of group E were provided by Italy

■ Table 42

Decommissioning cost evaluation in the USA (SOGIN, 2006)

Unit	Type	Capacity (MWe)	Overall cost (2004 currency) (M€)	Mean cost (2004 currency) (M€/MWe)
Plants under decommissioning				
Big Rock Point	BWR	67	290	4.32

"Cost group" comparison in various countries for the Biblis-A NPP (currency: million DM) (NISUNIPED 1997)

It can be noted that, while the costs associated with the dismantling activities are very similar and differences can be easily explained by the different unitary labor costs, for the activities of Planning, Licensing and Project Management, the range is a factor of 3 and for waste disposal the range extends to a factor of 10, not including the extreme case of South Africa.

The available data on decommissioning costs for gas-graphite reactors cannot be easily compared. It is worth mentioning that in the UK the strategy adopted is a very long Safstore, which will extend for a period longer than 100 years.

Some information has been provided by ENRESA (the Spanish company in charge of decommissioning activities) for the Vandellós 1 plant, whose total costs have been estimated in the range of 300 million euros.

In the already mentioned study performed in 2006 by SOGIN (Italy), the decommissioning costs for European plants (under decommissioning or operating) are evaluated as shown in

► [Table 44](#).

10 International Organizations Roles

Major international organizations are dealing with decommissioning in various roles and aiming at different goals. In the following section a brief review is presented, leaving to those interested the possibility to access to their web sites, where very often valuable documentation is downloadable for free.

10.1 UNO-IAEA (United Nations Organization-International Atomic Energy Agency)

The IAEA was created in 1957 in response to the deep fears and expectations resulting from the discovery of nuclear energy. Its fortunes are uniquely geared to this controversial technology that can be used either as a weapon or as a practical and useful tool.

The IAEA is the world's center of cooperation in the nuclear field. It was set up as the world's "Atoms for Peace" organization in 1957 within the United Nations family. The Agency works with its Member States and multiple partners worldwide to promote safe, secure and peaceful nuclear technologies. The IAEA Secretariat is headquartered at the Vienna International Centre in Vienna, Austria.

Decommissioning technology issues are dealt with the Division of nuclear fuel cycle and waste technology and in the waste technology section (WTS). The IAEA's WTS covers a broad spectrum of activities from radioactive waste characterization and conditioning to disposal, decommissioning and site remediation. The work covers the planning, technologies and approaches needed for the safe and efficient management of different types of radioactive waste, including waste from nuclear power plants, nuclear fuel cycle facilities, nonpower nuclear activities, decommissioning, and environmental remediation.

IAEA Decommissioning Activities include development of Safety Standards and supporting documents. Subjects include:

- Decommissioning of all types of facilities
- Release of the sites from regulatory control
- Release of material from regulatory control
- Safety assessment
- Management of contaminated material

The IAEA also publishes safety-related documents for each thematic or facility-specific area. These publications, commonly referred to as supporting documents, are designed to complement the Safety Standards.

A selected list of IAEA publications on the theme of decommissioning is presented in the References section.

10.2 OECD-NEA (Organization for Economic Cooperation and Development)

The NEA is a specialized agency within the OECD, an intergovernmental organization of industrialized countries, based in Paris, France.

The mission of the NEA is to assist its Member countries in maintaining and further developing, through international co-operation, the scientific, technological and legal bases required for the safe, environmentally friendly and economical use of nuclear energy for peaceful purposes. To achieve this, the NEA works as: a forum for sharing information and experience and promoting international co-operation; a center of excellence which helps Member countries to pool and maintain their technical expertise; a vehicle for facilitating policy analyses and developing consensus based on its technical work.

The NEA Secretariat serves seven specialized standing technical committees under the leadership of the Steering Committee for Nuclear Energy – the governing body of the NEA – which reports directly to the OECD Council.

The standing technical committees, representing each of the seven major areas of the Agency's program, are comprised of Member country experts who are both contributors to the program of work and beneficiaries of its results.

One of the committees is the Radioactive Waste Management Committee, within which there are two major groups dealing with decommissioning:

- The Working Party on Decommissioning and Dismantling (WPDD)
- The Cooperative Project on Decommissioning (CPD)

A list of major publications is reported in the section on References.

10.3 EC (European Commission)

Since 1979, the European Commission's DG Research has conducted four successive 5-year research and development programs on the decommissioning of nuclear installations performed under cost-sharing contracts with organizations within the European Union. The main objective of these programs was, and still is, to establish a scientific and technological basis for the safe, socially acceptable and economically affordable decommissioning of obsolete nuclear installations.

These programs were carried out by public organizations, research institutes and private companies in the Member States under shared-cost contracts and concerted actions. The main objectives of these activities were to strengthen the scientific and technical knowledge in this field, with a particular view to enhance safety and environmental protection aspects, minimizing the occupational exposures and dismantling costs as well as the radioactive waste arisings.

Within the EC program, *two databases* on decommissioning have been created:

1. EC DB TOOL for collecting technical performance data
2. EC DB COST for collecting data on waste arising, doses, etc.

Both are now being merged into one database, EC DB NET, which will be available on the internet (so far only, in first instance, for members of the project group).

The interest from the IAEA and the OECD/NEA and EC in the development of a common understanding of the decommissioning process led to the creation of a list of *Standardized Decommissioning Cost Item Definitions* (INCOSIT), another project under FP-4, to ease a world-wide comparability and transferability of data on decommissioning.

European Commission also proposes Directives, recommendations and laws of the European Union dealing directly and indirectly to the issues of decommissioning.

10.4 WANO (World Association of Nuclear Operators)

The World Association of Nuclear Operators (WANO) is an organization created to improve safety at every nuclear power plant in the world.

Part of the mission is to exchange operating experience and improve the safety culture. In these areas attention is given also to decommissioning activities.

10.5 WENRA (West European Nuclear Regulator Association)

West European Nuclear Regulator Association (WENRA) is a nongovernmental organization comprised of the Heads and senior staff members of Nuclear Regulatory Authorities of European countries with nuclear power plants.

The main objectives of WENRA are to develop a common approach to nuclear safety, to provide an independent capability to examine nuclear safety in applicant countries and to be a network of chief nuclear safety regulators in Europe exchanging experience and discussing significant safety issues.

In January 2009 the following publications are related to decommissioning:

- WGWD – Waste and Spent Fuel Storage Safety Reference Levels Report (version 1.0, working document)
- WGWD – Decommissioning Safety Reference Levels Report (version 1.0, working document)
- WENRA Reactor Safety Reference Levels January 2007

Abstract: Waste is produced at every stage of the nuclear fuel cycle. While large volumes of short-lived radioactive waste are already handled by the nuclear industry in surface storage facilities, the management mode of high-activity, long-lived waste has not been decided in detail and is still under study in all nuclear countries. Scientific knowledge is in progress, technical solutions are emerging, in a context where science and technology interact strongly with social and economical issues.

With a closed fuel cycle, waste management from its production to its final destination looks like a chain whose links are treatment recycling, conditioning, storage, and disposal of the final waste. With the open cycle option, the first link is absent.

This chapter provides the concepts and data that form the scientific basis of nuclear waste management.

➤ **Section 1** deals with the origin, nature, volume, and flux of nuclear waste, and describes the management options.

➤ **Section 2** deals with waste conditioning, with special emphasis on two important conditioning matrices: cement-like materials and glass. The elaboration and long-term behavior of these matrices are treated successively. In many countries, spent fuel is considered as waste, and must be conditioned as such. A special section is devoted to this issue.

➤ **Section 3** deals with waste storage and disposal. Interim storage of long-lived waste is already an industrial reality, and the design and properties of the corresponding installations are described. The final disposal of ultimate waste in deep geological repositories is more prospective, but the main concepts are described, with emphasis on the mechanisms, models, and orders of magnitude of the main physical and chemical phenomena that come into play in the long-term evolution of these installations. Finally, a short description of the methodology used to evaluate the safety of these installations is given. A simplified example of application of this methodology is given to evaluate the order of magnitude of the radiological impact of geological disposal of long-lived waste.

1 Generalities on Waste

In the world, 16% of the electricity is generated by nuclear power plants. The properties of radioactivity are also used in many other applications: in chemistry, biology (study of cells), geology, archaeology (dating), agriculture, and medicine (diagnosis and treatment of cancers). It also has many uses in industry, for example, food preservation, the inspection of welds in metallurgy, the sterilization of medical equipment, or the detection of fire.

All these activities produce waste, some of which are radioactive.

Radioactive waste is material that cannot be reused or reprocessed. Its radioactive nature makes it potentially dangerous for health. It must therefore be specifically managed.

The purpose of this chapter is to provide a general background on the scientific basis of radioactive waste management. The aim is to display the scientific disciplines involved, and to

show how they are used and put together to manage nuclear waste. We shall concentrate on the methods and principles, on the main physical and chemical processes at play, and on the orders of magnitude.

Definitions

The notions that seem intuitive are often quite difficult to define precisely, and such is the case for nuclear waste. In order to avoid any misunderstanding, we propose the following set of definitions, inspired from French law:

A *radioactive substance* is a substance containing natural or artificial radionuclides in a concentration such that it justifies some radioprotection action or control.

Radioactive matter is a radioactive substance for which an ulterior use is foreseen or envisaged, eventually after some processing.

A nuclear fuel is regarded as spent fuel when it has been irradiated in a nuclear reactor and withdrawn definitively.

Radioactive waste is a radioactive substance for which no ulterior use is foreseen or envisaged.

Ultimate radioactive waste is radioactive waste, which cannot be processed under present technical and economic conditions, either to extract its valuable part, or to reduce its dangerous or polluting character.

The legislator has introduced much flexibility in these definitions, to take into account a variable technical and economic context. The important thing is that the notion of waste is less a matter of nature than a matter of destination foreseen or envisaged.

Although the nuclear waste management policy of the nuclear states in the world differs widely, the above definitions seem to apply rather generally.

Nuclear energy is a very concentrated form of energy. Consequently, the volume of nuclear waste generated by the production of a given amount of nuclear energy is very small as compared to that generated by the production of the same amount of energy from fossil fuels. To give an order of magnitude, the typical mass of waste produced yearly per person in an average western country is:

Domestic waste	2,200kg
Industrial waste	800kg(100 kg of high toxicity)

If this country used exclusively nuclear energy to produce its electricity, the yearly production of nuclear waste would be 1kg (10 g of high activity), excluding the uranium mine tailings (uranium is usually much diluted in the ore [grades range from 0.1% to 10%], therefore, uranium mining produces much waste in volume) (🔗 [Table 1](#)).

1.1 Origin, Nature, Volume, and Flux of Waste

In order to understand the origin of nuclear waste, a possible approach is to follow the nuclear fuel cycle step by step.

At the front-end of the fuel cycle, waste is produced during the mining operations. After chemical extraction of the uranium from crushed ore, the tailings still contain the daughter nuclides of uranium, and especially radium. These mine tailings can be considered as waste. Its

Table 1
Origin, nature, volume of nuclear waste

Waste	Origin	Nature	Radioactive half-life	Volume	Activity	Management
Mine tailings	Uranium mines	After chemical extraction of the uranium from crushed ore, the tailings still contain the daughter nuclides of uranium, and especially radium	A few thousand years	50 million cubic meters of mine tailings have been produced in France	Very low (a few ten thousand Becquerel per kilogram)	In situ storage. The mine tailings are covered by a layer of sterile rock and soil to prevent their dispersion, to screen the gamma radiation and to limit radon exhalation
Very low level waste (VLL)	VLA waste comes mainly from dismantled nuclear facilities	Steels, and concrete rubble containing activation products	Variable	The dismantling of the present French nuclear fleet (58 reactors) will produce 80 million tons of VLA waste	Very low (a few ten thousands Becquerel per kilogram)	Sort them, decontaminate whenever possible, then store in surface facilities (such a storage already exists in France in Morvilliers)
Low level short-lived waste (LL-SL)	Operation of nuclear plants	Gloves, boots, filters immobilized in concrete	Short (10–100 years) After 300 years, all the radioactivities will be disappeared	The production of 1 GW electricity during 1 year with a typical LWR generates 120 m ³ of short-lived low activity waste	Low (smaller than 3.710 ⁸ Bq/kg)	Surface storage of the concrete blocks in dedicated surface installations. The waste is stored above the water table, covered with an impermeable clay layer and a few meters of soil. Two such storage facilities already exist in France in La Hague and Soullaines

Table 1 (continued)

Waste	Origin	Nature	Radioactive half-life	Volume	Activity	Management
Intermediate level long-lived waste (IL-LL)	Fuel reprocessing	Processing residues and fuel claddings immobilized in concrete	Long (up to million years)	The production of 1 GW electricity during 1 year with a typical LWR generates 5 m ³ of long-lived medium activity waste	Medium (smaller than 3.7·10 ¹¹ Bq/kg) This waste does not generate heat	Probably underground disposal (The WIPP facility is already in operation in USA; disposal is not yet decided in other countries)
High level long-lived waste (HL-LL)	This waste comes from spent fuel	Glass blocks (if the spent fuel is processed); spent fuel assemblies (if no processing)	Long (up to a million years)	The production of 1 GW electricity during 1 year with a typical LWR generates 2.5 m ³ of long-lived high-activity glass (if processing); or 40 m ³ of spent fuel (if no processing)	High (of the order of 10 ¹³ Bq/kg)	No decision yet about what to do with this category of waste. Technical solutions already exist or are under study for the separation, transmutation conditioning of HLA waste, and for its storage or underground disposal In the mean time, these wasteforms are stored in interim storage facilities (pools, or dry storage surface facilities)

activity is very low, indeed less radioactive than the original ore (a few ten thousand Becquerel per kilogram), but its volume is very large, in the order of $100,000 \text{ m}^3$ to produce the uranium necessary to fuel a 1 GW light water power plant during 1 year.

The main waste stream comes from the back-end of the fuel cycle: the spent fuel itself can be considered as waste if no ulterior use is foreseen; if the spent fuel is reprocessed, process waste is produced, for example, the solution of fission products and minor actinides, which will be vitrified, or structure waste of the fuel assemblies, which will be compacted. This waste type is usually of intermediate or high-level activity; the corresponding volume is relatively small: the production of 1 GW electricity during 1 year with a typical LWR generates 5 m^3 of long-lived medium activity waste and 2.5 m^3 of long-lived high-activity glass (if processing) or 40 m^3 of spent fuel (if no processing).

Technological waste is produced in small amounts during the operations of conversion, enrichment, and fuel fabrication at the front-end of the fuel cycle as well as at the back-end. It consists mainly of solid waste (gloves ion exchange resins, or waste from the dismantling of installations) and liquid waste (decontamination effluents, used solvents, and scintillating liquids used for analysis). Even though the activity is much smaller for technological waste as for processing waste, the volume of technological waste can be relatively large: the production of 1 GW electricity during 1 year with a typical LWR generates 120 m^3 of short-lived low-activity technological waste.

Another waste stream comes from the dismantling of nuclear installations. It consists of steels, and concrete rubble containing activation products. The dismantling of the present French nuclear fleet (58 reactors) will produce 80 million tons of very low-level waste.

The radioactive content of nuclear waste is a specific feature, which imposes special precautions for its management.

1.1.1 Waste Classification

Usually, radioactive waste is classified on the basis of two criteria: its activity and the period of the radionuclides it contains (► [Figs. 1](#) and ► [2](#)).

Note the apparent contradiction between high activity and long life. In fact, another factor comes into play: the high-level (HL) waste is highly concentrated!

This HL waste represents a very small volume (► [Figs. 3](#) and ► [4](#)), but its high activity and heat generation prevent us from assembling it in a small-size disposal facility.

1.1.2 Volume and Flux of Waste

1.1.3 Which Radionuclides in the Spent Fuel?

There are two main categories of radionuclides in the spent fuel:

- *Actinides* (U, Pu, Am, Np, Cm). Pu, Cm, and Am are produced by successive neutron capture on uranium and plutonium in the core of the reactor. These nuclei have a high-specific activity and contribute to heat generation in the waste.

		Short life (SL) Period < 30 years	Long life (LL) Period > 30 years
< A few 10^5 Bq/kg	Very low level (VLL)	VLL	
< A few 10^8 Bq/kg ($\beta\gamma$) < A few 10^6 Bq/kg (α)	Low level (LL)	LIL-SL	LL-LL
< A few 10^{11} Bq/kg ($\beta\gamma$)	Intermediate level (IL)		IL-LL
10^{13} Bq/kg ($\beta\gamma$) 10^{11} Bq/kg (α)	High level (HL)	HL	

Figure 1

Waste classification. The radioactivity limits given here are only indicative. They may vary from country to country

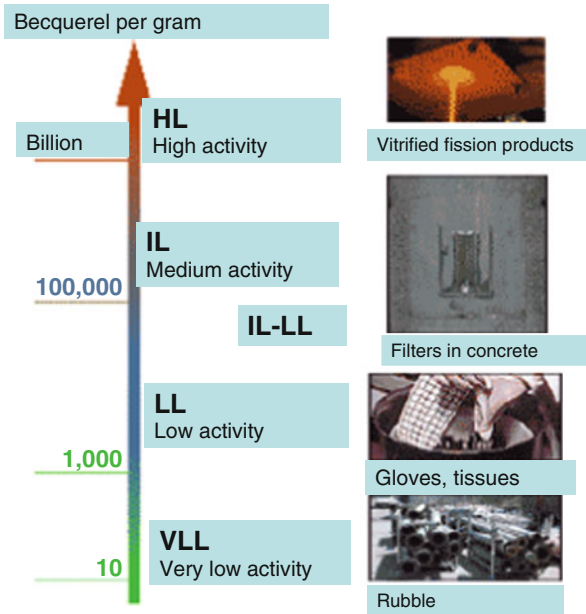

Figure 2

Waste nature and classification

Figure 3 Origin of radioactive waste in France per sector and by volume (Source: National inventory of recoverable materials and radioactive waste 2009)

Volume and flux of waste

Figure 4 Volume and level of radioactivity, by type of radioactive waste. Typical distribution of the volume and level of radioactivity by type of radioactive waste: the example of France (France’s National Inventory 2009). Note the inversion in the diagram: the high-activity waste concentrates most of the activity under a very small volume, whereas most of the volume is in the low-activity waste

- *Fission products* (e.g., Cs, Sr, Tc, I) are medium mass nuclei produced by the scission of fissile nuclei (^{235}U , ^{239}Pu) during the fission. In the spent fuel, one finds short-lived FPs ^{137}Cs , ^{90}Sr , ^{90}Y (about 30 years) and long-lived FPs, ^{99}Tc , ^{135}Cs , ^{129}I (about 1 million years).

■ Figure 5

The activity of spent fuel, expressed in Bq/t of heavy metal, in the case of an LWR fuel, irradiated with a burnup of 33 GWd/t, after 3 years cooling time

In the structure materials used in the reactor core, one also finds *activation products* (e.g., ^{14}C , ^{36}Cl , ^{60}Co , ^{93}Zr , ^{63}Ni), which result from nuclear reactions (neutron capture). This category is much less important in terms of activity) (● Figs. 5–7).

Fission products are the unavoidable ashes of the fission process. The quantity of fission products is directly proportional to the amount of energy produced in the reactor. It does not depend much on the nuclei, which undergo fission (uranium or plutonium). It is also almost independent of the energy of the neutrons, which cause the fission in the reactor (fission induced by fast neutrons tends to be more symmetrical than fission induced by slow neutrons, but the difference is small). Therefore, fission products will be present in same amounts in the spent fuel of nuclear fission reactors, whatever the kind of reactor or the type of fuel used.

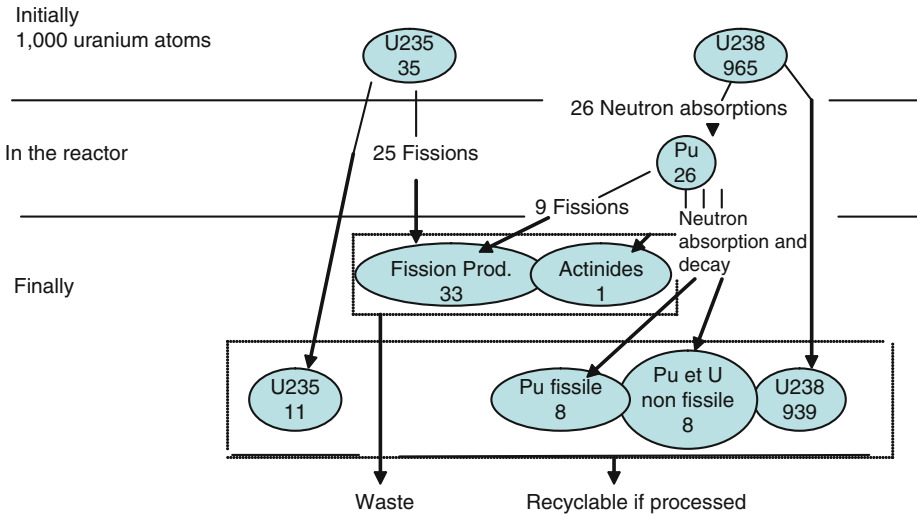

Figure 6

Transformation of the nuclear fuel during its stay in a light water reactor. The fuel of the light water reactors, which constitutes the major part of the world nuclear fleet, is enriched uranium, with an enrichment ratio of the order of 3–5%. This diagram follows the fate of 1,000 uranium atoms (965 fertile atoms of U238 and 35 fissile atoms of U235) present in the initial nuclear fuel. A fuel rod stays about 4 years in the reactor. At the exit, the spent nuclear fuel still contains 939 atoms of U238 and 11 atoms of U235, plus fission products, plutonium isotopes, and a small quantity of heavier nuclides, the “minor actinides”

Figure 7

The main long-lived radionuclides produced in the spent fuel (in the case of an UOX LWR fuel, with 3.5% enrichment in U235 and irradiated with a burnup of 33 Gwd/t)

1.1.4 Fission Products Are Radioactive

Fissile nuclei are heavy nuclei, with a large ratio of neutrons versus protons. Fission fragments inherit this ratio. Consequently, they are too neutron-rich to be stable (on [Fig. 8](#), the dashed line is the bottom of the stability valley). Most of the fission products are radioactive, and tend to turn into more stable nuclei by getting rid of this neutron excess. Their radioactive period can go from a microsecond to a million years. They are the true ashes of nuclear combustion.

The fission process does not give the same pair of fission products every time. Fission is a stochastic phenomenon characterized by a probability distribution for the mass of the fission products. Fission is most often asymmetric, producing a light fragment (around mass 90) and a heavy fragment (around mass 140).

This bimodal distribution of the fission fragments is illustrated in [Fig. 8](#).

[Figure 9](#) shows what happens when a ^{235}U nucleus undergoes fission to give, for example, the fission products ^{90}Br and ^{143}Xe . One has in fact two cascades of radioactive decay. The radionuclides upstream in the cascades are in general so unstable (and thus short-lived) that they decay in situ, and are never seen in the waste. The fission products, which are present in the waste, have at least a few months (or even years) of half life ([Fig. 10](#)).

Figure 8

The Z-N diagram of fission products

Figure 9
 An example of a decay chain of fission products

Figure 10
 The activity of fission products in spent fuel, as a function of time

Two types of fission products are found in the waste:

1. ‘Short-lived’ ones ($T < 30$ years), for example, ^{137}Cs , ^{90}Sr (very short-lived FP also exist, but they generally decay before their exit from the reactor, e.g., ^{131}I).
2. ‘Long-lived’ ones ($T > 1$ million years), for example, ^{99}Tc , ^{135}Cs , ^{129}I .

1.1.5 Formation of Transuranic Isotopes in the Reactor Core

The isotopes heavier than uranium are formed in the reactor core by successive neutron captures on uranium nuclei, followed by radioactive alpha and beta decay (\odot Fig. 11).

The longer the irradiation, the higher the minor actinide content of the spent fuel (\odot Table 2).

One should note that for a given amount of energy produced, the quantity of minor actinides produced depends on the fuel burnup. The higher the burnup, the higher the amount of minor actinides produced. This is especially true for the heaviest actinides, which are produced by successive neutron captures on lighter actinides in the reactor core. This self-promoted production of minor actinides is an undesirable feature of light water reactors.

The inventory of actinides evolves with time in a complicated manner, because some actinides are produced by the decay of others (e.g., ^{241}Am gives ^{237}Np). This explains why the activity of ^{237}Np increases with time during the first 1,000 years (\odot Fig. 12).

Figure 11
Transuranic element formation

Table 2
Actinide formation in UOX fuel in LWRs as a function of the burnup

Burnup (GWd/t)	Initial enricht. (%)	Pu quality (%)	Np 237	Am 241	Am 243	Cm 244	Cm 245
42	3.70	66	1.81	0.58	0.49	0.14	0.01
55	4.50	63	1.70	0.47	0.56	0.22	0.02
65	4.95	60	1.90	0.48	0.71	0.34	0.03

Figure 12
The activity of the actinides contained in spent fuel, as a function of time

1.1.6 Radioactive Decay

The radioactive decay of a nucleus is a purely random event governed by the laws of quantum mechanics. However, the decay probability per unit time is determined, and is a characteristic of the radionuclide considered. The random character of the decay results in an exponential decrease of the population of radioactive nuclei with time.

$$N = N_0 \cdot \exp(-\lambda t) \quad \lambda = \text{radioactive decay constant}$$

$$t = \text{time}$$

$$N_0, N = \text{initial and final number of radioactive nuclei}$$

$$A = \lambda \cdot NA = \text{activity}$$

The half-life of the radionuclide is defined as the time needed for its population to decrease by a factor 2: $T_{1/2} = \ln 2 / \lambda$.

If the daughter nucleus itself is radioactive, we have a chain of radioactive parents and daughters (► Figs. 13 and ► 14), and the population of radionuclides obey more complicated laws.

■ Figure 13

An example of radioactive filiation, of relevance for waste management: Am 241 is the daughter nucleus of Pu 241, which decays mainly via beta-radioactivity

4N+1 Disintegration chain

Figure 14

A disintegration chain. For heavy nuclei, four disintegration chains exist: labeled 4N, 4N + 1, 4N + 2, 4N + 3

1.1.7 What Kind of Radioactive Emission Do We Expect from the Nuclear Waste?

The types of radioactivity are different for nuclei placed differently with respect to the stability valley (🔍 *Fig. 15*). All decay modes tend to bring the daughter nucleus closer to the bottom of the valley. For example, nuclei with an excess of neutrons decay mainly via a beta-radioactivity process, which transforms one of their neutrons into a proton. This is the case of fission products.

Another example is that of very heavy nuclei which get rid of their excess weight by alpha-radioactivity, with the departure of four nucleons at the same time. This is the case of actinides, which are mainly alpha emitters.

Of course, this particle emission generally leaves the daughter nucleus in an excited state. The return to the fundamental state implies the emission of gamma photons.

It is important to note the order of magnitude of the energy taken away by these radioactive decays:

An alpha particle takes away roughly 5 MeV

Beta and gamma particles take away a fraction of MeV.

🔍 **Figure 15**
Radioactive decay modes

1.1.8 Penetration of Ionizing Radiations into Matter

When dealing with nuclear waste management, it is also important to know *how ionizing radiations penetrate into matter* (🔗 [Table 3](#)).

■ **Table 3**

The typical range of ionizing radiations emitted by radioactive substances

	α (5 MeV)	β (1 MeV)	γ (1 MeV)
Air 1.293 mg/cm ³	3.6 cm	3 m	90 m
Water 1 g/cm ³	36 μ m	4.3 mm	10 cm
Pb 11.34 g/cm ³	15 μ m	3 mm	9 mm

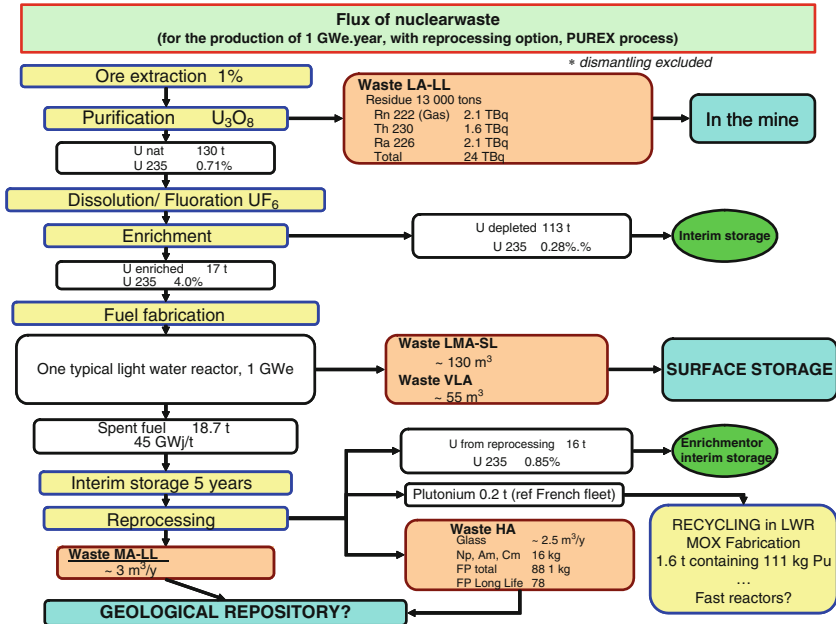

Alpha particles have a very short range, of the order of 1 μ m, in solid matter. They therefore dissipate much energy into a very small volume. In the ceramic of spent fuel or in vitrified waste, the alpha emitters will dissipate their energy in the matrix itself; almost no alpha particles will come out of the waste. The waste will generate heat, will possibly degrade with time, but will not represent a significant danger of external irradiation for the operator.

Beta particles are electrons with a range of a few millimeters in condensed matter. This range is of the same order of magnitude as the diameter of a fuel rod, and is not much smaller than the size of a vitrified glass package. One therefore expects that part of the energy of the decay will be dissipated in the matrix, and part of it will be radiated outside (with some danger of irradiation for the operator).

Gamma photons have a larger range in condensed matter, on the order of 1 dm to 1 m depending on their energy and on the atomic weight of the matter traversed. They contribute marginally to the power dissipation in the waste, but are very effective to make the waste irradiating and therefore dangerous for the operators.

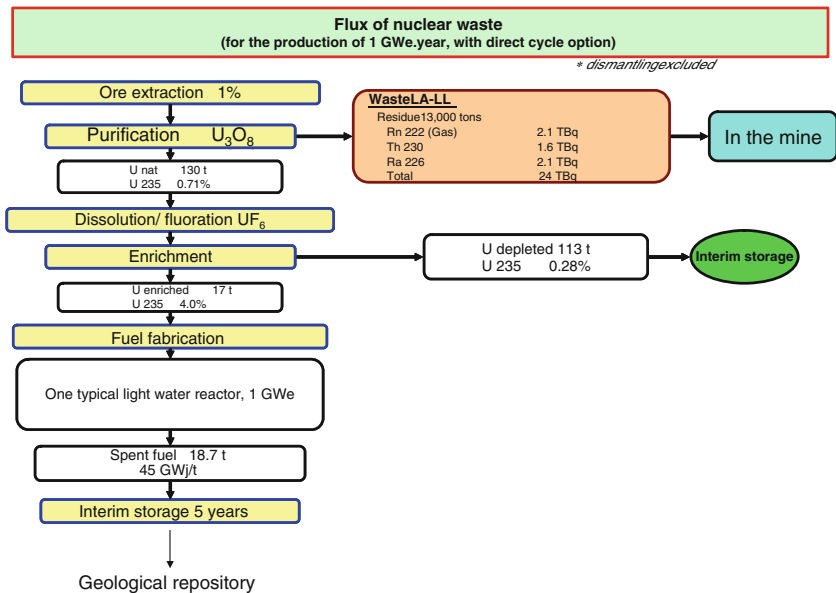

1.1.9 The Radioactive Half-Life of the Main Radionuclides Found in Nuclear Waste

Spent fuel contains a cocktail of short-lived and long-lived radionuclides. Each category brings specific problems: short-lived RNs generate heat and make spent fuel highly irradiating; long-lived RNs do not pose acute problems, but their presence obliges us to care about the spent fuel – or waste generated from spent fuel – for very long periods of time (🔗 [Figs. 16](#) and 🔗 [17](#); 🔗 [Table 4](#)).

■ Figure 16

The waste flux produced by a typical light water reactor producing 1 GWe.year (closed cycle option, i.e., the spent fuel is reprocessed)

■ Figure 17

The waste flux produced by a typical light water reactor producing 1 GWe.year (open cycle option, i.e., the spent fuel is not reprocessed)

Table 4
The half-life of some radionuclides relevant for waste management

Fission products	T1/2
¹²⁹ I	1.5 e7 years
¹³⁵ Cs	2.0 e6 years
⁹⁹ Tc	2.1 e5 years
⁷⁹ Se	1.1 e6 years
¹³⁴ Cs	754 days
⁹⁰ Sr	28.8 years
¹³⁷ Cs	30 years
¹²⁶ Sn	1. e5 years
¹⁵⁴ Eu	8.59 years
¹⁰⁶ Ru	373 days
¹⁴⁴ Ce	285 days
Actinides	T1/2
²³³ U	1.6 e5 years
²³⁵ U	703 million years
²³⁸ U	4.5 e9 years
²³⁷ Np	2.1 million years
²³⁸ Pu	87 years
²³⁹ Pu	24,110 years
²⁴¹ Pu	14.3 years
²⁴¹ Am	432 years
²⁴³ Am	7,370 years
²⁴⁴ Cm	18 years
²⁴⁵ Cm	8,500 years
²⁴⁶ Cm	4,730 years
Activation products	T1/2
¹⁴ C	5,730 years
³⁶ Cl	3.0 e5 years
⁶⁰ Co	1,925 days
⁹³ Zr	1.53 e6 years
⁶³ Ni	100 years

1.1.10 Radioactive Waste: How Dangerous Is It?

The danger of radioactive waste depends on how it is managed! Despite its small volume, high-activity waste is very radioactive.

For example, an HL glass package from spent fuel reprocessing (400 kg glass) has an activity of 16,000 TBq after 6 years, and the dose rate is 500 Gy/h at contact and 80 Gy/h at 1 m distance. This is several $\times 10$ times the lethal dose in 1 h. These values are divided by 10 after 100 years. The same orders of magnitude also hold for a 500 kg spent fuel assembly.

As a consequence, a very tight confinement of HLA waste is compulsory, and the packages must be handled with caution.

1.2 Management Options: An Overview

1.2.1 Dispersion or Concentration?

From the beginning of the nuclear industry, the choice has been made to concentrate the radionuclides in the waste, for three main reasons:

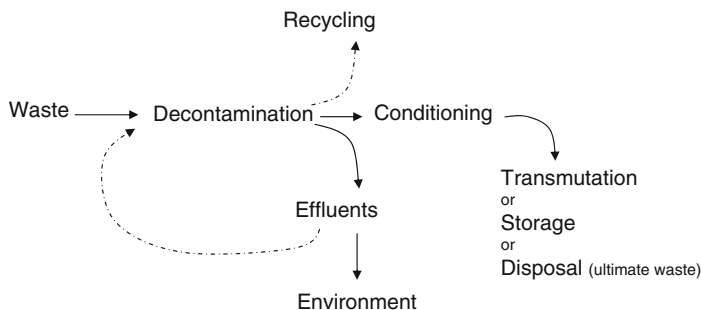

- An environmental reason: the travel of radionuclides in the biosphere is poorly known and difficult to control. It is thus difficult to prove that there is no risk of reconcentration of some radionuclides in some specific compartments of the biosphere. Such events have already occurred with chemicals dumped in the sea: heavy metals tend to concentrate at the end of the trophic chain, with very detrimental consequences for the local populations.
- An industrial reason: processing the spent fuel already implies concentration.
- An image reason: very low levels of radioactivity are easily detectable in the environment.

For these reasons, the concentrated waste is then isolated from the environment by means of several barriers, both complementary and redundant (multibarrier concept).

This philosophy, concentrate and isolate, is applied to all radionuclides, with a few notable exceptions: Tritium, Chlorine 36, Krypton 85, and Iodine 129. Iodine is volatile and soluble, two characteristics that make it very difficult to confine. The iodine present in spent fuel is released during the operations of processing of the spent fuel. A small part of it is sent to the atmosphere, the major part is sent to the sea, where it is rapidly diluted. For example, at the La Hague processing plant, 1 km away from the release point, the radioactivity level due to Iodine 129 is already very small compared to the natural radioactivity of seawater, but this activity can be detected even in the North Sea.

1.2.2 Waste, Effluents, Decontamination, and Conditioning: A Systemic Vision

Radioactive waste is a radioactive substance for which no ulterior use is foreseen. Ultimate radioactive waste is the waste, which cannot be treated to extract any reusable fraction, or to reduce its polluting or dangerous character in the present technical or economic situation (➤ Fig. 18).

■ **Figure 18**
Waste, effluents, decontamination, and conditioning: a systemic vision

An effluent is the liquid or gaseous residue of a chemical treatment. In some cases, these residues are dispersed in the environment; another option widely used in the nuclear industry is to separate their toxic fraction (decontamination) and to put this fraction under a stable form (conditioning).

The reusable fraction can optionally be recycled.

Conditioning (of radioactive waste) is the ensemble of operations aiming at putting radioactive waste under a stable form, which will permit its ulterior safe management, e.g., transmutation, storage, or disposal.

1.2.3 Reprocessing or Not Reprocessing?

A chapter on waste management cannot avoid the question of spent fuel reprocessing, because the choice to reprocess or not has a strong influence on the nuclear waste management (► [Table 5](#)).

The principle of reprocessing is to separate chemically U and Pu from the fission products, in order to:

1. Reuse valuable materials (U et Pu)
2. Optimize the final waste management by reducing the quantities (mass, volume, radiotoxicity) and by confining it in suitable long-lasting materials

The process commonly in use today is the PUREX process (► [Figs. 19–21](#)). Several variants of PUREX can be envisaged to extract U and Pu separately or together. Several complements to the PUREX process can also be envisaged to extract the minor actinides from the fission products. These variants or complements are not yet implemented at the industrial scale.

The processing operations result in a partitioning of the radionuclides, but their total amount remains the same as the initial one (no transformation).

The choice to reprocess or not is a matter of industrial strategy, guided by many criteria, including economy and politics. A complete discussion on the pros and cons of reprocessing is outside the scope of this chapter. We shall restrict ourselves to the waste management point of view.

Figure 19
The principle of the PUREX processing process

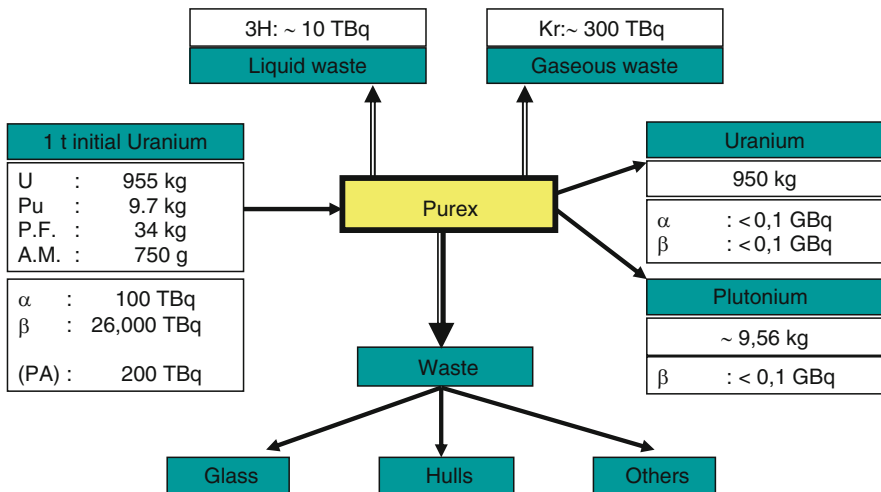

Figure 20
The mass and activity flow of the PUREX process, for 1 t of initial uranium irradiated with a burnup of 45 GWd/t

The advantages are:

- A volume reduction of the waste, which is put under a compact, stable, and durable form (vitrification). The waste from reprocessing is thus easier to manage (handling, storage, disposal) than the spent fuel.
- A reduction of the potential radiotoxicity of waste, by removal of the plutonium it contains.

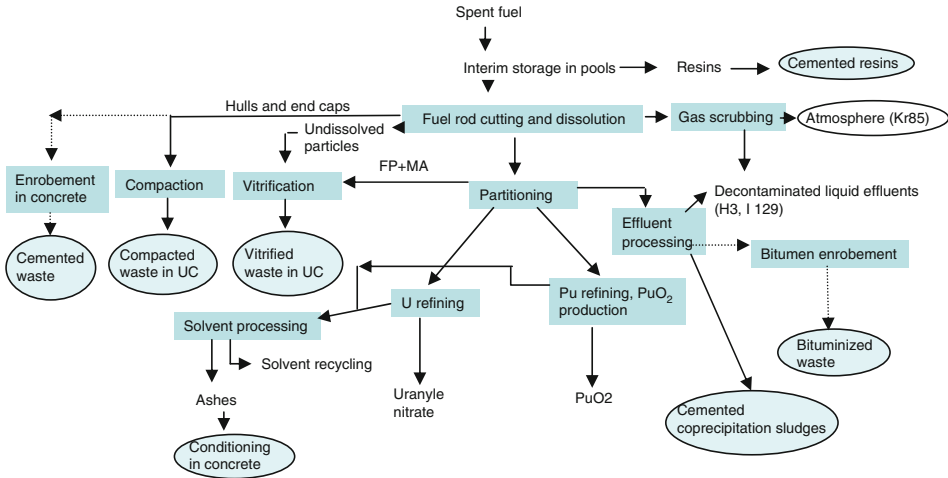

Figure 21
Overall scheme of the waste streams from reprocessing

The drawbacks are:

- The use of heavy technology, with safety concerns during the processing operations
- The need to transport very active nuclear material to and from the processing plant
- The production of effluents with a significant radioactive content

1.2.4 World Situation for Waste Management

About 15 countries are involved in nuclear waste management, including the USA, Canada, Japan, France, Finland, Sweden, Germany, Belgium, Spain, Switzerland, UK, Korea, China, and India.

In those countries, many storage facilities are in operation for short-lived waste. Three repositories are in activity for IL LL waste (East Germany, Sweden, USA). High-Level waste is stored in interim storage facilities.

No repositories are in operation for high-level long-lived waste (but there is a general consensus among experts about their feasibility). Decision to build has been taken in Finland and Sweden.

There is no international consensus on spent fuel processing.

Waste management remains a national issue: even though it might make sense from a technical point of view to group the waste from different countries, such a decision would raise such ethical and political problems that no move in this direction can be envisaged in the near- or mid-term future.

1.2.5 The Institutions In Charge of Waste Management in the World

■ Table 5

Main organizations in charge of waste management in the world

Country	Name	Status	Waste managed
USA	OCWRM (US-DOE)	PO	HL and SF
Germany	BfS	PO	LL, IL, HL
	DBE	50% PO, 50% UT	
Belgium	Ondraf/NIRAS	PO	LL, IL, HL
France	ANDRA	PO	VLL, LL, IL, HL
Spain	ENRESA	PO	VLL, LL, IL, HL
Japan	Numo	PO	IL, HL
Switzerland	Nagra/Cedra	UT	LL, IL, HL
Sweden	SKB	UT + PO	LL, IL, HL (SF)
Finland	POSIVA	UT	HL (SF)
Canada	SGDN/NWMO	UT	HL
UK	NDA	PO	LL, IL, HL

PO: public organization, UT: utility, VLL: very low level waste, LL: low level waste, IL: intermediate level waste, HL: high level waste, SF: spent fuel

1.2.6 The Waste Management Process

■ Figure 22

Waste management process

Waste management features the following successive operations: identification, characterization, selection, treatment, conditioning, transportation, storage, and disposal (🔍 Fig. 22).

The ensemble of these operations is specifically adapted to the nature of each category of waste.

1.2.7 Uranium Mine Tailing Management

During the extraction operations, the uranium ore is crushed down to a granulometry of the order of a fraction of a millimeter, and exposed to the action of an acid (generally sulfuric), more seldom of an alkali, depending on the nature of the minerals. This treatment extracts 90–98% of the uranium from the ore, but leaves in the tails all the daughter atoms from the uranium decay chains, including radium. The mine tailings, which are the true waste of the mining operations, thus contain 80% of the initial radioactivity. These tailings are gamma emitters. Since they also contain Radium 226, they are also able to emit its daughter, Radon 222. This atom can eventually exit in gaseous form from the mineral grains, all the more easily if the grains are smaller. It is necessary to protect the public and the workers both from the gamma emissions and from the radon exhalations. The quantities of mine tailings are such that these tailings cannot be stored elsewhere, but in the mine itself. The tailings are used to backfill the excavations in the mine, a form of storage, which enables one to monitor their evolution. After the closure of the mine, the residues are covered by a layer of sterile rocks a few meters thick, in order to shield the gamma emissions and to prevent the exit of radon to the open air (🔍 Fig. 23). This method is effective because ^{222}Rn (period 3.8 days) atoms have no time to diffuse out of this layer.

However, the mine tailings have been perturbed by the chemical attack, and may undergo mineralogical transformations, with subsequent release of radium and residual uranium in the water, which percolates through the residues. These waters are therefore drained and chemically treated to get rid of their radium before their release in the hydrographic network. The control is maintained as long as the radium content of the water remains significant.

Another option to manage the uranium mine tailings is to keep them under water. The water shields the environment from the gamma radiation emitted by the tails, and prevents the release

🔍 Figure 23

The uranium mine of Puydelage (France) during its exploitation and after its closure

of radon in the atmosphere. This management mode is convenient in lake regions, and has been used, for example, in Canada. Here again, the radioactive content of the water is monitored.

1.2.8 Management of Low and Intermediate Level, Short-Lived Waste (LIL-SL)

This type of waste is mostly conditioned in concrete or metallic drums:

Metallic drums for the least noxious waste (gloves, masks, clothes, etc.)

Concrete shells for medium radioactive waste

Concrete casings, containing compact metallic drums or nuclear plant filters

Metallic casings for the most bulky waste (tubes, scraps, etc.)

The management principle for this type of waste is to leave the waste stored for two or three centuries (more than ten times the period of the longest-lived radionuclides contained in the waste), a time sufficient for all radionuclides to decay.

The conditioned waste is piled up in watertight cells. The voids are filled with gravel or mortar, the cells are closed by a concrete cover and coated with a watertight polymer. Later on, the storage is covered by a watertight blanket, plus a few meters of soil. After 300 years, the radioactivity will have almost completely decayed.

Several installations for the storage of LIL-SL waste exist in the world, shared almost equally between underground storage-disposal facilities and surface storage installations.

Geological storage facilities at medium depth (100 m) exist in Sweden and in Finland.

A geological disposal in sedimentary host rock is in operation in the ancient iron mine site of Konrad (Germany). In 2007, this site obtained the authorization to store all types of non-exothermic waste, short-lived or long-lived.

In Canada, the utility OPG is preparing the project of deep geological disposal (DGR) LIL-SL waste in the site of Kincardine (Ontario).

Surface installations are also working in France (Centre de l'Aube), in Spain (El Cabril,  Fig. 24), in the UK (Drigg), and in Japan (Rokkasho-Mura).

 Figure 24

Example of LIL-SL waste storage facilities: the Spanish site of El Cabril has a capacity of 76,000 m³ (LIL-SL waste) and 130,000 m³ (VLL waste) (photographs ENRESA)

In Switzerland, as in other countries where the search for storage sites has triggered much local opposition, a unique storage facility for all types of waste is being sought.

1.2.9 Interim Storage of Spent Fuel

An assembly of spent fuel is made of fuel rods (tubes of zirconium alloys containing the UO_2 or $\text{UO}_2\text{-PuO}_2$ pellets). These rods are 4–5 m long, closed at both ends, and bound together in a square lattice by grids and spacers, which maintain a specified distance between them. A device at the top of the assembly permits the handling of this bundle (► Fig. 25).

After their unloading from the reactor core, the bundles of spent fuel can be stored, most often in pools (► Fig. 26), but also possibly in dry casks. This storage leaves some time for the fuel to cool down by decay of its short-lived radionuclide content. After a few years of cooling,

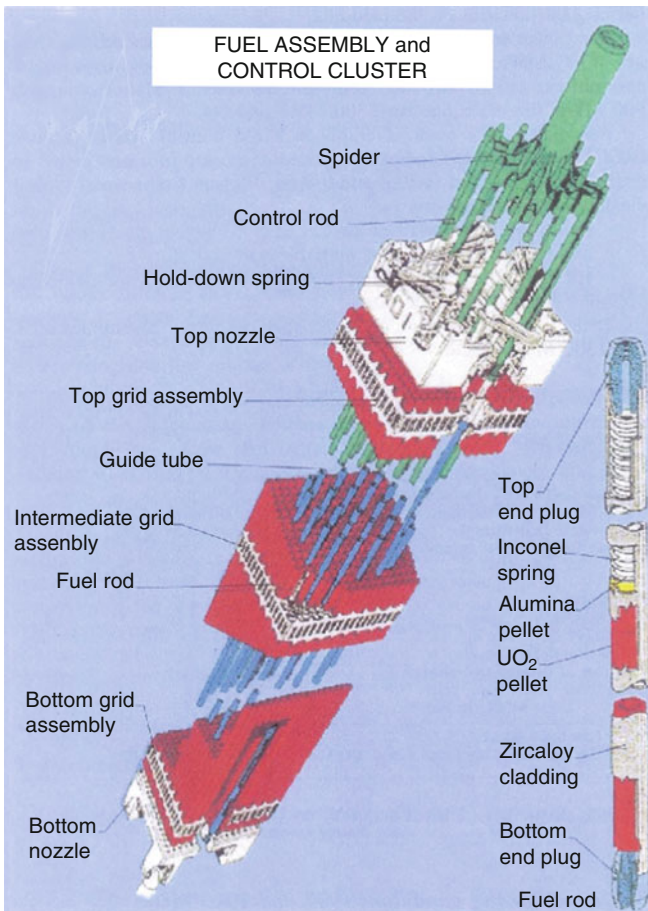

Figure 25
A PWR fuel bundle

■ Figure 26

A pool for the interim storage of spent fuel

the spent fuel can then be reprocessed (closed fuel cycle option) or considered as final waste (open fuel cycle option) (See ▶ Sect. 3.1).

1.2.10 High Activity Waste from Reprocessing is Vitrified

The idea is to cast the waste into a very stable form, able to confine the radionuclides (▶ Figs. 27 and ▶ 28).

The vitrified waste is stored in ventilated wells, close to the processing unit (▶ Fig. 29). This storage is (by definition) temporary.

■ Figure 27

Glass casting of high-activity waste from reprocessing

■ Figure 28
An example of vitrified waste package

■ Figure 29
The EEV-SE facility for the interim storage of vitrified HL waste

1.2.11 Options for the Management of Long-Lived Nuclear Waste

Partitioning and Transmutation

The main purpose of partitioning and transmutation is to minimize the waste quantity and toxicity (🔍 [Fig. 30](#)).

The general idea of partitioning is to separate transmutable radionuclides from others and to separate long-life radionuclides from others in order to manage these categories of waste separately. The general idea of transmutation is to transform the long-lived radionuclides into inactive or short-lived isotopes.

There are good prospects to transmute actinides in Fast Reactors. This could permit a big gain on waste radiotoxicity and residual power (this last parameter dictates the size and cost of a repository). But before transmuting actinides, one needs to separate, and to store them.

Figure 30
Options for the management of long-lived nuclear waste

Thanks to considerable progress in hydrometallurgy, selective extraction methods have been developed. Nowadays, separation between Fission Products (^{129}I , ^{99}Tc , and ^{135}Cs) and Minor Actinides (Np, Am, Cm) (more than 95%) has been proven feasible at the laboratory scale and will not pose big problems at the industrial scale because the new processes are merely adaptations and variants of the PUREX process.

Separation of Minor Actinides would permit one to avoid their incorporation in vitrified waste, with a considerable gain in radiotoxicity and thermal load of the glass. This option will become interesting if (and when) minor actinides can be transmuted efficiently.

Transmutation of Fission Products is very difficult because these nuclei require one neutron per transmutation, or even more than that, because the result of this transmutation is often another radioactive nucleus.

Transmutation of Minor Actinides is technically feasible, especially in a fast neutron reactor, because these nuclei are fissile in fast neutron spectrum. Their fission produces additional neutrons and energy. However, the timescale for the transmutation is quite slow, of the order of 10–100 years.

Conditioning

Waste conditioning consists in putting the waste under a stable and safe form, with packages, which can be handled.

It has been shown that glass and cementitious materials are satisfactory conditioning matrices for long-life waste (see [Sect. 2](#)).

Interim Storage

The main idea behind interim waste storage is to give time for the waste to cool down and time to decide on an appropriate waste posttreatment.

Interim storage is temporary by definition. It implies the possibility of a secure and safe recovery of waste from a facility able to protect the waste durably.

Interim storage appears as an option, which gives some flexibility to the nuclear waste management: it acts as a buffer for the waste stream, between production and disposal. An important parameter is the *duration* of the interim storage.

Long-term interim storage (>100 years) in surface or subsurface has been proven to be feasible technically (see [Sect. 3.1](#)).

Deep Geological Disposal

The main idea of deep geological disposal is to get rid of the waste definitively, without leaving the burden of our waste to future generations (note the apparent contradiction with the interim storage philosophy).

This solution could be the ultimate one, for ultimate waste. The geological medium ensures a stable long-lasting barrier.

A *reversible* disposal gives the possibility to retrieve the waste after some time. The idea of reversibility bridges the gap between storage and disposal. All degrees of reversibility are possible. The reversibility option is still under study. If chosen, this option will hamper somewhat the safety of the repository, and increase its cost. To what extent?

Interim storage and disposal facilities do not differ only in their philosophy: they are objects of two different natures. While disposal facilities are designed to be safe without any surveillance or maintenance, interim storage facilities require both. Secondly, there is no return of experiment on the operation of nuclear waste repositories, whereas interim storage facilities are already an industrial reality. Thirdly, the lifetime of the interim storage facility is of the order of a century, i.e., a duration familiar to engineers who build bridges or other artifacts, whereas the lifetime of a repository is so long that it challenges the human imagination. Lastly, the radiological impact of an interim storage is designed to be zero for the public (no leaks) during its entire lifetime, whereas such a goal is inaccessible for a repository. However, the radiological impact for the workers in the storage facility will be nonzero, and the hazards, which might affect the storage facility are nonnegligible. Consequently, the duration of the interim storage must be decided, taking into account these factors, and weighing them against the industrial advantages of this option.

Thanks to the studies in underground laboratories, the technical feasibility of a reversible geological disposal has been established (see [Sect. 3.2](#)).

These options for the management of long-lived nuclear waste are complementary, not antagonistic. They are listed here in an order that could be chronological. The deep geological disposal is at the end of the sequence.

1.2.12 Waste Management and Radioprotection

The units of radioactivity

Quantity	Units	Definitions
Activity	Becquerel (Bq)	Measure of the number of disintegrations per unit time within a radioactive source. 1 Bq = 1 disintegration/s
Absorbed dose	Gray (Gy)	Measure of the energy received per mass unit of irradiated matter. 1 Gy = 1 J/kg
Equivalent dose	Sievert (Sv)	Measure of the biological damage on irradiated living tissues. 1 Sv corresponds to 1 Gy (in the special case of gamma irradiation, on the whole body); ponderation factors are introduced to take into account the nature of the radiation and the vulnerability of the different organs

1.2.13 From Radioactivity to Radiotoxicity

One defines the radiotoxicity of a given quantity of a radioactive substance as the dose that would be received by someone who would ingest this quantity.

$$\text{Radiotoxicity} = \sum X_i^* \text{DF}_i,$$

where X_i is the activity of radionuclide i in the substance, and DF_i is a dose factor associated to radionuclide i . The sum runs over all radionuclides contained in the substance.

Each radionuclide has a characteristic “dose factor” DF (expressed in Sv/Bq), which characterizes its intrinsic radiotoxicity. This dose factor depends on the type and energy of the radioactivity emitted by the RN, on its biological period (i.e., the time during which it stays in the organism) and on the organs in which it tends to concentrate.

Radiotoxicity is merely an indicator of the danger induced by the waste, used to compare different waste management options.

1.2.14 Ingestion Dose Factors

Relationship Between Radioactive Dose and Effect

The effect of low doses (<10 mSv/year, i.e., the domain of interest for waste management) is poorly known. In the absence of scientific evidence, the radioprotectionists assume a proportionality between the dose and the effect. This assumption facilitates the evaluation of danger, and the establishment of radioprotection rules (► [Fig. 31](#); ► [Table 6](#)).

■ **Table 6**

The ingestion dose factors of some radionuclides of interest for waste management

	<i>FD (Sv/Bq)</i>
Tritiated water	1.8×10^{-11}
^{14}C	5.8×10^{-10}
^{40}K	6.2×10^{-9}
^{90}Sr	2.7×10^{-9} à 2.8×10^{-8}
^{99}Tc	7.8×10^{-10}
^{129}I	1.1×10^{-7}
^{131}I	2.2×10^{-8}
^{135}Cs	2.0×10^{-9}

The dose–effect relationship

1.2.15 The Long-Term Radiotoxicity of Spent Fuel

For a short time after the fuel discharge, the radiotoxicity of spent fuel is shared about equally between actinides and fission products; after a few decades, actinides (and especially plutonium) dominate. Plutonium is the main contributor to the long-term radiotoxicity of the waste (🔍 Fig. 32).

The radiotoxicity of waste decreases with time. The rule of thumb generally adopted for the management of LLW is to confine the waste long enough for its radiotoxicity to decrease below the level of the initial uranium in mined ore (🔍 Fig. 33).

If spent fuel is considered as waste, one then has to confine it during several hundred thousand years.

Figure 32
The radiotoxicity of spent fuel

Figure 33
Comparison of the radiotoxicity of spent fuel and of HL waste from reprocessing

Reprocessing brings a drastic reduction of the radiotoxicity of the waste, as well as a reduction of the needed confinement time.

A removal of the actinides from the glass would permit another reduction of both toxicity and confinement time, which could be cut down to a few centuries.

1.2.16 Deep Geological Disposal: The Multibarrier Concept

The principle of a deep geological disposal is to interpose several barriers (🔍 Fig. 34), i.e., confinement matrix (glass, concrete), engineered barrier (overpack, clay layer), and geological barrier (host rock) between waste and biosphere, in order to prevent and delay the radionuclide migration. The delay must be long enough for the radioactive decay to take place.

The curves of the radiotoxicity versus time (▶ Fig. 33) give the timescale needed for this delay. They are of the order of several 100,000 years for spent fuel, several 10,000 years for “classical” glass, and several 100 years for “light” glass.

The challenge is to predict the evolution of the repository over the next 100,000 years. No direct demonstration is possible. One can only try to convince (oneself and others) by means of modeling and partial experiments.

■ Figure 34

The multibarrier concept applied to the deep geological disposal of nuclear waste

2 Waste Conditioning

Waste conditioning ensures the confinement of the radioactivity on the long range, based on the timescale of the storage or disposal. The usual methodology of waste conditioning involves several steps:

Treatment of the waste: this step covers two major goals.

Putting the waste under a form compatible with the confinement matrix and reducing the waste volume through methods (decontamination, incineration of organic waste, compacting, etc.) designed to produce the smallest possible quantity of secondary waste.

Packaging: this step consists of incorporating the waste in an adapted confinement matrix, then in a container. Conditioned waste is under the form of a “package.”

Characterization of the package: this step involves determination of the quantity, the nature, and the location of the radioactivity contained in the package, in order to forward it toward the most adapted exutory (and to check that the regulatory requirements are complied with).

The aim is to demonstrate the quality of the radioactivity confinement on a timescale related to the type of exutory considered for the waste: some 10–100 years for storage and up to several hundred thousand years for geological disposal. This constitutes the stake of studies on the long-term behavior of packages.

Nowadays, this methodology has been widely tried. In the first place, a research should be carried out on the laboratory scale (under inactive conditions, but also in the presence of actual radio-elements) for a detailed description of the waste alteration phenomena, which could lead to a dispersal of radioactivity in the environment. Alteration can be endogenous to the package (waste radioactivity effects on the confinement matrix, or chemical reactions between the waste and the matrix), possibly leading to a modification in the package confinement properties (swelling, fissuring, etc.), or exogenous, and linked to the environment. It may occur when different engineered barriers have been soaked through by the water of the site. Alteration phenomena can also be linked to the interaction between the package and the environment; for instance, when the package alteration products or the radiolysis modify the properties of the water of the site (heat production, increase of the pH in presence of cement, increase of the oxidizing nature of the water by radiolysis, etc.).

These phenomena are then modeled, taking into account the safety margins. One then obtains an operational model, which will constitute a basis for the safety demonstration. With that aim, this model must be evaluated and its conservative character must be ascertained. This can be achieved quantitatively by means of a set of laboratory tests, or using geological or archeological analogues of the waste under study.

We recall that if the reprocessing option has been chosen:

- The solution of fission products and minor actinides is vitrified.
- Fuel cladding and end caps are rinsed and compacted or cemented.
- Sludges are bituminized or cemented.

In the following, we describe these conditioning processes, together with the long-term behavior of these different matrices, cement, glass, and bitumen. In countries, which have chosen the open fuel cycle option, spent fuel is considered as waste. The end of the chapter is devoted to the conditioning of spent fuel.

Decontamination is an important part of the waste treatment process. Decontamination of raw waste aims at extracting from the waste some of its radioactive content, which will then be isolated from the initial waste and conditioned into an ad hoc form.

Decontamination operations are carried out daily in the nuclear industry on solid, liquid, and gaseous waste. Eventually, the residual radioactivity level of the initial waste becomes sufficiently low to downgrade the waste or even to transform it into reusable material. In the case of solid waste, decontaminating small equipment (pumps, valves, or waste packages) can allow the equipment to be reused. Larger equipment items (hot cells, fission product storage tanks, pipes, steam generators, etc.) are decontaminated for maintenance or dismantling. The difficulty of

decontaminating a solid generally results from the chemical form in which the contamination is fixed:

- In layers adhering to the substrate such as fat, grease, and extraction solvents (e.g., the tributyl-phosphate used in the PUREX process),
- In oxide layers that trap radionuclides,
- In inorganic precipitates that may or may not adhere to the bottom of vessels,
- In the material bulk, radionuclides can migrate into the solid, for example, tritium in metals, or cesium in porous concrete.

Carefully identifying the physicochemical form of the contamination ensures that the most suitable decontamination processes can be implemented. Each process must minimize the quantity of waste produced and must be designed or developed with attention to a range of parameters: the nature of the contamination and its accessibility, the temperature and humidity, the nature of the contaminated material, etc. For this reason, there is no universal process. A suitable process must be specified for each decontamination operation.

Research carried out on decontamination techniques has led to efficient processes to decontaminate solids with high efficiency, in replacement of conventional acid–base rinsing operations that generate large quantities of liquid effluents:

- Dryable gels, sprayed or brushed onto the surface to be decontaminated (▶ Fig. 35). After drying, these gels produce a small quantity (typically $250 \text{ g} \cdot \text{m}^{-2}$) of solid residue in the form of flakes containing the radioactivity transferred from the decontaminated surface, and suitable for vacuum recovery. This decontamination technique eliminates the need for rinsing and thus produces no liquid effluent requiring subsequent treatment.
- Tensio-active foams (▶ Fig. 36). The aqueous foams considered for decontaminating components or structures in nuclear facilities consist of air bubbles dispersed in water containing one or more foaming surfactants and one or more chemical decontaminating agents (acids, bases, oxidizing or reducing agents). This technique is an attractive alternative to liquid phase processes, because it diminishes the quantity of chemical reagents used and the volume of liquid effluents generated.
- Decontamination by laser or super-critical fluids, which produce no effluent.

■ Figure 35
Decontamination by dryable gel

■ Figure 36

Decontamination of a tank contaminated by adhering deposits by a tensioactive foam

Volume of the waste conditioned in the UP3 processing unit in La Hague (long-life waste for one ton of initial uranium)

■ Figure 37

The volume of conditioned waste has steadily decreased, thanks to the producer's efforts. It is shown here that the processing of spent fuel also permits a reduction of the volume of the waste, by a factor larger than 4 as compared to the original spent fuel.

The first two methods (gels and foams) reached a development level permitting their use on an industrial scale.

Continuous improvement of the waste treatment and conditioning results in a large reduction of the waste volume over the last 20 years (► Fig. 37).

2.1 Conditioning of LL and IL Waste in Cement-Based Matrices

Cement-based materials are widely used in radioactive waste conditioning: grouts for waste embedding, mortars for immobilization operations, and concretes for container manufacturing on disposal sites.

Cementitious matrices are used to encapsulate waste such as:

- Sludges of co-precipitation
- Evaporation concentrates of effluents
- Fuel cladding (<1995 in France)
- Ion exchange resins
- Technological waste (small materials, compacted drums, etc.)

The advantages of such a conditioning are as follows:

- Cementitious materials are versatile; they are able to confine a number of physicochemical waste forms, and to immobilize a high number of radionuclides owing to the interstitial solution basicity.
- Cementitious materials are cheap and readily available.
- Implementation is simple (cold process); liquid effluents can be directly incorporated into the concrete mixes.
- They have interesting mechanical properties (compressive strength).
- This conditioning permits handling and confinement by embedding (➤ Fig. 38) or homogeneous mixing (➤ Fig. 39).

■ Figure 38
Embedding of heterogeneous metallic waste

■ Figure 39
Cementation of ion exchange resins

The main drawback is linked to the fact that the incorporation rate is small, hence large volumes of waste are produced.

2.1.1 Elaboration of Cement-Based Materials

Cements are mixtures of calcium, silicon, and aluminum oxides under powder form, which react chemically with water to produce a solid made of hydroxides (mainly calcium hydroxide called portlandite and hydrated calcium silicates, under the generic acronym of C-S-H) (► [Table 7](#)).

Cement-based materials (grout, mortar, concrete) result from the setting of a mixture of anhydrous cement, aggregates of various sizes, and water (► [Fig. 40](#)).

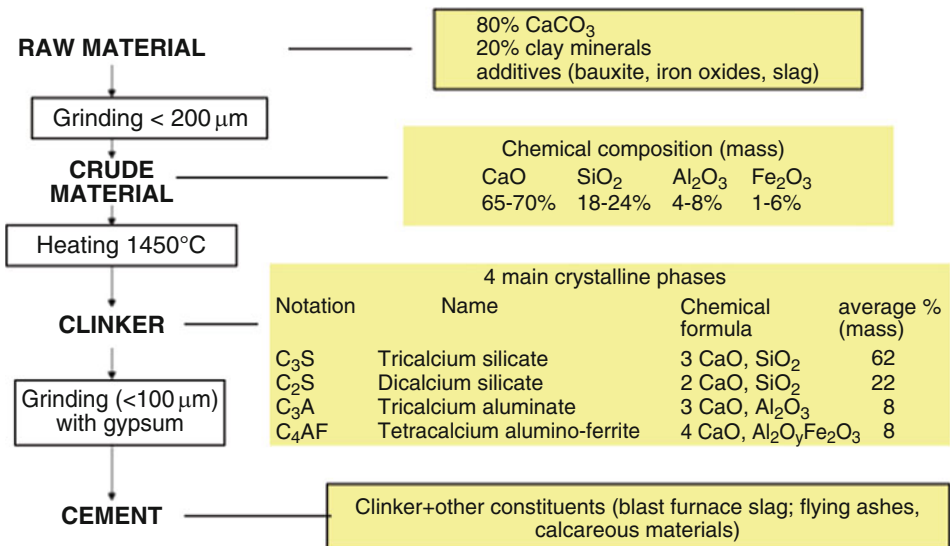

Hydration reactions start as soon as cement and water come into contact. Mechanical features change very rapidly in the hours following the setting, then this evolution goes on more and more slowly for several months.

Hardened cement paste is a heterogeneous material, which consists of a porous solid, a liquid phase and, generally, a gaseous phase present in the pores. The solid is formed with hydrated minerals and possibly residual anhydrous cement.

The interstitial pore solution is very basic (pH around 13.5) and its composition varies with the material age.

C-S-H minerals have a stoichiometry close to $C_{1.5}-S-H_{2.5}$ (calcium to silicon ratio about 1.7). They are responsible for the mechanical properties of the material.

The CH mineral, $Ca(OH)_2$, called portlandite plays a role in the material durability. It makes big crystals which are soluble in water ($s = 1.6 \text{ g/L}$ at 25°C). This dissolution has two important consequences: an increase of the porosity of the material; and a very basic porewater (pH

■ **Figure 40**
Manufacturing of cement

increases up to 13.5 during hydration). This high pH contributes to the passivation of the steel reinforcement in concrete.

Basic reaction of hydration in cements

■ Table 7

Composition of the cements most widely used in the area of nuclear waste conditioning and disposal. CEM I Portland cements are those used conventionally in the building industry. CEM III and CEM V cements differ from the CEM I Portland cement by the addition of large quantities of blast-furnace slag and pozzolanic materials

Composition of standardized cements								
Main types	Notation		Composition (wt %)					
			Clinker	Blast-furnace slag	Pozzolans			Secondary constituents
					Natural	Natural calcinated	Silica-containing fly ash*	
CEM I	Portland cement	CEM I	95–100	–	–	–	–	0–5
CEM III	Blast-furnace cement	CEM III/A	35–64	35–65	–	–	–	0–5
		CEM III/B	20–34	66–80	–	–	–	0–5
		CEM III/C	5–19	81–95	–	–	–	0–5
CEM V	Composite cement	CEM V/A	40–64	18–30		18–30		0–5
		CEM V/B	20–38	31–50		31–50		0–5

2.1.2 Waste Conditioning in Cement-Based Materials

One should distinguish between the following:

- Embedding of solid waste in a cementitious matrix (e.g., fuel claddings) (➤ Fig. 41)
- Homogeneous mixing, for which the waste is incorporated in liquid form into the cement matrix (e.g., sludges of co-precipitation, evaporation concentrates of effluents) (➤ Fig. 42).

■ Figure 41
Industrial implementation of waste cementation (embedding of solid waste)

■ Figure 42
Industrial implementation of waste cementation (case of a homogeneous mixing)

2.1.3 Long-Term Behavior of Cement-Based Materials

The long-term behavior of cementitious materials in water-saturated media is rather well understood. The main mechanism is first the leaching of alkalis (Na, K) and then the dissolution of portlandite (which releases calcium ions), and the diffusion of these calcium ions in the cement porewater (➤ Fig. 43). This mechanism predicts an altered zone with a thickness growing roughly like the square root of time, a fact well confirmed by experiment.

The Ca flux in the altered zone is

$$\vec{j} = -D_e \cdot \text{grad}(c),$$

where c is the concentration of calcium ions in the porewater and D_e is the effective diffusion coefficient of calcium ions in the porous cement.

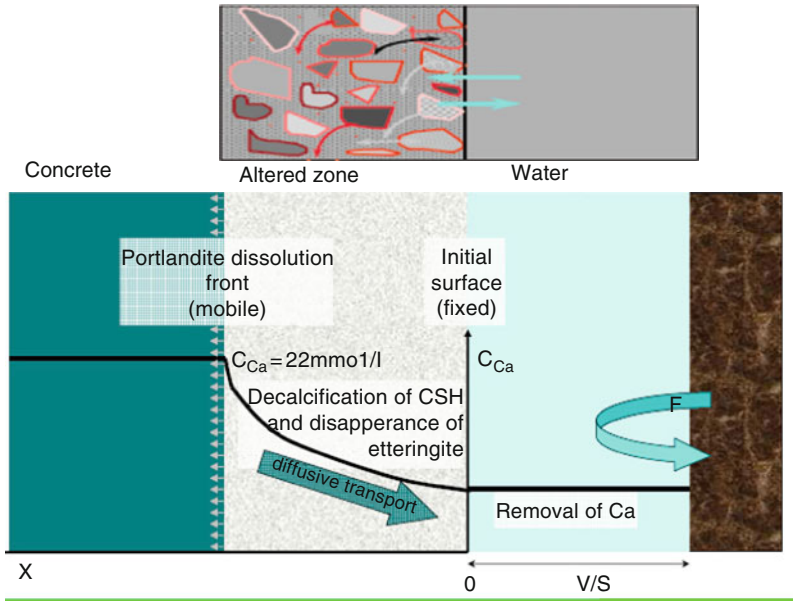

Figure 43
Schematic representation of the mechanism of cement-based material alteration by water

The progression of the alteration front obeys the differential equation:

$$\frac{de}{dt} = \frac{|j|}{X},$$

where X is the molar concentration of soluble portlandite in the cement and e the thickness of the already altered zone at time t .

The concentration of calcium ions in the porewater of the unaltered cement is assumed to be limited to c_{sat} , solubility of the portlandite. The concentration gradient is approximated as uniform throughout the altered zone:

$$grad(c) = -c_{sat}/e.$$

This leads to a differential equation for the evolution of the thickness of the altered zone:

$$\frac{de}{dt} = \left(\frac{D_e \cdot c_{sat}}{X} \right) \cdot \frac{1}{e}.$$

This equation is easily solved:

$$e(t) = (2 \cdot D_e \cdot c_{sat} \cdot t/X)^{1/2}.$$

The thickness of the altered zone increases as the square root of time.

Orders of magnitude for the parameters are:

$8,000 \text{ mol} \cdot \text{m}^{-3}$ of soluble portlandite in the cement paste (20% of portlandite)

Effective diffusion coefficient of Ca^{2+} ions in the cement = $10^{-11} \text{ m}^2 \cdot \text{s}^{-1}$

Solubility limit of portlandite in the interstitial medium = $22 \text{ mol} \cdot \text{m}^{-3}$ (at 25°C)

These figures give an altered thickness of 2 mm in 200 days, in rough agreement with the experiment (► Fig. 44).

This very rough modeling, displayed here only to give orders of magnitude, neglected the fact that the dissolution of portlandite modifies the porosity of the material, and the diffusion coefficient of calcium ions in the porewater.

In fact, the equilibrium between calcium-rich phases ($\text{Ca}(\text{OH})_2$, C-S-H) and in-solution calcium concentration leads to a more complicated, but well-established relationship between calcium concentration in the solid phase and that in the solution (► Fig. 45).

■ Figure 44

Experimental quantification and modeling of leached species (Ca^{2+}), along with the visualization of the associated solid phases during chemical degradation tests on CEM I-type cement pastes in pure water

■ Figure 45

Calcium equilibrium between the solid phase and the interstitial porewater solution of a Portland cement-based material (Compiled from Berner 1992)

Porosity evolution is directly linked with the mineralogical evolution of the system, which later on allows the diffusion coefficient of the material to be traced according to the material degradation state. The application of this model is fully validated on CEM I pastes and concretes (Bejaoui et al. 2006).

The validation of models of cement alteration can be done by means of leaching experiments on samples, with circulating water (with or without a controlled composition).

2.1.4 R&D on Cement-Based Materials for Waste Conditioning

The incorporation of waste in the Cement-Based matrices can perturb the formation of the minerals, which constitute the cement (chemical perturbation), and reduce the mechanical resistance of the material (physical perturbation). In order to reduce the consequences of these perturbations, the waste may require a pretreatment (precipitation in the case of effluents, pyrolysis in the case of organic resins). This causes a limitation of the waste concentration in the cement, and research is going on to determine reasonable limits to the incorporation rate.

Phosphated or borated waste is not easily conditioned in cement, and research is going on to find cement formulations compatible with these components.

Phosphate ions are found in evaporation concentrates from the facilities of treatment of liquid effluents. These ions are known to delay or prevent the hardening of the cement matrix, and to degrade its mechanical properties (with a pessimism around a concentration of the order of 30 g/L (Bernard et al. 2005)). The mechanism involves the adsorption of phosphate ions on the C_3S phase, thereby inhibiting its hydration. A possible solution to this problem would be the addition of small amounts of hydroxyapatite to the cement, to help the precipitation of phosphate ions.

Borate or zinc ions also prevent the hardening of the Portland cement paste. Sulfo-aluminous cements are less inhibited, and offer interesting perspectives for waste containing these two ions.

Radiolysis is another topic of interest for the R&D on cemented nuclear waste. Cementitious materials contain water in their pores, and this water is irradiated by the radionuclides enclosed in the cemented package. Under these radiolytic conditions, water can decompose and form dihydrogen. This dihydrogen itself can cause an increase in pore pressure, and thus threaten the integrity of the matrix. Recent results show that the main parameter, which determines the kinetics of hydrogen production is the dose rate, and that with the dose rate expected from a medium activity waste package ($< 510^{-2}$ Gy/s), the pore pressure will remain well below the resistance limit of the material (Bouniol 2004).

Atmospheric carbonation and degradation of steel-reinforced concrete is another subject of active research. However, this material is mainly used in civil engineering rather than in waste management, and the mechanisms of its degradation are therefore outside the scope of this chapter.

2.1.5 Waste Container Manufacturing

Cementitious materials are used not only for confinement of waste by embedding or homogeneous mixing, but also for the waste container elaboration.  *Figure 46* shows the example of a standardized concrete package, designed to facilitate the handling and storage of intermediate-level long-lived waste.

■ **Figure 46**
Sketch of an IL LL waste package concept involving a concrete container

Several types of waste can be accommodated in this universal concrete container:

- Activated metal waste
- Bituminized sludge
- Cemented technological waste
- Cemented hulls and nozzles
- Compacted structural and technological waste

2.2 Conditioning of HL-LL Waste in Glass

2.2.1 Vitrification of Solutions of Fission Products

After being preconcentrated so as to reduce their volume, fission product solutions are stored in stainless steel tanks where they are constantly stirred and cooled. Their activity, related to spent fuel burnup, may reach $4 \cdot 10^{13}$ Bq/L and the power released is significant (up to 7 W/L). These nitric solutions (1–2 N) feature high physicochemical complexity. Their chemical composition generally includes:

- Corrosion products (Fe, Ni, Cr)
- Additive products (Al, Na, etc.)
- Solvent degradation products (P)
- Elements issued from clad materials (Al, Mg, Zr, etc.)

There is also a broad range of radioactive elements, fission products, and actinides, ranging from germanium ($Z = 32$) to californium ($Z = 96$). Contrary to what is suggested by the word “solution,” usually reserved for homogeneous liquids, “solutions of fission products” also prove physically complex as they contain flocculates and precipitates (zirconium phosphates and molybdates) as well as small metallic particles (undissolved platinoids such as ruthenium,

■ **Figure 47**
Vitrification of a solution of fission products

palladium, rhodium, or intermetallics, e.g., with molybdenum), and particles resulting from fuel clad shearing (zirconium, for LWR fuels) (► *Figs. 47* and ► *48*).

The conditioning of solutions of fission products is aimed at:

- Turning waste from the liquid to solid state
- Reducing the volume to be stored and, then, disposed off
- Getting a material that complies with the safety requirements peculiar to storage and disposal

Glass was selected by the world's community as the confinement material for solutions of fission products, due to the flexibility of its disordered structure that enables glass to confine many chemical elements. It must be emphasized that the aim is not a mere embedding, but an atomic-scale confinement, since radionuclides are intimately incorporated in glass structure.

Glass is an interesting material for the confinement of radionuclides, because it is endowed with satisfactory properties of thermal stability, chemical durability, quasi-insolubility in water, and resistance to self-irradiation.

Glass resists very well to irradiation (little swelling, no recrystallization observed, no degradation of the glass mechanical properties). Thanks to the flexibility of the lattice, broken bonds reform easily a few picoseconds after the ionizing radiation.

Glass incorporates well the He that will be produced by the alpha disintegrations.

■ Figure 48
Vitrified waste package (CSD-V)

2.2.2 Requirements for the Glass Material

- Glass must be able to incorporate the various elements from the fission product solution to be vitrified (15% in mass).
- Glass must be homogeneous.
- Crystallization must be avoided.
- Elaboration must be easy (radioactive ambiance): the melting temperature must not be too high to limit volatility, the viscosity must be small to allow glass pouring, and the melted glass must not be too corrosive for the crucible.
- Large chunks of glass must solidify without too much fracturing.
- Glass must withstand irradiation and alteration by water.

2.2.3 Physicochemistry of Glass

Glass is solid like a crystal, and disordered at the atomic scale, like a liquid.

Upon cooling below the melting point, most liquids crystallize, but glass has a continuously increasing viscosity (this viscosity is higher than 10^{13} Poise below the glass transition temperature, $T_g = 520^\circ\text{C}$ for borosilicated glass). It is thermodynamically metastable, and could

■ **Figure 49**

Glass structure: a silica tetrahedron (left), and a chain of tetrahedra with lattice modifiers (right)

recrystallize, yet this process can be very slow (we know of geological glass which is 100 million years old).

Glass melt and glass properties depend upon the atomic ordering of the elements.

The cohesion of the oxide glass skeleton is ensured by the ionic-covalent chemical bonds, which are formed by the glass network formers (Si, B, Al) in combination with oxygen atoms. One oxygen atom bound with two network formers is said to be “bridging,” whereas one oxygen atom bound with a single network former is said to be “non-bridging.” These bonds are oriented and take part in the formation of tetrahedra SiO_4 , BO_4 , AlO_4 , and of triangles BO_3 . Silicon tetrahedra and Boron triangles are connected by one oxygen summit. These elementary structures form chains and rings of different sizes, thus contributing to the solidity of the edifice (► Fig. 49). These covalent bonds coexist with bonds with a more ionic character, formed between the alkaline or alkaline-earth metals (Na, Ca) and the oxygen atoms.

The Na and Ca elements may play two distinctive roles within the glass network. They may either behave as charge-compensators near a locally negative-charged BO_4^- or AlO_4^- -type group, or they may behave as “modifying” elements, forming a X-O-Na or X-O-Ca bond (with X being a network former).

The progressive addition of network modifiers to silica, SiO_2 , leads to network depolymerization by the formation of non-bridging oxygen atoms.

Modifying elements contribute to reduce the melting temperature and viscosity, and increase molten glass reactivity, which makes its fabrication easier. Their presence makes the glass structure flexible, and permits the incorporation of radionuclides in the glass structure.

2.2.4 Glass Composition

The glass composition generally chosen for the conditioning of the fission product solutions from the reprocessing of LWR spent fuel is a borosilicated glass, because of several interesting properties:

- Its lower temperature of elaboration compared to silica
- Its very low tendency to crystallization
- Its very good resistance to water alteration
- In addition, boron helps digest the calcinate during glass elaboration and lowers the equilibrium pH after leaching

The good performance of nuclear borosilicate (a temperature melting not too high *and* a good chemical durability) comes from the right balance between boron and the intermediate elements (Al, Fe, Zr) on one side and the alkali elements on the other side, allowing a high polymerization rate as most of alkali are found as charge compensators rather than forming non-bridging oxygen links.

Typical French “R7T7” glass incorporates up to 18.5% (mass) of fission product oxides and 0.9% of actinide oxides (🔍 [Table 8](#)).

■ **Table 8**

Typical composition of borosilicated glass for the conditioning of HL waste

Chemical composition range of R7T7 glasses produced in the AREVA - La Hague plant workshops			
Oxides	Specified interval for the industry (wt%)		Average composition of industrial glasses (wt%)
	min	max	
SiO ₂	42.4	51.7	45.6
B ₂ O ₃	12.4	16.5	14.1
Al ₂ O ₃	3.6	6.6	4.7
Na ₂ O	8.1	11.0	9.9
CaO	3.5	4.8	4.0
Fe ₂ O ₃		<4.5	1.1
NiO		<0.5	0.1
Cr ₂ O ₃		<0.6	0.1
P ₂ O ₅		<1.0	0.2
Li ₂ O	1.6	2.4	2.0
ZnO	2.2	2.8	2.5
Oxides (PF + Zr + actinides)	7.5	18.5	17.0
Fines suspension			
Actinide oxides			0.6
SiO ₂ + B ₂ O ₃ + Al ₂ O ₃	>60		64.4

2.2.5 Incorporation of Radionuclides in Glass: Where Is the Limit?

In order to minimize the number of glass packages produced per ton of spent fuel, one tries to produce glass with a high load of fission products and minor actinides. The increase of fuel burnup results in a higher content of radionuclides in the spent fuel. This is also an incentive to increase the radionuclide load in the glass.

However, one should keep in mind that the dimensions (and cost) of a geological repository are determined mainly by the total heat load of the waste, and are not changed by reducing the number of glass packages and increasing the RN concentration in the glass at the same time.

Moreover, the RN load is limited by the need to make homogeneous glass. The temperature of elaboration of the glass plays an essential role. In most vitrification processes, this temperature is around 1,150°C.

Phenomena to be avoided are:

- Crystallization. For example, chromium tends to form chromites (spinel) with Ni, Fe, Zn beyond a concentration of 1% in mass. Aluminum and cerium oxide crystallites dissolve slowly in the glass melt if their concentration is larger than 10% and 1%, respectively
- Phase separation. The oxides, MoO₃ and P₂O₅, lead to a phase separation (one silicated, the other molybdc or phosphatic) if their concentration is beyond 2–3% in mass
- Settling of platinoïds at the bottom of the crucible. Platinoid fission products do not incorporate well into the glass matrix. They tend to coalesce into metallic particles, or as droplets of low melting point alloys (typically 700°C) that can settle at the bottom of the melter.
- Foaming, for instance, by oxygen bubble formation due to some change in redox state.

Some of these problems would be alleviated by the redox control or by an elevation of the glass elaboration temperature (► Fig. 50), but limitations arise from the corrosion of the melting pot. Cold crucible vitrification will make it possible to overcome this.

■ Figure 50

Solubility limit of various elements versus temperature in borosilicate glasses manufactured under standardized conditions. The results reported for Americium and Curium stand for the highest content incorporated without reaching their limit of solubility

2.2.6 Glass Fabrication: The Hot Crucible Vitrification Process

Two techniques of hot crucible are used in the world:

The melter can be metallic (lifetime of the melter = 5,000 h) and heated inductively (France [La Hague], UK [Sellafield];  Fig. 51). It is fed with calcinated waste and glass frit.

The melter can also be made of ceramic (liquid-fed ceramic melter) (lifetime 6 years), the glass is heated by Joule effect. It is fed directly by the liquid solution; the steps of water evaporation and calcination take place at the surface of the molten glass (USA, Savannah, West Valley), Japan (Tokai Mura, Rokkasho Mura), Russia (Mayak).

With the hot crucible technique, the melt temperature is limited to 1,150°C approximately, due to corrosion of the metallic melter. In the case of high-level borosilicate nuclear glasses, made through a reaction between FPs calcinate and glass frit, the series of steps is the following:

- The glass frit (centimetric flakes, a few millimeters thick) is turned discontinuously from the elastic solid state to the viscous liquid state, beyond the glass transition region around 510°C.
- The viscous frit impregnates the calcinate fragments, which consist of FPs nitrate- and oxide-type complex compounds. The calcinate is a highly refractory product, as it is rich in rare-earth oxides, Zr and Al. Crystals such as rare-earth silicates and cerium oxides, as well as chromites (mixed oxides of Fe, Zn, and Cr) are formed as a result of localized supersaturations. This results in the formation of a heterogeneous product.
- The following step – helped by the stirring of the mixture – dilutes the crystallized aggregates, which are then dissolved. The final glass becomes homogeneous in chemical composition. In this final step, only insoluble particles of noble metals remain, the size of which is about 10–100 μm.

 Figure 51

An inductive metallic melter for the waste vitrification (hot crucible)

■ **Figure 52**
RuO₂ crystals in the glass matrix

Platinoïds do not incorporate readily in glasses. Depending on redox conditions, they form oxide crystals (e.g., RuO₂) in the glass matrix (► [Fig. 52](#)), or metallic particles, e.g., Rh, Pd-Te metallic particles. These particles can segregate to form undesired phases at the bottom of the crucible.

In order to control the redox potential of the glass during its elaboration, one adds iron and cerium in the glass frit (Pinet et al. [2005](#)).

2.2.7 The Vitrified Waste Package

The “R7T7” waste package (► [Fig. 48](#)) is given here as an example of vitrified waste package. The envelope is 5-mm thick stainless steel and contains 150 L of glass (diameter 40 cm, height 1.3 m).

Composition contains 12–18% (in weight) of fission products. Each package is made of two castings, 200 kg each.

13,000 CSDV glass canisters have been produced as of September 2007 in La Hague, confining a total radioactivity of 2.10^8 TBq beta gamma.

One glass package (400 kg) corresponds to the treatment of 1.3 t of spent fuel. It contains 95–99% of the radioactivity of the spent fuel.

Radioactivity of this glass package: 5,800 Ci ($2.1 \cdot 10^{14}$ Bq) alpha; 400,000 Ci ($1.5 \cdot 10^{16}$ Bq) beta gamma; dose 500 Gy/h (contact).

One ton of glass corresponds roughly to 1 TWhe of energy produced.

Power of a glass package due to the radioactivity (processing of UOX fuel) is 2.5 kW (after conditioning), 1 kW (10 years later), and 0.4 kW (50 years later). This power must be evacuated in the glass package storage facilities. The size of the package has been chosen such that, with a convective air cooling, $T < 500^\circ\text{C}$ at the center of the package (i.e., below the glass transition temperature).

2.2.8 Cold Crucible Vitrification

The vitrification processes currently in industrial operation in the world (ceramic furnace or metallic pot) display limitations as regards the following features:

- The lifetime (about 5,000 h) of metallic pots, which stand as a source of secondary waste
- The capacity of metallic pots (about 25 kg/h in the case of R7T7 glass), which requires several parallel treatment lines
- Dismantling difficulties for end-of-life metallic or ceramic furnaces, as they account for a big volume of technological waste
- A composition range limited to glasses with a glassmaking temperature of 1,150°C

A new melting technology has been developed in order to cope with all these limitations. It is based upon the use of a cooled metallic crucible coupled with direct induction heating in glass.

The cold crucible technique consists in inductively heating the glass itself (► Fig. 53). The crucible is protected by a solidified glass layer, and does not undergo corrosion. The temperature of elaboration of the glass can be increased, with subsequent benefits on all the items listed above.

Cold crucible technology makes it possible to reach high temperatures without corrosion of the crucible. This opens the possibility to vitrify many types of waste, for example, the solutions from the processing of high burnup fuel with a high fission product content. Vitrification of the solutions from the processing of the fuel from research reactors or graphite-gas reactors is also possible with this technology.

The absence of contact between molten glass and the crucible extends considerably the crucible lifetime.

The cold crucible technology already replaced the hot crucible in one of the six vitrification lines of the La Hague processing plant.

■ Figure 53

The cold crucible for high-temperature vitrification

2.2.9 Long-Term Behavior of Glass

Glass alteration by water, autoirradiation, and fracturation must be studied because these phenomena may cause the release and migration of radionuclides from the glass matrix (🔍 Fig. 54).

■ Figure 54

The sequence of alteration of a vitrified waste package. In the case of a deep geological disposal for vitrified waste packages, underground water will come into contact with glass sooner or later, after corroding the containers and overcontainers. Glass matrix alteration by water is the chief factor likely to lead to the radionuclide release into the natural environment

2.2.10 Long-Term Behavior of Glass in Contact with Water

When the underground water reaches the glass package after the loss of the tightness of the envelopes, a slow dissolution of the components of the glass then occurs (🔍 Fig. 54). Its rate depends on the glass composition and on its degree of fragmentation, which determines the reactive surface area between glass and water. Other parameters also come into play, e.g., temperature and ion content of the water. These parameters determine the dissolution-precipitation phenomena in the vicinity of the glass. The leaching of the glass can cause the release of its radioactive content.

2.2.11 Phenomenology of Glass Alteration by Water

When a silicated glass is exposed to water, after a quick period of alkali and water interdiffusion, one observes the dissolution of silica in water. The initial kinetics of this dissolution is quite rapid at high temperature (typically a few $\text{g} \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ at 100°C , pH 7, i.e., $1 \mu\text{m day}^{-1}$, and 1 nm day^{-1} at 20°C), but a significant slowdown occurs after some time if the water renewal is small.

One also observes the formation of an amorphous layer of hydrated silica (🔍 Fig. 55). Its thickness depends on the experimental conditions, and especially on the modalities of the water circulation around the glass sample.

One also often observes the precipitation of newly formed crystals (phyllosilicates) onto the outer surface of the hydrated layer.

■ Figure 55

Scanning electron microscope view of a borosilicated glass sample altered at 150°C for 4 months in pure water. One can distinguish from *top to bottom*: the unaltered glass, the hydrated layer, and the secondary phases, which precipitated from the solution

If the water flow is slow enough, the mass flow of dissolved silica is independent of the glass surface area, and is simply proportional to the water flow and to the solubility limit of amorphous silica (60 mg/L at pH 8 and 90°C). This dissolved silica comes probably from the dissolution of the hydrated layer itself.

The release rate of tracers contained in the glass (e.g., Li, B) is initially high, and decreases slowly with time (► Fig. 56). However, this tracer release never goes to zero for very long times, even in the absence of water renewal and in water already saturated with silica. The residual alteration rate becomes a constant, which can be as low as 10^4 times smaller than the initial alteration rate. This rate depends on the pH of the water and the glass composition.

Isotopic tracer experiments suggest that the hydrated layer forms at the internal interface (between the layer and the pristine glass) by transformation of oxide glass into a hydrated oxide layer.

In the alteration regimes of borosilicated glasses, one can distinguish (◄ Fig. 57):

The initial rate, limited by the hydrolysis of the silicated 1 μm lattice.

The rate drop, associated with the formation of a dense and passivating layer within the hydrated layer. This zone is built by ion exchange reactions, hydrolysis reactions, and in situ recondensation of a fraction of the hydrolyzed silica. At the same time, this layer gets dissolved on its external interface, as long as the solution does not become saturated. This layer acts as a diffusive barrier for water, and for the hydrolyzed species from glass.

The residual rate regime corresponds to a dynamic equilibrium between formation (at the internal interface) and dissolution (at the external interface) of the hydrated layer. When this dynamic equilibrium is reached, the hydrated layer thickness becomes constant, as well as the glass alteration rate. Water renewal and precipitation of secondary phases like phyllosilicates can withdraw silica from the solution. By acting as silica sinks, these two mechanisms are the motors by which the glass alteration goes on in this “residual” regime.

Figure 56
 Kinetics of glass alteration by water. Evolution of the thickness of R7 T7 altered glass at 90°C. In the conditions of the experiment (large glass surface area, small quantity of water, the residual regime (where the alteration rate is constant) is rapidly reached. Note the order of magnitude of the residual alteration rate: $0.03 \mu\text{m year}^{-1}$, or 3 cm in 1 million years at 90°C (After Gin et coll, 2003)

Phenomenology of glass alteration by water

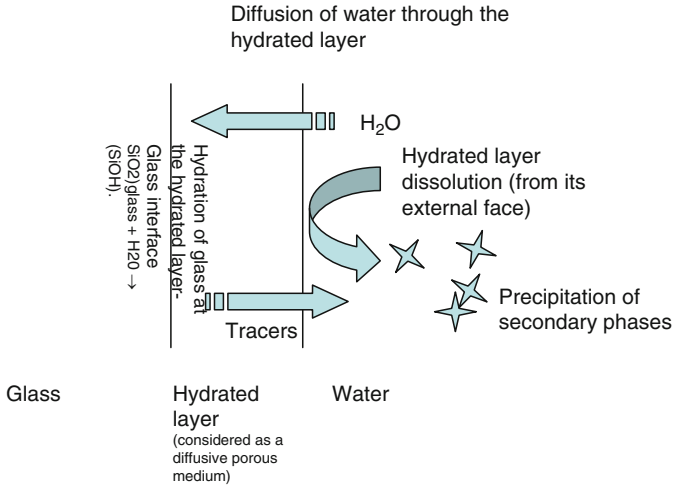

Figure 57
 Phenomenology of glass alteration by water

A possible alteration uptake can eventually occur in special cases, when the composition of the porewater surrounding the glass permits the precipitation of zeolitic secondary phases. Conditions for this to occur are met only in very basic waters, which are not likely met in geological media, except possibly in the vicinity of concrete artifacts (Vernaz 2002).

■ **Figure 58**
Mechanism of glass alteration by water

■ **Figure 59**
Simulation of the alteration of glass by Monte-Carlo method. Bond-breaking and bond-forming probabilities are treated as free parameters. Water appears in blue, Si in red, Zr in black, and B in black. The porosity of the hydrated layer evolves with time. In soft alteration conditions, this porosity tends to close, thus enhancing the protective properties of this layer (Cailleteau et al., 2008)

The four mechanisms at play during the alteration of glass by water are (↻ [Figs. 58](#) and ↻ [59](#)):

- The building of a hydrated layer by hydration of the pristine glass at the interface between this pristine glass and the hydrated layer
- The destruction of this hydrated layer by dissolution at its external interface
- The diffusive transport of water through the hydrated layer
- The precipitation of secondary phases in the water surrounding the glass

2.2.12 Glass Alteration by Water Depends Greatly on Temperature

The activation energy of the reaction of glass hydration is of the order of 73 J/mol. This means that the glass alteration rate increases by a factor 30 when the glass temperatures increase from 25°C (rest temperature of the geological medium) to 90°C (maximum temperature of the host rock at the peak of the waste thermal crisis). This increase is not a major concern for the disposal of vitrified waste because the thermal crisis is supposed to occur before the water comes into contact with the glass.

On the other hand, this temperature dependence is used to accelerate the glass alteration in laboratory experiments.

2.2.13 Toward a Model of Glass Alteration

We describe in the following a typical model of glass alteration. The GRAAL model incorporates the known phenomenology in a form as simple as possible (Frugier et al. 2008, 2009).

Please keep in mind that it is not the only possible model. This is a domain where research is open.

Hypotheses

The hydrated layer is soluble; it is the dissolution of this layer, which provides the silica present in the water. Hydrated layer dissolution goes on if water is renewed.

The hydration reaction, which transforms the glass (oxide) into a hydrated oxide, is initially rapid, but becomes limited by the transport of water through the hydrated layer.

The hydrated layer plays the role of a diffusive barrier for the water, which goes from the solution to the reactive glass interface.

The hypotheses listed above can be easily transcribed into equations:

- One equation for the dissolution of the hydrated layer (assuming, for example, a first-order kinetics)
- One equation for the glass hydration (assuming a first-order kinetics)
- One equation for the transport of water through the hydrated layer (assuming a diffusive transport and uniform water concentration gradient across the hydrated layer)
- One equation for the precipitation of secondary phases (assuming a zeroth- or first-order kinetics).

In the simple case of a glass sample placed in a recipient where the concentrations can be considered uniform everywhere in the solution, these equations close the system, which can then be readily solved.

In the more complicated case of a glass sample embedded in a porous environment (for instance, clay), the concentration in dissolved silica cannot be considered uniform in the porous medium, and one must add another equation for the transport of solute in the medium to close the system.

Such a model reproduces all phases of glass alteration, including the transient ones at the beginning of alteration, and the residual regime, where the hydrated layer reaches a dynamic

■ Figure 60

A typical laboratory experiment for the study of glass alteration

equilibrium between its building by glass hydration at the internal interface and its dissolution at the external interface.

Parameter values can be extracted from independent experiments. We give here a few orders of magnitude:

- $C_{\text{sat}} = \text{hydrated layer solubility} = 2 \text{ mol} \cdot \text{m}^{-3}$
- $D = \text{diffusion constant of water in the hydrated layer} = 5.10^{-21} \text{ m}^2 \cdot \text{s}^{-1}$
- $V_{\text{hydr}} = \text{kinetic constant of glass hydration} = 10^{-11} \text{ m} \cdot \text{s}^{-1}$
- $V_{\text{disso}} = \text{kinetic constant of hydrated layer dissolution} = 10^{-12} \text{ m} \cdot \text{s}^{-1}$
- $V_{\text{pr}} = \text{kinetic constant of secondary phase precipitation} = 10^{-15} \text{ m} \cdot \text{s}^{-1}$.

The laboratory experiments on glass alteration are usually performed by putting glass (often in a divided form to increase the glass surface area) in a recipient where water is controlled in temperature, and renewed with a determined flow rate (● Fig. 60). The concentration in glass constituents and tracers (Si, B) in the water are then measured at the exit of the recipient. The total amount of altered glass can then be deduced from these concentration measurements.

2.2.14 The Residual Alteration Regime of Glass

The residual alteration regime of glass is of special importance for the safety of a glass repository, because the glass will spend most of its time in this regime. The residual alteration regime is reached when the hydrated layer reaches its equilibrium thickness. From that moment onwards, the layer growth by glass hydration at the hydrated layer–glass interface compensates the hydrated layer dissolution at the hydrated layer–water interface. The residual alteration rate then equals the hydrated layer dissolution rate. This rate depends on the modalities of water renewal in the vicinity of the altering surface. The important parameter, which describes this water renewal is the ratio Q/S (water flow rate/glass surface area).

If the water renewal is very fast (case of a piece of glass in a stream of running water), the alteration rate V is limited by the kinetics of dissolution of the hydrated layer, and the residual rate is simply equal to the kinetic constant of this dissolution V_{disso} .

If the water renewal is very slow, the water in the glass vicinity has enough time to become saturated in dissolved silica, and the residual alteration rate depends on the rate of secondary phase precipitation kinetics V_{pr} .

It should be noted that precipitation of secondary phases removes silicium from the solution and is equivalent to an effective renewal of the water. The model thus predicts the existence of a residual alteration even in the case of perfectly static water.

This residual alteration rate of glass depends strongly (three orders of magnitude) on the glass environment: surrounding minerals and modalities of water renewal.

Altogether, the model reproduces reasonably well the laboratory experimental data on the residual alteration rate of glass, for various values of the rate of water renewal (🔗 Fig. 61).

Laboratory experiments are unable to demonstrate the confinement properties of a glass matrix on a million-year timescale. The longest laboratory experiment on glass alteration has lasted for 25 years only. But Nature did the experiment for us with *natural analogues*, both geological and archaeological (🔗 Fig. 62).

The study of *glass natural analogues* permits to:

- Validate the long-term model predictions, and confirm the orders of magnitude of the alteration rates
- Stress the importance of environmental parameters (glass in a clay environment does not alter at the same rate as a glass in seawater, because the clay environment limits the renewal of water around the glass, inhibits the transport of silica, and favors the precipitation of newly formed phases).

Figure 61
 The residual alteration rate as a function of the water renewal rate. Comparison between the experimental results and the GRAAL alteration model

■ Figure 62

A natural analogue of glass alteration: Iceland hyaloclastite (basalt, 90,000 years)

2.2.15 Long-Term Behavior of Glass: The Effect of Self-Irradiation

During its lifetime, the nuclear glass will undergo self-irradiation (► Table 9): Alpha disintegrations cause atomic displacement and ionization. It is mainly the recoil nuclei from these alpha disintegrations, which cause the atomic displacements.

Beta gamma irradiation causes only ionization.

During the lifetime of a high-activity glass in a repository, one atom out of three will have been displaced once, due to radioactive decays in the glass. One needs to know whether this self-irradiation modifies the glass structure and hampers the long-term durability of the glass matrix.

The typical kinetic energy of a recoil nucleus due to alpha decay is 70 keV. Its range in the glass is of the order of 30 nm. The maximum temperature of the heat wave is about 1,200 K, and the typical cooling time is 12 ps. The number of displaced atoms is about 2,000. Most broken bonds are restored within a few picoseconds (► Fig. 63). Glass is a self-repairing material.

For research purposes, one can accelerate irradiation damage in glass by doping the glass with actinides. For example, a glass doped with a few percent ^{244}Cm undergoes the same number of alpha disintegrations in a few years as an industrial glass during its whole life.

The question as to whether the glass alteration rate can be altered by self-irradiation has been investigated. No significant influence of the self-irradiation on the glass initial dissolution rate is observed for the fluences encountered in high-activity, long-life waste.

A slight modification of the glass density is observed, but a little swelling has stabilized at a level below 1% after a cumulative dose of $2 \cdot 10^{18}$ alpha disintegrations per gram.

The glass mechanical properties are also modified by irradiation: fracture toughness is increased and then stabilizes at the same cumulative dose.

Molecular dynamics enable one to understand why the glass properties get stabilized beyond a cumulated dose of $2 \cdot 10^{18}$ alpha disintegrations per gram: beyond this limit, the number of broken bonds no longer increases.

Table 9

Characteristics of the various radiation sources in nuclear glass

Radiation sources	Path in the glass	Energy deposited (Gy)		Number of atomic displacements prevent	Number of disintegrations per gram of glass over 10 ⁴ years	Number of atomic displacements per gram of glass over 10 ⁴ years
		over 10 ⁴ years	over 10 ⁴ years			
α Disintegration Helium ion (4–6 Mev)	~20 μ m	~3.10 ⁹	~10 ⁹	~200	~3.10 ¹⁸	~6.10 ²⁰
Recoil Nucleus (0,1 Mev)	~30 nm	~6.10 ⁷	~3.10 ⁸	~2.000		~6.10 ²¹
β Disintegration	1 mm	~3.10 ⁹	~4.10 ⁹	~1	7.10 ¹⁹	7.10 ¹⁹

2.3 Other Conditionings for Waste

2.3.1 Bituminization of Low- or Intermediate-Level Waste

Bituminization is used for embedding co-precipitation sludges arising from either effluent insolubilization treatments or evaporation concentrates issued from spent fuel chemical treatment.

Co-precipitation consists in adding reagents to effluents so as to form various strongly insoluble salts. Radionuclides are carried over in the solid phases according to different mechanisms, which ensure effluent decontamination up to the levels prescribed by release standards. Co-precipitation treatments may vary according to the treatment station considered. Co-precipitation sludges typically contain barium sulphate, nickel, and potassium ferrocyanide, as well as different hydroxides, for example, iron hydroxide. This sludge also contains variable contents in soluble salts, which mostly are sodium sulfate and sodium nitrate. This wet sludge may then be cemented (see above) or bituminized.

Although bituminization is to be replaced more and more by cementation, the amount of bitumen drums already produced in the world justifies that a section of this chapter should be devoted to this process.

The bituminization process, commonly used to condition the sludges resulting from the treatment of liquid effluents by chemical precipitation, is a well-known process, which benefits from a wide experience backup. As a conditioning matrix, its advantages and drawbacks are as follows:

Advantages:

- Bitumen is cheap and readily available.
- It is insoluble in water.
- It is chemically inert with respect to the environment.

Drawbacks:

- Large volumes are needed (e.g., 36,000 m³ were produced in France).
- Exothermic reactions during the mixing create risks of fire.
- Long-term behavior is poorly mastered (radiolysis, gas generation, swelling).

2.3.2 Bitumen Manufacturing

The embedding process consists in hot mixing of sludge waste to bitumen in an extruder (➤ Fig. 64). The resulting mixture is dehydrated and poured into a steel drum (about 222 L) where it can cool down. Hot extruding ensures sludge dehydration, waste homogeneous dispersion, and radionuclide immobilization within the bitumen matrix. The waste incorporation rate into bitumen is typically 40 wt%. From a chemical viewpoint, the embedded waste mostly consists of salts insoluble in water (barium sulfate, ferrocyanides, cobalt sulfide), and soluble salts (sodium nitrate, sodium sulfate). The use of soft bitumen from straight distillation of crude oils allows the embedding process to be implemented with moderate temperatures ranging between 130°C and 180°C in the extruder, thereby limiting fire risks.

The waste packages thus produced are of low or intermediate level and, for some of them, long-lived.

Once they have cooled down, packages are stored on the production sites and periodically monitored pending their transfer to the disposal site. An important concern in bituminization is related to thermal behavior control in the short term, that is, in the hours following the pouring so as to take fire risks into account. The studies carried out on the control over fire risk led to the determination of a safe operating domain. This simulation relies on the kinetic parameters of the

■ **Figure 64**
Schematic of the industrial-scale process of bituminization in an extruder

■ **Figure 65**
A drum of bituminized waste

exothermic reactions taking place inside the enrobed drum. These parameters are determined by micro-calorimetric measurements prior to embedding.

The typical bitumen drum issued from the conditioning of co-precipitation sludges or effluent concentrates has the following characteristics (● [Fig. 65](#)):

- *Volume* 0.23 m^3
- *Typical activity* 1.6 TBq (beta gamma), 0.03 TBq (alpha)
- *Ratio bitumen/dry precipitate* = 1.5
- *Dose rate at 1 m* = 0.1 Gy/h

Once the bituminized package has been manufactured, its good behavior has to be ensured in the long term. The two phenomena to be considered are the radiolysis caused by the package self-irradiation and the leaching induced by a possible package contact with water.

2.3.3 Bitumen Package Evolution Under Self-Irradiation

Bitumen is a continuum of organic compounds of molar masses between 400 and 4,000 g/mol, most of which are unsaturated and polycyclic. This organic composition endows bitumen with the property of emitting radiolytic gases, essentially hydrogen, under self-irradiation. These gases are issued from the cleavage of the existing C–H bonds.

According to the activity incorporated, about 1–10 L of radiolytic gases per year are generated by a drum on the production line. The gas source term falls to less than 1 L after 1,000 years owing to decay. The volume of accumulated gas over 1,000 years is about 1 m^3 per drum.

The gases generated in the whole volume of the embedded waste are first dissolved in the matrix up to saturation (about 1% in volume). Beyond this step, hydrogen forms gas bubbles,

the growth of which may lead to the swelling of the embedded waste. A swelling rate of about 1 cm/year could be observed in some packages.

In some cases (e.g., packages manufactured with no apical vacuum), swelling evolution can cause the embedded waste to overflow out of its container, or even induce the pressurization of the container if the overflow is halted (e.g., by a lid).

This swelling does not impair bitumen confinement properties with respect to radioactivity, but requires a suitable package management during the storage period and the reversibility period of the geological disposal phase.

The swelling of bitumen can be controlled by three main ways:

- Limiting the incorporated activity
- Limiting the drum filling
- Trapping the radiolytic hydrogen by means of salts added to the bitumen (cobalt sulfur)

2.3.4 Bitumen Alteration by Water

Although pure bitumen is not very permeable to water and dissolved species, the initial presence of salts favors water uptake through diffusion and osmosis. On contact with water within the embedded waste, the most soluble salts are dissolved locally. Formation of saline solution bags results in porosity developing, which facilitates the dissolved species diffusion back to the outer leachant. The kinetics that characterize water uptake and the release of the most soluble salts comply with square-root laws for time, specific of a diffusion mechanism. These kinetics are chiefly controlled, first, by the contents and solubilities of the various embedded saline species, and, secondly, by the leaching solution. It is noteworthy that water uptake is about 100 times faster than the release of the most soluble salts, due to the low values of effective diffusion coefficients, of the order of $10^{-15} \text{ m}^2 \text{ s}^{-1}$ for solubilized salts. This difference results in the swelling of the embedded waste, due to the porous area maturation and the leaching front progress. Regarding the latter, it proceeds at a rate of the order of $\text{mm} \cdot \text{yr}^{-1/2}$.

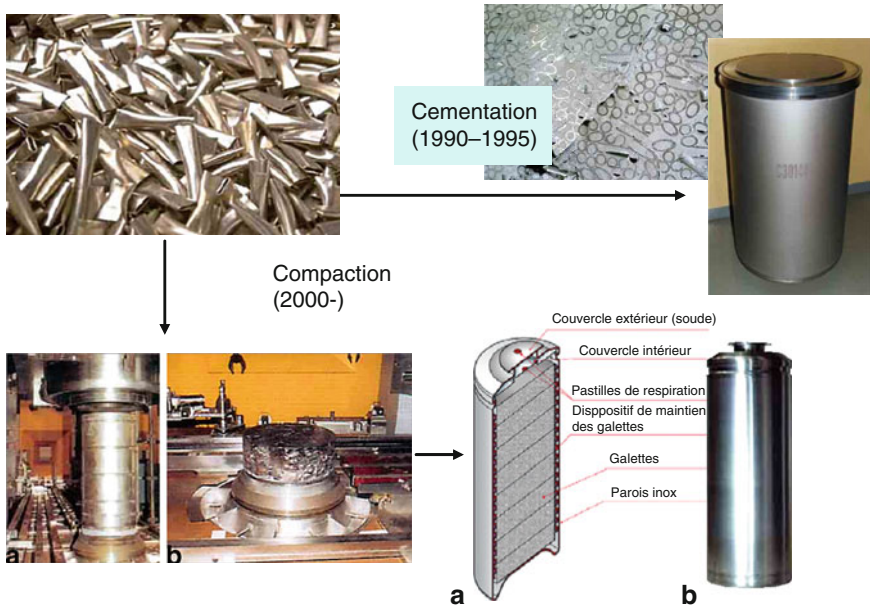

Globally, bitumen is a good confinement matrix: the rate of release of radionuclides, controlled by the diffusion, is slow and altogether compatible with the requirement of a disposal facility. The return of experiment acquired from industry shows that the risk of fire can be mastered if the chemical reactivity of the sludge is correctly analyzed and taken into account.

Similarly, the swelling of bitumen can be managed by limiting the activity in the package, by imposing a void space in the upper part of the drum, and by adding cobalt salts.

However, bituminization is increasingly replaced by cementation as a conditioning matrix.

2.3.5 Conditioning of Fuel Claddings and End Caps

After the dissolution of the spent Fuel in the processing facility, one obtains metallic residues: the undissolved end caps and grids of the fuel assembly (made of stainless steel), and pieces of the zircaloy fuel cladding. Despite a thorough rinsing, this waste contains activation products (distributed in the entire volume of the metal), 0.2% of the total inventory of fission products, and 0.03% of the actinides from the spent fuel (located close to the surface of the metal). It is thus classified as intermediate level activity, long-lived waste. In the 1990s, hulls and end caps were conditioned in concrete. The cement package weighs about 4 t, its activity is of the

■ Figure 66
Conditioning of fuel claddings and end caps

order of 50 TBq beta-gamma, and 0.1 TBq alpha. This gives a dose rate of 10 Gy/h at the package surface.

In the 2000s, this process of cementation of hulls has been replaced by a process of compaction, thereby enabling a volume reduction of a factor 5. The waste is introduced in a metallic case and compressed hydraulically up to a density of 65% of the metal density. The obtained “cakes” are piled up in a stainless steel container (► Fig. 66). The obtained package (CSD-C) has no confinement matrix. Each container contains five to ten compacted cakes. For standardization purposes, these containers have the same external geometry as the standard container of vitrified waste (CSD-V).

2.3.6 The Long-Term Behavior of the Compacted Metallic Waste Package

The CSDC package is essentially heterogeneous. Its confinement properties depend on the durability of the materials, which contain the radionuclides (metal, oxide, hydride). For 300 years, the package is expected to remain leak tight. Later on, the RN release occurs, at a rate, which depends on their location within the metal. Fission products and minor actinides (located close to the metal surface) are expected to be released soon after water reaches the waste. Activation products (distributed in the entire volume of the metal) will be released at the rate of the metal corrosion. Typical confinement durations are of the order of 10,000 years for zircaloy; 100,000 years for stainless steel, and 1,000 years for nickel-base alloys.

2.3.7 Melting: A Possible Future Conditioning for Metallic Waste

Research is being carried out on melting the metallic waste. The process would enable one to reduce further the waste volume, to decontaminate the ingot by transferring the alpha emitters, Cs and Sr in a slag, which would then be separated from the ingot and vitrified. The remaining radioactive nuclei would be distributed within the bulk of the ingot. The alloy composition and reduced surface of the ingot would make it able to withstand corrosion.

2.3.8 Specific Conditioning for Minor Actinides and Fission Products

Tailored Ceramics for the Confinement of Specific Radionuclides

Today, vitrification constitutes “the” reference solution for conditioning high-level waste from reprocessing. Yet, conditioning some radionuclides within a glass matrix may prove to be difficult owing to low solubility in the glassy lattice or to high volatility during high-temperature manufacturing.

Although they do not display the chemical flexibility of a glassy matrix (i.e., the capacity to integrate into the structure a number of elements), ceramics can be optimized for the radionuclide considered, thereby presenting the best confining properties.

Example of ceramics displaying good RN confinement properties: zirconolite, hollandite, apatite (➤ [Table 10](#)).

- Zirconolite could confine minor actinides
- Hollandite could confine cesium
- Apatites $M_{10}(PO_4)_6X_2$ could confine iodine

These ceramics are cited here only for the sake of completeness, because they will probably never be used for the confinement of radionuclides on the industrial scale. Their good resistance to lixiviation does not compensate for the drawbacks associated to their use: production of secondary waste, and complexity of a chemical separation of each radioelement.

■ **Table 10**

Main characteristics and fabrication processes for the ceramic matrices developed for the conditioning of long-lived radionuclides (From Clefs CEA n°53, 2006)

Radionuclide	Matrix	Radionuclide loading factor (wt%)	Fabrication process	Chemical durability (g/m ² .d)	Behavior under self-irradiation
Iodine (I)	Iodoapatite (composite matrix) $Pb_{10}(VO_4)_4O(PO_4)_12I_2$	7	 Sintering under load (580°C-25 MPa)	$V_f(I): 10^{-4}$ at 90°C (confined environment)	-
Cesium (Cs)	Hollandite $Ba_1Cs_{0.26}(Fe_{0.02}Al_{1.46})Ti_{5.72}O_{16}$	5	 Natural sintering (1,250°C)	$V_f(Cs): 10^{-5}$ at 90°C (confined environment)	Point defects with no effects on structure
Actinides (An)	Britholite $Ca_{10-x}An_x(PO_4)_5(SiO_4)F_2$	10	 Natural sintering (1,475°C)	$< 10^{-6}$ (confined environment)	Slight damage (external irradiation)
	Monazite-brabantite $La_{1-3x}An_xCa_xTh_xPO_4$	10	 Natural sintering (1,450°C)	Ongoing investigations	No amorphization (natural analogs)
	TPD $Th_{4-x}An_x(PO_4)_2P_2O_7$	10	 Natural sintering (1,250°C)	10^{-6} at 90°C -pH 7 (confined environment)	Ongoing investigations
	Zirconolite $(Ca_{1-x}An_x^{3+})Zr(Ti_{2-x}Al_x)O_7$	10	 Natural sintering (1,450°C)	$< 10^{-6}$ (confined environment) cessation of alteration	Amorphization of the structure with no loss of confinement

Synroc (a polycrystalline material based on titanates, and developed by ANSTO (Australia)) is also a possible challenger for the confinement of fission products, but its implementation is complex, and has never been made on an industrial scale.

2.4 Conditioning of Spent Fuel

2.4.1 Can Spent Fuel Be a Conditioning Matrix?

At the reactor output, the spent fuel can be considered in two radically different ways, depending on the strategy followed on fuel cycle:

Should the “closed cycle” be selected, the spent fuel will be in remission; it will have to undergo storage (by definition, temporary), awaiting its treatment.

Should the “open cycle” be chosen, the spent fuel will be considered as waste. It will then have to undergo not only storage, but also disposal (final, by definition, accompanied, however, by a reversibility option) in a geological repository.

Whatever the selected option, the spent fuel will have to undergo a storage period, ranging from 5 years (minimum time to allow the fuel to “cool down” before treatment processes) to 100 years. Even with the “closed cycle” option, the storage time can be as long as a century; for instance, for the spent MOX fuels, the preferred option is to store the assemblies and to wait for future fast neutron reactors, capable of efficiently recycling their plutonium.

This storage can be carried out under water or in dry conditions, but, in any case, the spent fuel sheath will have to play its part and prevent the dispersion of radionuclides produced during the time the fuel stayed in the reactor. Under dry storage conditions, this raises the question of *dry corrosion* and of the mechanical behavior of the spent fuel rod under the pressure generated by the gas produced by the radioactive disintegration of actinides within the fuel. Under dry storage, the spent fuel is locked within a container, which protects it, allows its handling, and plays the role of a confinement barrier. The degradation modes of this container must also be studied.

Under water storage, the temperature reached by the fuel is lower. Thermomechanical problems liable to affect the spent fuel are less critical. However, attention should be paid to radiolysis, as well as to *aqueous corrosion* problems.

With the “open cycle” option, the spent fuel, encased in its container, will have to ensure the retention of radionuclides during an even longer time period.

Hundred of thousands of years will be necessary to allow the radioactive decay to bring back the spent fuel radioactivity to the level of that of the initial uranium ore. It will be probably impossible to avoid direct contact of the fuel ceramic with underground water, as the metallic casings wrapping the latter will not be able to withstand corrosion over such long time periods. The problem to study in that case is that of the leaching of the ceramic. Contrary to glasses, which have an amorphous microstructure, the fuel ceramic is polycrystalline.

It is also fragmented, due to the temperature gradients within the reactor. When contact occurs with underground water, some of the radionuclides located at the interfaces and at the grain boundaries will be freed very rapidly. This “*instant release*” fraction is also subject to detailed studies, as it determines the “source term” of deep storage carried out on used fuels.

Definition of the fuel burnup

- $\text{FISSION YIELD } (Tf) = \text{fissioned atoms/fissionable atoms}$

fissionable = fissile + fertile (= "heavy atoms")

- $\text{BURNUP } (BU) = \text{extracted energy per ton of irradiated initial heavy metal}$
(M(G)Watt.day per ton)
- Standard UOX LWR spent fuel:
 - Tf ~ 3–6%
 - BU ~ 30–60 GWd/t
- 1 fission: ~200 Mev

$$BU \text{ (GWd/t)} = 9.6 \text{ Tf}(\%)$$

The burnup is defined as the energy extracted per ton of irradiated initial heavy metal in the nuclear fuel. It indicates how many nuclei have undergone fission within the fuel. It depends on the neutronic flux and on the staying time of the fuel element within the reactor.

If the spent fuel is to be considered as a waste, the burnup is an important indicator of the physicochemical state of the fuel element: in particular, it tells how much fission products will be found in it.

2.4.2 Spent Fuel Evolution After Unloading

An important characteristic of the spent fuel is its large residual power (several kW per assembly after 10 years storage) (► Figs. 67 and ► 68). This residual power is larger than for glass

■ Figure 67

Radioactivity of spent fuel versus time. Case of a package of 4 PWR assemblies, for a burnup of 45 GWd/t (ANDRA and Dossier 2005, argile)

■ Figure 68

Residual power of spent fuel versus time. Case of a package of 4 PWR assemblies, for a burnup of 45 GWd/t) (ANDRA, Dossier 2005, argile)

packages coming from the processing of the same amount of fuel, because plutonium is present in the spent fuel whereas it has been removed from the glass.

2.4.3 Packaging Spent Fuel

The packaging of spent fuel has to be seen in the context of the whole disposal system and has different functions, which are determined by the time for interim storage, considerations of transport and emplacement, and the duration of containment.

A package is necessary for storing assemblies of spent fuel, because the irradiated fuel pellet is not a containment matrix: it degrades over the very long term through auto-irradiation. Moreover, the integrity of the cladding cannot be easily demonstrated.

Two confinement barriers are recommended: a case and a container (🔗 Figs. 69 and 🔗 70). It must ensure functions of confinement, taking into account the mechanical and thermal constraints, and avoiding any risk of criticality. It must permit both spent fuel transportation (optionally), long-term interim storage, and spent fuel retrieval.

Canisters are usually made from stainless steel and contain an array of storage sleeves to hold the bundles of spent fuel. Canisters are filled with an inert gas such as helium and sealed by welding.

In Europe, a typical cask design for dry storage of spent fuel is the German CASTOR concept. CASTOR casks provide an overpack for the medium-term storage and transport of heat-generating waste.

Figure 69
An example of packaging of spent fuel

Figure 70
An example of spent fuel packaging: the SKB Swedish concept, with a thick-walled copper canister (photo SKB) (Papp 1998a)

■ Figure 71

Examples of packages for spent fuel, intended both for transportation and for dry storage

Another type of spent fuel dry storage package is BNFL's TranStor system, which is extensively used in the United States (*ref. IAEA, 2000. Multi-purpose Container Technologies for Spent Fuel Management. IAEA, Vienna. Report no. IAEA-TECDOC-1192*).

In this design, the casks are made of concrete with a thick internal steel liner for enhanced shielding and strength. The cask is designed to provide radiological shielding and to create a natural air circulation path for cooling of the canister. TranStor casks can be stored in the open air on a reinforced concrete pad without building cover. Such open-air storage is implemented at several sites in the United States (📍 *Fig. 71*).

2.4.4 Choice of the Container Material

Availability, cost, and industrial feasibility factors have led to a limited choice of **candidate materials for containers**. These materials can be classified into two main categories:

- Consumable materials, like low-alloyed steels. Given the order of magnitude of their corrosion rate in a reducing environment (a few $\mu\text{m}\cdot\text{year}^{-1}$), these materials must be used in thick foils to last a long time. These materials are cheap. They also have the advantage of undergoing generalised corrosion, easier to foresee and control than localised corrosion. Conversely, the drawback is the production of hydrogen by the corrosion reaction.
- Non-consumable materials, either thermodynamically or kinetically stable. These expensive materials (copper, stainless steels, nickel or titanium alloys) are much more durable, but are potentially sensitive to localised corrosion.

2.4.5 Corrosion Rates of Low-Alloyed Steels

Dry corrosion of low-alloyed steels is much slower than aqueous corrosion (🔗 Fig. 72). The storage facility must therefore be designed so as to avoid aqueous corrosion. Another reason to avoid water in interim storage is that corrosion rates could be affected by water radiolysis. Irradiation of water molecules close to the radioactive waste surface creates free radicals that are very reactive.

Archaeological analogues can help understand the corrosion of metals on a long timescale. The corrosion rates of low-alloyed steel evaluated on analogues spans over three orders of magnitude, depending on the material and surrounding environment. The average value is on the order of $1 \mu\text{m}/\text{year}$ (B. Kursten et al. Eurocorr, Nice, Sept. 2004.)

Note that the picture of a constant corrosion rate may be oversimplified. The corrosion of metals in an underground environment does not proceed generally at a constant rate. Indeed, an equilibrium between the metal and the environment establishes itself. Progression of the corrosion then slows down and can even stop completely if the environment is stable.

Recent results indicate that the aqueous corrosion rate of low-alloyed steels is enhanced in presence of argillaceous minerals. The influence of clay minerals on the pH and eH of the water is one possible explanation. Sorption of iron ions onto clay minerals or precipitation of iron-containing minerals on the clay mineral surfaces can also remove iron from the solution, and explain the acceleration of corrosion in presence of dispersed clay minerals. This acceleration effect can be counterbalanced by the fact that clay layers act as barriers for the transport of water and chemical species, and can thus limit the availability of reagents in the vicinity of the metallic surface. All these effects combine in a complicated manner. Research is going on to understand the influence of the clay environment on the corrosion resistance of steel overpacks.

■ Figure 72
Orders of magnitude for the corrosion rate of unalloyed steel

This problem of the influence of the surrounding mineral environment on the alteration rate is quite general: it is also encountered in the case of glass alteration.

2.4.6 Post-Irradiation State of the Spent Fuel

Irradiated Clad State

During in-reactor irradiation, the microstructure of clad and structure materials is altered on account of both irradiation (alteration of the dislocation structure) and corrosion (oxidation and hydride formation). In-reactor irradiation thus results in a strong hardening of materials.

The thickness of the oxidized layer depends upon the axial temperature profile during irradiation and the type of alloy used. Internal oxidation remains superficial, affecting only the first 10 μm . Outer oxidation of clads is deeper: its depth reaches a maximum level in the hotter area, and generally remains lower than 100 μm in the clad alloy Zircaloy-4 (it is reduced to 25 μm after six irradiation cycles with more advanced zirconium alloys).

On the other hand, clad oxidation by water releases hydrogen, part of which is absorbed into the metal. This hydrogen forms hydride plates, which make the clad more fragile.

Besides, following the fission gas release in the free volumes of the rod, the pellet swelling and the clad creep under the coolant external pressure during in-reactor irradiation; the rod internal pressure after irradiation is higher than the filling pressure. For UOX fuel rods clad with Zircaloy-4, it is 40 bars on the average (after cooling) for an initial helium pressure of 26 bars and a burnup of 60 GWd/t. In the same conditions, it is slightly higher for a MOX fuel (50 bars).

It is this very clad, with enhanced fragility and high stresses following in-reactor irradiation, which will have to contain radioactivity in spent fuel under storage conditions. This implies that the weaknesses mentioned above will have to be taken into account in the design of containers and storage facilities.

Post-Irradiation Physical State of Spent Fuel Pellet

The developing of a high radial temperature gradient in the pellet during its in-reactor irradiation induces considerable mechanical constraints, which lead to the pellet cracking. Whatever the burnup reached, the spent fuel pellet after in-reactor irradiation may be seen as cut into 15 fragments or so on the average (► [Figs. 73](#) and ► [74](#)).

The macroscopic swelling observed during the irradiation results from fission products formation, irradiation defects, and emerging fission gas bubbles in UO_2 grains.

In-reactor irradiation strongly alters the microstructure of the fuel pellet, especially in the two following zones:

- The grain boundaries in which metallic precipitates as well as fission gas bubbles accumulate (► [Fig. 75](#)). Even if the grain boundaries withstand high constraint levels, they are made more fragile by in-reactor irradiation. For the burnups and irradiation temperatures considered herein, post-irradiation fractographies of spent fuel pellets evidence chiefly intergranular ruptures, save in the central zone of the pellet, whereas they are of the transgranular type in the unirradiated fuel.

Figure 73
Radial macrograph of a spent fuel pellet

Figure 74
Schematic representation of the nature and location of the main radionuclides in a UO₂ fuel with a low burnup (no rim formation) (From IAEA 1991)

- The restructured zones in the peripheral part of the pellet (rim), in UOX fuels where burnup is higher than 40 GWd/t and in big Pu-rich aggregates (of size >10 μm) located in the outer zone of the MOX fuel pellet. These restructured zones are characterized by a porosity of micrometric size of about 10% (closed after in-pile irradiation) and small-sized grains (0.1–0.2 μm) (► Fig. 76).

■ Figure 75

■ Figure 76

Microphotographs of restructured zones on the pellet circumference in an UOX fuel (*left*) and in a MOX fuel plutonium agglomerate (*right*)

2.4.7 Fuel Evolution in a Closed System

Radionuclide radioactive decay is the origin of the physicochemical phenomena, which characterize the long-term intrinsic evolution of spent fuel.

Helium generation through *alpha* decay of actinides raises an important issue for the long-term behavior of spent fuel. ▶ [Figure 77](#) shows the residual alpha activity on a timescale of 10,000 years for an irradiated uranium dioxide fuel with a burnup of 47.5 GWd/t. Helium concentration will reach 0.7 at.% per heavy metal atom over 10,000 years. For a MOX fuel with the same discharge burnup, it would reach 4%. If helium is released to the free volumes of the fuel rod, this would entail a significant increase of internal pressure in the rod, and, consequently, of the clad tangential constraint.

Reversely, if helium is retained in the fuel pellet, it will precipitate as nanometric-sized bubbles, or pile up at the grain boundaries (trapping in preexisting fission gas bubbles) in the event of reduced mobility in the crystalline network. The helium atoms have been shown to be much more mobile in the grain boundaries than in the crystal itself (Martin et al. 2006; Roudil et al. 2004).

The production of helium in spent fuel can cause potential damage in the ceramic *via* bubble formation, formation of fissures, and decohesion of the grains. This grain decohesion itself is a matter of concern because some radionuclides localized on the surface of grains can be released

■ **Figure 77**
Evolution of the alpha activity of an irradiated UOX fuel versus time

during this process. However, the helium amount formed within 10,000 years in UOX fuels is not sufficient to alter the initial microstructure of the spent fuel pellet (Bonin 2009).

Under incidental conditions in a dry storage facility, the irradiated fuel runs the risk of being in contact with air or an oxidizing gaseous atmosphere. UO_2 conversion into U_3O_8 , a pulverulent oxide with a density much lower than that of UO_2 , constitutes a major risk of fuel rod degradation under storage conditions.

2.4.8 Spent Fuel in a Water-Saturated Repository

Part of the activity is released instantly, as soon as water comes in contact with the ceramic.

The Instant Released Fraction (IRF) depends on the degree of decohesion of the matrix (decohesion induced by irradiation in the reactor, and by self-irradiation and He production thereafter). This Instant Released Fraction can be as high as 10% of the RN inventory (► [Table 11](#)). It usually dominates the radiological impact of a spent fuel disposal facility (SPA Benchmark).

After the instant release, the UO_2 matrix undergoes leaching. The rate of lixiviation (and the rate of RN release) depends on the redox potential of the surrounding environment: the release is fast in oxidizing conditions, and slow in reducing conditions.

Although uranium oxide solubility is very small (typically 10^9 mol/L) under the reducing conditions usually encountered in a repository site, this solubility can increase significantly because of the water radiolysis induced by the long-lasting alpha irradiation field. Radiolysis can create oxidizing radicals close to the UO_2 -water interface. The kinetics of leaching then depends on the alpha dose rate, and on the modalities of transport of the species around the fuel.

■ Table 11

Instant release fraction estimates (% of total inventory) for various radionuclides for PWR UOX fuel, best estimates values, with pessimistic estimate values in brackets (Research program on the long-term evolution of the spent fuel [PRECCI] project 2008; Johnson et al. 2005; Ferry 2008)

BURNUP (GWd/tU)	41	48	60	75
RN	IRF	IRF	IRF	IRF
fission gas	1(2)	2(4)	4(8)	8(16)
¹⁴ C	10	10	10	10
³⁶ Cl	5	10	16	26
⁹⁰ Sr	1(2)	1(3)	1(5)	1(9)
⁹⁹ Tc, ¹⁰⁷ Pd	0.1(1)	0.1(3)	0.1(5)	0.1(9)
¹²⁹ I	1(3)	2(4)	4(8)	8(16)
¹³⁵ Cs, ¹³⁷ Cs	1(2)	2(4)	4(8)	8(16)

2.4.9 Conclusion on the Storage and Direct Disposal of Spent Fuel

The above section demonstrates that the spent fuel *is not* a confinement matrix.

At the reactor output, the fuel rod is indeed still tight, but its state does not permit one to guarantee a long-term confinement of the radionuclides.

The ceramic matrix has been damaged through irradiation and thermal stress; the rod is under pressure due to an accumulation of gaseous fission products and helium inside it; the cladding has been weakened through irradiation; it has been corroded inside by fission gas, and outside by the pressurized water from the reactor.

In spite of this, the studies on the corrosion kinetics under storing conditions indicate that the spent fuel will be able to confine the radionuclides *under storing conditions*, that is to say, protected from external aggressions, and during a limited time period.

Storage under dry conditions is more favorable than storage under water for a long-term preservation of the spent fuel, as the corrosion phenomena, which endanger the integrity of the cladding are slower, provided, however, that the latter storage be well conceived and maintains the fuel under acceptable temperature and hygrometric conditions.

However, *under disposal conditions*, the corrosion of metal envelopes and of the cladding will make its way in the long term, with the risk of putting the ceramic in contact with underground water. This situation is absolutely to be avoided, as the instant release fraction (a few percent) of the radioactive inventory would be released, with consequences that would not be acceptable for the safety of the disposal.

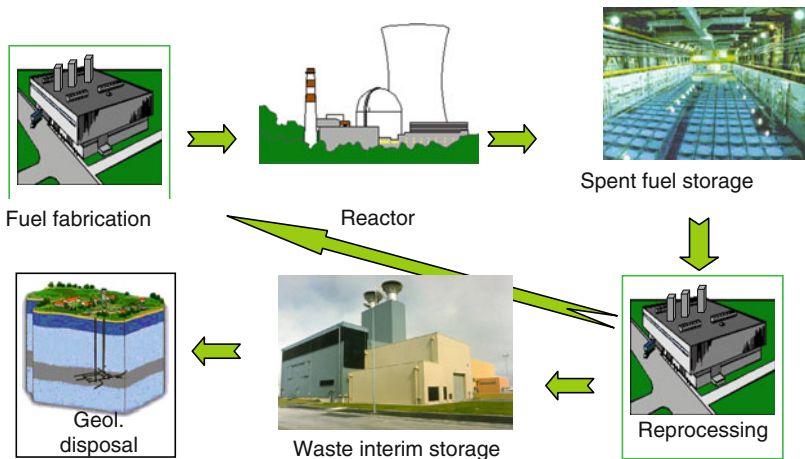

The countries that have chosen the final disposal of spent fuel (Sweden, Finland, the USA) are facing this problem. In order to solve it, all of them make the disposal safety rely on sophisticated engineered barriers, which will ensure long-term confinement of radionuclides.

3 Waste Storage and Disposal

3.1 Interim Storage of Long-Lived Waste and Spent Fuel

Today, long-lived waste is mostly stored in industrial facilities, exploited by utilities, with the prospect of retrieving it later and giving it a more definitive destination.

In any industrial process, storage plays the role of a buffer between two steps of the process (► Fig. 78). In the case of nuclear waste, storage provides some flexibility in the management of spent fuel, between its production and processing, giving some time for the spent fuel or the waste to cool down by radioactive decay, and allowing the possibility to wait for the availability of the geological disposal of the final waste.

► Figure 78

The position of waste or spent fuel storage in the back-end of the fuel cycle

In countries that reprocess spent fuel, it is stored before reprocessing; vitrified waste is also stored before its geological disposal.

3.1.1 Storage: A Temporary Solution for Waste Management

A storage period of a few years is necessary before the reprocessing of spent fuel, in order to let the short-lived radionuclides decay and make the spent fuel less irradiating. Another period of storage is also needed after the processing, in order to reduce the thermal power of the vitrified waste.

3.1.2 An Important Stake of Interim Storage: Reduce the Cost of the Disposal

The dimension (and cost) of a geological disposal facility of high-activity waste is roughly proportional to the thermal power produced by the waste. Indeed, the thermal conductivity of the host rock is generally so poor that the heat generated by the waste is not easily evacuated. In order to avoid an excessive heating of the waste and of the surrounding host rock, the waste packages must be spaced in the disposal in such a way that the average power is less than a few tens of watts/m^2 (see [Sect. 3.2](#)). The surface area needed for the geological disposal of high-activity waste decreases considerably with cooling time (typically a factor 2 for a 40-year cooling time). This could be an incentive for the facilities to postpone the disposal of the waste.

3.1.3 The Objects To Be Stored

Before its storage, waste is conditioned in the form of packages designed to confine the radioactivity, and facilitate its handling. These packages are, for example, 400 kg glass canisters for the high-activity waste from the reprocessing of spent fuel ([Fig. 79](#)) or the spent fuel bundles

■ Figure 79

themselves, gathered by groups in sheaths (🔍 Fig. 80). These packages are the objects that are to be stored.

In the case of intermediate-level waste, the form in which the waste can be conditioned is more diverse (🔍 Fig. 81), but the outer envelope of the package is generally made of concrete, and an effort is made to standardize the packages in order to facilitate the waste management (🔍 Fig. 82).

3.1.4 The Storage Facilities for Long-Lived Waste

The storage of spent fuel or of vitrified waste is already a mature industrial process. The storage facility is generally a surface installation consisting of a building or massive structures securing the protection of the packages. The conception of the storage facility makes possible the retrieval of the package, and warrants the safe confinement of the radioactive materials. There are two main types of storage facilities: pools (🔍 Figs. 83 and 🔍 84) and dry storage facilities (🔍 Figs. 85–87). Both types require some monitoring and maintenance to perform their function in accordance with the objectives generally ascribed to these installations by the Safety Authorities.

While the wet storage is used only for spent fuel (which is waste only if no reprocessing is envisaged), dry storage is used for both spent fuel and glass.

In pool storage facilities, the water of the pool cools the spent fuel and shields the operators from the radiation. The presence of water must be permanent; its chemical composition must be monitored and adjusted, if necessary, to avoid corrosion phenomena and subsequent radioactive leaks from the fuel.

■ Figure 83

Pool for the interim storage of spent fuel at the La Hague reprocessing plant (France) Dimensions: L: 50 m; l: 16 m, P: 9 (about 7,200 m³ water) Storage capacity: 730 baskets, each bearing 9 PWR assemblies or 16 BWR assemblies (~4,000 t, ~ 200 reactor.years)

■ Figure 84

An example of pool storage of spent fuel at CLAB (Sweden) 1. Receipt building; 2. Auxiliary systems building; 3. Offices; 4. Electric installation building; 5. Lift for the fuel; 6. Storage cave

Dry storage is generally preferred when long duration storage is envisaged (several decades).

In *dry storage* facilities, the radiation from spent fuel must be shielded, and the residual power produced by the waste must be evacuated to avoid an excessive heating of the waste. This is accomplished by organizing the circulation of air around the waste. Dry storage facilities come into three main categories: vault storage, cask storage, and silo storage.

Vault storage consists of a concrete structure containing storage wells or pits. The spent fuel can be bare or containerized. The fuel is stored in tubes and heat is removed by convection of air across the external surface of the well (🕒 Fig. 85).

In some vault systems, fuel is removed from the transport cask and moved without any container to its storage tube. In others, the fuel stays in the container in which it arrives, which is then placed in a transfer cask and moved by crane to its storage cylinder.

The radiological impact of spent fuel is minimized by shielding from the concrete structure. Criticality control is ensured by the geometry of the vault well array.

Examples are:

- Wylfa (UK) facility, for the storage of spent Magnox fuel.
- CASCAD facility (France) for the storage of research reactors and naval propulsion reactor spent fuels, and UNGG fuels from early French gas-cooled reactors. The fuel is stored in helium-filled canisters in vertical wells.
- Paks MVDS (Hungary) facility, for the storage of VVER 440 uranium dioxide fuel. The fuel assemblies are stored bare in carbon steel storage tubes filled with nitrogen.
- Idaho spent fuel facility, for the storage of Peach Bottom (graphite clad), TRIGA (Al and steel clad) and Shippingport (Zircaloy clad) fuels. The fuel is packaged into welded canisters at the facility, filled with inert gas and placed in sealed storage tubes.
- Chalk River (Canada) facility, for the storage of legacy Al clad uranium metal fuels.

■ Figure 85

Typical design of a vault for the interim storage of spent fuel

Cask storage consists of a moveable concrete or metal structure, which provides containment and shielding (Fig. 86). The casks do not require any building and can be stored in the open air. Heat is removed from the spent fuel by convection or conduction. Casks can be designed and licensed for both storage and transportation.

Examples are:

- The German CASTOR concept is a dual-purpose device (transport and storage) for PWR or BWR spent fuel. It consists of borated stainless steel baskets placed underwater into a cast iron cask, then drained and vacuum dried. CASTOR casks are stored in Gorleben,

Figure 86

Typical design of a cask for the storage of spent fuel (After NRC, <http://www.nrc.gov/waste/spent-fuel-storage.html>)

Ahaus (Germany) and Dukovany (Czech Republic). The Belgian Transnuclear concept is very similar, and is implemented in Doel (Belgium).

- MACSTOR concrete casks (Canada), for the storage of CANDU spent fuel. The fuel is cooled for 6 years, and then transferred to galvanized carbon steel canisters. Each MACSTOR module holds 20 CANDU canisters (alternatively two LWR canisters). Casks are stored in the open air.

Silo storage consists of monolithic or modular immovable structure, providing containment and shielding for canisters loaded into reinforced concrete modular storage modules.

An example is the NUHOMS Silo Storage designed for PWR and BWR spent fuel (► *Figs. 87* and ► *88*). The NUHOMS silo system incorporates neutron-absorbing panels for criticality control.

The facilities for the interim storage of vitrified waste are very similar to the vault concept for spent fuel. They feature the same precautions for the residual heat removal by convective air cooling.

Examples of interim stores for vitrified HLW include the French EEV-SE facility (► *Fig. 89*), BNFL's Vitrified Product Store, Japanese Nuclear Fuel's vitrified waste storage building, and COVRA's HABOG store in the Netherlands which opened in 2003.

The intermediate-level waste storage facilities do not request precautions to cool the waste, which can be put in nonventilated wells or cells (► *Fig. 90*).

All these storage facilities (wet or dry) work presently without any special difficulty, and their foreseen lifetime is of the order of several decades.

The thick concrete floor shields the operators from the radiation. Ventilation chimneys can be seen on the *left* photograph

■ Figure 90

An example of long-lived, intermediate-level waste storage: the compacted hulls storage facility ECC, at the La Hague plant (France)

Studies for longer-term storage have shown that the factors liable to limit the lifetime of these installations are the durability of structures made of concrete, and the corrosion of metals. However, the main weakness of the concept of long-term waste storage does not lie in technical issues. There remains the risk that the society may fail to maintain or may even forget the existence of these installations, which require continuous surveillance and maintenance. Another risk lies in the fact that long-term waste storage installations preserve the possibility of accessing the waste at any time, and are therefore vulnerable to malevolent or accidental human intrusions.

3.1.5 Duration of the Interim Storage

A nuclear waste interim storage facility looks very much like other facilities intended for the storage of other materials or goods, and the timescales that come into play are comparable. In normal exploitation, a nuclear waste storage facility has no radiological impact on the environment, since it is designed to confine totally the radioactivity it contains. The present return of experiment on these installations confirms these forecasts. However, even though nuclear waste storage facilities have never given rise to severe accidents, at least in the Western world, this does not mean that the risk is zero. These facilities are designed to make possible the retrieval of the waste, and are thus easily accessible. Their situation on the surface or subsurface implies some sort of surveillance in order to avoid unwanted human intrusions. As a result, the scenarios where everything does not go as scheduled can lead to a radiological impact on man and the environment. So far, these altered scenarios have been studied case by case, and are specific to each installation. They are characterized both by a low probability of occurrence, and by rather

severe consequences. The severity of the consequences is due to the fact that there is no geological barrier to slow down and dilute escaping radionuclides. That is why it remains advisable to limit the duration of the interim storage as much as reasonably possible. Who can guarantee that social structures will remain stable enough to ensure the safety of a storage facility over secular timescales?

On the other hand, a long-duration interim storage (longer than a century) would offer an appreciable flexibility in the nuclear waste management, giving time to make good decisions, to wait for the development of fourth-generation nuclear systems, and to take full benefit of the radioactive decay.

Ethics, economy, and technique will necessarily be involved in the decision on the duration of the interim storage of nuclear waste. The choice will be a compromise!

3.2 Geological Disposal

Deep geological disposal is at the end of the sequence of the waste management process (see  Fig. 30). This solution could be the ultimate one, for waste which has been adequately separated, conditioned, and cooled down.

3.2.1 The General Principles of Deep Geological Disposal

The main idea of a deep geological repository is the *definitive* disposal of the waste. The main argument is “do not leave the burden of our waste to future generations.”

A *reversible* disposal facility gives the possibility to retrieve the waste. Reversibility bridges the gap between the interim storage and the geological disposal concepts.

All degrees of reversibility are possible. A deep geological storage that could be gradually converted into a repository leaves time for debate, and for complementary solutions to emerge. And if one finally decides to leave the waste underground, there is not much to do to implement the decision! The reversibility option has many advantages. However, it raises some questions, such as: What is the additional cost for reversibility? Does it hamper safety by adding constraints to the conception of the disposal facility? Does this option increase the danger of proliferation, by making radioactive and fissile material accessible?

A particular challenge is posed by deep geological disposal; given the timescales of a repository, no direct demonstration of its safety is possible. One can only try to convince (oneself and others) by means of modeling, and (partial) validations.

3.2.2 The Technical Principles of Deep Geological Disposal

- Isolate the radioactive waste from man, by means of multiple barriers protecting the waste package (protect the waste from geological and human accidents, secure an environment favorable to the canister durability), and delaying radionuclide migration long enough for radioactive decay to take place.
- Secure a significant dilution at the exutories for the residual amount of radionuclides, which have managed to travel to the biosphere in spite of the abovementioned precautions.

3.2.3 The Multibarrier Concept

In order to isolate waste from man, the repository concept interposes several barriers between the two:

1. The matrix (glass, concrete, etc.). Its solid form and highly insoluble character prevents the release of radionuclides.
2. The engineered barrier (overpack, clay layer) protects the matrix, and delays the release of radionuclides.
3. The geological barrier (host rock) delays the release, and dilutes the radionuclides.

Although the multibarrier concept can be found in all designs of radioactive waste repositories (► *Figs. 91* and ► *92*), details can differ from site to site, depending on the nature of the waste to be disposed of, and on the nature of the host rock. For example, in the case of spent fuel disposed of in a granitic host rock, the backfilling with clay material is an important part of the concept. In the case of vitrified waste in a clay host rock, the engineered barrier does not necessarily feature any backfilling.

3.2.4 Repository Lifetime

The diagram of the total activity of spent fuel (actinides + fission products) shows that the initial activity is dominated by fission products during the first 200 years. Later on, the actinides activity dominates (► *Fig. 5* in ► *Sect. 1*).

Figure 91

Illustration of the technical principles of deep geological waste disposal, with the main phenomena at play

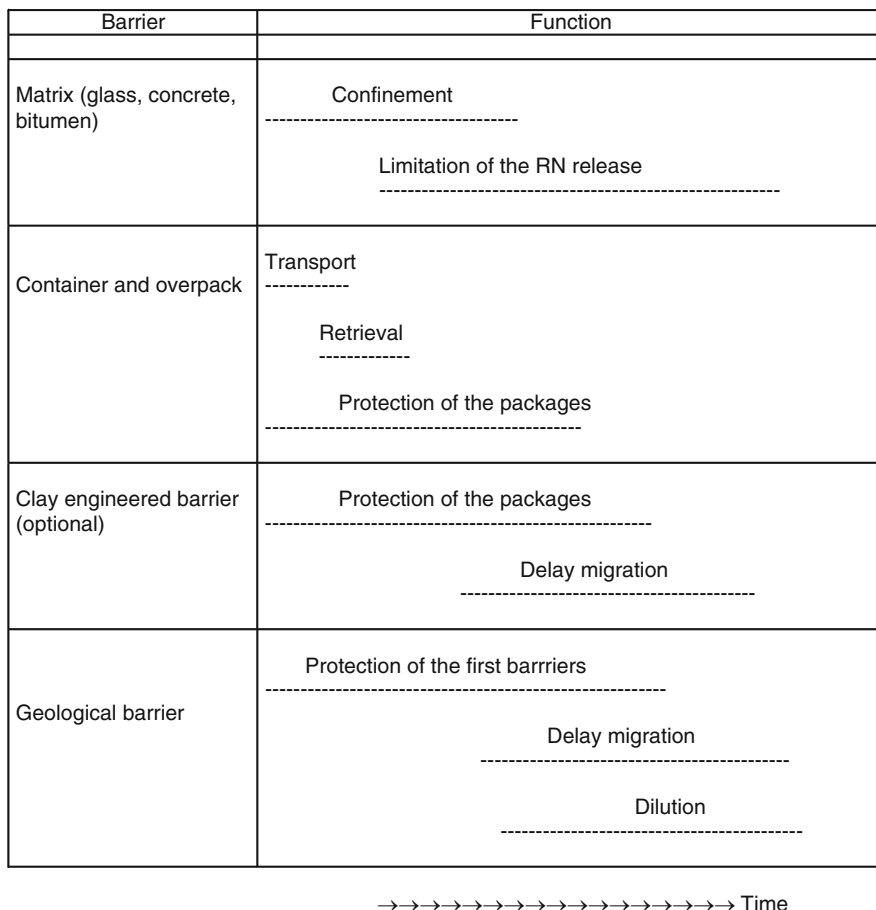

Figure 92
Functional analysis of the barriers in a deep geological disposal facility. All the barriers in a repository contribute to the safety, but they do not have the same role, and they come into play at different times

The diagram of the waste radiotoxicity as a function of time (► *Figs. 32* and ► *93*) gives the order of magnitude of the time during which the repository must be able to confine its radioactive content: 10,000 years for vitrified waste from reprocessing, and more than 100,000 years for spent fuel.

3.2.5 Repository Architecture

Details of the architecture are not completely defined yet, since no repository of high level, long-lived (HL LL) waste is in operation. They depend on the geological medium, but all the envisaged concepts share similar features.

Figure 93

The radiotoxicity of waste as a function of time. This picture gives the characteristic time needed for waste confinement in the various fuel cycle options. It is the time taken by the waste radiotoxicity to decrease the level of the initial uranium in mined ore. The spent fuel radiotoxicity is dominated by Pu and more generally by actinides. The needed confinement time in the repository is reduced by Pu recycling, and would be reduced further by minor actinides recycling. The cost and size of the repository would also be considerably reduced

The depth of the repository will be typically a few hundred meters, a compromise between safety (which depends on the thickness of the geological barrier), cost, and technical feasibility.

Dimensions of a High-Level Repository

There is one major difference between storage and disposal facilities of high-activity waste. In a storage facility, the heat generated by the waste can be removed by air convection. In a disposal facility, the heat must be removed by conduction through the host rock. This heat removal mechanism is much less efficient than convection, and that is why the power density in a repository has to be so small, in order to avoid excessive heating of the packages and of the surrounding host rock.

The dimensions of the repository are imposed by the thermal load of the radioactive inventory.

At its closure, a typical repository containing the HL LL waste generated by 50 years of exploitation of a 60 GW LWR fleet will produce a power P_0 of the order of 10 MW.

In order to minimize the heating of both the packages and the host rock, the heat-generating waste must be spread out as much as possible within the host rock. This constraint imposes a planar geometry for the repository, which can thus be assimilated to a heating plane of surface area A , embedded in a host rock with thermal conductivity λ and specific heat $\rho \cdot C_p$.

The temperature of the heating plane increases at the beginning of the repository life because of the heat generation, and decreases later on because of the decrease of the power generated by the decaying waste. Assuming that the power generated by the waste decreases with time, like $\exp(-\beta t)$, with $\beta = 0.024 \text{ year}^{-1}$, the maximum temperature reached by the heating plane is then:

$$T_{\max} \approx \frac{0.315 P_0/A}{\sqrt{\beta \cdot \lambda \cdot \rho \cdot C_p}} \tag{1}$$

This maximum temperature is reached at time $1/\beta$, that is, 40 years after the closure of the repository. In order to limit this maximum temperature to less than 100°C (beyond this temperature, the host rock might undergo mineralogical transformations), the power density P_0/A must be smaller than $10\text{ W}\cdot\text{m}^{-2}$, and this imposes a surface area of the order of a square kilometer for the repository. Equation (1) shows that the maximum temperature depends on the thermal properties of the host rock via the product $\lambda \cdot \rho \cdot C_p$. This product depends on the nature of the host rock (slightly larger for salt and granite, slightly smaller for clay, see [► Tables 12](#) and [► 13](#)), but the difference is not considerable, so the above conclusions about the size of the repository are valid for all repositories, at least for the order of magnitude.

Because they are comparable in depth, surface area, gallery length, and excavation technology, a geological repository of nuclear waste looks very much like a mine.

The HL waste is placed on a plane to put as much distance as possible between the heat-generating waste packages, and minimize the heating ([► Fig. 94](#)).

In order to make the general management and the handling easier, repository designs generally feature a separation of the waste categories in distinct zones.

The waste packages are accommodated in elementary cavities (alveoles) dug into the rock ([► Fig. 95](#)). These alveoles are grouped in ensembles or modules interconnected by galleries.

■ **Table 12**

Types of waste packages that could be disposed off in a geological repository

Waste	Matrix	Container
FP AND MA	Glass	Stainless steel
Sludges, concentrates	Bitumen	Carbon steel
		Stainless steel
Hulls and end caps	Cement	Stainless steel
Technological waste	Cement	Fiber-reinforced concrete
		Stainless steel
Spent fuel		Carbon steel
		Stainless steel

■ **Table 13**

Criteria and characteristics of host rocks suitable for waste disposal

	Impermeability	Chemical stability	Mechanical properties	Thermal properties
Granite (S, CH ?, Fine)	No (fractures)	Not bad	Excellent	Good
Salt (D, USA)	Yes	Good	Creep	Good
Clay (F, B, J, E ?)	Yes	Good	Mediocre	Mediocre

Figure 94
 Architecture of a repository (kilometric scale) (here, French concept, ANDRA and Dossier Argile 2005, http://www.andra.fr/interne.php?id_article=934&id_rubrique=160)

Figure 95
 Typical design of a repository of vitrified waste at the decametric scale (ANDRA, http://www.andra.fr/interne.php?id_article=934&id_rubrique=160) Note the overpack of the waste package. In this example, the overpack is made of thick (several cm) low-alloyed steel. Note that in this design, there is a liner separating the overpack and the host rock. This liner is intended to ensure the reversibility by avoiding an early collapse of the gallery under the lithostatic pressure

These horizontal access ways are connected to the surface by vertical shafts. The surface installations feature the support facilities, for example, the installations for waste characterization and conditioning.

■ Figure 96

Closure of a repository unit. Four steps of closure, in chronological order, and with a decreasing degree of reversibility: 1a: The tunnel plug is in place. At this stage, the installation is like an interim storage 1b: The unit is closed 1c: The handling drift is closed 2: All shafts and drifts are closed

As long as the drift is not backfilled, the waste canisters can be easily retrieved (reversibility) (► Fig. 96).

For medium-activity waste, the architecture of the repository can be more compact, because there is no heat generation.

3.2.6 Cost of an HL LL Waste Repository

According to ANDRA, the cost of a repository able to host the waste corresponding to 40 years of production of a 60 GWe nuclear fleet with closed cycle option would be of the order of 15 G€ (dossier ANDRA synthèse argile 2005). In this total, the investment cost is about 40%, the exploitation cost is 40%, and miscellaneous costs (taxes, overheads, insurance, and study costs) amount to 20%. The cost of the disposal facility depends largely on its size, hence the powerful incentive to design a compact facility.

Another example is that of the American repository of Yucca Mountain, envisaged for the disposal of spent fuel, which has a surface area of 6 km², with a honeycomb network of galleries 100 km long. Its capacity would be 70,000 t for a cost of 15 G\$ (Nuclear Waste, National Academy Press, 1996).

Utilities already pay provisions (under the form of dedicated assets) to prepare for this big investment. So, the money will be there on time, but the delayed nature of the investment is another incentive to postpone the decision of the disposal.

Far-field, near-field. Some terminology.

One usually distinguishes two zones in the geological barrier:

The near-field is the zone of the geosphere perturbed directly and rapidly by the repository.

The perturbations can be thermal, mechanical (decompression, cracks), hydraulic (desaturation etc.), and chemical (oxidation). They generate high gradients (stress, pressure, temperature, and concentration).

In the near-field, the system is well characterized (we know what the repository contains!), but its description is difficult because the phenomena, which take place in the near-field are complicated and coupled together.

The near-field encompasses the engineered barrier and a part of the geological barrier: EDZ, “Excavation Disturbed Zone”).

The far-field is the zone of the geosphere not perturbed directly by the repository, extending up to the biosphere.

The gradients are small, the thermo-hydro-mechanico-chemical couplings are weak.

The phenomena are simpler to describe phenomenologically, but the geological medium is generally ill-characterized and heterogeneous.

The far-field encompasses the geological barrier minus the EDZ.

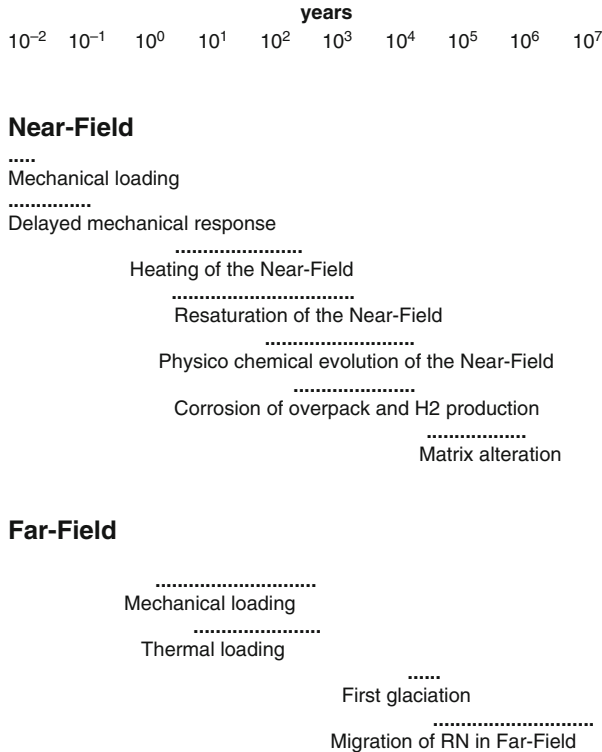

3.2.7 The Foreseen Evolution of a Repository

The First One Thousand Years

The likely evolution of the repository is described in the following “normal” scenario (🔍 Fig. 97). High-level waste packages will heat up the surrounding rock, until it reaches a temperature of about 100°C or so during the first 100 years, at the start of their time in disposal. The rock will then slowly cool down in step with the radioactivity decay rate. The clay barriers will become saturated at the same time. Rocks a few hundred meters below the surface will become resaturated with water because they are generally below the water table. It is also during the first millennium that the underground structures will settle, possibly opening fissures in nearby rock. This settlement, compounded by the corrosion of secondary metal canisters will make it harder – but not impossible – to recover the packages at a later date.

10,000 Years On and More

Much later (at least 10,000 years and no doubt much later) the glass packages and uranium oxide will have started to dissolve through the action of the underground water, causing the few released radionuclides to disperse. These will then slowly begin to migrate through the bedrock. The water will percolate through host rock pores and fissures before reaching a groundwater reservoir to migrate horizontally, finally ending up in a river. Very impermeable host rock will greatly slow down this migration while a “slow” aquifer and a distant outlet should lengthen the journey time even more. Calculations indicate that in low permeability geological formations, millions of years could elapse before any water would flow back to the outlet.

■ **Figure 97**

The foreseen evolution of a deep geological repository

Millions of Years On

A few radionuclides will surface their activity level diminished by radioactive decay: “*delay means decay*”!

At the end of its evolution, deep disposal will indeed have some radiological impact on the environment, as the quantity of radionuclides reaching the biosphere is not nil. But research carried out so far suggests that compared with natural radioactivity flows, a properly designed engineered barrier, combined with a well-chosen geological barrier will delay the return of the radionuclides to the biosphere to such an extent that the releases will be minute.

3.2.8 Geodynamic Evolution of a Deep Geological Repository

The above prediction of the evolution of a repository could be overturned by a volcanic eruption or a major earthquake, but the timescale of these internal geodynamic events is much larger than the lifetime of a repository. Time constants for the creation of new faults or new mountains are of the order of 10 million years. The local stress field can thus be considered constant during the next million years, except in the vicinity of active faults. Consequently, no creation of new faults across the repository is expected before several 10 million years, provided the repository is located in a tectonically inactive region. No extension of the existing faults across the repository is expected either, provided the repository is located far enough (more than a few kilometers

since the order of magnitude of the earth crust is typically a centimeter per year) from the nearest fault. If precaution has been taken to avoid well-known seismically active areas and to place the disposal far enough away from active faults, it is extremely unlikely that any new fault will cross the facility during its lifetime.

However, strong earthquakes are expected during the lifetime of the disposal. But their consequences should be fairly limited, if only seismic movement is weaker down in the depths than it is on the surface.

Erosion is potentially capable of exposing the disposal during its lifetime, but the risk is minimized by choosing sites on plains, where the erosion rate is smaller than 0.1 mm/year. Finally, glaciations will no doubt occur. They could slow down underground water circulation if the repository is located below the permafrost, thus increasing the efficiency of the geological barrier.

3.2.9 The Criteria for the Choice of a Suitable Location for a Deep Geological Repository

- **Hydrogeology**
 - Low permeability
 - Small hydraulic gradients
- **Site stability**
 - No active fault, no volcanism close to the site
 - Limited consequences of glaciations

- **Chemistry**
 - Good sorption capacities of the host rock
 - Chemical stability, buffering capabilities
- **Thermal and mechanical properties**
 - Excavations must be technically feasible
 - Good heat diffusivity
- **Minimal depth**
 - Protection against erosion, earthquakes, and human intrusions
- **No natural resources underground**

3.2.10 Choice of the Host Rock for the Waste Disposal

Granite is considered as a potential host rock by North European Countries (Sweden LSR Aspö, Finland) and Switzerland (LSR Grimsel).

It is a very hard rock, a favorable factor for civil engineering. It is a well-characterized medium with a well-known water chemistry and a very low porosity ($\sim 1\%$ if not less on the local scale), a factor, which simplifies the geochemical behavior of the medium.

Its good thermal conduction properties reduce to some extent the surface area needed for the repository.

However, in granite, large-scale fractures are frequently found. These fractures could represent fast transfer pathways for radionuclides, thus hampering the confinement properties of the geological barrier.

Salt is considered as a rock suitable for hosting a repository by the USA (WIPP) and Germany (Gorleben).

Salt is the host rock of the sole operating repository: the Waste Isolation Pilot Plant (New Mexico) for military IL LL waste. Its advantages are a high thermal conductivity, low water content, and a good plasticity. Cracks in salt are self-healing.

On the other hand, salt is a natural resource, potentially exploitable by future generations, with an associated risk of a human intrusion. Salt is a medium, which can be very aggressive chemically. The corrosion phenomena must thus be under control. The complexity of the chemistry of brines (salt concentration can be as high as 5 M!) is also an important drawback of salt.

Clay rocks are studied by France (LSR Bure), Switzerland (LSR Mt Terri), Japan, and Belgium (LSR Mol).

Clays are specially interesting for geological repositories, because they can be used as engineered barriers *and* as host rocks.

Water motion in clays is very slow because of the very low permeability (in soft clays, fractures can be self-healing). Solute motion is even slower, thanks to the strong sorption capacity of clays and to their nanofiltration capabilities. Moreover, clay waters are alkaline and reducing, two factors that promote the speciation of metallic radionuclides under the form of low-solubility compounds. Clays can also protect the waste forms due to their good chemical stability, combined with their strong ability to buffer chemical perturbations.

Plastic mechanical properties (provided the clay content of the rock is sufficient) give clayey rocks interesting sealing capabilities. However, these mechanical characteristics can also be viewed as a drawback, because they entail the necessity for an important gallery-supporting structure. In addition, the clay rocks have a bad thermal conductivity, and a strong variability.

Volcanic formations are studied exclusively by the USA on the site of Yucca Mountain. This geological medium is very specific at least in one respect: it is an unsaturated medium.

3.2.11 Hydrogeology

Hydrogeology is the study of water travel underground. Water will be the vector for the travel of radionuclides released by a waste repository. This justifies an overview on hydrogeology, to describe the main mechanisms and the order of magnitude. Hydrogeology can be divided into two parts: the study of the water motion (hydrogeology proper) and migration of solutes. Hydrogeology considers the underground medium as a porous medium, characterized by its porosity and permeability (► [Figs. 98](#) and ► [99](#), ► [Table 14](#)).

Hydrogeology: the important quantities and laws

ω Porosity (proportion of the porous medium left unoccupied by minerals).

K ($\text{m} \cdot \text{s}^{-1}$) Permeability.

$h(\text{m})$ Hydraulic potential, that is, the pore pressure expressed in water height units, and corrected from altitude: $h \equiv P(z)/(\rho_w \cdot g) - z$.

U ($\text{m} \cdot \text{s}^{-1}$) Darcy's velocity, that is, the water flow rate through a unit surface area of the porous medium. Darcy's velocity, permeability, and hydraulic potential are related, but the Darcy's law: $U = -K \cdot \text{grad}(h)$, which says how the water moves underground under the influence of pressure gradients.

U^* ($\text{m} \cdot \text{s}^{-1}$) Microscopic velocity, average water velocity of a water molecule. $U^* = U/\omega$.

Aquifer: Underground medium containing much water, and permeable enough to allow the circulation of this water.

Aquitard: Underground medium with little permeability.

■ **Figure 98**

Aquifers and aquitards in a typical sedimentary basin

Figure 99

The travel of water underground is generally vertical in aquitards and horizontal in aquifers

Table 14

Orders of magnitude for the permeability, porosity, and water velocity in aquifers and aquitards

	Permeability $K (m \cdot s^{-1})$	Porosity ω	Typical hydraulic gradient Grad h	Microscopic water velocity $U^* (m \cdot s^{-1})$
Aquitard	10^{-11}	$2 \cdot 10^{-1}$	1	$5 \cdot 10^{-11}$ (1.5 mm/year)
Aquifer	10^{-6}	$3 \cdot 10^{-1}$	10^{-3}	$3 \cdot 10^{-9}$ (10 mm/year)

The repository is placed in an aquitard, where the motion of water is very slow (► Fig. 98).

In general, the place of the repository will be below the water table. This means that in the surroundings of the repository, the host rock will be water-saturated.

The only exception is the site of Yucca Mountain (USA), located in a desert where the water table is very low, below the place foreseen for the repository.

3.2.12 Calculation of Water Flow in a Permeable Porous Medium

In the far field, one is interested mainly in determining the direction and velocity of the underground water fluxes. One assumes generally permanent flow regime. The rock is described as a porous permeable medium with imposed hydraulic potential. In those conditions, the problem would be mathematically very simple in the case of a homogeneous medium, with the same permeability everywhere. Unfortunately, the rock is, in general, very heterogeneous, and even fractured. The permeability of an equivalent homogeneous porous medium is then determined by means of homogenization techniques, which request good statistical information on the medium heterogeneities to determine the representative elementary volume (REV). In very heterogeneous media, for example, fractured media with a wide hierarchy of fracture sizes, homogenization over an REV may be illegitimate. In this case, large fractures must be taken into account explicitly, one by one.

3.2.13 Radionuclide Migration

Hydrogeology addresses the motion of water in the geosphere. It will be seen below that the migration of radionuclides is more complicated than transport under the sole influence of water *advection*, because of physicochemical effects like *diffusion and dispersion* (► Fig. 100). In addition to these three phenomena, chemical interactions between the solute and the porous skeleton must be taken into account.

Three main phenomena cause the migration of solutes in a porous media: molecular *diffusion*, kinematic *dispersion* and *advection*.

Advection is a very simple transport mechanism: the solute follows the water in its travel. The advective flux of solute is equal to

$$\mathbf{j} = \mathbf{c} \cdot \mathbf{U},$$

where c is the solute concentration and U is the Darcy velocity.

Diffusion occurs whenever a population of microscopic objects (atoms, molecules, electrons, ions, neutrons, etc.) collides with obstacles in the medium.

Diffusion is governed by the Fick's law, which relates the solute flux j to the solute concentration c :

■ Figure 100

The three main phenomena that cause the migration of solutes in a porous media are molecular *diffusion*, kinematic *dispersion*, and *advection*

3.2.14 Kinematic Dispersion

The flow in a porous medium is broken by the solid objects that constitute the skeleton of the medium. These dispersing objects can be of any size. They can be microscopic clay minerals, grains of sand, or rock blocks delimited by fractures.

The motion of a water molecule in this network resembles a random walk, and can be described by an effective tensor diffusion coefficient D_{kin} , which depends on the speed of the flow and on the size of the dispersing objects. If the dispersing medium is isotropic, the tensor D_{kin} reduces to a scalar:

$$D_{kin} = \alpha \cdot |U|.$$

The quantity α is the *dispersivity* of the medium. It is equal to the size of the largest dispersing objects in the geological medium. The dispersivity can be measured via tracer experiments. If the medium is heterogeneous and contains several scales of heterogeneity with a hierarchy in size, alpha will depend on the scale of the experiment.

➤ *Table 15* gives orders of magnitude for the dispersivity and kinematic dispersion of geological media:

Generally, in aquifers, alpha and U are large: the kinematic dispersion dominates over the molecular diffusion. The opposite is true in aquitards.

The phenomenon of kinematic dispersion is important to describe the dilution of tracers or pollutants in an aquifer.

■ **Table 15**
Typical dispersion in geological media

Media	Dispersivity (m)	Typical Darcy velocity (m · s ⁻¹)	Kinematic dispersion (m ² · s ⁻¹)
Sand	1 · e-3	1 · e-6	1 · e-9
Granite(fractured)1	1 · e-6	1 · e-6 (dominant)	
Clay	1 · e-8	1 · e-12	1 · e-20 (negligible)

3.2.15 The Tracer Equation

The contributions of solute flux due to molecular diffusion, kinematic dispersion, and advection must be added to obtain the total solute flux.

$$\vec{j} = \underset{\substack{\uparrow \\ \text{Solute} \\ \text{flux}}}{-D_{mol}} \cdot \underset{\substack{\uparrow \\ \text{Molecular} \\ \text{diffusion}}}{grad} \vec{c} - \overline{\overline{D}}_{Kin} \cdot \underset{\substack{\uparrow \\ \text{Kinematic} \\ \text{dispersion}}}{grad} \vec{c} + c \cdot \underset{\substack{\uparrow \\ \text{Advection}}}{\vec{U}}$$

The conservation law applied to the solute writes:

$$\frac{\partial c}{\partial t} = -\frac{1}{\omega} div(\vec{j}) - \lambda \cdot c$$

The term $\lambda \cdot c$ has been added to describe the case of a radioactive solute, which decays with a radioactive constant λ .

In the case of an isotropic medium, the concentration of radioactive solute obeys the equation:

$$\frac{\partial c}{\partial t} = \frac{1}{\omega} \left(D_e \cdot \Delta c - \vec{U} \cdot \text{grad}(c) \right) - \lambda \cdot c. \tag{2}$$

The equation above is the master equation, which describes the migration of the solute. It tells how the concentration field evolves in space and time.

This equation looks like a diffusion equation, with an added term associated to convection.

■ Figure 101

Solution of the one-dimension tracer equation in the special case of an instant and local release of a limited quantity of tracer. The plume shifts downstream by advection, with velocity U^* . It also spreads by diffusion, and its width increases as the square root of time

■ Figure 102

Solution of the one-dimensional tracer equation in the special case of a permanent and local release of tracer, limited by a saturation concentration. The plume keeps a constant concentration in the vicinity of the source. It extends downstream by advection with velocity U^* , and spreads by diffusion. The width of the concentration front is $\text{sqrt}(D \cdot t / \omega)$

Examples of solutions of the tracer equation in particularly simple cases are given below (Figs. 101–103)

Figure 103

Solution of the two-dimensional tracer equation in the special case of a permanent and local release of tracer, limited by a saturation concentration. In 2D, the flow has a cylindrical symmetry with respect to the axis defined by the water flow. The picture here is a cut of the plume across a plane containing the source and this axis

3.2.16 Characteristic Migration Time Through a Geological Barrier

We give here the order of magnitude of the migration time of a perfect tracer (no chemical interaction with the porous medium) through a geological barrier made of a homogeneous clay layer. We consider two extreme cases (Figs. 104 and 105):

1. Pure advection, under a typical hydraulic gradient of 1 m/m
2. Pure molecular diffusion (no hydraulic gradient)

The advective migration time is $\tau_{adv} = \frac{X \cdot \omega}{K \cdot |gradh|}$.

The diffusive migration time is $\tau_{diff} = \frac{X^2 \cdot \omega}{D_e}$.

With the transport characteristics of a typical clay layer (Table 16), $\tau_{adv} = 70,000$ years, and $\tau_{diff} = 6$ million years. These long travel times are favorable to the safety of repositories. It can be seen from this example that the advective migration time is shorter than the diffusive migration time. This dominance of advection over diffusion is general in the case of solute transport through hectometric geological barriers.

The Péclet number is a convenient indicator of the dominant transport mode. It is defined as the ratio between the diffusive and advective characteristic times through a barrier of thickness X:

$$Pe = \frac{\tau_{diff}}{\tau_{adv}} = \frac{X \cdot U}{D_e}$$

If the Péclet number is smaller than 1, that is, if the diffusion time is smaller than the advection time, diffusion dominates over advection. If $Pe > 1$, advection dominates over diffusion

Figure 104
Advective migration

Figure 105
Diffusive migration

Table 16

Typical transport properties of a clay layer usable for hosting a repository

Permeability K ($\text{m}\cdot\text{s}^{-1}$)	10^{-11}
Porosity ω	0.2
Effective diffusion constant De ($\text{m}^2\cdot\text{s}^{-1}$)	10^{-11} (kinematic dispersion is negligible compared to molecular diffusion)
Hydraulic gradient grad (h) (m/m)	1
Layer thickness X (m)	100

For more detailed data, see, for example, Distinguin and Lavanchy (2007)

(Fig. 106). For values of Péclet numbers of the order of unity, both phenomena come into play. Advective transport generally dominates over diffusive transport for large space scales. This is generally the case for transport of solutes from a geological repository.

Figure 106 The average travel distance of a tracer as a function of time, in the case of diffusion (red) and advection (blue)

3.2.17 Sorption of a Non-Perfect Tracer

We consider here the case of a non-perfect tracer, that is, a tracer which is able to be sorbed onto the mineral surface of the porous medium (► Fig. 107).

We consider here the case of a species A, which can exist both in solution and sorbed on the free surface of the porous medium. We introduce two concentrations: c is the concentration of species A in solution, and γ is the concentration of this species in sorbed form. Concentration c is expressed in $\text{kg} \cdot \text{m}^{-3}$, and γ in $\text{kg} \cdot \text{kg}^{-1}$.

One observes an equilibrium between the sorbed ions and the ions in the solution.

Figure 107 Sorption in a porous medium

Note: Note the very high value and large variability of Kd coefficients for different clay minerals
Source: Poinssot et al. (1999)

For a dilute solution, the law of mass action

$$\rho \cdot \gamma = \frac{K_1}{K_2} \cdot c$$

predicts a linear relationship between the number of ions in solution and the number of sorbed ions. The proportionality constant is denoted Kd(m³/kg).

Exact definition is

$$Kd \equiv \frac{\gamma}{c} = \frac{1}{\rho} \cdot \frac{K_1}{K_2}$$

This distribution coefficient Kd, that is, the ratio γ/c , can be measured in experiments where a known quantity of solute is put in contact during a long time with a known quantity of mineral. After reaching the sorption equilibrium, the quantity of species A remaining in solution is measured by titration. The distribution coefficient of caesium is given in ► [Table 17](#).

Note that the distribution coefficient Kd is constant (independent of Cs concentration) only for small values of the Cs concentration. For values higher than about 10⁻⁵ mol/L, the saturation of the sorption sites comes into play. Other factors, like the presence of chloride or carbonate ions influence the sorption equilibria and modify the Kd value. The distribution coefficient of different chemical species on bentonite is shown in ► [Fig. 108](#).

Several types of sorption sites can coexist in the same mineral, with different equilibrium constants. Their successive saturation gives several plateaux in the sorption isotherm (► [Table 18](#)).

The Kd model has many shortcomings, and its validity is limited by strong hypotheses:

Figure 108

Classical distribution coefficient at neutral pH for different radionuclides on a smectite-rich material used for bentonite engineered barrier, MX80

- The number of sorption sites is supposed to be large compared to the number of ions.
- The kinetic aspects of the sorption reaction are neglected (hypothesis of a reversible reaction, in thermodynamic equilibrium).

Consequently, the distribution coefficient K_d is not universal. It depends on the cation, the mineral, and the water composition (existence of concurrent ions, in particular H^+). Even on a pure mineral phase, several types of sorption sites can coexist, with various K_d values. Furthermore, in general, a natural rock is composed of many minerals.

Despite its shortcomings, the K_d model will probably remain in wide use, because of its convenience, which comes from a very simple property: the migration of a linearly sorbing tracer is the same as the one for a nonsorbing tracer, except for one thing: *it is retarded by a constant factor*. This retardation factor depends on the sorbing capability of the medium for the migrating chemical species.

For a more detailed treatment of sorption onto minerals, see Limousin et al. (2007) and Beaucaire et al. (2008).

3.2.18 Migration of a Sorbing Tracer

We consider here the case of a species A which can both sorb on the free surface of the porous medium and migrate through this medium. Here, we no longer assume that equilibrium is

reached everywhere in the porous medium, and we allow the migration of the solute, by the mechanisms (diffusion, dispersion, advection) described above.

The concentration of species A in solution and in sorbed form depends on space and time: $c = c(x, t)$ and $\gamma = \gamma(x, t)$. In order to determine the evolution of the concentration field in space and time, one must take into account both solute transport and the kinetics of the sorption reaction.

$$\begin{aligned} dc/dt &= TT + KT \\ d(\rho \cdot \gamma)/dt &= -KT \end{aligned}$$

where TT is the transport term of the tracer equation (2), and KT is the kinetic term:

$$KT = K_2 \cdot \rho \cdot \gamma - K_1 \cdot c.$$

In the case of a sorbing tracer, the equations for chemistry and transport are thus coupled.

If the chemical reaction is locally at equilibrium, one can write a relationship between the time derivative of concentrations in solution and in sorbed form (weak formulation of the law of mass action):

$$d(\rho \cdot \gamma)/dt = (K_1/K_2) \cdot dc/dt.$$

The ratio between these two quantities is the distribution coefficient K_d introduced previously. With this assumption, the equation of the evolution of the solute concentration becomes

$$dc/dt \cdot (1 + K_1/K_2) = TT.$$

This equation is formally identical to the transport equation for a non-sorbing tracer

$$dc/dt = TT,$$

with an important difference: the migration is R times slower, where R is a retardation factor given by

$$R = 1 + \rho^* K_d.$$

The exit time of a solute tracer across a barrier can be calculated:

$$\tau_{solute} = R \cdot \tau_{water},$$

where τ_{water} is the migration time of a water molecule (or of a non-sorbing tracer), as given by the tracer equation (2) (► Table 19).

Note that the porosity of clay is not accessible in the same way for all radionuclides: the clay minerals are negatively charged, and repel the anions. This **anionic exclusion** effect reduces the porosity accessible to anions (► Fig. 109).

For the same reason (electrostatic repulsion), anions are generally not sorbed on the porous skeleton: the retardation factor of anions (Cl, Se, I) is unity.

Typical values for the transport parameters of some radionuclides in claystones are given in ► Table 18.

The understanding and microscopical description of ion sorption phenomena onto rock minerals is an important challenge for geochemists.

3.2.19 Migration of Actinides

Laboratory experiments (Dossier ANDRA 2005) suggest that the actinides are very efficiently sorbed on many minerals present underground (especially clay minerals), and are therefore almost immobile in underground environment (total immobility would correspond to an infinite retardation factor R).

Indeed the *retardation factor* of actinides can be very large (of the order of 1,000) (see ► Table 19). For the Callovo-Oxfordian clay, precise values of retardation factors can be found in ANDRA and Dossier (2005), dossier argile.

3.2.20 Radionuclide Speciation and Solubility Limits

We have seen above that the solute concentration was limited by *sorption*.

We see here that it can also be limited by *solubility limits*, which depend on the speciation of the considered element in the geological environment.

► *Figures 110* and ► *111* show the example of the speciation and solubility of neptunium. In oxidizing conditions, Np can be in soluble form (ionic). In reducing conditions, Np is

■ Figure 109

Origin of anionic exclusion within clay-rich rocks. Due to the presence of negatively charged surfaces, anions have only access to a restricted part of the porosity, here the darker blue part (Descostes et al. 2008)

Existence of a maximal concentration in solution, depending on the physico-chemical conditions

Extremely low solubility limits for actinides

Strong limitation of the actinide amounts able to migrate

The example of Np speciation as a function of the redoxpotential

■ Figure 110

The example of Np speciation and solubility as a function of the redox potential in underground environment (From Vitorge and Poinssot 2005)

in solid form (oxide or hydroxide). This behavior is qualitatively the same for most metallic atoms.

Solubility of a species depends on the ionic content of the water. In principle, one should give a solubility product taking into account all the ions playing a role in the dissolution process. In practice, we give in [Table 20](#) a solubility domain for a typical water composition found underground (pH = 8, reducing conditions).

As a rule of thumb, the actinides present underground with the oxidation degree III and IV are immobile, whereas those with the oxidation degrees V and VI are more mobile ([Table 20](#), [Fig. 112](#)).

In the reducing conditions typical of underground environments, most actinides are immobile.

Figure 111

Pourbaix diagram of neptunium describing the dominant aqueous species as a function of pH and redox potential (E measured by comparison to hydrogen saturated electrodes) (Vitorge et al.). The red, white, green, and blue fields correspond to the respective stability fields of hexavalent, pentavalent, tetravalent, and trivalent Np. The open circle describes the chemical conditions measured in the French underground research laboratory (Meuse/Haute-Marne), whereas the open circle corresponds to the chemical conditions measured at Yucca Mountain. The dominant Np aqueous species is different in both cases, thus explaining the difference of Np mobility in these two underground environments (Lemire et al. 2001)

However, actinide migration has indeed been observed in some cases, for example, on the Nevada test site and in Mayak. This migration has been ascribed to actinide-bearing colloids (Kersting 1999; Ewing et al., 2006). The possibility of actinide migration via colloids is still an active field of investigation.

3.2.21 Porewater Chemistry

In order to determine the radionuclide speciation, one must know the ionic content of the water.

The composition of the porewater is determined by rock-water equilibria:

- Reactions of dissolution-precipitation: $A_nB \leftrightarrow nA^- + B^{n+}$, governed by a solubility product $K_s = (A^-)^n \cdot (B^{n+})$
- Interfacial ion-exchange reactions, for example, $\text{Mineral-Na} + C^+ \leftrightarrow \text{Mineral-C} + Na^+$

Many minerals come into play in these equilibria. In order to determine the groundwater composition, one must know the mineralogical composition of the rocks with which it is equilibrated. Even minerals present in small quantities in the rock can play an important role in determining (buffering) the water composition.

➤ Table 21 gives the composition of the Callovo-Oxfordian claystone. ➤ Table 22 gives the composition of the corresponding porewater.

■ Table 20

The dominant radionuclide speciation and solubility in underground waters (pH = 8, reducing conditions)

Radionuclide	Solubility limit (mol/L) min. value	Solubility limit (mol/L) ref. value	Solubility limit (mol/L) max value

3.2.22 How to Evaluate the Transport of RN Underground

The four steps of modeling of the transport of radionuclides underground are the following (➤ Fig. 113):

1. Rock-water equilibrium determines the *porewater composition*.
2. The characteristics of porewater (ion content, and more specifically pH, eH, $p\text{CO}_2$) determine the *radionuclide speciation*.

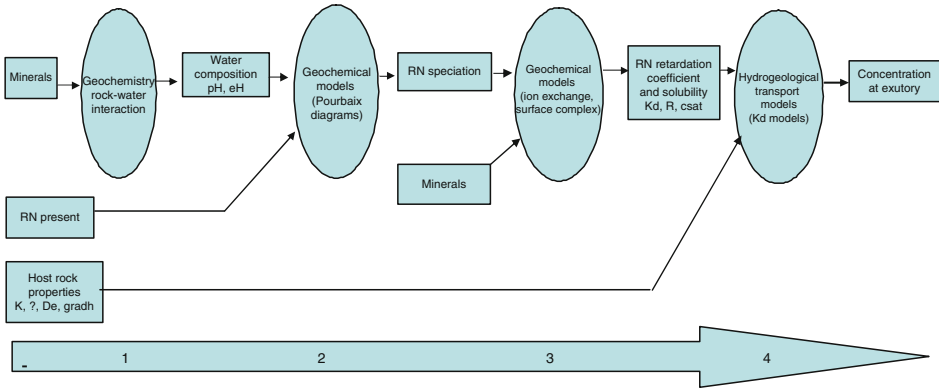

Figure 113

The four steps of modeling of the transport of radionuclides underground

3. The speciation of RN determines the *solubility* and *sorption* properties of these radionuclides.
4. Solubility and sorption properties determine the way RNs are *transported* underground.

The three first steps pertain to geochemical modeling with one single generic formalism: the law of mass action.

3.2.23 Validation of the Models of RN Transport Underground

Tracer experiments investigate the migration of radionuclides in the host rock by injecting a cocktail of tracers in a borehole. The rock around the injection point is then analyzed after some time (typically 1 year) to determine the migration distance of the various chemicals in the cocktail.

In clays, this migration distance in 1 year is very small (typically centimeters for non-sorbing tracers, depending on the modalities of the experiment, that is, pure diffusion or advection under the influence of an imposed pressure gradient). Given the reduced time and distance scales involved, these experiments cannot provide direct clues of the efficiency of the geological barrier. Natural analogues give evidence for tracer migration on larger time and length scales (Fig. 114). Generally, tracer experiments permit us to validate migration models, and participate in building the confidence in the safety of deep geological repositories.

The travel of nonreactive species through a geological barrier is already very slow. Reactive tracers are R times slower ($R = 10, 100, 1,000$ depending on the considered species, cf. Kd model). It is difficult to do human scale experiments to check this.

However, *natural tracers* enable us to study the migration of chemical species in the geosphere on large time and space scales. The principle is to measure the present distribution of some chemical or isotopic species in the geological medium. In order to reconstruct their migration during past eras, the source term must be known.

An example of useful natural tracers is the chloride ion and stable isotopes of water.

■ Figure 114

An example of natural tracer in the claystone of Tournemire (Aveyron): the analysis of the deuterium in the clay porewater shows that the migration of water through the argillaceous layer is very slow. Despite the very ancient age of the clay layer (Toarcian, 180 million years), the initial composition of the water (initially, seawater) has been partially preserved at the center of the layer. Close to the upper and lower aquifers, the isotopic composition of the porewater becomes equal to the composition of rainwater. The deuterium concentration profile has been measured along a vertical borehole across the horizontal layer. The profile is smooth for samples measured far from tectonic fractures (full points) and more irregular for samples measured close to the fractures (empty points). This suggests that fractures played a role in the migration of the tracer. (Source: Y. Moreau Le Golvan, IPSN). The shape of the deuterium profile in the unfractured region permits us to deduce a diffusion constant in the claystone, which matches the measurements made on samples ($10^{-12} \text{m}^2 \cdot \text{s}^{-1}$)

All the knowledge gained on RN migration will be applied to modeling of the *radionuclide travel* through the geosphere.

The radionuclides will be released slowly by the package through the near-field (altered package, engineered barrier), and will start their travel through the host rock, if they have not yet decayed. In all cases, they will be trace elements in the geological system, and will therefore obey the chemical conditions dictated by the major chemical constituents of the geological environment.

The rate of release of the radionuclides depends on the phenomena taking place in the near-field.

3.2.24 Thermo-Hydro Mechano-Chemical Effects in the Near-Field of a Geological Repository

In the near-field, one has to take into account simultaneously four types of effects:

1. Thermal (the waste generates heat)
2. Hydraulic (desaturation-resaturation of the host rock)
3. Mechanical (decompression due to the excavation; dilation; shrinkage/swelling)
4. Chemical (oxidation and other chemical perturbations of the host rock due to its exposure to air and to foreign elements)

It will be shown that THMC phenomena are *coupled*.

3.2.25 Thermal Behavior of High-Activity Waste

As has been seen in the section devoted to the architecture of the repository, a careful modeling of the thermal behavior of high-activity waste in a geological repository is important to avoid uncontrolled heating of the waste and of the surrounding rock. We give here the data necessary to perform such calculations (► Figs. 115 and ► 116, ► Table 23).

Figure 115

Heat emission contributors in spent fuel (UOX, 45 GWd/t, 4 years cooled). For short times, the residual power of spent fuel is dominated by short-lived fission products. For $t > 100$ years, actinides dominate

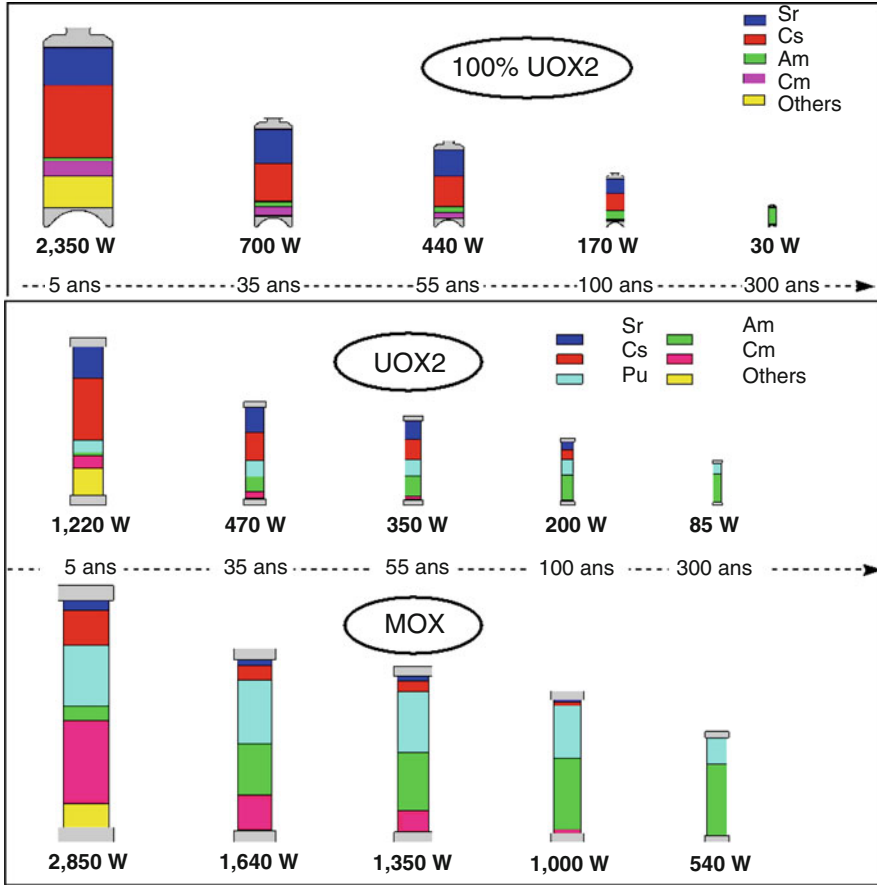

Figure 116
Thermal dissipation of spent fuel

Table 23
The thermal characteristics of some rocks

	Specific heat $\rho \cdot Cp$ ($J \cdot m^{-3} \cdot K^{-1}$)	Thermal conductivity λ ($W \cdot m^{-1} \cdot K^{-1}$)
Clay	2,040×940	1.5
Granite	2,700×800	2.5
Salt	2,150×850	5.2

The Heat Source-Term

A few years after its discharge from the reactor, the spent fuel generates a residual power of the order of 1 kW/t. It is approximately proportional to the burnup.

MOX fuels generate more heat than UOX fuels, and the decrease of the thermal power with time is slower.

The thermal power generated by glass after reprocessing of spent fuel is of the same order of magnitude, because most of the radionuclides, which contribute to the heat generation in the spent fuel are also in the glass, and because 1 t of spent fuel gives 0.5 t of glass.

The heat equation has the same form as the tracer equation discussed above:

$$\frac{\partial T}{\partial t} = D_{th} \cdot \Delta T + \frac{Q}{C}$$

where Q is the heat source-term, and D_{th} is the thermal diffusivity of the host rock.

$D_{th} = \lambda / (\rho \cdot C_p)$, with

ρ = material density

C_p = heat capacity

λ = thermal conductivity

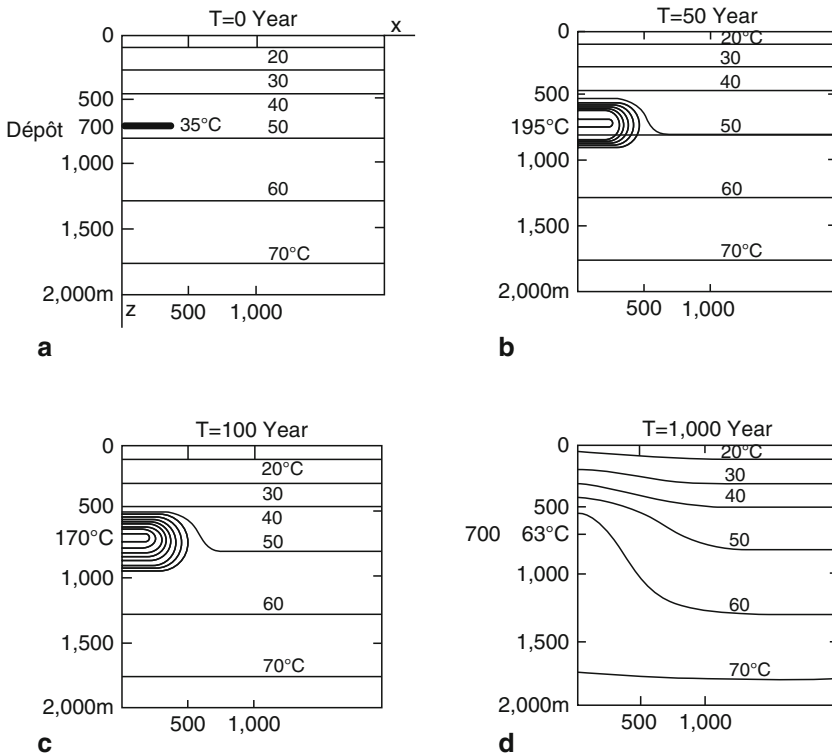

Figure 117

Thermal evolution of a repository at the kilometer scale (From Habib, La vie des Sciences)

The solutions of the heat equation have the same general form as the ones for the tracer equation. In particular, the typical size of the zone heated by a source after time t is $(D_{th} \cdot t)^{1/2}$. Rocks have a small thermal diffusivity D_{th} , of the order of $10^{-6} \text{ m}^2 \cdot \text{s}^{-1}$. Consequently, the size of the heated zone is small, even after very long heating times (this size is typically decametric after one century). This is rather bad news for a repository: it means that the heat generated by the waste will remain confined in a small space, and that the increase of temperature will be large, unless the heat-generating waste is widely spread within the host rock.

The evolution of the temperature in the repository is found by solving the heat equation. The temperature increases at first, because of the power dissipated by the waste. Later on, the temperature decreases back to the initial temperature, because the power dissipated by the waste decreases by depletion of its radioactive content.

► *Figure 117* gives an example of the temperature field as a function of time in the host rock around a repository.

Such thermal calculations must be made at the kilometer scale to check that the macroscopic waste distribution in the repository is not too dense. They must also be made at the scale of an alveole to check that the detailed geometry of the galleries or alveoles does not create hot spots liable to damage the host rock. Thermal calculations must also be made at the scale of the package, taking into account eventual air gaps, to make sure that the temperature at the interior of the package will not exceed a prescribed security value (e.g., the glass vitreous transition temperature in the case of vitrified waste).

3.2.26 Chemical Phenomena in the Near-Field

Chemical phenomena in the near-field are of various natures: *redox front propagation*, *dissolution-precipitation* with formation of new mineral phases, *corrosion*, etc. These complicated phenomena occur under radiation, mechanical stress, and thermal gradient. Fortunately, thanks to the very limited transport properties of the geological barrier, they are slow and affect a restricted zone in space.

Redox Front Propagation

The underground environment is often reducing. The excavation of the galleries of the disposal facility exposes the host rock to oxidizing conditions. Slow chemical reactions can then take place, with subsequent modification of the mineralogical composition of the host rock.

For example, clay rocks frequently contain pyrite (FeS). When exposed to humid air, this mineral is readily oxidized, producing sulfuric acid, with a drastic decrease of the pH of the porewater. Another example is that when put in contact with a host rock, a cemented material generates an alkaline perturbation, which propagates in the porous medium, with a remineralization of the perturbed zone (dissolution of the smectites and precipitation of CSH phases).

Dissolution–Precipitation

The exposure of the host rock to atmosphere during the excavation of the gallery has other consequences: the modification of the water chemistry due to redox front propagation combines with the modification of the water circulation to create conditions where the rock minerals can eventually dissolve and reprecipitate (e.g., in cracks) under the form of new mineral phases,

with subsequent modification of the porosity, permeability and diffusion constant of the host rock. For example, the carbonatation of concrete (either atmospheric or aqueous) results in the dissolution of portlandite and precipitation of calcite.

Corrosion

The metal of the containers and overpack are usually unstable thermodynamically in underground conditions (a possible exception is copper). A reaction of oxidation of the metal can then take place, which must be controlled, because its rate determines the lifetime of the containers, and therefore the contact time between the water and the waste. The products of this corrosion (oxides and hydroxides) accumulate in the near-field. They can locally modify the porosity of the medium and the solute transport.

Ideally, all these interlinked phenomena should be taken into account when describing the evolution of the near-field. The presence of radiation (which induces water radiolysis and the formation of reactive radicals), mechanical stress (which influences the dissolution-precipitation phenomena and the corrosion process), and thermal gradients (which influence the migration of solutes) complicate the picture even further. Fortunately, the rate of the chemical reactions in play is necessarily small, because it is limited by the transport of water and reactants in the host rock. Since the transport is slow, the spatial extension of the perturbation is quite small, typically tens of centimeters after a century.

3.2.27 Mechanical Behavior of a Repository

The excavation of a gallery underground causes a perturbation of the stress field in the host rock (► Figs. 118 and ► 119, ► Table 24).

In claystone, stress due to excavation can cause fracturing of the rock in the near-field, or modification of the existing fractures and local modification of the rock permeability.

■ Figure 118

Schematics of the inputs and outputs of a mechanical calculation applied to the near-field of a geological repository. The mechanical characteristics of the geological medium (Young's modulus, or more generally, material behavior laws) are known. The geometry of the excavation imposes the boundary conditions for the stress tensor at the tunnel surface. Application of the Hooke's law and/or the theory of effective stress gives the stress tensor field and strain field as a function of space and time. The stress field can then be compared to the resistance limit of the host rock to determine if fractures are to be expected

■ Figure 119
The principal components of the stress tensor in the vicinity of a tunnel

■ Table 24
Mechanical properties of geological barriers

	MOL (plastic clay)	Tournemire (claystone)	Granite

	$(\sigma_1 - \sigma_3)_{\max}$ (MPa)	$(\sigma_3 = 30 \text{ MPa})$	$(\sigma_3 = 3 \text{ MPa})$
Shear modulus G (GPa)	0.06–0.08	4–12	26–32

Note: Note that the above figures are only indicative. The mechanical properties of rocks are highly variable!

3.2.28 Mechanical Effects Due to the Excavation of the Galleries

The stress field in underground rocks is made of two terms: a vertical compression component due to the weight of the above lying rocks; and a horizontal component due to tectonics. This last component is very much site dependent. If a tunnel is excavated at a depth $h = 500 \text{ m}$ in a rock with negligible tectonic stress, the stress deviator in the vicinity of the tunnel will vary by $\rho \cdot g \cdot h = 10 \text{ MPa}$ due to the excavation (order of magnitude for a repository with a depth

■ **Figure 120**
Conceptual scheme of the Excavation Disturbed Zone (EDZ), and shape of the shear-stress fractures induced by the excavation (From ANDRA)

of 500 m). This figure is smaller than the rupture deviator of a hard rock like granite. Such a rock can be drilled without reinforcing the excavation by struts (borehole ovalisation has been observed in granite in locations with strong tectonic stress). However, 10 MPa is the order of magnitude of the rupture deviator in clay rocks. One therefore expects fracturing of the rock in the tunnel vicinity, and the creation of an Excavation Disturbed Zone (EDZ). Far from the tunnel, one finds again the lithostatic stress field (➤ Fig. 119).

Note that the fractured zone around the tunnel is created initially during the excavation (the cracks are perfectly audible!). When the cracks propagate, the stress field relaxes and extends outwards. The extension is initially rapid, and slows down with time. Ultimately, the perturbation of the stress field stops expanding when the stress deviator becomes smaller than the rupture deviator everywhere in the rock. When this happens, the extension of the fractured zone is of the order of the tunnel diameter (➤ Fig. 120).

Coupled thermal and mechanical effects are expected in the near-field of a repository of high-activity waste. Thermo-mechanical coupling occurs via dilation.

The stress deviator due to dilation is of the order of $E \cdot \alpha \cdot \Delta T$

with $E \equiv$ bulk modulus of the rock

$\alpha \equiv$ rock dilation constant

$\Delta T \equiv$ the temperature difference

This deviator amounts to a few tens of MPa, a value comparable to the rupture deviator in claystone, but smaller than the rupture deviator in granite.

In claystone, the dilation due to heating by the waste can thus cause a fracturation of the rock in the near-field, or a modification of the existing fractures and local modification of the rock permeability.

3.2.29 Hydraulic Effects

Hydraulic effects are expected in the near-field. They are induced by the excavation of galleries in an initially saturated host rock. This excavation can *desaturate* the rock in its vicinity, due to

evaporation of the porewater in the ventilated tunnel. After repository closure, the host rock will become *resaturated*. These phenomena of saturation-desaturation represent an important perturbation of the water circulation underground, because they generate hydraulic gradients considerably larger than the naturally preexisting gradients. They are governed by the permeability (via Darcy's law) and by the capillary behavior of the porous medium.

In a desaturated porous medium, the difference between the pressure in the liquid and the pressure in the vapor is given by the Jurin's law:

$$P_c = \frac{4.(E/A)}{a},$$

where a is the pore size, and E/A is the wetting energy per surface area ($E/A = 0.8 \text{ J.m}^{-2}$ for hydrophilic surfaces).

In finely divided media like clay, the capillary pressure P_c can reach very large values, in the order of 100 MPa. It can be interpreted as a hydraulic potential $h_c = P_c/(\rho.g)$, with the same meaning as in hydrogeology. It is this potential, which is imposed at an interface between the porous medium and the atmosphere.

The kinetics of the resaturation in a porous medium is governed by the Washburn equation, describing the motion of the front, which separates the saturated zone from the desaturated zone: neglecting poroelastic effects, evaporation, and gravity, in the very simple case of a one-dimensional porous medium with one end in free water, it takes a time

$$t = \frac{e^2}{2.K.h_c}$$

to resaturate a thickness e , where K and h_c are the permeability and capillary potential of the medium.

Desaturation-restoration phenomena in clays are quite slow. To give an order of magnitude, the resaturation time of a clay barrier with 1 m thickness is about 10 years.

3.2.30 Hydro-Mechanical Effects in the Near-Field

In a desaturated porous medium, the remaining fluid is under tension. This tension is transmitted to the porous skeleton and can cause shrinkage and even cracking of the material (cf. drying clay). Conversely, the resaturation of porous media causes a swelling. This swelling is exploited to ensure sealing in engineered barriers. The order of magnitude of the shrinkage/swelling due to desaturation/resaturation is $\Delta l/l \approx P_c/E$, where P_c is the capillary pressure of the material and E the Young's modulus of its porous skeleton.

3.2.31 Hydro-Chemical Couplings in the Near-Field

Hydro-chemical couplings in the near-field of a repository are of various natures: *dissolution-precipitation* phenomena, *corrosion*, and *osmosis* are only a few examples.

Dissolution-precipitation phenomena in the near-field host rock (mediated by water circulation) can be triggered by the local imbalance induced by the excavation (hydraulic perturbation)

or by the presence of the waste (chemical perturbation). Dissolution-precipitation might cause modifications of the permeability of the rock, with a subsequent modification of the water circulation itself. For example, fracture filling by precipitation of calcite in calcite-rich claystone has been observed in the Tournemire site.

Another example of hydro-chemical coupling is that of clays which can behave as osmotic membranes.

The osmotic pressure of an ideal solution can be evaluated via the kinetic theory, and obeys a law similar to the one for perfect gases:

$$p = (n/V) \cdot R \cdot T$$

↑

nb of solute moles per cubic meter of solution.

Osmosis can generate nonnegligible overpressures and hydraulic gradients in an heterogeneous rock. For a freshwater-seawater interface 100 m wide, the hydraulic gradient is about $h = 1.2 \text{ m/m}$, that is, the same order of magnitude as the gradients naturally found in aquitards.

■ Figure 121

Gas production and release in the vicinity of a canister in underground repository

3.2.32 Gas Production and Release in an Underground Repository: An Example of H–M–C Coupling

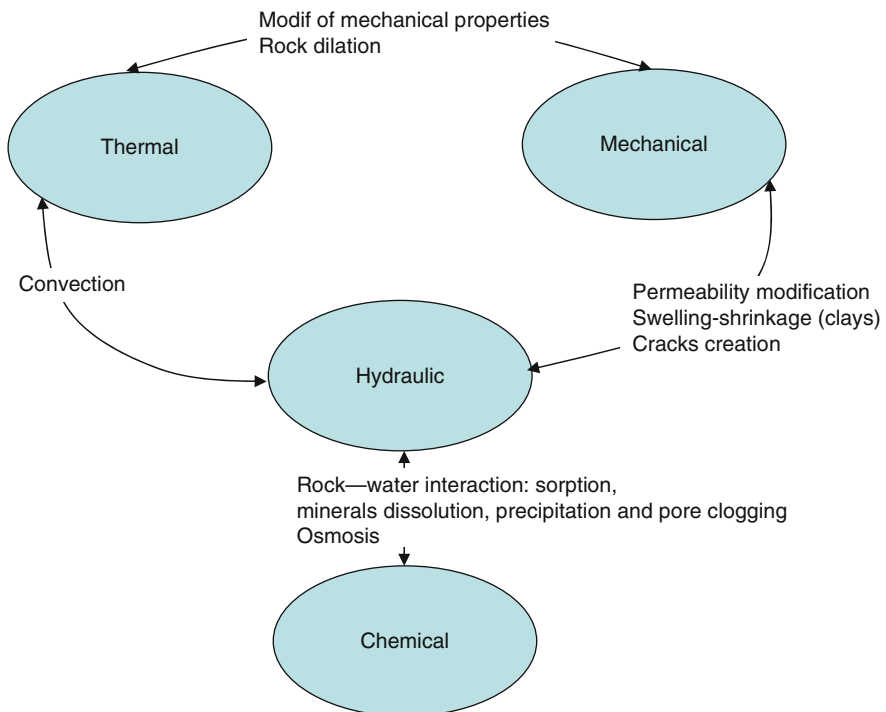

The radiolysis of water and the corrosion of steel canisters by water can generate significant amounts of hydrogen. After closure, anoxic corrosion of steel produces hydrogen via the reaction

In repository conditions, the corrosion rate of carbon steels is of the order of 0.2–2 μm/year (Neff 2003)

If the barrier is very impermeable, this hydrogen can cause pressure buildup and fracturation of the barrier (► Fig. 121). The quantitative evaluation of the consequences of this hydrogen release is the subject of active research.

As shown by the above examples, *thermal, mechanical, hydraulic, and chemical effects are intricately coupled*, and must be treated together. The main couplings are summarized in ► Fig. 122.

■ Figure 122
THMC couplings in the near-field

3.2.33 Underground Laboratories

All major nuclear countries are conducting a research program on waste deep geological disposal (🔍 [Table 25](#)). Studies in URLs are motivated by industrial feasibility assessments, and, more important, by safety assessments of the repository.

There are three categories of objectives:

Mechanism understanding

Model validation

Data acquisition

Site characterization

Development of techniques

Techniques of characterization

Excavation and sealing techniques

The geologic waste disposal poses several difficult scientific problems:

- The evolution of the repository over very large scales of space and time
- The reactivity of materials (glass matrix, steel container, engineered barriers of concrete, or clay)
- THMC couplings in the near-field

These open problems do not mean that the geological disposal concept is not mastered (by nature, it will never be completely mastered!). But they justify the continuation of research in underground laboratories. The main research topics are summarized in [Table 26](#):

3.2.34 Natural Analogues Can Help Validate the Models of Long-Term Behavior of a Repository: The Example of Oklo

The “Oklo phenomenon” was discovered in Pierrelatte in 1972. Routine measurements of the isotopic composition of uranium ore samples from this mine in Gabon showed a depletion in ^{235}U . The enquiry concluded that the anomaly was due to fission chain reactions. Divergence of “natural reactors” took place in 15 sites in the vein, shortly after its formation, 2 GY ago.

Nuclear reaction started in very rich parts of the deposit (grade 10%). The presence of water (playing the role of neutron moderator) was necessary to reach the criticality.

Pressure and temperature in the reactors were close to those encountered in the present PWRs. Even the isotope composition of the fuel was similar (3.7%)! However, the neutron flux was considerably smaller, and the nuclear reactions lasted much longer (20,000–350,000 years).

From the knowledge of the age of the event, and the depletion in ^{235}U , one could calculate the quantity of fission products, which formed during the active life of the reactors. Soon after the discovery of Oklo, the scientific community realized that the site was an interesting natural analogue of a waste repository. The study of the site confirms the efficiency of the geological barrier for radionuclide confinement (e.g., the uranium remained trapped in the vein for 2 billion years!). The extraordinary confinement power of some minerals like apatites was also discovered in Oklo. Unfortunately, all results are not as clear. Since 2 GY, most radionuclides formed by the nuclear reactions have decayed, and it is difficult to disentangle the migration properties of these radionuclides from the ones of their daughters, which have in general very different chemical properties. The numerous hydrogeochemical changes the site has undergone since 2 GY also complicates the migration pattern (Pourcelot et al. 1999; Gurban et al. 2003; Gauthier-Lafaye 2002).

Chain nuclear reaction occurred spontaneously on the Earth during the only possible time window: before 2 GY, vegetal life had not produced enough free oxygen in the atmosphere to allow the development of a geochemistry of uranium based on redox, and the concentration of uranium deposits rich enough to become critical. After 1.7 GY, the depletion of ^{235}U in the natural uranium due to radioactive decay forbade criticality. The possibility of underground chain reaction is a consequence of the emergence of life, much like the present nuclear industry, which is a consequence of the presence of man!

3.3 Safety of Waste Disposal Facilities

Waste disposal in a deep geological repository will have a nonzero radiological impact for the public, even if the installation evolves as foreseen according to the reference scenario.

The main purpose of this section is to evaluate the order of magnitude of this impact, and, more generally, to explain how a safety evaluation of a geological repository can be made.

In order to make the performance assessment of a geological repository, one needs to estimate the radiological impact of the installation.

The method to estimate this impact is as follows:

1. Define scenarios for the evolution of the installation. A scenario is a chronological sequence of elementary phenomena (Features, Events, and Processes, FEPs). Several scenarios can be envisaged: the “normal evolution” scenario is the most probable one; altered scenarios describe abnormal evolutions of the repository, leading to a degradation of its performance (human intrusion, for instance, the digging of a well close to the repository; failure of one or several barriers, for example, defective sealings, or containments).
2. Model the travel of the radionuclides from waste to man. This travel can be divided in two parts: from the waste to the biosphere, through the geosphere; and through the biosphere to man. The first step evaluates an activity flow from the repository to the exutury (this activity flow is expressed in Bq/year). The second step evaluates the dose rate to the population for the various scenarios (the dose rate is expressed in mSv/year). This last step requires the definition of a biosphere, a reference population, and a critical group.

In all cases, the dose received by the most exposed part of the population should not exceed a predefined limit. In most countries, the upper limit for this radiological impact should be smaller than a fraction of the radiological impact due to natural radioactivity, i.e., ~ 1 mSv/year.

3.3.1 How to Evaluate the Radiological Impact of a Deep Geological Repository?

The three main indicators for the impact of a radioactive waste repository are the *activity* (in Bq/m^3) and *activity flux* (in Bq/s) at the exutory, and the *collective dose* (in Sv) to the population.

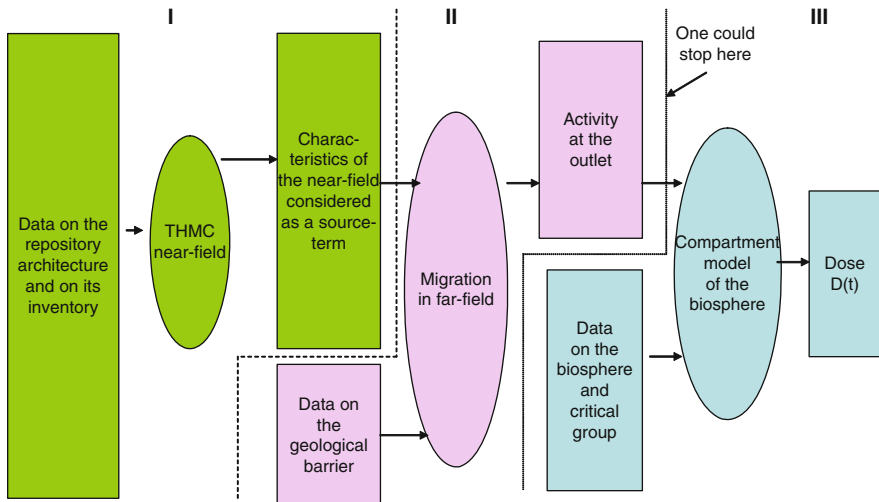

We have reviewed and modeled the elementary phenomena.

Now we arrange them together to evaluate successively

- The source-term
- The activity flux at the exutory, deduced from the source-term characteristics and from a transfer function
- The exposure of the population

► **Figure 123** shows the general scheme to articulate the models together to evaluate the impact of a geological repository.

- Data on the repository and on its content enable us to calculate the characteristics of the near-field, seen as a *source-term* (step I).
- One lets the radionuclides migrate from this source-term to calculate the *activity at the exutory*. This calculation requires the knowledge of the characteristics of the geological barrier (step II).
- From the activity at the exutory, one can then calculate a *dose* as a function of time. This calculation requires the definition of a biosphere and of a critical population (step III).

■ **Figure 123**

General view of the impact evaluation of a geological repository. The ellipses represent models; the rectangles represent the input or output data used or produced by the models

Step III is probably the most difficult part of the evaluation: the dose calculation is uncertain, dose factors are poorly known, and the definition of the biosphere and critical group can raise many discussions. Fortunately, two important indicators of the impact of the repository (the activity [in Bq/m³] and activity flux [in Bq/s] at the exutory) do not require the passage through this step.

Step I: Evaluation of the source-term

In the near-field, thermal, hydro, mechanical, and chemical effects are intricately coupled. Modeling the evolution of this near-field is difficult. Fortunately, the release rate of radionuclides in the near-field will be limited by the physicochemical phenomena described in ▶ Sect. 3.2: residual alteration rates of the confinement matrixes, or solubility limits of the RN themselves. With this remark in mind, one can attempt to model the near-field as a *maximum source-term*, even if we do not know in detail what happens in this zone. Altogether, we need to evaluate the properties of this source-term (geometry, concentration at the boundaries, duration of the activity) (▶ Fig. 124).

Step II: Migration of RN in the far-field

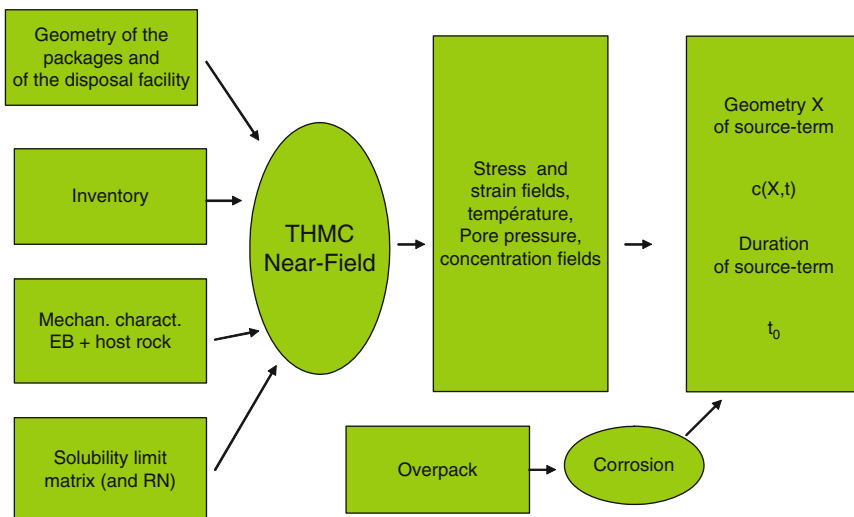

The geological barrier is represented by a few porous permeable, homogenized domains, whose characteristics are supposed to remain constant in time.

The transport of radionuclides is described by a linear sorption model (Kd) (▶ Fig. 125).

Step III: From the exutory to man

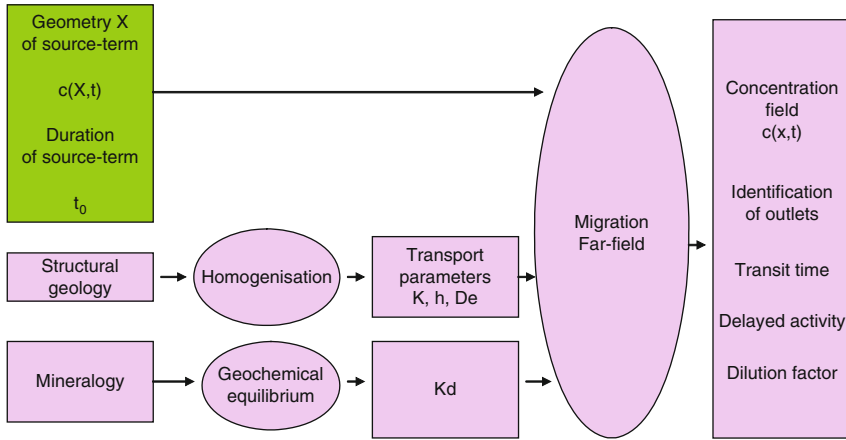

The evaluation of a dose to man requires the modeling of the travel of the radionuclides through the biosphere. This is the subject of radioecology (▶ Fig. 126).

The biosphere is modeled as several compartments, which can exchange radioactivity (usually, one assumes that the transfer coefficients between compartments depend linearly on the

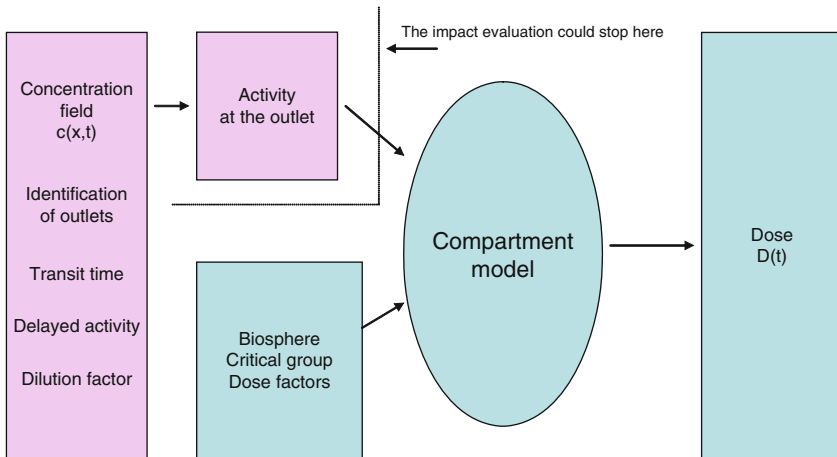

■ Figure 124

The impact evaluation of a geological repository (detail of step I, evaluation of the characteristics of the source-term)

■ Figure 125

■ Figure 126

The impact evaluation of a geological repository (detail of step III) from the exutry to man

radionuclide concentration). Compartments include rivers, lakes, air, soil, sea, and various kinds of plants and animals. The top compartment is the population, and, more precisely, the critical group, which is the part of the population liable to receive the highest dose (► Fig. 127).

■ **Figure 127**
 An example of compartment model describing the transfer of radionuclides from the geosphere to man, through the biosphere

■ Figure 128

Schematics of the repository and the migration path of the radionuclides from the repository to the exutury

3.3.2 Evaluation of the Order of Magnitude of the Activity at the Exutury for a Simplified Repository

In order to show the methodology of the evaluation, we propose to evaluate the activity at the exutury for a very simplified repository of vitrified waste. This exercise requires the modeling of the travel of the radionuclides from the repository to the exutury. As a prerequisite, this exercise requires the knowledge of the radionuclide inventory in the repository, the knowledge of the long-term behavior of glass, and the knowledge of the site hydrogeology and geochemistry. All these elements have been addressed previously in ► Sect. 3.2; now is the time to link them together.

Schematically, the travel of radionuclides from repository to exutury can be divided into two parts (► Fig. 128):

1. The travel through the host rock (in an aquitard): very slow, over a short distance (typically the thickness of the aquitard layer, i.e., about 100 m). In the present exercise, we shall assume that the radionuclides migrate vertically upwards.
2. The travel from the aquitard to the exutury (in an aquifer): faster, but over a large horizontal distance (typically the distance between the repository and the nearest river, i.e., about 10 km).

3.3.3 The Source-Term

In this example, for the sake of simplicity, we neglect the possible precipitation of all radionuclides (including actinides) in the geological medium. This hypothesis is conservative.

We assume that the glass alteration is a constant, equal to the residual alteration rate V_r (the notation is the same as the one used in ► Sect. 2.2 “glass long-term behavior”). In the residual

alteration regime, there is a congruent release of all RNs from the glass (same proportion of RN in the source-term as in the matrix).

With these assumptions, the source-term takes a very simple form: for each radionuclide i , it is defined by an activity flux at its boundary, expressed in Bq/s, and given by the expression:

$$\phi^i = V_r \cdot S \cdot A_{matrix}^i,$$

where S is the total surface area of glass, which undergoes alteration, and A_{matrix}^i is the activity of radionuclide i in one unit volume of glass.

The activity of the matrix is conveniently expressed as a function of the activity of radionuclide i in the waste generated by the production of a given amount of nuclear power.

Therefore, we pose

$$S \cdot A_{matrix}^i = W \cdot \sigma \cdot A_{specific}^i,$$

where σ is the specific surface area of the glass matrix (in m^2/m^3 , taking into account its degree of fragmentation), W is the total nuclear power whose production generated the waste (in TWhe), and $A_{specific}^i$ is the specific activity of radionuclide i generated per unit generated power (in Bq/TWhe).

The activity flux of the source-term is therefore

$$\phi^i = V_r \cdot W \cdot \sigma \cdot A_{specific}^i.$$

The RN flux described by this constant source-term will then migrate through the geosphere.

The release of radionuclides from the matrix lasts as long as the glass alteration goes on. The alteration time is thus given by

$$\tau_{alteration} = X/V_r,$$

where X is the typical size of the glass blocks, taking into account the degree of fragmentation of the package. Assuming a more or less regular shape for the glass blocks, X is related to σ , the specific surface area of the glass by $X = 6/\sigma$.

With realistic values for σ (250/m) and for V_r (10^{-15} m/s), we get $\tau_{alteration} = 1$ million years. The source-term thus produces radionuclides at a constant rate ϕ during the time $\tau_{alteration}$, of the order of 1 million years.

3.3.4 Transit Time from the Repository to the Exutory

In order to evaluate the transfer time from the repository to the exutory, we assume that the transport of radionuclides through the geosphere is mainly advective (► Fig. 129). The dominance of advection over diffusion has been justified earlier for large space scales (cf. ► Sect. 3.2 on the transit times through a barrier in diffusive and advective regimes). This dominance holds for both parts of the RN travel: through the aquitard and through the aquifer.

The transit time of the radionuclides from the repository to the exutory is the sum of the transit time through the engineered barrier and aquitard and the transit time through the aquifer. These two components can readily be evaluated using Darcy's law applied to these two different geological media.

$$\tau_{aquitard \text{ or } aquifer} = \left(\frac{X \cdot \omega}{K \cdot \text{grad}(h)} \right)_{aquitard \text{ or } aquifer}.$$

■ **Figure 129**
Radionuclide travel through the geosphere

With typical values for the transport parameters $X, \omega, K, grad(h)$ in aquitards and aquifers (cf. ▶ [Tables 14](#) and ▶ [16](#)), one gets the following orders of magnitude for the transit time of a perfect tracer through the geosphere.

The above evaluation of the order of magnitude of this transit time is robust: even though the actual pathway of the water may be very different from the one sketched here, the journey will always entail crossing at least one aquitard and one aquifer. Moreover, since the transit times through aquitard and aquifer have the same order of magnitude, a failure of one of these two barriers would not modify drastically the total transit time through the geosphere (▶ [Table 27](#)).

■ **Table 27**

Order of magnitude of the transfer time of a perfect tracer from the source-term to the exutory

Transport through engineered barrier and aquitard	$\tau_{aquitard}$	$\approx 70,000$ years (cf. ▶ Sect. 3.1)
Transport aquifer \rightarrow river	$\tau_{aquifer}$	$\approx 100,000$ years
Total	τ	≥ 0.1 million years

For sorbed radionuclides, the transit time is $R^i \cdot \tau$, where R^i is the retardation factor associated with radionuclide i .

3.3.5 Transfer Through the Geosphere

Here again, we assume that advection is the dominant transport mode through the geosphere.

The radionuclide travel through the geosphere can be represented as a transfer function in a pipe through which water and radionuclides flow from the source to the exutory (▶ [Fig. 130](#)). This pipe is somewhat abstract:

The water flux is not conserved along the pipe.

The activity per unit water volume is not conserved along the pipe.

But the activity flux ϕ (product of the water flux by the activity per unit volume) is conserved (or, more precisely, would be conserved if radioactive decay did not take place).

Figure 130 The transfer through the geosphere is modeled as a travel in a “pipe,” in which the activity flux Φ is conserved

This prescription of conservation of the activity flux along the pipe is valid only if no accumulation of RN occurs in the geosphere. This is consistent with the previously stated assumptions: no RN precipitation; and diffusion is neglected.

With this prescription, the activity flux transferred at the exutory for each radionuclide i is given by the following transfer function:

$$\begin{aligned} \phi_{exutory}^i(t) &= 0 \quad (t < R^i \cdot \tau) \\ \phi_{exutory}^i(t) &= \phi_{source-term}^i(t - R^i \cdot \tau) \quad (R^i \cdot \tau < t < \tau_{alteration}) \\ \phi_{exutory}^i(t) &= 0 \quad (t > \tau_{alteration}) \end{aligned}$$

3.3.6 Activity at the Exutory

The activity at the exutory (expressed in Bq per unit volume of water) is simply deduced from the activity flux at the exutory, by

$$A_{exut}^i = \phi_{exut}^i / Q, \text{ where } Q \text{ is the flow rate of the exutory.}$$

Therefore,

$$A_{exut}^i(t) = \left(\frac{V_r \cdot W \cdot \sigma}{Q} \right) * A_{specific}^i(t - R^i \cdot \tau) \quad (R^i \cdot \tau < t < \tau_{alteration}).$$

Because of the *delay*, the activity at the exutory is zero for early times. The first radionuclides arrive at exutory around time $t = R^i \cdot \tau$, where R^i is the retardation factor of radionuclide i due to sorption.

Figure 131
The activity at exutory

Because of the *decay*, the maximum activity at the exutory is smaller than the one we would have had for a non-radioactive tracer, by a factor $\exp(-R^i \cdot \tau / T_{1/2}^i)$ (👉 Fig. 131).

We define the “delayed activity” as the specific activity of radionuclide *i* in the matrix at time $R^i \cdot \tau$:

$$\text{Delayed activity} \equiv A_{\text{specific}}^i(R^i \cdot \tau).$$

For each radionuclide, the delayed activity can be read on a diagram like the one shown in 👉 Fig. 132. It is the activity, which remains after time $R^i \cdot \tau$ (circles on the diagram), where $R^i \cdot \tau$ is the duration of the travel of the considered radionuclide through the geosphere.

Figure 132
The delayed activity of fission products

Here, a value of $\tau = 0.1$ million years has been assumed. A retardation factor of 5 has been assumed for Tc, 30 for Cs, 1 for Se, and 30 for Sr.

The delayed activity of ^{90}Sr (a fission product with a period of only 28 years) is zero. Only long-lived radionuclides can have a significant delayed activity.

Three important long-lived fission products (^{99}Tc , ^{135}Cs , ^{79}Se) found in glasses have been represented on the diagram. The highest delayed activity is the one of ^{99}Tc , but this result is valid only under the hypothesis of migration in oxidizing conditions, where the Tc is under the form of pertechnetate ion. In the reducing conditions, which will prevail in a repository, the retardation factor of Tc is of the order of 100,000, and the delayed activity of Tc drops to zero. Thus remain only ^{135}Cs and ^{79}Se , the two “winners” of the radionuclide survival race through the several barriers of the repository (► [Table 28](#)).

Table 28
The delayed activity of some important radionuclides

	Retardation factor R	Initial activity $A_m(t=0)$ (Bq/TWhe)	Delayed activity $A_m(t=R \cdot \tau)$ for $\tau = 0.1$ MA (Bq/TWhe)	Remarks
^{135}Cs	30	5.510^{10}	10^{10}	
^{99}Tc	5	1.810^{12}	2.10^{11}	$R = 5$ if ion TCO_4^-
	$> 10^5$		0	$R > 10^5$ if other chemical forms
^{79}Se	1	2.510^9	2.510^9	
^{242}Pu	$> 10^4$	2.10^{11}	0	
^{237}Np	$> 10^4$	2.610^{10}	0	No actinides will come out of the repository
^{229}Th	$> 10^5$	0	0	

Laboratory experiments (Dossier ANDRA and Dossier 2005) suggest that the actinides are very efficiently adsorbed on many minerals present underground (especially clay minerals), and are therefore almost immobile in an underground environment (this would correspond to an infinite retardation factor R). Here, we have taken the retardation factors given by ANDRA in ANDRA and Dossier (2005), Dossier argile. This retardation is more than enough to “kill” the actinides; radioactive decay occurs before the actinides make it through the geological barrier.

The maximum activity arriving at the exutory is given by

$$A_{exut\ max}^i = \left(\frac{V_r \cdot W \cdot \sigma}{Q} \right) * A_{specific}^i(t = R \cdot \tau). \tag{3}$$

For each radionuclide, this maximum activity occurs a time $t = R \cdot \tau$. This depends on the retardation factor of the considered radionuclide, that is, 0.1 million years for ^{79}Se and 3 million years for ^{135}Cs .

This activity is maximum because for earlier times, the radionuclides have not yet reached the exutory; and for later times, the radioactive decay reduces the activity.

With realistic figures for V_r , W , σ , Q and $A_{specific}^i$,

$V_r = 10^{-15}$ m/s, corresponding to the order of magnitude of the secondary phases precipitation rate in a clay environment (Frugier et al. 2009)

$\sigma = 250$ /m (taking into account the degree of fracturation of glass in R7T7 packages)

$Q = 4$ m³/s, order of magnitude of the volumic flow rate of the nearest river flowing closer than 10 km away from the repository, in a hydrographic network typical of temperate climate

$$A_{specific}^{(R,\tau)} = 10^{10} \text{ Bq/TWhe for Caesium 135, we obtain :}$$

$$A_{exut \max}^{Cs135} = 6.10^{-4} \text{ Bq} \cdot \text{m}^{-3} / \text{TWhe}$$

For a typical repository containing the vitrified waste corresponding to 50 years of activity of a fleet of 60 GW light water reactors ($W = 2.10^4$ TWhe), the maximum caesium 135 activity at the exutory will be of the order of 10 Bq/m³.

One can compare this “added” activity to the activity of a natural mineral water, which can be as high as 10,000 Bq/m³.

Equation (3) clearly shows the important factors, which determine the activity at the exutory:

- As expected, the activity at the exutory is proportional to the RN inventory in the repository.
- The residual alteration rate of glass is of prime importance because the activity at the exutory is proportional to $V_{residual}$.
- The degree of fracturation of the glass is also very important, for the same reason.
- The characteristics of the geological barrier (permeability, hydraulic gradients) are also important because they determine, together with the retardation factor R , the travel time of the radionuclides, and, subsequently, the delayed activity of the RN.

Additionally, the equation also shows the unimportant factors: the activity at the exutory, as given by (3), is quite insensitive to the details of the travel of the radionuclides in the geosphere: the only significant quantity is the total travel time through the geosphere.

It is also quite insensitive to the coupled THMC phenomena taking place in the near-field: the only significant outcome of these phenomena is the value of the residual alteration rate V_r .

3.3.7 Evaluation of the Order of Magnitude of the Dose to Man

The radiological impact of the repository can now be evaluated. Continuing in the same line of extreme simplicity of the above exercise, we assume here that the main contributor of the dose to man is drinking water, and we neglect all other contributions coming from other compartments of the biosphere; with a consumption of 1 m³/year, and a caesium 135 ingestion dose factor of 2.10^{-9} Sv/Bq (cf. ➤ Table 6 in ➤ Sect. 1, ICRP 72), the maximum annual impact of caesium 135 will be

Figure 133 Result of the international exercise PAGIS “Performance Assessment of Geological Isolation Systems,” evaluation of the radiological impact of a deep geological repository of vitrified HALL waste. The impact depends on the nature of the host rock, and on the studied scenario, but in all cases, this impact is small (microsieverts/year for worst cases, i.e., 1,000 times less than the total dose induced by natural radioactivity), local, and delayed (migration is so slow that nothing arrives at the exutory before 100,000 years)

$Dose = A_{exut}^{Cs135} \cdot W \cdot Consumption \cdot DF^{Cs135} = 2 \cdot 10^{-8}$ Sv/year in the case of the above repository, containing the waste production from 50 years of exploitation of a 60 GW light water reactor fleet. . . . For a drinker 3 million years from now!

The small exercise proposed above gives orders of magnitude of released activities and timescales, but it is by no means sufficient to evaluate the radiological impact of a repository. More detailed simulations have been made using meshed codes, in the frame of national research programs. International benchmarks have also been performed to compare the modeling tools, and their results (PAGIS, EVEREST, SPA) (Fig. 133).

The impact of *altered scenarios* can be much higher than the one of the *reference scenario*; and other radionuclides, with shorter lifetime, can come into play. In granite, the impact of these altered scenarios can be higher than the natural dose. In clay, the situation is more favorable. Even for the altered scenarios, the impact is well below the dose induced by the natural background radiation, and below the legal limits.

Altogether, thanks to the efficiency and redundancy of its multiple barriers, a geological repository of radioactive waste is a robust concept. The radiological impact of deep geological disposal should remain small, local, and postponed.

4 Conclusions

4.1 Waste: The Achilles' Heel of the Nuclear Industry?

The nuclear waste issue is often presented by the media and seen by the public as an unsolved problem that hampers the future of nuclear energy. However, the nuclear industry took care of this problem very early on and has developed proven technical solutions.

4.2 Technical Solutions and Political Advances for Waste Management

While large volumes of short-lived radioactive wastes are already handled by the nuclear industry in surface storage facilities, the management mode of high-activity, long-lived waste has not been decided in detail and is still under study in all nuclear countries. Scientific knowledge is in progress, technical solutions are emerging, in a context where science and technique interact strongly with social and economical issues. Many advances have been made during the last 20 years in fields as varied as partitioning, transmutation, waste conditioning, storage, and underground disposal.

4.3 The Main Principles of Nuclear Waste Management

The following principles pertaining to domestic waste management also apply to nuclear waste: reducing the dangers induced by waste, decreasing its volume, partitioning the waste into homogeneous categories, and recycling.

With a closed fuel cycle, waste management from its production to its final destination looks like a chain whose links are treatment recycling, conditioning, storage, and disposal of the final waste. With the open cycle option, the first link is absent.

4.4 Recycling: The First Link of the Waste Management Chain

The first option is thus to close the fuel cycle. This option has a very important influence on the nature of the waste produced, as well as on its ulterior management.

The alternative options (direct storage of spent fuel or specific conditioning of separated actinides) have been studied throughout the world. These options may have distinct advantages for the nuclear industry considered as a whole, but as far as waste management is concerned, the closed fuel cycle is clearly more favorable, because it offers the possibility of considerably reducing the radiotoxic inventory, and putting the waste into a stable and safe form. Recently, the validity of this option has been further reinforced by the rise of the price of natural uranium, which provides a powerful incentive to save on fissile matter.

In the long run, the probable development of fourth-generation nuclear systems will make the closed fuel cycle compulsory. With these new systems, one can hope to reduce further the waste toxicity by transmuting actinides.

Indeed, the nature of the final nuclear waste (by definition non-recyclable) depends on the nuclear technology at hand; final waste 30 years from now may well be different from the present

final waste. For example, it may be possible to further reduce the radiotoxicity of vitrified waste by eliminating some radionuclides (e.g., minor actinides) from the inventory. The exclusion of these radionuclides from the waste would also reduce the exothermicity of the waste, with a subsequent simplification of the waste management. This objective of a cleaner and cooler waste is the main stake for the research on partitioning and transmutation. However, in order to gain a substantial benefit in terms of radiotoxicity, one needs to transmute the separated radionuclides. The technology is already at hand for recycling plutonium, but research is still needed to make the recycling of other radionuclides viable on the industrial scale.

4.5 Transmute, Recycle: Where Is the Limit?

It is already clear that fission products are not readily transmutable, neither with the present nuclear reactors, nor with the fast reactors envisaged for the future. Whatever the nuclear system, fission products will therefore remain present in the final nuclear waste. The issue of actinides is less certain, since the future of these radionuclides depends on the nuclear reactors available, as well as on the policy of fuel cycle chosen. With the present reactors, plutonium can be recycled under a MOX form, but minor actinides tend to accumulate in the waste. Fast reactors might offer the possibility of transmuting these radionuclides, but this transmutation will remain slow and difficult. Moreover, putting minor actinides in the fuel complicates both fuel fabrication and reactor operation, and one can doubt that those responsible for the facilities will be very enthusiastic about taking on this burden. The actinides are very insoluble and immobile in geological media, and could go in an underground repository without compromising its safety. The only important stake for the transmutation of actinides is the relief of the waste thermal loading and toxicity, with the associated reduction of the size and cost of the repository.

The first two links of the waste management chain, fuel processing and waste conditioning, work well together, and are already implemented in some countries (e.g., France, at the La Hague facility, or Japan at Rokkasho-Mura). Once conditioned under the form of a package, one still has the problem of deciding what to do with the package. Thanks to their chemical and mechanical stability, the present conditioning forms (concrete, metallic compacted waste, glass) are well adapted to storage, eventually followed by an underground disposal for long-lived waste. These links of the waste management chain are coherent, and this coherence will be kept with the development of fourth-generation nuclear systems, since future reactors will call for a closed fuel cycle with processes of treatment of the spent fuel that will complete rather than replace the existing process.

4.6 Waste Conditioning: The Essential Second Link in the Chain of Waste Management

The industrial processes for the conditioning of nuclear waste are already ripe and operating. Basic research has permitted a good understanding of the physicochemical mechanisms at play during both the fabrication and the aging of the conditioning matrices, glass, concrete, or bitumen. The safety study of waste management relies on this scientific knowledge of the long-term behavior of the confinement matrices.

Suitable conditioning forms have been developed for all types of wastes.

Solutions of fission products and minor actinides, which possess by far the highest radiotoxicity, are vitrified in facilities, which work on the industrial scale. The quality of the glass obtained is well established. For instance, the R7T7 glass developed for the confinement of fission products from the processing of light water spent fuel has become a world reference. There are probably more scientific articles on this glass than on any other industrial glass.

Structure waste from the spent fuel bundles is compacted and introduced in steel canisters identical to the ones used for glass casting. The radiological impact of this waste form in a geological repository would probably be very small.

Technological waste associated with the exploitation of nuclear facilities is conditioned in concrete. Most of these wastes are short-lived, low or medium activities. In many countries, including France, this waste is already stored in dedicated surface or subsurface facilities. A wide spectrum of concrete formulae has been developed to fit the diversity of the waste to be conditioned, solid or liquid. These concrete packages are well characterized, and a sufficient knowledge of their alteration mechanisms enables one to guarantee their confinement properties.

4.7 What To Do with the Final Waste?

Radioactivity possesses two important characteristics, which might somewhat mitigate the fear it inspires: it is easy to detect, even at very low levels. A unique disintegration can be detected, whereas billions and billions of molecules must be present to detect chemicals. Once detected, it is relatively easy to protect oneself from the radioactivity, by combining shielding, distance, limitation of the exposure time, and radioactive decay.

The problem of the final nuclear waste then boils down to confining the radionuclides in an isolated, shielded installation, during a time long enough for radioactive decay to operate. This is the idea behind both storage and underground disposal facilities.

4.8 Interim Storage, A Temporary Solution That Gives Flexibility to the Management of Waste

Whatever the fate envisaged for the spent fuel, this spent fuel must, at first, be stored temporarily. Countries that have chosen the open fuel cycle option must store the spent fuel before its disposal; the ones which have opted for the closed fuel cycle option must store it a few years, in order to let it cool before its processing. The vitrified final waste is then stored temporarily. In all cases, storing is a temporary solution, which provides flexibility for the management of waste, because it permits one to let the waste cool down, thereby decreasing its thermal load in the ulterior disposal facility, and the cost of the installation. However, the safety of storage facilities is less well assured than that of an underground disposal facility, because these installations demand active maintenance, and are more vulnerable to human intrusions. Even if economical arguments plead in favor of a long-term interim storage, public policy would be well advised to limit the duration of this storage to a reasonable maximum.

4.9 Underground Disposal, The Last Link of the Chain: A Final Place for the Final Waste

Last but not the least, one has to find a final place for the final waste. The deep geological underground disposal seems to be the only long-term solution, which does not require a continuous control by the society. A general consensus has been reached on this issue, under the aegis of the International Agency for Atomic Energy (IAEA) and of the Nuclear Energy Agency of OECD. No alternative solution has appeared.

Disposal in a geological repository will always be a rare and expensive resource; hence there is a need for reducing the volume and the thermal power of the waste as much as possible. These two parameters largely determine the repository capacity, and therefore, its duration of exploitation and its cost. The processing of spent fuel is already a major step toward this reduction, since it involves the removal of the uranium (which represents 90% of the mass of the spent fuel) and the removal of the plutonium (which represents the major contribution to the total waste radiotoxicity). The American Advanced Fuel Cycle Initiative (AFCI) is exemplary in this respect. After more than 20 years of efforts leading to the project of disposal of spent fuel in the Yucca Mountain repository, the US Department of Energy is reconsidering the optimization of its use, and the nature of the objects that will be disposed of.

4.10 Underground Disposal: A Simple and Robust Concept

The safety of the underground disposal relies on its capacity to confine radionuclides within an underground facility, until radioactive decay has brought their radiotoxicity down to an acceptable level. The safety demonstration of such an installation will rely *in fine* on the confidence that the installation will behave as foreseen. Studies have thus been made to better understand the evolution of the waste packages in an underground situation, and the migration of radionuclides through the man-made and geological barriers that isolate them from the biosphere. Removing from the waste the long-lived radionuclides, which contribute most to its long-term radiotoxicity, could significantly shorten the duration over which the waste will remain dangerous. This could also reduce the scientific uncertainties associated with long timescales. This option will only be open if and when one is able to separate and transmute minor actinides.

The concept of underground disposal is flexible. Initially designed with the idea of definitively and irreversibly getting rid of the waste, the underground disposal concept imposed itself in all nuclear countries, with a major evolution in its philosophy: the idea of reversibility (which means being able to retrieve the waste from the repository after some time) seems to have become a prerequisite for public acceptance of these installations. It contributes to modifying the image of underground repositories, without changing their general conception too much.

Thanks to the efficiency and the redundancy of its barriers, underground disposal is also a robust concept. The radiological impact of a deep geological waste disposal evolving should normally remain very small, local and delayed. However, the altered evolution scenarios, which are by definition unpredictable (especially those associated with human intrusions) can have a larger impact.

Strictly speaking, the safety of a deep geological repository cannot be *demonstrated*, because the very long timescales make direct experiments inaccessible. Therefore, the objective must be

more modest: showing by means of partial experiments that the main physical and chemical phenomena at play are understood and mastered, and therefore validating the main pieces of the modeling of repository evolution.

All national and international studies show that the impact of a repository on man and on the environment will remain negligible, even in the very long term. In order to convince, it will be necessary to build confidence with convergent indications showing that all the possible events liable to affect the repository have been envisaged and are found to be within acceptable limits... in short, that the repository conception is well mastered.

This confidence is already there among most of the specialists, but not in the public. And, as long as public opinion doubts, the politicians will tend to postpone their decisions. The example of Finland and Sweden, two countries that decided democratically to build geological repositories for nuclear waste, shows that it is possible to overcome this obstacle.

So, even if the majority of the public still thinks the opposite, one can conclude: "We know what to do about nuclear waste!"

4.11 Let Us Behave Responsibly, Let Us Try To Be Sensible

We have inherited nuclear waste from our predecessors, and we produce some waste ourselves. We cannot transmit this burden to our children. That is why we must put all our efforts into minimizing final waste, and disposing off this waste in the best safety conditions, with the technologies available today. The technologies exist, but their implementation requires a political decision. Contrary to a view widespread within the public, much progress has been made toward technically and socially acceptable nuclear waste repositories. Most of the experts agree, but the public and the political circles are still reluctant, and must be convinced by a faultless process of confidence building. In any case, one thing appears very clear to the author: it would be an irresponsible attitude to store this waste for a long time, awaiting a hypothetical scientific advance. Science also has its limits!

As shown above, even if one considers only the scientific and technical aspects, waste management is a very pluridisciplinary problem. Knowledge in reactor physics is needed, because the nature of the waste produced depends on the reactors used; knowledge in chemistry, to determine which radionuclides are left in the waste after the processing of the fuel; in physico-chemistry and material science to understand waste conditioning and the long-term behavior of waste; in engineering to master the thermal and aerodynamic phenomena at play in the storage installations; in mining engineering to design the underground repository; in earth sciences to understand and predict the long-term evolution of these installations; in radioprotection to evaluate the impact of all the processes and installations on man and environment. The global view on all these subjects is shared by very few people. Nonetheless, a global vision is necessary to keep research and industry focused on the main priorities, to keep the common sense. This common sense is already under stress when it comes to choosing the right options for the management of nuclear waste; even more so when one must give its right importance to the problem of nuclear waste, in the hierarchy of the problems caused by industrial development.

A nuclear renaissance seems inevitable at present: this makes the issue of nuclear waste management even more important. This problem is not only a technical one, it has also economic

and social implications. If this document has given to the reader the technical elements enabling him to forge for himself not only an engineer's vision, but also a citizen's opinion on nuclear waste management, it will have reached its aim.

5 Glossary

Actinides	The rare earth element group with atomic numbers 89–103, corresponding to electron subshells 5f and 6d. Actinides have very close chemical properties.
Activation (radioactivation)	Action tending to make certain nuclides * radioactive when bombarded by neutrons * or other particles, particularly within reactor structural materials.
Activity	1. For a radioactive substance: the number of spontaneous nuclear transitions per unit time within a radionuclide or mixture of radionuclides. It is expressed in becquerels * (Bq). A becquerel is equivalent to one disintegration per second. 2. In a chemical reaction: the chemical activity of a species corresponds to the active concentration of this species. Electrostatic interactions between the various species within a solution reduce their reactivity potential. Therefore, the concentration term must be corrected with a coefficient lower than one unit, the so-called activity coefficient. Substituting activity for chemical species concentration allows the mass-action law to be applied.
Advection	The movement or transfer of a substance, heat, etc. by the motion of the fluid medium (e.g., air or water) in which it is present.
Alpha	See Radioactivity .
Alpha particle (or <i>alpha radiation, alpha ray</i>)	A positively charged particle made up of two neutrons and two protons. It is the least penetrating of the three forms of radiation most commonly encountered.
Amorphous	Of a solid with a disordered crystalline structure.
Assembly	See Fuel assembly .
Barrier (confinement)	See Confinement barrier .
Becquerel (Bq)	A unit of radioactive decay equal to one disintegration per second. 37 billion becquerels are equal to 1 curie (Ci). 30,000 disintegrations per second occur in a household smoke detector. As the becquerel is a very small unit, large multiples are often used: mega-, giga-, or terabecquerel (MBq, GBq, and TBq, respectively).

Beta particle (or beta radiation, beta ray)	An electron (or a positively charged particle with a mass equal to that of an electron) emitted from a radionuclide. It means less damage than the same dose of <i>alpha</i> radiation, but has a higher penetrating power. A <i>beta</i> radiation may be stopped by a thin sheet of metal or plastic.
Biosphere	Ecosystem encompassing all living organisms and their environment (soils, water, atmosphere).
Burn-up (or burn-up, burn-up fraction, burn-up rate)	Strictly speaking, it corresponds to the percentage of heavy atoms (uranium and plutonium) that have undergone fission * over a given time interval (referred to as the " burn-up fraction "). It is commonly used to determine the thermal energy produced in a reactor per unit mass of fissile * material, between fuel loading and unloading operations, expressed in megawatt.days per ton (MWd/t). (see also Specific burn-up *). The discharge burn-up * is the value for which a fuel assembly must be effectively unloaded (i.e., after several irradiation cycles).
Capture	The capture of a neutron by a nucleus. The capture is said to be "radiative" if it is immediately followed by emission of gamma radiation. It is said to be "fertile" if it induces the generation of a fissile nucleus.
Cask	A vessel for the transport and/or storage of spent fuel and other radioactive materials. The cask serves several functions. It provides chemical, mechanical, thermal, and radiological protection, and dissipates decay heat during handling, transport, and storage.
Clad (or cladding)	The envelope surrounding the fuel material, intended to ensure its insulation and mechanical resistance within the reactor core.
Cleanup (radioactive)	All the operations intended to reduce radioactivity in a facility or at a site, especially by decontamination or equipment removal.
Conditioning (of radioactive waste)	All the successive operations to be performed to bring radioactive waste to a stable, safe form suitable for its future management, whatever it may be: storage *, transmutation *, or disposal *. In particular, these operations may include compaction, embedding *, vitrification *, and enclosing in containers (packaging).
Confinement barrier (or containment barrier)	A device able to prevent or limit dissemination of radioactive materials.

Containment barrier	See Confinement barrier .
Contamination (radioactive)	See Radioactive contamination .
Critical group	A group of members of the public, which is reasonably homogeneous with respect to its exposure for a given radiation source and given exposure pathway and is typical of individuals receiving the highest effective dose or equivalent dose (as applicable) by the given exposure pathway from the given source.
Criticality	A configuration characteristic of a mass of material containing fissile elements, and possibly other elements, with a composition, proportions, and a geometry such that a fission chain reaction * can be maintained within it.
Decay (radioactive)	The transformation of a radionuclide into different nuclides by spontaneous emission of <i>alpha</i> , <i>beta</i> , or <i>gamma</i> radiation, or by electron capture. The final product is a nucleus of lower energy and higher stability. Each decay process has a well-defined radioactive half-life.
Decontamination (radioactive)	See Radioactive decontamination .
Deep geological disposal (of radioactive waste)	See Disposal (of radioactive waste)*.
Delayed activity	The specific activity of a given radionuclide in its original confinement matrix after a time equal to its transit time between the repository and the exutory .
Direct disposal	The act of sending spent fuel to a disposal facility without going through the steps of treatment and recycling.
Discharge burn-up	See Burn-up *.
Disposal (of radioactive waste)	The action of radioactive waste emplacement in a facility specifically laid out to confine it in a potentially permanent way. The disposal facility in which waste is placed without intent to retrieve it is called repository . Retrieval would still be possible, however, in the case of a reversible disposal (see also Storage *). Deep geological disposal of radioactive waste is the disposal of such waste in an underground facility specifically laid out for this purpose. The underground disposal facility is referred to as a deep repository or a geological repository.
Distribution coefficient, Kd	The ratio of the amount of substance sorbed on a unit mass of dry solid to the concentration of the substance in a solution in contact with the solid, assuming equilibrium conditions.

Dose	A general term for the amount of energy from radiation that is absorbed in a specific mass.
Effluents	The residues of a chemical treatment under liquid or gaseous form. In some cases these unwanted residues are released to the environment. Another option widely practised in the nuclear industry is separating the toxic fraction and condition it into a tailored matrix so that the remainder may be released with no significant harm to the environment. Radioactive waste discharges to the environment are subject to authorization and control.
Embedding (or immobilization US, immobilization UK, encapsulation) (of radioactive waste)	The immobilization of radioactive waste through fixation within a material in order to obtain a solid, compact, and stable product, which is physically indispersible.
Encapsulation (of radioactive waste)	See Embedding (of radioactive waste)
Exutory	The compartment of the biosphere, which firstly receives the radionuclides released by a waste repository . In the scenario describing the normal evolution of the repository, the exutory is generally a nearby river.
Fast neutron reactor (or fast reactors)	Referred to in French as “RNR” (standing for <i>Réacteurs à Neutrons Rapides</i>).
FEP (Features, Events, Processes)	Elementary phenomena in the evolution of a waste storage or disposal facility.
Fertile	Refers to a material the nuclei of which yield fissile * nuclei when they absorb neutrons. This is the case with uranium-238, which yields plutonium-239. Otherwise, the material is said to be sterile.
Fissile	Refers to a nucleus capable of undergoing fission * through neutron * absorption. Strictly speaking, it is not the so-called fissile nucleus that undergoes fission, but rather the compound nucleus formed after neutron capture.
Fission	The splitting of a heavy nucleus into two fragments of approximately equivalent masses. This transformation, a special case of radioactive decay in some heavy nuclei, releases a large amount of energy and is accompanied with neutron and <i>gamma</i> radiation emission. The fission of the so-called fissile heavy nuclei can be induced by a collision with a neutron.
Fission products (FPs)	Nuclides * generated either directly through nuclear fission, or indirectly through the disintegration of fission fragments.

Fly ash	The pulverulent residues resulting from combustion. They fall into two categories: calcium fly ash arising from the incineration of some lignites recovered in thermal power plant scrubbers, and coal fly ash arising from pulverized coal combustion, which mostly contain silica and alumina in a glassy form. Fly ash may be used as additives in concretes.
FPs	See Fission products .
Fuel	The constituent material of a nuclear reactor core, which contains the fissile * nuclides maintaining the chain reaction * in the core.
Fuel assembly	In the core of a water reactor, fuel rods are gathered together in clusters of suitable rigidity, which are set in place with a definite position in the reactor core. The so-called assembly is the whole of this structure, grouping 100 to a few hundred rods, which is loaded into the reactor as a single unit.
Fuel cycle	The industrial operations which fissile * materials are subjected to. The cycle includes ore mining, fissile material concentration, enrichment, fabrication of fuel elements, fuel use in reactors, spent fuel treatment, waste conditioning, and the disposal of the resulting radioactive waste *.
Fuel pellet	See Pellet (fuel) .
Fugacity (for a gaseous substance)	An expression of chemical activity * (see acceptance 2). The fugacity of a gas equals its partial pressure weighed by its activity coefficient. This is also the pressure that the real gas would have if behaving as an ideal gas.
Gamma radiation (or <i>gamma rays</i>)	High-energy, short-wavelength, electromagnetic radiation emitted from atomic nuclei. It can be stopped by a sufficient layer of lead, concrete, or other materials.
Geological repository	See Disposal (of radioactive waste)*.
Geosphere	Those parts of the lithosphere not considered to be part of the biosphere . In radioactive waste management, usually used to distinguish the subsoil and rock from the soil that is part of the biosphere. See also biosphere.
Half-life	The time it takes for half the initial number of radioactive * atoms in a radioactive nuclide sample to disappear by spontaneous decay.
Immobilization (or immobilization UK) (of radioactive waste)	See Embedding (of radioactive waste).

Instant release fraction	Refers to the radionuclide fraction likely to be released very rapidly from a waste on contact with water.
Inventory (of radionuclides)	See Radionuclide inventory .
Ionizing radiation (or ionizing radiation UK)	Radiation capable of producing ions when it passes through matter.
Isotopes	The different forms of atoms of the same chemical element, the nuclei of which have an identical number of protons, but a different number of neutrons (i.e., the same atomic number, but different atomic masses). Uranium-238 and uranium-235 are uranium isotopes. Isotopes may be stable (i.e., not decay spontaneously) or unstable (i.e., decay spontaneously emitting ionizing radiation).
Leaching	The contacting of a solid body with a liquid with the purpose of extracting some elements. By extension, refers to any experiment focusing on the alteration of a solid in a liquid.
Major actinides	Heavy nuclei of uranium and plutonium occurring or formed in nuclear fuel.
Minor actinides	Heavy nuclei formed in a reactor through successive neutron captures from the fuel nuclei. These isotopes * mainly are neptunium (237), americium (241, 243), and curium (243, 244, 245).
Mixed OXide fuel	See MOX .
MOX (<i>mixed oxides</i>) (or Mixed OXide fuel)	A nuclear fuel containing Mixed OXides of (natural or depleted) uranium and plutonium.
Nuclear waste	An unusable residue arising from nuclear energy utilization.
Package (spent fuel)	Conditioned spent fuel in a form suitable for transport, storage and/or disposal.
Package (waste)	The product of conditioning that includes the waste form and any container(s) and internal barriers (e.g., absorbing materials and liners), prepared in accordance with the requirements for handling, transport, storage, and/or disposal.
Partitioning	See Separation .
Pellet (fuel)	A small cylinder made up of ceramic consisting of uranium, plutonium, or other actinides, which is used as nuclear fuel and stacked within a clad * to make up a fuel rod .
Potential radiotoxicity (of a certain quantity of radionuclides, e.g., in waste)	Radionuclide inventory multiplied by ingestion dose factor, indicating the potential harmfulness of a given quantity of radionuclides under accident conditions.

PWR	<i>Pressurized Water Reactor.</i>
Pyrochemistry	High-temperature chemistry (several hundred degree Celsius). Pyrochemistry does not involve water or organic molecules, only liquid metals and molten salts.
Radioactive cleanup	See Cleanup (radioactive) .
Radioactive contamination	The undesirable presence of a radioactive substance on the surface of or within a medium.
Radioactive decontamination.	Partial or total removal of radioactive contamination through methods that allow contaminating materials to be recovered in a controlled way.
Radioactive half-life	See Half-life (radioactive) .
Radioactive waste	Any radioactive substance for which no subsequent use is planned or contemplated. Ultimate radioactive waste is the radioactive waste, which can no longer be treated under current technical and economic conditions, especially through extracting their valuable content or reducing their polluting or hazardous character.
Radioactive waste disposal	See Disposal (of radioactive waste).
Radioactivity	The property of some isotopes with an unstable nucleus to spontaneously emit <i>alpha</i> and <i>beta</i> particles or <i>gamma</i> radiation. This term more generally designates the emission of radiation accompanying the decay * of an unstable element.
Radiolysis	The breakdown of molecules by ionizing radiation.
Radiolytic species	Products arising from water radiolysis * by ionizing radiation. They fall into two categories: radical species (e_{aq}^- , $\bullet OH$. . .) and molecular species (H_2 , O_2 , H_2O_2 . . .). Radiolytic yields associated with the generation of the various species depend upon the radiation type through linear energy transfer.
Radionuclide	An unstable nuclide * of an element, which spontaneously decays emitting radiation.
Radionuclide inventory	Quantities of fission products and actinides contained in irradiated fuel, generally expressed in Bq/gIHM (Becquerels per gram of initial heavy metal) or g/tIHM (grams per ton of initial heavy metal). These quantities and the associated isotopic spectra depend on various parameters, such as fuel type and irradiation conditions (burn-up, etc.). Average inventories are calculated at a given date using computer codes. Reversely,

	distribution of radionuclide inventories, which depends on irradiation conditions and fuel thermal behavior, requires the implementation of characterization tools (electron microscope).
Radiotoxicity (potential)	See Potential radiotoxicity .
Recycling (or recycle)	Reuse in a reactor of nuclear materials derived from spent fuel treatment *.
Repository	See Disposal (of radioactive waste).
Reprocessing	See Treatment (of spent fuel).
Rheology	The study of the deformation and flow of materials. It includes the study of viscosity, elasticity, and plasticity.
Rim effect (or rim)	See Rim zone .
Rim zone	The restructuring of a zone on the very edge of the pellet as a result of irradiation and thermal gradient.
Rod	A small-diameter tube closed at both ends, making up the core of a nuclear reactor and containing fissile, fertile, or absorbing material. When containing fissile material, the rod is a fuel element.
Scenario	Chronological sequence of elementary phenomena (FEPs) in the evolution of a waste storage or disposal facility.
Separation	A chemical process among treatment * operations through which the various constituent elements of spent fuel are separated. The PUREX process isolates uranium and plutonium. Other more advanced chemical processes (DIAMEX, SANEX, GANEX) are currently being studied to separate actinides from lanthanides, or actinides from one another (which is referred to as partitioning).
SF	See Spent fuel .
Sorbed	See Sorption .
Sorption	The light, reversible fixation of an atom or a molecule onto a solid surface.
Source term	The nature and quantity of radioactive products released or likely to be released from a nuclear facility or a package of radioactive materials. In particular, the “source term” used in computational models can help evaluate the consequences of an accidental radioactive release into the environment.

Specific burn-up (or specific burn-up, burn-up rate, burn-up)	The total amount of energy released per unit mass in a nuclear fuel. Generally expressed in megawatt × day per ton (MWd/t).
Spent fuel (or spent nuclear fuel, SF)	The fuel assemblies definitively removed from a nuclear reactor after a period of useful energy output. They are also referred to as “irradiated fuel.”
Spent fuel treatment	See Treatment (of spent fuel).
Spent nuclear fuel	See Spent fuel .
Storage (of radioactive materials or waste)	The action of placing radioactive materials or waste temporarily in a surface or subsurface specially designed facility, pending their retrieval. The facility in which waste is placed with the intention of further retrieval is referred to as a storage facility (see also Disposal).
Transmutation	The transformation of one nuclide into another through a nuclear reaction. Transmutation considered in relation to radioactive waste management aims at converting a long-lived nuclide into a shorter-lived or stable nuclide.
Treatment (of spent fuel) (or reprocessing, spent fuel treatment)	An operation that consists in separating valuable materials in spent fuel from the remainder, which can be then considered as waste and conditioned accordingly.
UOX	The standard fuel used in light-water reactors, composed of uranium oxide enriched with uranium-235.
Uranium	The heaviest natural element with an atomic number of 92.
Vitrification	An operation, which consists in incorporating radioactive wastes into a glass melt to ensure their conditioning in a stable form as packages likely to be stored or disposed off.
Waste (nuclear)	See Nuclear waste .
Waste (radioactive)	See Radioactive waste .
Waste immobilization (or waste immobilization UK)	See Embedding (of waste).

Abstract: The Nuclear Nonproliferation Treaty (NNPT or NPT) is the primary cornerstone of international efforts to prevent the proliferation of nuclear weapons. Currently, 189 countries are party to the treaty, with only four sovereign states abstaining: India, Israel, Pakistan, and North Korea. The treaty is broadly interpreted as having three pillars: (1) nonproliferation, (2) disarmament, and (3) the right to the peaceful use of nuclear technology.

Five countries are recognized by the NPT as nuclear weapon states (NWSs): the United States (US), the Soviet Union (obligations and rights now assumed by Russia), France, the United Kingdom, and the People's Republic of China. These five nations are also the five permanent members of the United Nations (UN) Security Council. In accordance with the NPT, the NWSs agree to not transfer nuclear weapons to a nonnuclear weapons state (NNWS) or assist NNWSs in acquiring nuclear weapons. Additionally, the NNWSs party to the NPT agree not to receive or manufacture nuclear weapons. NNWSs also agree to accept safeguards monitoring by the International Atomic Energy Agency (IAEA) to verify that they are not diverting material derived from the peaceful use of nuclear technology to weapons.

The NPT's preamble also contains language affirming the desire of all signatories to halt the production of nuclear weapons worldwide and to develop an additional treaty related to complete nuclear disarmament and liquidation, including their delivery vehicles. However, the NPT wording does not strictly require all signatories to actually conclude a disarmament treaty, but rather to negotiate in good faith. Some NNWSs belonging to the Non-Aligned Movement (an international organization of states considering themselves not formally aligned with or against any major power block) have interpreted the NPT as requiring the NWSs to disarm themselves and argue that these states have failed to meet their obligations.

The Strategic Arms Reduction Treaty (START) between the United States (U.S.) and Soviet Union is considered by many to be the largest and most complex arms control treaty in history. The treaty was signed on 31 July 1991, but entry-into-force was delayed until 5 December 1994 due to the collapse of the Soviet Union. By way of the Lisbon Protocol to the START treaty signed 23 May 1992, Russia, Belarus, Kazakhstan, and Ukraine became Parties to the treaty as legal successors to the Soviet Union. Upon initiation of the START II negotiations, the original START was renamed to START I. START II was signed by the U.S. and Russian presidents on 3 January 1993, banning the use of multiple independently targetable reentry vehicles (MIRVs) on intercontinental ballistic missiles (ICBMs). Russian ratification of START II was contingent on preservation of the Antiballistic Missile (ABM) treaty. START II was never entered-into-force because the U.S. withdrew from the ABM treaty 13 June 2002 in order to pursue a missile defense system, whereupon Russia withdrew from START II one day later. As a result of START I, there has been a significant reduction in the number of deployed warheads for both the U.S. and Soviet Union.

Under the May 2002 Strategic Offensive Reductions Treaty (SORT), both the U.S. and Russia pledged to reduce the number of deployed strategic nuclear weapons to between 1700 and 2200 by the year 2012. SORT is different from START in that it limits actual warheads, whereas START I limits warheads only through their means of delivery (ICBMs, SLBMs, and Heavy Bombers). Experts have estimated that by the year 2009, the U.S. and Russia arsenals for strategic nuclear weapons ranged from 2200 to 3000 each. The U.S. and Russian presidents signed a preliminary agreement on 6 July 2009 to further reduce the number of active nuclear weapons to between 1,500 and 1,675 from 2,200. In accordance with the agreement, the new caps on nuclear arsenals will need to be fully implemented by 2012.

Although the START and SORT treaties have been the backbone of joint US and Russia efforts toward nuclear disarmament, the treaties have not addressed the discontinuation

of weapons-grade fissile material production and disposition of excess weapons-grade materials. The 1993 UN Assembly resolution 48/75L called for negotiations leading to a verifiable treaty banning the production of fissile materials for nuclear weapons. Additional UN activities have followed the initial resolution; however, a final treaty has not yet been completed. The current situation is that the US, France, and the United Kingdom have ceased production. In 1997, the US and Russia signed the Plutonium Production Reactor Agreement (PPRA) to cease production of plutonium for weapons production, which included provisions for monitoring. Although Russia still operates nuclear reactors used previously for production of weapons material, to generate heat and electricity, they do not process the spent fuel. Plans are in place to decommission the Russian production reactors. Unsubstantiated reports indicate that China also has instituted a moratorium on production. Both India and Pakistan apparently are still producing weapons-grade material, and Israel's position is unclear.

Throughout the Cold War, the US and the Soviet Union produced ~100 and 150 metric tons (MT) of weapons-grade plutonium, respectively. In September 2000, the US and Russia each formally agreed to transform 34 MT of excess military plutonium into a more proliferation-resistant form over the course of 20 years. Current plans for both countries are to irradiate all 34 MT of its plutonium in nuclear power reactors. Plutonium disposition programs in both countries are still in the early stages. The start-up costs of plutonium disposition are extremely high. Currently, Russia favors irradiation in a new generation of fast reactors yet to be developed, and the US favors irradiation in their existing commercial light-water-reactor (LWR) fleet. Additionally, a joint program was developed by the US and Russia to disposition excess highly enriched uranium (HEU). Excess HEU is currently being dispositioned by way of the joint HEU downblend program. The HEU downblend program includes 500 MT of HEU from Russia (of the 1,000–1,500 MT of HEU produced by the USSR during the Cold War), whereas ~175 MT of HEU from the US (from 500 to 750 MT of HEU produced during the Cold War) has been declared excess. The HEU is downblended with natural uranium to produce low enriched uranium (LEU) for commercial power reactor fuel. Over 300 MT of HEU from Russia and tens of MT from the US have already been downblended.

1 Proliferation Resistance

Proliferation resistance refers to the ability to hinder the theft or diversion of weapons, weapon components, special nuclear materials (SNMs), or alternate nuclear materials (ANMs). With regard to nuclear power, or more generally the nuclear fuel cycle, theft or diversion of SNM is the primary concern. This section focuses only on the nuclear fuel cycle. A long standing debate among global participants involved with the nuclear fuel cycle has been material attractiveness of the various SNMs and in some cases ANMs. This ranges from differences between weapons-grade plutonium and reactor-grade plutonium, to the consideration of actinides such as americium and neptunium. The debate over weapons-grade versus reactor-grade plutonium is related to the distribution of its isotopes, and their effect on the construction and deployment of a nuclear weapon. One aspect of this debate is centered on the question of how much intrinsic heating is sufficient to thwart the construction and deployment of a weapon. The advocates of plutonium denaturing claim that 6–12% ^{238}Pu content provides a sufficient heat deterrent (see Saito et al. 2008 and references therein), whereas others, including the authors, assert that $\geq 80\%$ ^{238}Pu is required to eliminate any risk. The amount of ^{238}Pu required ultimately is dependent upon an assessment of the technical ability of the proliferator.

Conservatively speaking, entry into the “nuclear club” is more dependent upon the fact that the device will produce nuclear yield, than it is on the amount of nuclear yield that is produced. The point at which the nuclear explosive energy exceeds the conventional explosive energy, is the point at which there is a credible nuclear threat. At this point, the weapon is referred to as a threshold nuclear device. Consequently, the authors have focused on nuclear devices that are capable of a threshold yield. The factors that are relevant to building a threshold device are bare critical mass, internal heat generation, and radiation dose rate. Neutron background rate is another aspect of material attractiveness that is relevant to optimizing the nuclear yield, but it is not relevant to whether there is a credible nuclear threat.

A long standing objective for those involved with proliferation assessments has been the development of a methodology for quantifying proliferation risk. This becomes particularly complex recognizing that one may want to assess an individual component of a nuclear fuel cycle, or compare entire fuel cycles. Comparison of aqueous reprocessing versus electrochemical reprocessing is an example of individual components. An example of comparing entire fuel cycles is the open fuel cycle based on light-water reactors (LWRs) with an underground repository for spent fuel, compared with a closed mixed oxide (MOX) fuel cycle based on LWRs with an underground repository for high level waste (HLW). Recently, interest has centered on quantifying the reduced proliferation risk for a closed transmutation fuel cycle, where the minor actinides americium, neptunium, and curium are considered for reburning in fast reactors (FRs).

1.1 Material Attractiveness

This section introduces the concept of “material attractiveness” for potential use in threshold nuclear weapons by proliferators. A figure of merit (FOM) is given for calculating material attractiveness. The FOM is then applied to a comparison of the “material attractiveness” of intermediate and end products associated with the UREX, COEX, ^{238}Pu spiking, and PYROX reprocessing schemes. The results of the comparison are expressed in terms chosen for consistency with those normally used for nuclear materials (Bathke et al. 2008a, b; Bathke et al. 2009a, b). These results illustrate the inverse relationship between material attractiveness and proliferation resistance, and can be used to inform policy makers about some of the issues related to reprocessing.

1.1.1 Figure of Merit

The metric used for evaluating the attractiveness of SNM or ANM for use in a threshold nuclear device is the FOM shown in (1) (Ebbinghaus et al. 2006a, b):

$$\text{FOM} = 1 - \log_{10}(x), \quad (1)$$

where x is given by:

$$x = M \left[\frac{1}{800} + \frac{h}{4,500} \right] + \left[\frac{D}{500} \right]^{\frac{1}{\log_{10} 2}},$$

M is the bare critical mass of the metal in kg, h is the heat content in W/kg, and D is the dose rate at 20% of M evaluated at $1 - m$ from the surface in rad/h.

The FOM applies to pure elements (e.g., U, Np, Pu, Am, etc.) and to actinide metal mixtures. It also conservatively bounds impure metal mixtures such as mixtures of actinides and lanthanides. How the FOM is to be applied depends upon the capability of the adversary and the time available to the adversary. In one extreme, one must assume that the adversary has sufficient capability and time to purify the material. In this case, it is only valid to apply the FOM to pure elements (e.g., Pu, U, Np, Am, etc.). In the other extreme, it is possible that the adversary has limited technical ability or limited time, and the best for the adversary is an actinide or impure metal mixture. In this case, it is appropriate to apply the FOM to the actinide metal or the impure metal mixture. The authors have calculated both extremes as shown in the following figures.

1.1.2 Meaning of FOM Values

An absolute scale to judge numeric values of the FOM is given in [Table 1](#), which casts the FOM in terms of the utility of SNM for use in threshold nuclear device. Materials with high utility require greater safeguarding than low utility.

In Bathke et al. (2008a, b) and Bathke et al. (2009a, b), the FOM was mapped into the US Department of Energy (DOE) attractiveness levels (Nuclear Material Control and Accountability, the US Department of Energy manual DOE M 470.4-6, see [Table 2](#)). The DOE requires more stringent material control and accountability for higher attractiveness levels. Such a mapping is not strictly applicable, because the DOE attractiveness levels are determined by both quantity and quality of the SNM. Nevertheless, a meaningful correlation still exists between the FOM, utility, and the attractiveness levels. From a safeguards perspective, SNM of high (H) utility ($FOM > 2$) is comparable in quality to material with an attractiveness level of B. Similarly, SNM of moderate (M), low (L), and offscale (O) utility are comparable to material with the Attractiveness levels of C, D, and E, respectively. To avoid confusion for those dealing with SNM that must be safeguarded according to US DOE regulations, the FOM henceforth is only described in terms of its utility. From a safeguards and security perspective, the products of an ideal reprocessing scheme would have utility L or O (i.e., $FOM < 1$).

1.1.3 Comparison of Various Reprocessing Schemes

The reprocessing schemes analyzed to date and reported herein are: UREX, COEX, ^{238}Pu spiking, and PYROX. The source of material for all the reprocessing schemes analyzed herein

Table 1
Mapping of the figure of merit (FOM) into utility

FOM for metals	Utility	Designation on plots
> 2	High	H
1–2	Moderate	M
0–1	Low	L
< 0	Off scale	O

■ **Table 2**

US Department of Energy (DOE) attractiveness levels

Attractiveness level	Description
B	Pure products
C	High-grade materials
D	Low-grade materials
E	All other materials

is spent uranium oxide from pressurized water reactors (PWRs) and boiling water reactors (BWRs). Such spent fuel is typically characterized by its burnup, expressed in MW d/kg of initial heavy metal. The average burnup of spent fuel in the United States historically has ranged from ~15 MW d/kg for BWRs and from ~25 MW d/kg for PWRs (Spent Nuclear Fuel Discharges from US Reactors 1994) to present day values of 45–50 MW d/kg. For this analysis, the isotopic composition of spent fuel was generated with ORIGEN2.2 (Ludwig and Croff 2002) for burnups ranging from 7.5 to 90 MW d/kg. Calculations of the required ^{235}U enrichment for the fuel charge, and the spent fuel compositions, are in good agreement with similar published results (AFCF Development of LWR Fuel Source Terms and Non-Fuel Bearing Component Elemental Weights for 4-Corners Study 2007; Neeb 1997; Hill et al. 2002; Pellaud 2002; Stillman et al. 2004; Xu et al. 2005; Secker et al. 2005). Also varied was the spent fuel age at the time of reprocessing relative to the time of discharge and the time after reprocessing.

The UREX process is a suite of alternate reprocessing schemes based on similar chemistry. A list of the possible UREX products that contain transuranic elements and their associated process version is given in ▶ Table 3. The FOM results for the non-uranium-bearing products listed in ▶ Table 3 are shown in ▶ Fig. 1. The products with the highest FOM are Pu and Pu + Np, which have the same FOM value. The FOM for both Pu and Pu + Np decreases significantly with increasing burn-up, because the concentrations of ^{239}Pu and ^{241}Pu (i.e., the isotopes with relatively high fission cross sections) decrease and the concentration of ^{238}Pu , which is an intense heat source, increases with increasing burn-up. The age of the spent fuel at the time of reprocessing has only a minor effect on the FOM (i.e., the FOM increases slightly with increasing age). Heat is the primary proliferation barrier for Pu and Pu + Np.

The next highest FOM value belongs to TRU (i.e., the transuranic elements). The FOM of TRU decreases significantly with increasing burn-up, because the concentration of highly fissile isotopes (e.g., ^{239}Pu and ^{241}Pu) decreases with increasing burn-up. However, the FOM for TRU increases significantly with increasing spent-fuel age, because ^{242}Cm and ^{244}Cm , which are intense heating sources, quickly decay away (their half lives are 163 days and 18 years, respectively).

In contrast, the FOM of Am increases with increasing burn-up, because of the build up of ^{243}Am relative to ^{241}Am as the burn-up increases and because ^{243}Am produces less heat relative to ^{241}Am . The FOM of Am decreases with increasing spent-fuel age, because of the build up of ^{241}Am relative to ^{243}Am with increasing age due to the beta decay of ^{241}Pu to ^{241}Am .

The FOM of Cm also increases with increasing burn-up, because of the build up of ^{244}Cm relative to ^{242}Cm , where ^{244}Cm produces less heat relative to ^{242}Cm . As with TRU, the FOM of Cm increases significantly with increasing spent-fuel age. Although Cm has a significant

■ **Table 3**
List of UREX products and associated processes

Product	Process(es)
Pu + Np	UREX + 2, UREX + 3, UREX + 4
Pu + Np + U	UREX + 2a, UREX + 3a, UREX + 4a
TRU	UREX + 1A
TRU + U	UREX + 1B
TRU + Ln	UREX + 1
Am	UREX + 4, UREX + 4A
Cm	UREX + 4, UREX + 4A
Am + Cm	UREX + 3, UREX + 3A
Am + Cm + Ln	UREX + 2, UREX + 2A

neutron dose, the FOM is dominated by its heating. Interestingly, the Am + Cm mixture has a maximum utility of low, independent of burnup, and age.

The retention of the lanthanides (Ln) with TRU or with Am + Cm, greatly reduces the FOM (the FOM of Am + Cm + Ln is very low), because the lanthanides provide an intense photon dose and, more importantly, an intense heat source. The FOM of TRU + Ln decreases with increasing burn-up, because of the relative buildup of lanthanides. The FOM of TRU + Ln increases with increasing spent-fuel age, because the lanthanides have half lives that are of the order of 100 years. Although the addition of the lanthanides ameliorates the safeguards and security issues, it would pose huge problems for any subsequent fuel fabrication using these materials.

The effect of diluting Pu and TRU with spent uranium is shown in ► Fig. 2. The FOM is reduced with the addition of spent uranium. However, significant quantities of uranium are required to attain a low utility. For example, >80% U is required for Pu, and ≥75% U is required for TRU, both obtained from 10-year old spent fuel burned to 45 MWt d/kg. It should be noted that this study focuses only on the utility of uranium mixtures and does not consider any subsequent reprocessing by an adversary.

The effect that the period of time after reprocessing has on the FOM of Pu is shown in ► Fig. 3. Increasing the post-reprocessing time decreases the FOM of Pu, because of the buildup of ^{241}Am from the beta decay of ^{241}Pu and the resulting increase in heating. As the age before reprocessing of Pu increases, there is less ^{238}Pu which is the dominant heat source in Pu. Consequently, as the spent fuel age increases, the effect of the period of time after reprocessing decreases.

The effect that the period of time after reprocessing has on the FOM of TRU is shown in ► Fig. 4. The behavior of TRU is dominated by the concentration of ^{242}Cm and ^{244}Cm , which are intense heating sources that quickly dissipate (their half lives are 163 days and 18 years, respectively). Then, for TRU taken from relatively fresh spent fuel, increasing the post-reprocessing time significantly increases the FOM. As the age of the spent fuel from which the TRU is taken increases, the change in the FOM with increasing post-reprocessing time decreases.

■ Figure 1

Figure of merit (FOM) of non-uranium bearing UREX products versus burn-up for various spent-fuel ages at time of reprocessing (lower left corner). The letters H, M, L, and O refer to the utility of the material (► Table 1)

The effects of “denaturing” the plutonium isotopic vector are shown in ► Fig. 5 (Kessler 2007; Saito et al. 2008). The plutonium in spent fuel has up to 8% ^{238}Pu , depending on the burn-up. Adding additional ^{238}Pu does reduce the utility of the plutonium. However, 80% ^{238}Pu is required to reduce the plutonium to low utility. A source for that much ^{238}Pu has not yet been identified.

There are two PYROX products: U with trace (~100 ppm) amounts of TRU and a U + TRU mixture that is 1/3-U with small amounts (12,500 ppm) of the rare earth fission products (Bathke et al. 2008a, b; Bathke et al. 2009a, b). The U product is effectively void of ^{235}U , and is innocuous. The PYROX U + TRU mixture is similar to the UREX + 1B product shown on the right of ► Fig. 2, and can be of moderate to high utility depending on the age and burn-up of the source material. However, there are locations in the flow-sheet where the TRU is diluted with only a ~5% mixture of active metal and rare earth (i.e., lanthanides) fission products, and may have higher utility than the end product. Consequently, this section examines TRU with various concentrations of U and various concentrations of fission products, where the fission products

Figure 2 FOM of Pu (left) and transuranic elements (right) versus spent uranium concentration for various burn-ups

Figure 3 FOM of Pu versus burn-up for various spent fuel ages (lower left corner of each plot) and range of times after reprocessing (alongside of curves)

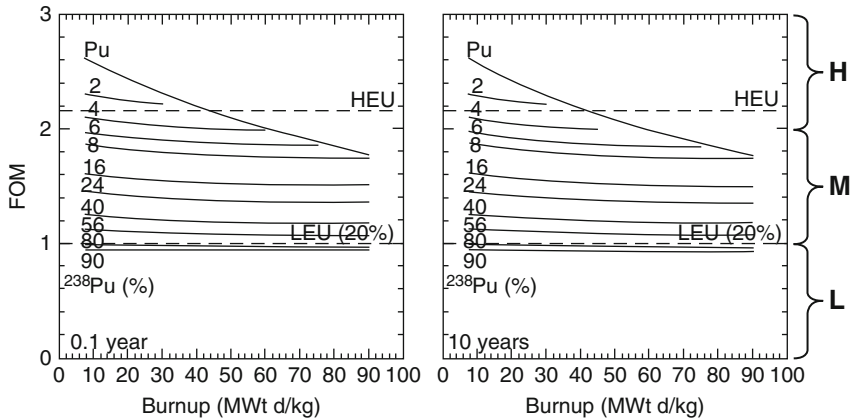

are either the active metal and rare earth fission products that represent the contaminants at an intermediate step in the flow-sheet, or just the rare earth fission products that are the only contaminants in the end product.

The FOM for a range of mixtures of U, TRU, and fission products is shown in Fig. 6. The addition of increasing quantities of fission products relative to TRU monotonically reduces the FOM, as seen in the two plots on the right-hand side of Fig. 6. However, the FOM reduction is accelerated significantly once sufficient fission products have been added to make the heating term dominant in (1). The effect of adding U relative to TRU upon the FOM is shown in the upper left plot of Fig. 6 and depends on which term in (1) is dominant. At low fission-product concentrations relative to TRU, the bare-critical-mass term is dominant, and the addition of

■ Figure 4

FOM of TRU versus burn-up for various spent fuel ages (lower left corner of each plot) and range of times after reprocessing (alongside of curves)

■ Figure 5

FOM of Pu versus burn-up for various concentrations (%) of added ^{238}Pu

increasing quantities of U decreases the FOM. At high fission-product concentrations relative to TRU, the heating term is dominant, and the addition of increasing quantities of U increases the FOM, because these additions reduce the amount of heating. Further additions of U in this regime eventually reduce the importance of the heating term and establish the bare-critical-mass term as the dominant term. Then, further additions of U decrease the FOM. Note that the combined active metal and rare earth fission products afford a significantly greater deterrent than just the rare earth fission products.

For a nominal reactor discharge that has been burned to 45 MWt d/kg and then cooled for 10 years before reprocessing, the TRU from that discharge would require $\geq 75\%$ -U to qualify as low utility material for $M_{\text{FP}}/M_{\text{TRU}} = 0$, where M_{FP} is the mass of the fission products and M_{TRU}

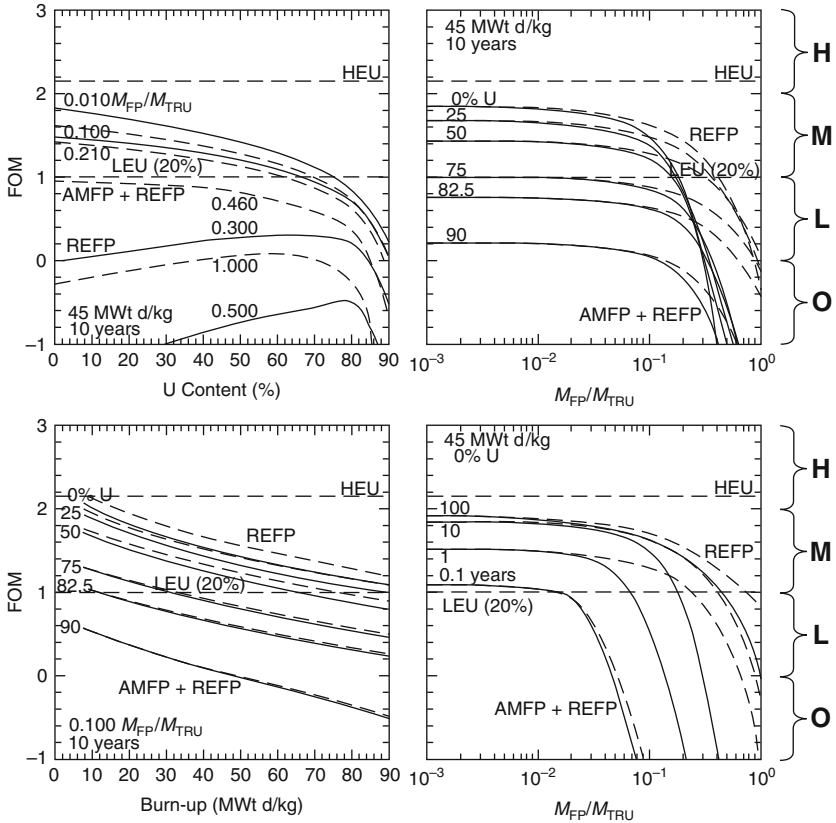

Figure 6
 FOM of PYROX material versus uranium concentration (%), ratio of fission-product mass to TRU mass, and burn-up for various mass ratios, uranium concentrations, and spent fuel ages. The fission products are either all of the active metals and rare earths (solid lines) or just the rare earths (dashed lines)

is the mass of the TRU. If both active metal and rare earth fission products are retained, then that same TRU would require $M_{FP}/M_{TRU} > 0.15$ to qualify as low utility material for 0%-U. If, however, just the rare earth fission products are retained, then that same TRU would require $M_{FP}/M_{TRU} > 0.4$ to qualify as low utility material for 0%-U. Similarly, an infinite number of combinations of U and M_{FP}/M_{TRU} can be used to achieve low utility. For example, 65%-U and $M_{FP}/M_{TRU} = 0.1$ is also low utility with active metal and rare earth fission products, whereas 70%-U and $M_{FP}/M_{TRU} = 0.1$ is low utility with rare earth fission products. It should be noted that the value of M_{FP}/M_{TRU} in spent fuel ranges from ~ 1.0 for 15-MWt d/kg spent fuel to 3.0 for 90-MWt d/kg spent fuel for active metal and rare earth fission products, and from $\sim 2/3$ for 15-MWt d/kg spent fuel to ~ 2.0 for 90-MWt d/kg spent fuel for rare earth fission products.

1.1.4 Conclusions

The FOM of Pu + Np is the highest of the UREX products. The FOM of TRU, which is a UREX + 1A product, is dependent upon spent-fuel age and burn-up. Because the FOM of TRU increases significantly with spent-fuel age, spent fuel should be reprocessed as soon as is practical. Furthermore, reprocessed TRU should be burned as soon as is practical, because the FOM of TRU increases significantly with increasing post-reprocessing time. For 10-year, 45-MWt d/kg UREX + 1A material (i.e., TRU), a U content > 75% is required to reduce the FOM to L.

The Pu + Np product has the same FOM as Pu product; coextracting Np with Pu does not reduce its utility. Conversely, extracting only Pu leaves attractive Np in the waste stream and ultimately in a repository. Both the Np-laden waste stream and repository have to be safeguarded (spent fuel requires safeguarding as well). For 10-year, 45-MWt d/kg COEX material (i.e., Pu), a U content \geq 82% is required to reduce the FOM to L. The FOM of Pu (and Pu + Np) is not significantly affected by changing the postirradiation time or by changing the post-reprocessing time.

The FOM of Pu denatured with ^{238}Pu concentration < 80% is still at least a utility of M. On the basis of the FOM formula used in this study, there is not enough ^{238}Pu (nor Np for breeding ^{238}Pu) to reduce the FOM to L.

The PYROX (or any pyro-processing product) is potentially of moderate to high utility. The PYROX product shares many properties with TRU. Its FOM is also dependent upon spent-fuel age and burn-up. It can also be made low utility with a U content > 75%. The PYROX product differs from TRU in that it can also be made low utility with $M_{\text{FP}}/M_{\text{TRU}} > 0.15$ for 0%-U and active metal and rare earth fission products or with $M_{\text{FP}}/M_{\text{TRU}} > 0.4$ for 0%-U and rare earth fission products.

There is a safeguards and security benefit with respect to diluting the reprocessing end products with lanthanides, and/or reprocessed, natural, or depleted U. *However, there is no single measure that fully eliminates the proliferation risk. None of the proposed flow-sheets examined to date justify reducing international safeguards or physical security protection levels. All of the reprocessing products evaluated to date need to be rigorously safeguarded and provide the highest levels of physical protection.*

1.2 Nonproliferation Impact Assessments

A generic nuclear fuel cycle (GNFC) is used here to demonstrate the methodology of a Nonproliferation Impact Assessment (NPIA). This methodology is partly based on the proliferation resistance and physical protection (PR&PP) approach (Evaluation Methodology for Proliferation Resistance and Physical Protection of Generation IV Nuclear Energy Systems 2006) that was developed as part of the Generation IV International Forum (GIF) (www.gen-4.org/Technology/horizontal/PRPPEM.pdf). The NPIA assessment consists of a short list of technical and policy factors. To the extent possible, each factor is graded (or rated) for each alternative to or within the GNFC. Where appropriate, the factors that are expected to be important in the subsequent assessments, the GNFC technology, or sites, are listed. The grading is expressed in qualitative terms, with each grade supported by specific technical and policy evaluations as described in the following subsections.

A clear definition of proliferation resistance, as relates to nuclear power generation, is needed to establish a firm foundation for the analysis and assessment to be performed in the

NPIA. The definition given below has been agreed to by the GIF, and agrees with the definition established at the international workshop sponsored by the IAEA in Como, Italy, in 2002 (Proliferation Resistance Fundamentals for Future Nuclear Energy Systems 2002). For comparison and distinction, the PR&PP definition of physical protection is also given.

Proliferation resistance is a characteristic of a Nuclear Energy System (NES) that impedes the diversion or undeclared production of nuclear material or misuse of technology by the host state seeking to acquire nuclear weapons or other nuclear explosive devices. The GNFC is regarded here to be the facilities that comprise it, their safeguards, physical security, the fuel supply and take-back services among its participants, and the corresponding transportation of nuclear materials or sensitive technology. Thus, the GIF definition of proliferation resistance applies to the GNFC. Notably, although the PR&PP definitions provide a foundation for evaluating the relative PR&PP risks of the GNFC, other factors can influence the nonproliferation impact of the GNFC. For example, the nuclear fuel cycle decisions of various countries need to be considered with regard to the benefits and challenges for the GNFC.

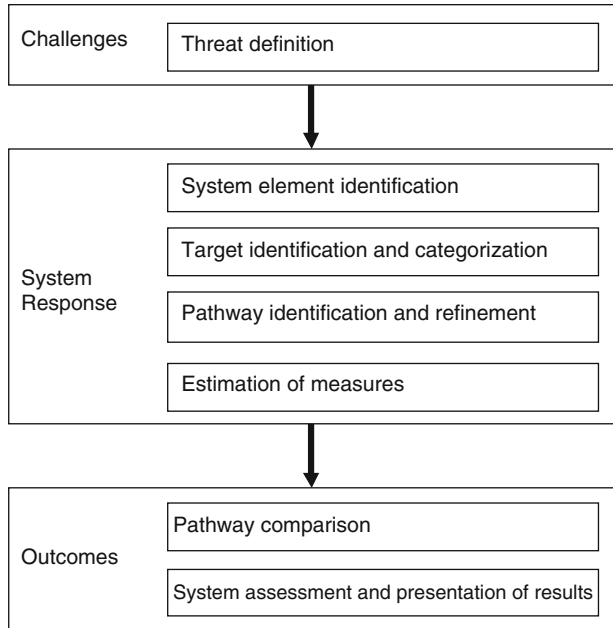

Physical protection is a characteristic of an NES that impedes the theft of materials suitable for nuclear explosives or radiation dispersal devices (RDDs), and the sabotage of facilities and transportation by subnational entities and other nonhost state adversaries. Although PP is discussed here for completeness and to distinguish it from PR, it is not evaluated for the GNFC in this NPIA.

1.2.1 Methodology

The PR&PP methodology is based on defining a set of challenges, analyzing the system response to these challenges, and finally assessing the outcomes. The challenges to the GNFC are the threats posed by potential proliferant states and by subnational adversaries. The technical and institutional characteristics of the NES are used to evaluate the response of the system and determine its resistance to proliferation threats and robustness against sabotage and terrorism threats. The outcomes of the system response are expressed in terms of PR&PP measures. The evaluation methodology accounts for both the intrinsic and extrinsic protective features of the GNFC system. Intrinsic features include the physical and engineered aspects of the GNFC system; extrinsic features include the institutional aspects such as safeguards and external barriers.

➤ *Figure 7* provides an outline of the methodological approach. The first step is threat definition. For both PR and PP, the threat definition describes the challenges that the system may face and includes characteristics of both the actor and the actor's strategy. For PR, the actor is the host state within the GNFC system, and the threat definition includes both the proliferation objectives, and the capabilities and strategies of the host state. For PP threats, the actor is a subnational group or other nonhost state adversary. The characteristics of the PP actors are defined by their objective, which may be either theft or sabotage, and their capabilities and strategies.

Challenges to the GNFC are defined in terms of a standard reference threat set (RTS), which covers the anticipated range of actors, capabilities, and strategies. System response to a given threat is evaluated independent of the probability that the system is actually challenged by the threat. In other words, PR&PP evaluations are contingent on the challenge occurring.

■ **Figure 7**

Detailed framework for the proliferation resistance and physical protection (PR&PP) evaluation methodology

For PR, the threats include

- Concealed diversion of declared materials
- Concealed misuse of declared facilities
- Overt misuse of facilities or diversion of declared materials
- Clandestine dedicated facilities

For PP, the threats include

- Radiological sabotage
- Material theft
- Information theft

After the threats have been sufficiently detailed for evaluation, the system response is performed and consists of four components:

System Element Identification

The GNFC system decomposes into smaller elements or subsystems at a level amenable to further analysis. The elements can comprise a facility (in the systems engineering sense), part of a facility, a collection of facilities, or a transportation system within the identified the GNFC subsystem where acquisition (diversion) or processing could take place.

Target Identification and Categorization

Target identification is conducted by systematically examining the GNFC system for the role that materials, equipment, and processes in each element could play in each of the strategies identified in the threat definition. PR targets are nuclear material, equipment, and processes to be protected from threats of diversion and misuse. PP targets are nuclear material, equipment, or information to be protected from threats of theft and sabotage. Targets are categorized to create representative or bounding sets for further analysis.

Pathway Identification and Refinement

Pathways are potential sequences of events and actions followed by the actor to achieve objectives. For each target, individual pathways are divided into segments through a systematic process and analyzed at a high level. Segments are then connected into full pathways and analyzed in detail. The selection of appropriate pathways will depend on the scenarios themselves, the state of design information, the quality and applicability of available information, and expert input.

Estimation of Measures

The results of the system response are expressed in terms of PR&PP measures. Measures are the high-level characteristics of a pathway that affect the likely decisions and actions of an actor, and, therefore, are used to evaluate the actor's likely behavior and the outcomes. For each measure, the results for each pathway segment are aggregated as appropriate to compare pathways and assess the system, so that significant pathways can be identified and highlighted for further assessment and decision making.

For PR, the measures are:

- *Proliferation technical difficulty* (TD): The inherent difficulty, arising from the need for technical sophistication and materials handling capabilities, required to overcome the multiple barriers to proliferation.
- *Proliferation cost* (PC): The economic and staffing investment required to overcome the multiple technical barriers to proliferation, including the use of existing or new facilities.
- *Proliferation time* (PT): The minimum time required to overcome the multiple barriers to proliferation (i.e., the total time planned by the host state for the project).
- *Fissile material type* (MT): A categorization of material based on the degree to which its characteristics affect its utility for use in nuclear explosives (material attractiveness).
- *Detection probability* (DP): The cumulative probability of detecting a proliferation segment or pathway.
- *Detection resource efficiency* (DE): The efficiency in the use of staffing, equipment, and funding to apply international safeguards to the NES.

For PP, the measures are:

- *Probability of adversary success* (PAS): The probability that an adversary will successfully complete the actions described by a pathway and generate a consequence.
- *Consequences*: The effects resulting from the successful completion of the adversary's action described by a pathway.

- *Physical protection resources*: The staffing, capabilities, and costs required to provide PP, such as background screening, detection, interruption, and neutralization, and the sensitivity of these resources to changes in the threat sophistication and capability.

The final steps in PR&PP evaluations are to integrate the findings of the analysis and to interpret the results. Evaluation results include best estimates for numerical and linguistic descriptors that characterize the results, distributions reflecting the uncertainty associated with those estimates, and appropriate displays to communicate uncertainties.

1.2.2 Technical Factors and Metrics

As noted previously, two categories of factors and metrics are essential to the NPIA: technical factors and policy factors. The former are derived from the PR&PP methodology, whereas the latter capture the broader suite of policy, legal, and institutional approaches used to secure non-proliferation objectives. This section elaborates on the technical aspects, and policy aspects are discussed later sections.

The link between technical factors, and PR&PP measures and their underlying metrics can be summarized by the following:

1. The measures are the fundamental constituents of proliferation resistance.
2. The metrics are the scales or units in which they are expressed.
3. The technical factors are higher-level expressions of proliferation resistance that are more readily usable by the decision maker. They are supported by the measures.

Three high-level technical factors are evaluated in this NPIA:

T1: Avoiding proliferator success

T2: Facilitating cost-effective international monitoring

T3: Resulting in less-attractive material types and forms

These technical factors are informed by the PR&PP measures using the association of

➤ [Table 4](#).

Grading Structure for Technical Factors

A grading structure has been proposed for the three technical factors:

- Immediate and substantial impact
- Delayed but substantial impact
- Significantly delayed and/or minimal impact

Other grading approaches exist as well, but undefined notions of high, medium, and low are not useful because of their vagueness. The example “grades” shown here provide a qualitative notion of time and scale of possible consequence.

Proliferation Resistance Measures

For an evaluation of proliferation resistance to host state threats, after measures have been estimated for pathways, the pathways are compared and ranked according to significance. To facilitate pathway comparison, quantitative metrics are applied to the TD, PC, PT, MT, and

■ **Table 4**

Technical factors and associated proliferation resistance and physical protection (PR&PP) measures

Technical factors	Associated PR&PP measures
Avoiding proliferator success (T1)	Technical difficulty (PR)
	Proliferation cost (PR)
	Proliferation time (PR)
	Detection probability (PR)
	Probability of adversary success (PP)
	Consequences (PP)
Facilitating cost-effective international monitoring (T2)	Detection resource efficiency (PR)
	Detection probability (PR)
	Physical protection resources (PP)
Resulting in less-attractive material types and forms (T3)	Material type (PR)
	Consequences (PP)

DP measures to relate them to linguistic values, from very low to very high, based on decision making by a proliferant state. Likewise, for the DE measure, a quantitative metric is applied to reflect the magnitude of required resources, relative to the resources that the IAEA commonly applies to safeguard facilities. The analyst may select other quantitative metrics appropriate for comparing pathways for the specific threat being considered. As a starting point, the analyst may choose to apply the approximate, representative metrics given in ▶ [Table 5 \(continued\)](#). These metrics are presented as an example. The evaluation of measures is not prescriptive and is generally tailored to the specific questions being addressed.

In ▶ [Table 5 \(continued\)](#), the PP measures have also been included for completeness. However, explicit example metrics are not shown in this report. These metrics would be tailored to the purposes and needs of a national assessment and would be associated with the specific threats to be addressed. A brief discussion of the PP measure is given at the end of this section.

Each of the PR measures and corresponding metrics is discussed in greater detail in the following section.

Proliferation Technical Difficulty (TD) Measure

The TD measure is estimated using a metric scale as shown in the example given in ▶ [Table 5 \(continued\)](#). Technical difficulties arise from inherent characteristics of the pathway that create a potential for failure from technical problems. When scaled to reflect the state's capability, the TD measure assists in distinguishing pathways that a proliferant state would judge to have a higher risk of technical problems, and to have the potential to greatly increase the time and resources to complete a pathway, or to result in the failure to complete a pathway.

An estimation of TD uses expert judgment to identify the sources of intrinsic difficulty in completing a pathway segment, such as difficulty from criticality hazards, radiation, a lack

■ Table 5

Example quantitative metrics and scales for PR measures

Measures and metrics	Metric scales bins (median)	Proliferation resistance
Proliferation resistance measures determined by intrinsic features		
Proliferation technical difficulty (TD): Example metric: probability of pathway failure from inherent technical difficulty considering threat capabilities	0–5% (2%)	Very low
	5–25% (10%)	Low
	25–75% (50%)	Medium
	75–95% (90%)	High
	95–100% (98%)	Very high
Proliferation cost (PC): Example metric: fraction of national resources for military capabilities	0–5% (2%)	Very low
	5–25% (10%)	Low
	25–75% (50%)	Medium
	75–100% (90%)	High
	>100% (>100%)	Very high
Proliferation time (PT): Example metric: total time to complete pathway	0–3 months (2 months)	Very low
	3 months to 1 year (8 months)	Low
	1–10 year (5 year)	Medium
	10–30 year (20 year)	High
	>30 year (>30 year)	Very high
Fissile material type (MT): Example metric: dimensionless ranked categories (HEU, WG-Pu, RG-Pu, DB-Pu, LEU); interpolation based on material attributes	HEU	Very low
	WG-Pu	Low
	RG-Pu	Medium
	DB-Pu	High
	LEU	Very high
Proliferation resistance measures determined by extrinsic measures and intrinsic features		
Detection probability (DP): Example metric: cumulative detection probability	a	Very low
	b	Low
	c	Medium
	d	High
	e	Very high
Detection resource efficiency (DE): Example metric: GW(e) years of capacity supported (or other normalization variable) per person days of inspection (PDI) (or inspection \$)	<0.01 (0.005 GWyr/PDI)	Very low
	0.01–0.04 (0.02 GWyr/PDI)	Low
	0.04–0.1 (0.07 GWyr/PDI)	Medium
	0.1–0.3 (0.2 GWyr/PDI)	High
	>0.3 (1.0 GWyr/PDI)	Very high

■ Table 5 (continued)

Measures and metrics	Metric scales bins (median)	Proliferation resistance
Probability of adversary success (for PP)		Very low
		Low
		Medium
		High
		Very high
Consequences (for PP)		Very low
		Low
		Medium
		High
		Very high
Physical protection resources (for PP)		Very low
		Low
		Medium
		High
		Very high

Notes: HEU high-enriched uranium, nominally 95% ^{235}U ; WG-Pu weapons-grade plutonium, nominally 94% fissile Pu isotopes; RG-Pu reactor-grade plutonium, nominally 70% fissile Pu isotopes; DB-Pu deep burn plutonium, nominally 43% fissile Pu isotopes; LEU low-enriched plutonium, nominally 5% ^{235}U

^aSignificantly lower cumulative detection probability than the IAEA detection probability and timeliness goal for depleted, natural, and LEU uranium

^bFifty percent in 1 year (this equates to IAEA detection probability and timeliness goal for one significant quantity of depleted, natural, and LEU uranium)

^cTwenty percent in 3 months, 50% in 1 year (this equates to IAEA detection probability and timeliness goal for one significant quantity of spent fuel/irradiated material)

^dFifty percent in 1 month, 90% in 1 year (this equates to IAEA detection probability and timeliness goal for one significant quantity HEU/separated Pu)

^eSignificantly greater cumulative detection probability than the IAEA detection probability and timeliness goal for HEU/separated Pu

of design information, a lack of access, or the inability to fabricate or produce equipment or materials covered by export controls. An estimation of TD for a complete pathway uses the combined sources of difficulty for all segments.

The metric scale for the TD measure reflects the probability that a pathway will end in failure, and thus depends on the resources and capabilities available to a proliferant state. Thus, for example, the TD of an external segment to construct and operate a concealed centrifuge enrichment plant may become lower if a state has an operating commercial enrichment capability, or can access expert guidance. However, the TD for manufacturing specific components for centrifuges, such as frequency invertors, may remain high if a state does not have a domestic commercial capability to manufacture these components. Most of the nuclear components that have high TD to manufacture are monitored by international export controls and by national intelligence services. The evaluation of the DP measure may include the potential for export controls to detect the acquisition of such equipment.

■ **Table 6**

Summary of characteristics for the proliferation technical difficulty (TD) measure

Characteristic	Description
Definition	Inherent difficulty of the segment
Typical attributes to be considered for estimation	Criticality hazards Radioactivity levels Availability of open information Access to specialized export-controlled components or materials
Example metric	Probability of pathway failure from inherent technical difficulty considering threat capabilities
Segments-to-pathway aggregation method	Calculation of the probability of pathway failure on the basis of the segments involved

■ **Table 7**

Summary of characteristics for the proliferation cost (PC) measure

Characteristic	Description
Definition	Total cost of segment
Typical attributes to be considered for estimation	Minimum cost for setting up the minimum needed infrastructure to complete the segment Cost from misuse of civilian infrastructure/personnel
Example metric	Fraction of national resources for military capabilities
Segments-to-pathway aggregation method	Sum of segment estimates. Can be normalized to national resources for military capabilities

The use of probabilistic methods can facilitate aggregation of the TD measure associated with each segment in a pathway. Examples based on Markov models are contained in Yue et al. (2005). ➤ [Table 6](#) summarizes key characteristics of the TD measure.

Proliferation Cost (PC) Measure

The PC measure is estimated in dollars and can be scaled with the total resources available to a proliferant state for military expenditures, which may be on the order of \$2 billion per year for a reactor state or \$20 billion per year for a fuel cycle state. ➤ [Table 7](#) provides an index for scaling the value of PC from low (<10%) to very high (>100%). This measure expresses the economic and staffing investment required to overcome the multiple barriers that impede completion of the action associated with the segment.

■ **Table 8**

Summary of characteristics for the proliferation time (PT) measure

Characteristic	Description
Definition	Total time required to complete segment
Typical attributes to be considered for estimation	Maximum diversion or production rate Storage duration Extent of required equipment modifications
Example metric	Total time to complete pathway (e.g., months, years)
Segments-to-pathway aggregation method	Appropriate aggregation of parallel and serial activities

The PC measure is aggregated over a pathway by summing the value of the measure for each segment in the pathway. In many cases, this measure is dominated by one segment. Notably, this measure does not include the cost of the declared Generation IV NES, but does include the cost of modifications made to that system to complete the segment. These modifications may include process modifications, as well as modifications intended to defeat safeguard verification activities. ➤ [Table 7](#) summarizes key characteristics of the PC measure.

Proliferation Time (PT) Measure

The PT measure is estimated in units of time, as shown in ➤ [Table 8](#), and ranges from very low (<3 months) to very high (>30 years). The proliferation time is the minimum time required to overcome the multiple barriers that impede completion of the action associated with the acquisition and processing segments. Typically, PT is measured from the time that the proliferant state initiates its first detectable activity (e.g., its first action to divert material or misuse a declared facility). However, the analyst may select other initiation times, such as the time when the proliferant state's planning starts if the analyst judges this to be important in affecting the state's preferences between pathways. The analyst should state explicitly the basis used for selecting an initiation time and use it consistently. Typically, PT is estimated at the end of the processing segment and does not include the weapon fabrication time.

For example, abrupt diversion of spent fuel from a storage facility might require <1 month. Extraction of plutonium from irradiated targets might require 3–12 months, assuming that the extraction facility (whether clandestine or obtained through misuse of a declared facility) is already available. In making these estimates, the analyst must clearly state assumptions. These assumptions include what preparations the proliferant state has completed before initiating the action associated with the segment (e.g., an assumption that the proliferant state constructed and commissioned a clandestine plutonium extraction facility before initiating this segment).

For a pathway, the PT measure is aggregated by summing serial activities and taking into account parallel activities. Parallel and serial activities depend on the details of each pathway. ➤ [Table 8](#) summarizes key characteristics of the PT measure.

■ **Table 9**

Summary of characteristics for the fissile material type (MT) measure

Characteristic	Description
Definition	Characteristics of metal for weapons fabrication
Typical attributes to be considered for estimation	Spontaneous neutron emission rate Heat generation rate Gamma radiation activity Bare-sphere critical mass
Example metric	Dimensionless ranked categories (HEU, WG-Pu, RG-Pu, DB-Pu, LEU); interpolation based on material attributes
Segments-to-pathway aggregation method	Not applicable

Fissile Material Type (MT) Measure

The MT measure ranks types of fissile material produced by the processing segment based on their utility for use in fabrication of a nuclear explosive, and the relative preference of a proliferant state. As such, the MT measure is only estimated for pathways; it is not estimated for segments. However, it is of interest to report MT at the end of major stages. For example, as an intermediate result, an analyst may want to know the various possible MTs emerging from the acquisition stage.

The PR methodology applies an approximate ranking (🔍 [Table 9](#)) of nuclear material types. This ranking reflects relative PR based on the preferences of a proliferant state in attempting to acquire its first few weapons. The basic range is as follows:

- Very low PR – HEU
- Low PR – weapons-grade plutonium (WG-Pu)
- Medium PR – reactor-grade plutonium (RG-Pu)
- High PR – “deep-burn” plutonium (DB-Pu)
- Very high PR – LEU

The very low PR ranking for HEU results primarily from the extremely low spontaneous neutron emission rate as compared with all plutonium compositions.

For plutonium, a very wide range of isotopic compositions can be generated, depending on the conditions of reactor operation and recycle of spent fuel. The basis for categorizing the attractiveness of different plutonium compositions is complex. Here the MT PR ranking for plutonium compositions is based on the study of the US National Research Council on the spent-fuel standard (The Spent-Fuel Standard for Disposition of Excess Weapon Plutonium: Application to Current DOE Options [2000](#)):

If it is assumed that proliferators in all categories will ultimately be capable of obtaining reasonably pure plutonium metal... then the main intrinsic barriers in this category are those associated with deviation of the plutonium’s isotopic composition from “weapons grade.” ...

In the case of... a proliferant state we rate the barrier (from reactor-grade plutonium) as “moderate” in importance: such a state would probably prefer to avoid if possible the burdens posed by isotopic deviations for design, fabrication, and maintenance of nuclear weapons, but it would also probably

have the capabilities to cope with the burdens in ways that achieved a level of weapon performance adequate for the proliferant state's initial purposes.

When plutonium is recycled, it is possible to further degrade the isotopic composition. For the MT measure, such degraded plutonium is listed as DB-Pu, which would have high concentrations of ^{238}Pu and thus high heat generation rates. A proliferant state would be expected to expend great effort to identify proliferation pathways that would result in acquiring material with a lower MT PR ranking; thus, the MT PR ranking of DB-Pu is listed as high. A more detailed discussion regarding the level of preference that a proliferant state would display between materials of higher and lower MT ranking is contained in Appendix D of the PR&PP methodology report (Evaluation Methodology for Proliferation Resistance and Physical Protection of Generation IV Nuclear Energy Systems 2006).

In many cases, the simple MT ranking, along with the qualitative discussion of MT provided above and in Appendix D.4 of the PR&PP methodology report (Evaluation Methodology for Proliferation Resistance and Physical Protection of Generation IV Nuclear Energy Systems 2006), is sufficient to allow pathways to be compared and ranked.  Table 9 summarizes key characteristics of the MT measure.

Detection Probability (DP) Measure

The DP measure expresses the probability that action described by a pathway segment is detected. DP results from measurements that (1) detect anomalies generated during the execution of pathway segments and (2) are performed to assess that anomalies originate from actions in actual pathway segments rather than legitimate, inadvertent sources. DP is generally expressed as a cumulative probability function. However, if a defined safeguards approach is not available, DP can be expressed only by a very wide uncertainty band.

In addition, a variety of concealment strategies may affect the DP. The effects of a concealment strategy are determined by analyzing pathways that include the strategy, not by assigning an arbitrary DP uncertainty for assumed effects of concealment methods.

Safeguards involve continuously evolving technology. Many system attributes can affect both the optimal approach for the application of safeguards and the effectiveness of that approach in providing high DP. The following paragraph assumes a robust IAEA safeguards regime with the attendant technologies that would promote the ability to safeguard facilities and operations.

To detect *internal material diversion segments*, measurements may be combined to detect the material transfer, and the resulting change in material inventory detection error arises from three sources: (1) instrument measurement uncertainty; (2) the possibility that a measured anomaly has a legitimate origin, such as inadvertent hold up of material, inadvertent operator destruction of a seal, or inadvertent delay of an inspection due to legitimate safety or access restrictions; and (3) uncertainty that the actual facility configuration is the same as that assumed in the design of the safeguards system where, for example, an undeclared penetration may exist in or be added to a facility.

To detect *internal facility misuse segments*, measurements to detect misuse must be tailored to detect anomalies that the action of a segment would generate. Uncertainties in detection of misuse have similar origins to those listed previously for internal material diversion segments.

To detect *external segments*, methods include the use of tools, such as commercial satellite photography and environmental sampling, as well as the use of various types of information that may be supplied by third-party sources. These sources include information from national export

control programs, which monitor and detect purchases or transfers of sensitive or dual purpose equipment and technologies, and information gathered by national technical means. External segments that use equipment diverted from declared facilities, such as frequency invertors in enrichment plants, could also be detected by monitoring the inventory of this equipment in declared facilities. Although the IAEA does not currently have goals for detection of clandestine activities and facilities, the IAEA uses information obtained from a variety of sources, including nonsafeguards databases, open sources, and third parties.

A potentially significant tool for enhancing the detection of external segments is the additional protocol (AP). In NPT countries, this tool enables programs to develop more transparent nuclear capabilities, including enrichment and reprocessing, (and also subject to verification). It would create a broader IAEA toolkit, including location-specific environmental sampling, to verify the declarations. AP, for example, would be a principal means of verifying that a user states that had agreed to forego development of enrichment, in exchange for fuel assurances, was in fact in compliance with such an undertaking and that there was no evidence of activities that might be inconsistent with this. AP is thus relevant to both internal segments – misuse of a declared facility – and external segments.

Under modern integrated safeguards, safeguards detection resources such as the frequency of inspections are increased progressively as anomalies are detected. These resources provide a higher cumulative confidence of detection with lower detection resources. Likewise, safeguards approaches that provide multiple and diverse measurements capable of detecting the actions described by a pathway segment increase the DP.

For internal pathway segments, the reference metric scale for the DP measure, shown in [▶ Table 10](#), is based on a comparison with the applicable IAEA safeguards detection goals contained in the IAEA Safeguards Criteria. A “medium” DP meets the IAEA safeguards detection goals for spent fuel and irradiated materials. A “high” DP meets IAEA goals for HEU and separated plutonium, and a “low” DP meets IAEA goals for depleted uranium, natural uranium, and LEU.

For external pathway segments, DP may have large uncertainty unless the segment generates obvious visual, thermal, or other signatures. If detection uncertainty is large, it may be useful to provide decision makers with a qualitative, general description of the methods available to detect the external segment, particularly if the actual DP cannot be readily evaluated and presented on a metric scale such as that of [▶ Table 10](#). [▶ Table 10](#) summarizes key characteristics of the DP measure.

Detection Resource Efficiency (DE) Measure

The DE measure is estimated for each pathway segment by summing estimates of the manpower (e.g., person days of inspection (PDI)) or the cost (in US dollars) required to implement the detection methods for the segment. Safeguards resources are then aggregated for all segments of a pathway, using logical assumptions (e.g., a single instrument may provide detection capabilities for multiple segments). Estimates of time or cost will necessarily be based on currently accepted safeguards approaches, but anticipated changes to safeguards approaches and safeguards technology (e.g., increased use of remote monitoring) should be considered that could occur over the multi-decade life cycle for most nuclear facilities. The DE measure is normalized by a variable, such as the energy production supported by the system element, and is presented as the ratio of that normalization variable divided by the inspection time or cost (e.g., in units of gigawatt years per PDI). [▶ Table 11](#) summarizes key characteristics of the DE measure.

■ **Table 10**
Summary of characteristics for the detection probability (DP) measure

Characteristic	Description
Definition	Cumulative probability and confidence level for detection of a pathway segment
Typical attributes to be considered for estimation	<p>Attributes important to design information verification</p> <p>Transparency of layout</p> <p>Possibility to use 3D scenario reconstruction models</p> <p>Possibility to have visual access to equipment while operational</p> <p>Comprehensiveness of facility documentation and data</p> <p>Attributes important to nuclear material accounting</p> <p>Uniqueness of material signature</p> <p>Hardness of radiation signature</p> <p>Possibility of applying passive measurement methods</p> <p>Item/bulk</p> <p>Throughput rate</p> <p>Batch/continuous process</p> <p>Nuclear material heat generation rate</p> <p>Attributes important to containment and surveillance</p> <p>Operational practice</p> <p>Extent of automation</p> <p>Standardization of items in transfer</p> <p>Possibility to apply visual monitoring</p> <p>Number of possible transfer routes for items in transit</p>
Example metric	Cumulative detection probability
Segments-to-pathway aggregation method	<p>Calculate the probability of pathway detection on the basis of the segments involved (e.g., the probability of pathway detection will be $P(d) = 1 - P(nd)$, where the probability of pathway nondetection, $P(nd) = \prod(1 - P_i(d))$, with $P_i(d)$ being the probability of detection of the ith segment, under the hypothesis of the independence of detection events)</p>

Physical Protection (PP) Measures

The three PP factors are considered differently.

- **Probability of adversary success (PAS):** The probability that an adversary will successfully complete the actions described by a pathway and generate a consequence. This measure assesses the probability that an adversary will successfully complete the actions described by a pathway and generates a consequence. If the actions required to complete the pathway are within the resources and capability of the adversary, then the PAS depends on the capability of the physical protection system (PPS) to detect the actions, delay the adversary, and neutralize the adversary before the actions can be completed. The PAS measure is commonly used in the design and analysis of PPSs, and various tools are available to quantitatively

■ **Table 11**
Summary of characteristics for the detection resource efficiency (DE) measure

Characteristic	Description
Definition	Total inspector time or cost of safeguarding the segment
Typical attributes to be considered for estimation	See Table 2.10 of Evaluation Methodology for Proliferation Resistance and Physical Protection of Generation IV Nuclear Energy Systems (2006)
Example metric	GW(e) years of capacity supported (or other normalization variable) per PDI (or inspection \$)
Segments-to-pathway aggregation method	Aggregation to total inspection time or safeguards cost, normalized to an appropriate scale, such as nuclear energy production supported (GW(e) year)

evaluate the measure. For some pathways, the PAS may be controlled by a small number of segments, such as the physical difficulty in obtaining access to safety equipment in attempting to sabotage passively safe nuclear reactors and the difficulty of removing and processing spent-fuel assemblies in attempting to steal plutonium.

- **Consequences (C):** The effects resulting from the successful completion of the adversary's action described by a pathway. Consequences are defined as the effects resulting from the successful completion of the adversary's intended action described by a pathway. This measure reflects both the attractiveness to the adversary and the relative importance of a pathway in generating adverse effects. Theft consequences can be expressed in terms of the quantity and quality of the material removed. Sabotage consequences can be measured by the number of physical quantities, acute fatalities, latent fatalities, quantities of material per unit area, etc. Perhaps the most meaningful measurement of sabotage consequences at the coarse pathway level is whether a release is contained, kept to the plant site, or released offsite.
- **Physical protection resources (PPR):** The staffing, capabilities, and costs required to provide PP, such as background screening, detection, interruption, and neutralization, and the sensitivity of these resources to changes in the threat sophistication and capability. This measure reflects the resources devoted to provide extrinsic features, for instance a PPS to detect, delay, and neutralize an adversary. At the lowest end, in system elements that provide very long intrinsic delay times, this measure may involve the cost of alarm systems and offsite police response. At the high end, this measure may involve extensive investments in maintaining large, armed security forces and in detection, delay, and response systems. The PPR measure quantifies the staff, capabilities, and costs (both infrastructure and operation) required to provide a level of PP for a given NES. As with the DE measure for PR, the PPR measure for a given pathway is evaluated for each pathway segment and then aggregated appropriately, noting that some PPS elements can provide responses to multiple segments. PPR for targets can be evaluated by aggregating resources for all pathways associated with the target. Likewise, PPR for a system element can be evaluated by aggregating the resources required for all targets in the system element. The PPR measure can also be expressed as a cost per unit of energy (TWh) produced.

The three measures for PP are consistent with those commonly used by national programs to make efficient investments to protect critical infrastructure and key assets. PP is a national

responsibility and thus involves national policies. The goal is to allocate resources optimally to limit risk to a uniform level across both nuclear and nonnuclear critical infrastructure and key assets. Quantitative analysis for PAS, C, and PPR will also be required to support licensing and deployment decisions for new nuclear infrastructure.

1.2.3 Policy Factors and Grading

In addition to “technical factors” that are supported by the PR&PP metrics and measures, the final GNEP NPIA should evaluate alternative actions against notable nonproliferation “policy factors.” The purpose of this additional aspect of the approach is to capture any high-level US nonproliferation policy value. It is difficult to evaluate fully the nonproliferation merit of the GNEP “architecture” as a technology transfer restraining mechanism, when measuring purely against technical factors that do not consider the broader suite of policy, legal, and institutional approaches used to secure nonproliferation objectives.

The following draft policy factors are proposed for use in the NPIA analysis.

1. This factor would allow policy effect analysis for GNEP approaches, products, and facilities that contribute to restraint in the spread of sensitive fuel cycle technology beyond existing technology holding states. This President-of-the-US (POTUS)-level policy factor was put forward in the National Defense University speech by President George Bush in February 2004.

2. Minimizes and avoids accumulation of stocks of separated weapons useable material.

This factor would allow policy-effect analysis for GNEP approaches, products, and facilities that contribute to minimization and avoidance of accumulation of separated stocks. This POTUS-level policy factor was put forward in National Security Presidential Directive 17 (NSPD-17) (President George Bush, December 2002) and other documents.

3. Enhances US tangible nonproliferation policy and legal influence on the structure of the international fuel cycle.

This factor would allow policy-effect analysis for GNEP approaches, products, and facilities that contribute to tangible enhancement of US influence, for example, through the system of legal obligations set forth in bilateral peaceful nuclear cooperation agreements. The word “tangible” is used to indicate that the effect should be as direct as practicable through policy, regulatory, or legal mechanisms. Indirect effects are also meaningful (setting an “example”), but of much lesser value generally. For example, the “no domestic reprocessing policy” of the US was an indirect policy approach. Some argue that this approach formed the basis for a policy of global restraint that largely retarded development of reprocessing technology worldwide, whereas others argue that fuel cycle economics have been largely responsible for the current situation rather than the policy. By way of comparison, the general decline of US nuclear manufacturing capability is having a direct and long-term impact on the ability of the US to influence the future international fuel cycle through an accelerating loss of nuclear trade obligations on technology and material – a direct effect.

4. Strengthens nuclear nonproliferation and nuclear security by encouraging the adoption and implementation of sound nonproliferation infrastructures.

This factor would allow policy effect analysis for GNEP approaches that lead to the adoption by others, for example, of additional protocols; the IAEA Convention on Physical Protection of Nuclear Materials (CPPNM) and its amendment; export controls, and

implementation of the UN Security Council Resolution 1540 (UNSCR/1540). It could look at capacity building efforts to help others put in place the appropriate legal and regulatory frameworks and develop and deploy the human resources needed. This factor speaks both to the issue of reducing the risk of terrorism worldwide and of promoting nonproliferation practices.

Proposed Grading Structure

The policy analysis should cast logical arguments as to how GNEP approaches, products, and facilities participate and enable US nonproliferation policy objectives. The analysis should be as brief, straightforward, and understandable as possible as to educated lay persons. The following set of “grades” is suggested to be applied to the above policy factors:

Meets US Nonproliferation Policy Objectives This grade is given if the vast majority of reasoned arguments supports the conclusion. The main points for should be laid out in a bulletized list.

May Create US Nonproliferation Policy Uncertainty This grade is given if significant reasoned arguments can be made for and against. The main points for and against should be laid out in bulletized pro and con lists.

Raises US Nonproliferation Policy Concerns This grade is given if the vast majority of reasoned argument supports the conclusion. The main points against should be laid out in a bulleted list.

1.2.4 PR&PP Example

A Markovian model is used as an example for detailed pathway analysis to quantify the measures of proliferation resistance for an advanced light water reactor (ALWR). This example can serve as a baseline for comparison of Generation IV concepts (Generation IV International Forum, www.gen-4.org). The scenarios evaluated include reactor misuse and diversion at both front-end and back-end of the ALWR once-through fuel cycle. The full set of analyses and results are too extensive to present here. Rather, to provide a sense of the methodology, the case of material diversion is illustrated here. For additional detail see Aigner et al. (2002).

The goal of diversion is to accumulate a significant quantity (SQ) of either HEU or reactor grade plutonium. In this study, obtaining one SQ of material is defined as a successful diversion. Generally, diversion may occur before the fuel assemblies are loaded into the reactor, which corresponds to the front-end of the fuel cycle, and after the fuel assemblies are taken out of the reactor, which corresponds to the storage and reprocessing of spent fuel (the back-end). It should be noted that diversion while the fuel is in an operating ALWR is almost impossible. For reactors, in general, diversion is possible during the refueling process. Thus, the reactor is also included in this diversion scenario study.

The diversion along the path leading to fuel fabrication, the front-end, will first be considered. A standard fuel fabrication process is shown in  Fig. 8. Here the goal of the proliferator is to obtain HEU. After mining and milling, the so-called “yellowcake” of about 0.7% enrichment is obtained and converted chemically UF_6 . This material needs to be enriched to about 4% either through gaseous diffusion or gaseous centrifuge facilities before regular fuel assemblies, the fresh fuel, can be fabricated for a light water nuclear reactor. It is assumed that the proliferator may possess the necessary clandestine facilities to produce the desired weapons grade

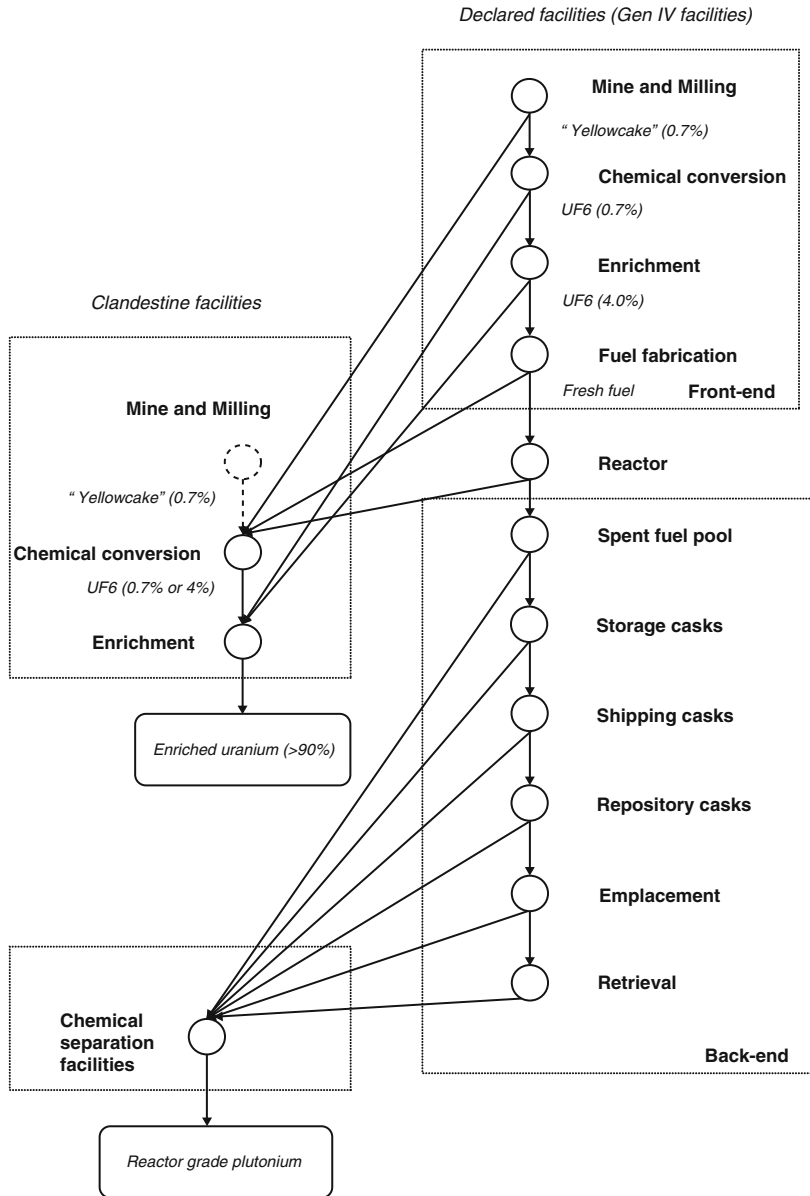

Figure 8
Diversion scenarios

materials. Therefore, all the material may be attractive to the proliferator despite the different levels of enrichment along this path. To avoid the mixed scenario of diversion and misuse (this will be considered in the future), clandestine facilities are solely used to obtain the enriched uranium material of weapons grade, i.e., once the material is diverted it will not be returned to

the declared facilities for further processing. In the front-end diversion, the clandestine facilities are used for chemical conversion and for enrichment as shown in [▶ Fig. 8](#).

The path of diversion at the back-end is also shown in [▶ Fig. 8](#). Spent fuel may contain enough reactor grade plutonium to fabricate nuclear weapons after proper processing. After the spent fuel is unloaded from the core of the reactor, it needs to be cooled down inside the spent fuel pool, then stored onsite, shipped, and emplaced within different casks or containers. Diversion may occur at various stages of this process. Furthermore, retrieval of emplaced fuel could also happen although the spent fuel is intended to be emplaced permanently.

The parameters for the Markov model are determined from the point of the view of the proliferator. The materials flow through the NES continuously, i.e., the material may be diverted from all or some of the facilities of the system at any moment. In the diversion goal, which is to obtain I-SQ HEU or reactor grade plutonium, the transition time periods between declared and clandestine facilities are determined based on the amount of the material the NES can process and by the diversion rates at different facilities. The detection time periods are determined by the periods of inspection, verification, and confirmation of the diversion activities.

The cumulative probability of detection with time for each stage of diversion in the front-end of the fuel cycle is shown in [▶ Fig. 9](#). Similar results can be shown for the back-end of the fuel cycle.

The aim of this study is to investigate the Markov approach as a design tool to be used by Generation IV designers at an early stage of the design process. It is a fast running software tool

Figure 9
Detection probability for front-end diversion

that can be used to quickly explore “what if” scenarios and to perform design trade-offs. It fully allows the time-dependent nature of the proliferation process to be explored and displayed. The model can incorporate both declared and undeclared facilities and operations into a uniform framework. Further, if an additional protocol is in place, then detection rates for the clandestine facilities and operations can be incorporated. The possibility of technical failure by the proliferators due to the technical difficulty of key step on the path to proliferation is readily modeled in the Markov approach. Material quality is determined as an input to the proliferator’s scenario and strategy, i.e., the proliferator decides, before acting on which type of material to go after in the overall scenario. If successful, it is not a surprise to the proliferator that she/he obtained the material that was the objective of the act of proliferation.

Future work is guided by the needs of the Generation IV program and the proliferation resistance methodology in particular. The near term emphasis will be on further exploration of an example sodium fast reactor system and on consideration of recycle scenarios whereby reprocessing is part of the fuel cycle. It would be worthwhile to incorporate more data on safeguards approach, particularly where realistic alternative can be explored. A more comprehensive exploration of alternative scenarios should be explored, especially to investigate how to identify dominant scenarios and pathways.

2 Safeguards

Safeguards are measures taken to reduce proliferation risk. The terms or expressions (1) safeguards and (2) material control and accountability (MC&A) are often used interchangeably. Frequently, their definition depends on whether the audience is domestic or international. Material protection, control, and accounting (MPC&A) can be considered MC&A with the addition of physical security.

The governing agencies that regulate safeguards are both domestic and international. In 1953, the United States President Dwight Eisenhower suggested the creation of an international organization to develop and control atomic energy, in his “Atoms for Peace” speech before the UN General Assembly. The IAEA was established to promote the peaceful use of atomic energy while safeguarding against its use for military purposes. The IAEA reports directly to the UN General Assembly and Security Council; however, it was formed independently by way of its own international treaty, the IAEA Statute. The relationship between the IAEA and UN is described in INFCIRC/11, 30 October 1959. For the European Union, the IAEA has delegated selected responsibilities to Euratom (INFCIRC/263, October 1978).

Domestic agencies typically defend against the subnational threat (or theft), and the IAEA defends against the state threat (i.e., diversion). As such, it is the plant operator’s responsibility to satisfy the domestic and international safeguards requirements. However, domestic requirements are typically verified by auditing operations; whereas, international requirements are verified by independent and authenticated measurements and monitoring.

In addition to the IAEA Statute that is concerned with the peaceful use of atomic energy, bilateral agreements such as the United States and Russia MPC&A program have been established to enhance the safeguards of military facilities (<http://library.lanl.gov/cgi-bin/getfile?00326622.pdf>). While safeguards measures are often similar whether for civilian or military purposes, the focus of this chapter is civilian nuclear energy.

2.1 Domestic Safeguards: Implementing a State System of Accounting and Control (SSAC)

The application of safeguards is the responsibility of any state that possesses nuclear materials, and the control of their use should be a priority for the security interests of the state. A state therefore is obligated to establish an infrastructure for domestic safeguards for its own domestic purposes, to ensure the protection and accountability of its nuclear assets. However, this infrastructure is also required of all states with a comprehensive safeguards agreement (CSA) in place with the IAEA. The requirements of a CSA are that “The state shall establish and maintain a system of accounting for and control of all nuclear material subject to safeguards under the Agreement” (INFCIRC/153, para 7). The mandate for accounting and control of all nuclear materials subject to safeguards is commonly referred to as a State System for Accounting and Control (SSAC) of nuclear materials.

In the “Guidelines for States’ Systems of Accounting for and Control of Nuclear Materials,” the IAEA is quick to point out that a system of accounting for and control of nuclear material may have dual objectives:

- (a) A national objective, to account for and control nuclear material in the state and to contribute to the detection of possible losses, or unauthorized use or removal of nuclear material.
- (b) An international objective, to provide the essential basis for the application of IAEA safeguards pursuant to the provisions of an Agreement between the state and the IAEA (IAEA Safeguards Criteria, INF/2, 2004, p. 2).

A state’s SSAC may be entrusted with the execution of both international safeguards and domestic safeguards duties because in many states, the objectives of these two distinct interests coincide to a large degree. The elements of an IAEA-mandated SSAC and a domestic safeguards program share many features that are summarized in [▶ Table 12](#).

2.1.1 Primary Features of an SSAC

The term “State System for Accounting and Control” suggests first that the state has the ultimate authority for nuclear material, and second that the requirements for discharging its duties can be generally grouped into two categories: the duty of controlling the use of nuclear materials and the duty of maintaining an accountability system that tracks their use. Although a state takes the final responsibility for nuclear material in its possession, it is likely to authorize entities within the state to own and use these materials. Thus, a primary feature of an SSAC is the legal structure in which a state authorizes nuclear activities and those laws and norms that govern their use. The oversight of these activities is a second feature of an SSAC – the regulatory body in charge of establishing guidelines for the control and accounting of material and for ensuring compliance with these guidelines is commonly considered the primary element of an SSAC. However, a third important element is the facilities themselves that have direct responsibility for material accounting and control. It is at this level that accounting data are generated, which become the basis of national accounting reports submitted to the IAEA, and it is the facilities that must ensure the materials in their possession are controlled.

Table 12
Features of international and domestic safeguards objectives

SSAC functional area	International safeguards objectives	Additional domestic safeguards objectives
National policy	Ensure adherence to safeguards agreements (INF/CIRC 66 or 153, 540)	Ensure adherence to all treaties and agreements governing nuclear use to which the state is a party
National authority	Demonstrate compliance with IAEA requirements; bolster international	Ensure that nuclear materials in the state are within control of the state Demonstrate compliance with national requirements, which will be determined based on state determination of threat Bolster confidence that nuclear materials are safe from insider and outsider attack or sabotage through establishing requirements for all facilities that operate with nuclear material and ensuring compliance with these requirements through effective oversight
Facility safeguards organization	Provide data for required reports and verification visits	Meet operating requirements, operational costs, production schedules, profit demands, etc., as determined by facility owner
	Perform activities in accordance with safeguards requirements	Comply with all national regulations; demonstrate compliance
	Cooperate with IAEA verification activities	Ensure safeguards provide minimum detection, as prescribed by state

These three elements of an SSAC – legislative, regulatory, and facility – each have a role in addressing the specific aspects of accounting and control that comprise an effective safeguards system for nuclear materials. These aspects include practices such as establishing the starting point, terminating and exempting accounting and control, categorizing nuclear material, delineating material balance areas (MBAs), the capacity to generate records and reports from facility data, definition of material flows, performing physical inventory taking (PIT), analyzing shipper/receiver differences, evaluating the material balance closing, performing measurements within a regimented measurement control system, making use of containment and surveillance systems, and properly documenting material transfers, particularly international transfers. These aspects comprise the basis of effective accounting and control.

Taken together – the organizational elements of an SSAC and the functional aspects of their duties – the need for a system becomes clear. To carry out the necessary requirements of safeguards, the impetus from the state must exist to adhere to international treaties and promulgate legislation within the government to enforce adherence to the treaty obligations. Next, a state-designated authority must establish requirements for nuclear material accounting and control within the state and have the authority to ensure compliance through inspections and audits of facilities with nuclear material holdings. This authority must also be responsible for maintaining an information system that collects accounting and control information for the state as a whole. This system may be used for both domestic and international safeguards purposes. Finally, the operators at facilities where nuclear material is used are responsible for incorporating all safeguards elements mandated by the state authority into their operations to ensure that material is properly accounted for and controlled. The records of these practices must be provided to the state authority and demonstrated through periodic audits. The interaction of these three levels becomes the system in which nuclear safeguards practices are mandated, implemented, and verified.

► **Table 13** summarizes the requirements at each level of an SSAC. This table summarizes the requirements found in the IAEA “Guidelines for States’ Systems of Accounting for and Control of Nuclear Materials” (IAEA/SG/INF/2). Further elaboration of the specific elements of the system can also be found in the IAEA safeguards glossary (www-pub.iaea.org/MTCD/publications/PDF/nvs-3-cd/PDF/NVS3_prn.pdf). With these elements in place, a state can have an effective international system of accounting for and control of nuclear material.

2.2 IAEA Inspection Regime

IAEA defines in the model CSA (IAEA, INFCIRC/153, p. 1)

...the objective of safeguards is the *timely detection of diversion of significant quantities of nuclear material* from peaceful nuclear activities to the manufacture of nuclear weapons or of other nuclear explosive devices or for purposes unknown, and *deterrence of such diversion by the risk of early detection*.

The italics are inserted to emphasize the essential technical metrics of safeguards.

1. Timeliness
2. Significant quantities of nuclear material
3. Deterrence by risk of early detection

Table 13

Requirements at each level of an State System of Accounting and Control (SSAC)

Elements required in the design of the SSAC	Element description	Specific requirements
Legal structure	National legislation is required to ensure that domestic practices meet international safeguards requirements. An oversight agency should be granted authority to set requirements and ensure compliance. Provisions for enforcement should also be stipulated	Conditions for possession and use of nuclear materials Facility requirements Conditions for international transfer of nuclear material
SSAC information system	Information on nuclear material control and accounting should be collected by the National Authority	
Accounting and control requirements	Accounting and control requirements should be established by the National Authority and adhered to by all facilities possessing nuclear materials	Starting point, termination, and exemption of accounting and control
		Material categorization
		Material balance areas
		Measurement and measurement control systems
		Defined nuclear material flows
		Physical inventory taking
		Shipper/receiver difference
		Material balance closing
		Containment and surveillance
		International transfers of nuclear material
Ensure compliance with requirements	The National Authority is responsible for ensuring that facilities possessing nuclear material meet IAEA and any additional domestic requirements. Compliance will be verified by the IAEA through periodic inspections	

The IAEA provides guidelines for timeliness and significant quantities of nuclear material. The timeliness guidelines are based on open-source estimates of the conversion time for various types of nuclear material into a weapons-usable form. The significant quantities of nuclear material are amounts estimated to be needed to create one weapon. These material amounts include production losses and the level of skills possessed by first-time weapons designers and builders. This section shows how the IAEA has built its safeguards system to fulfill this technical aim of safeguards, by defining the concepts of timeliness of detection, significant quantities of nuclear material, and deterrence by risk of early detection. Thus, the principles behind the IAEA Safeguards Criteria are based on defining a set of guidelines using the concepts of significant quantities and timeliness allow inspectors to fulfill the technical aims of safeguards for the suite of facilities that the IAEA must inspect. Safeguards inspectors and their management use these criteria and established IAEA practices for a facility to lay out an inspection schedule for a material balance period (MBP), which is approximately one calendar year and no more than 14 months long, and is the period between two IAEA physical inventory verification (PIV) inspections.

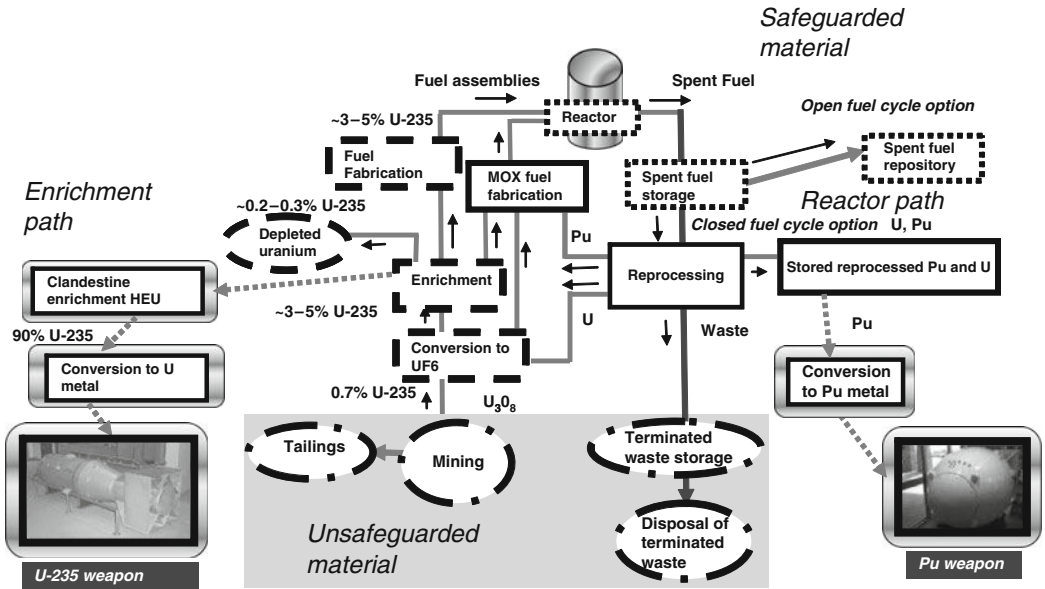

The types and amounts of nuclear materials and their physical forms determine the quantity goals and timeliness goals for a facility. This section provides the driving philosophies behind the material accountancy regime of IAEA safeguards. Verification of material accountancy in traditional safeguards is a keystone of IAEA safeguards, and even with the implementation of INFCIRC/540 additional protocols, and the move to more investigative safeguards as part of the Strengthened Safeguards System (SSS) (Hooper 1997), material accountancy will remain the keystone of the safeguards system. Thus, traditional comprehensive safeguards must be understood as a first step in comprehending the challenges the IAEA safeguards system faces. This section also shows the significance and relevance of the SSS.

The first step in understanding IAEA safeguards is to take a broad overview of the nuclear fuel cycle to understand the proliferation pathways available to a state intent on obtaining a nuclear weapon. ► *Figure 10* shows a nuclear fuel cycle with reprocessing.

The difficulty of obtaining HEU or plutonium has helped keep the number of declared nuclear weapons states to five and the nondeclared nuclear weapons states to under a half-dozen. The HEU path requires an infrastructure capable of enriching natural uranium to HEU, and the production and handling of HEU metal. As shown by the industrial scale efforts of the five nuclear weapons states, this is not a trivial technical or industrial endeavor. The plutonium path requires reactors to produce plutonium from uranium, a reprocessing facility to separate plutonium from the uranium and fission products, and a conversion facility to be capable of making plutonium metal and shaping it into weapons-usable forms. Thus, the key nuclear fuel cycle technology in the HEU path is the enrichment facility. In the plutonium path, the key technology is the reprocessing facility. Both facilities provide unirradiated direct use material, which provides highly attractive material.

The next step in understanding IAEA safeguards is to define what the Agency (i.e., IAEA) sees as nuclear material, as defined in IAEA, Statute of the IAEA, Article XX, 1957:

1. The term “special fissionable material” means plutonium-239; uranium-233; uranium enriched in the isotopes 235 or 233; any material containing one or more of the foregoing; and such other fissionable material as the Board of Governors shall from time to time determine; but the term “special fissionable material” does not include source material.
2. The term “uranium enriched in the isotopes 235 or 233” means uranium containing the isotopes 235 or 233 or both in an amount such that the abundance ratio of the sum of these

Dashed line represents indirect-use material
 Dotted line represents irradiated direct-use material
 Solid line represents unirradiated direct-use material
 Gradient shaded background represents diverted nuclear material
 Dashed plus dotted line represents waste or material not in safeguards

Figure 10
 The closed nuclear fuel cycle with highly enriched uranium (HEU) and plutonium weapons paths

isotopes to the isotope 238 is greater than the ratio of the isotope 235 to the isotope 238 occurring in nature.

3. The term “source material” means uranium containing the mixture of isotopes occurring in nature; uranium depleted in the isotope 235; thorium; any of the foregoing in the form of metal, alloy, chemical compound, or concentrate; any other material containing one or more of the foregoing in such concentration as the Board of Governors shall from time to time determine; and such other material as the Board of Governors shall from time to time determine.

The IAEA also defines a threshold between LEU and HEU as follows: HEU is uranium enriched greater than or equal to 20% of ²³⁵U. Thus, LEU is any uranium enriched in ²³⁵U beyond natural but <20% of ²³⁵U. Natural uranium (NU) is uranium with 0.711% ²³⁵U, and depleted uranium (DU) is uranium depleted in ²³⁵U to below 0.711% ²³⁵U.

2.2.1 Timeliness Goals

The timeliness criteria for thorium, uranium, and plutonium in a nuclear facility originate from estimates of the conversion time for uranium into a weapon, as shown in [Table 14](#). The

■ **Table 14**

Estimated material conversion times for finished uranium and plutonium metal components

Beginning material form	Conversion time
HEU or plutonium metal	Order of days (7–10)
HEU, plutonium, or other pure uranium compounds MOX or other unirradiated pure mixtures containing plutonium and uranium ($^{235}\text{U} \geq 20\%$) HEU or plutonium in scrap or other miscellaneous impure compounds	Order of months (1–3)
HEU or plutonium in irradiated fuel	Order of months (1–3)
Uranium containing $<20\%$ ^{235}U Thorium	Order of months (3–12)

■ **Table 15**

Timeliness goals for thorium, uranium, and plutonium

Material	Timeliness goal
Unirradiated direct use material: plutonium, ^{233}U , or HEU	1 month
Irradiated direct use material: plutonium, ^{233}U , or HEU	3 months
Indirect use material: LEU, NU, DU, thorium	1 year

■ **Table 16**

Quantity goals for uranium in GCEPS

Material	Quantity goal
Pu ($<80\%$ ^{238}Pu)	8 kg Pu
^{233}U	8 kg ^{233}U
HEU, $\geq 20\%$ ^{235}U	25 kg ^{235}U in uranium
LEU, $<20\%$ ^{235}U	75 kg ^{235}U in uranium
NU	10 tons NU (= 71.1 kg ^{235}U in uranium)
DU	20 tons depleted uranium ($\sim 40\text{--}60$ kg ^{235}U in uranium)
Thorium	20 tons thorium

timeliness goals for thorium, uranium, and plutonium are given in [▶ Table 15](#). The timeliness goals assume that a state have clandestine facilities that can process diverted material. Thus, timeliness and conversion time are roughly equivalent.

2.2.2 Quantity Goals

The quantity criteria for uranium, thorium, and plutonium in a nuclear facility arose from estimates of the material needed to produce a weapon, as shown in [▶ Table 16](#). These estimates are seen as reasonable for a first-time weapon designer and include material production losses.

■ **Table 17**
Probability of detection goal bands

Probability of detection	Goal (%)
Random high	90
Random medium	50
Random low	20
Random low–low	10

2.2.3 Deterrence by Risk of Early Detection

Once the definition of the timeliness and quantity goals for the material is set, the level of measures needed to safeguard the material can be judged by providing probabilities of detection, with higher probability and certainty of detection for more strategic materials. ➤ [Table 17](#) outlines the level of probability of detection the IAEA uses. Thus, in general for unirradiated direct use material, a random high-detection probability is desired for a 90% probability of detection. For indirect use material, a random medium probability of detection of 50% is deemed sufficient to detect the diversion of LEU or NU.

2.2.4 Frequency of Inspection to Fulfill Technical Objectives of Safeguards

When the above-defined goals are used for timeliness, quantity, and probability of detection, an inspection regime can be defined to provide coverage for verifying enough material in a satisfactory statistical manner to ensure that the detection goals can be met. In general, an annual PIV is required for all facilities except those with extremely small amounts of material. The IAEA requires interim inspections for timeliness for facilities having material with timeliness of <1 year. Thus, a facility with irradiated direct-use material, such as spent fuel in the core of a reactor, needs inspections every 3 months for timeliness. A facility with unirradiated direct use material, such as HEU fresh fuel for a research reactor, or separated plutonium in a reprocessing plant, or MOX fuel fabrication plant, requires 1 month timeliness inspections. It should be noted that inspection frequency is not determined just by the type of material at a facility, or the amount at any moment in time. If a production facility such as a conversion, fuel fabrication, or enrichment plant has indirect use material with a timeliness of 1 year, it could still require more frequent inspection. If the amount of material received in-site, processed, and shipped off-site during the year is such that an annual inspection does not give a representative random sample of the total material yearly throughput, then interim inspections are needed to verify that enough material throughput occurs to statistically satisfy inspection goals.

2.2.5 IAEA Nuclear Facility Categories

The IAEA attempts to define nuclear facilities by functional categories. A current estimate of the number of each type of facility that is under IAEA safeguards is given in ➤ [Table 18](#) (IAEA

■ Table 18

Facilities under safeguards

Facility type (defined by IAEA Safeguards Criteria)	Approximate number of facilities under IAEA safeguards worldwide
LWRs	180
On-load reactors (OLRs)	20
Other types of reactors	10
Research reactors and critical assemblies (RRCAs)	170
Natural and low enriched uranium conversion and fabrication plants	50
Fabrication plants handling direct-use material (MOX or HEU)	5
Reprocessing plants	10
Enrichment plants	20
Storage facilities	80
Other facilities (~60 other facilities under SGs)	60
Locations outside facilities (LOFs)	60–70

Annual Report 2006). The Agency classifies the facilities into two basic categories of item or bulk-handling facilities. The item facilities have nuclear material that is contained in an “item” form such as fuel rods and fuel pins, while bulk handling facilities have nuclear material that is contained in a “bulk” form such as UF_6 in cylinders, UO_2 powder, or reprocessed plutonium stored in containers. Item facilities have the advantage to the inspector of having the nuclear material being in an integral physical form that will not change. Bulk handling facilities have the disadvantage of having nuclear material being in gas, liquid, or powder forms that is altered chemically or isotopically.

In a bulk handling facility, the inspector will encounter material stored in containers where an uncertainty of the measurement regarding just how much material is present will always exist for both the operator and the inspector. The operator will always have, over the course of a material balance period (as stated above to be approximately 1 year), some material unaccounted for (MUF). MUF is calculated for a MBA over a material balance period (MBP) using the material balance equation, commonly written as:

$$MUF = (PB + X - Y) - PE, \quad (2)$$

where

- PB = the beginning physical inventory
- X = the sum of increases to inventory
- Y = the sum of decreases from inventory
- PE = the ending physical inventory

Because book inventory is the algebraic sum of PB, X and Y, MUF can be described as the difference between the book inventory and the physical inventory. (The equivalent term in US

domestic safeguards, for both the US Nuclear Regulatory Commission (NRC) and the DOE, is inventory difference (ID), as described in 10CFR 74.4 and DOE Manual 470.4-6.) For item MBAs, MUF should be zero, and a nonzero MUF is an indication of a problem (e.g., accounting mistakes), which should be investigated. For bulk-handling MBAs, a nonzero MUF is expected because of measurement uncertainty and the nature of processing bulk materials. The operator's measurement uncertainties associated with each of the four material balance components are combined with the material quantities to determine the uncertainty of the material balance (IAEA Safeguards Glossary 2001, p. 55).

Thus, the operators of large enrichment plants and large reprocessing plants, with their large throughputs of material, find it statistically difficult to obtain an MUF that is smaller than a significant quantity of nuclear material using the best measurement techniques. Verification of the large amounts of material moving through these facilities is a major challenge for the IAEA and its inspectors.

2.2.6 Keystones of Bookkeeping, Material Accountancy, and Containment and Surveillance

The verification regime of the IAEA can be seen as analogous to an audit of a major corporation by a large accounting firm. For the IAEA, the goal is to be able to not only ensure that the bookkeeping of material accountancy records is in order, but to verify the material using a battery of physical tests and measures. The Agency then uses containment and surveillance techniques to maintain "continuity of knowledge" (CoK) of the verified material.

Material accountancy is seen as a safeguards measure of fundamental importance. The Agency breaks down the accountancy verification methods available to the inspectors in an alphabetical system as follows:

- A Identification
- B Weighing
- C Volume determination
- D Sampling and analysis
- E Variables by non destructive assay (NDA) (bias defects)
- F Variables by NDA in attribute mode (partial defects)
- G Criticality check for verification
- H Attribute test by NDA (gross defects)
- M Facility specific method for in-process inventory verification

Other methods include the following:

- I Item counting
- K Spent fuel inventory check for verification (only for multiple layer spent fuel stores)
- T Tag check
- Z Other

Thus, the inspector can use Method A, combined with Methods I and T, to verify material in containers or fuel elements by checking serial numbers, counting the items, and checking tags on items. An example of this technique is counting fuel items in an LWR reactor core and verifying the serial numbers through the use of an underwater TV camera.

An inspector can use Method B to weigh a container holding nuclear material, or an LWR or research reactor fuel assembly, to obtain the mass of nuclear material.

An inspector can use Method C to get a volume determination of nuclear material in a liquid form in a reprocessing facility, to ensure the operator's declaration of material in process or in process tanks.

An inspector can use Method D to get a destructive assay (DA) sample on the order of grams to be able to perform very accurate laboratory analysis that allows for the measure the isotopics of plutonium or uranium on the order of 0.1% uncertainty. The IAEA routinely performs DAs at reprocessing and enrichment facilities.

Methods E, F, and H are NDA bias, partial, and gross defect tests of material verification, respectively. The concept of defect, as defined by the IAEA, is a difference between the declared amount of nuclear material and the material actually present (IAEA Safeguards Glossary 2001, p. 78). The IAEA defines the three levels of defect testing as the following:

- (a) Gross defect refers to an item or a batch that has been falsified to the maximum extent possible so that all or most of the declared material is missing.
- (b) Partial defect refers to an item or a batch that has been falsified to such an extent that some fraction of the declared amount of material is actually present.
- (c) Bias defect refers to an item or a batch that has been slightly falsified so that only a small fraction of the declared amount of material is missing.

For these three NDA and one DA techniques described above, [Table 19](#) describes the desired uncertainties for safeguards measurements where total (relative) measurement uncertainty is defined as:

$$\delta_i = (\delta_O^2 + \delta_I^2)^{1/2}.$$

The subscripts O and I designate operator and inspector measurements, respectively. Thus, any systems used to meet gross, partial, or bias defect tests should have these recommended measurement uncertainties.

In addition, Methods I, K, T, and Z can be facility-specific methods (e.g., the method for in-process inventory verification in the case of near real-time accountancy and item counting that can be specified for use as verification methods (IAEA Safeguards Glossary 2001, p. 55).

Other methods are also part of the containment and surveillance (C/S) realm that is a huge part of the IAEA safeguards effort in maintaining CoK. CoK is common phrase in IAEA safeguards that reflects the use of the following methods:

- S Stratum under surveillance
- V Seal verification
- X Monitors

C/S allows the IAEA to have confidence that a verified nuclear material item has not been diverted or tampered with. [Figure 11](#) shows the difference between containment and surveillance.

Containment, as shown here, attempts to provide a means to show if a nuclear asset has been tampered with. A seal, such as an Agency metal seal, is not a lock. The seal is a tamper indicating device (TID) if broken, tampered with, or counterfeited that provides evidence to the tampering. Surveillance, as shown here, allows access to a nuclear asset but should be able

Table 19
Operator/inspector measurement system recommended error limits

Method codes	Interpretation	Relative error ranges	Detectable defect size
H	Quantitative through NDA (verification in the attribute mode using the least accurate method)	$0.0625 < \delta_i \leq 0.125$	Gross
	Qualitative through NDA (e.g., Cerenkov, bundle counter)	Error cannot be assigned	Gross
F	Quantitative through NDA (verification in the attribute mode using a more accurate method)	$0.010 < \delta_i \leq 0.0625$	Partial
E	Quantitative through NDA (verification in the variables mode using the most accurate method) e.g., K-edge densitometer	$\delta_i \leq 0.01$	Bias
D	Quantitative through DA (verification in the variables mode using the most accurate method)	$\delta_i \leq 0.01$	Bias

Figure 11
Containment and surveillance examples options at VVER-440 reactor

to determine if an asset has been diverted or tampered with by the images. Method X, using monitors such as radiation detectors, can be seen as surveillance attempting to use radiation signatures to discern if an asset is moving through a strategic point as declared or is a diversion.

2.2.7 Strengthened Safeguards

The SSS evolved after the first Gulf War and the discovery of the Iraqi clandestine nuclear program. The SSS has the following objectives, as defined by the IAEA board of governors (BOG) in March 1995: “The safeguards system should be designed to provide credible assurances that

there has been no diversion of declared nuclear material, and that there is no undeclared nuclear material and activities.” Thus, the SSS conclusions should be able to determine that the

1. State’s nuclear material declarations are correct
2. State’s nuclear material declarations are complete

This goes beyond the traditional safeguards that focused on goal #1 and had for 20 years a tacit assumption of completeness for goal #2. With the SSS, goal #2 was seen to be reached by additional information from a state and analysis of open sources. The codification of how to gain more access to a state, and codify the information to reach goal #2, was reached in the AP. The AP gives the IAEA more information from the state, and increased access to verify the completeness of a state’s declaration. Thus, the IAEA has an increased ability to provide credible assurances that no declared nuclear material has been diverted, and that no nuclear material or activities are undeclared.

2.3 Safeguards Design

Safeguards design is essentially two tier, the first being instrument and/or equipment level and the second systems level. Like all design efforts, safeguards design is dictated by requirements. Unlike process design requirements that are based on the desired product, safeguards design requirements are usually dictated by the regulating and/or governing agencies based on the need for control of nuclear materials.

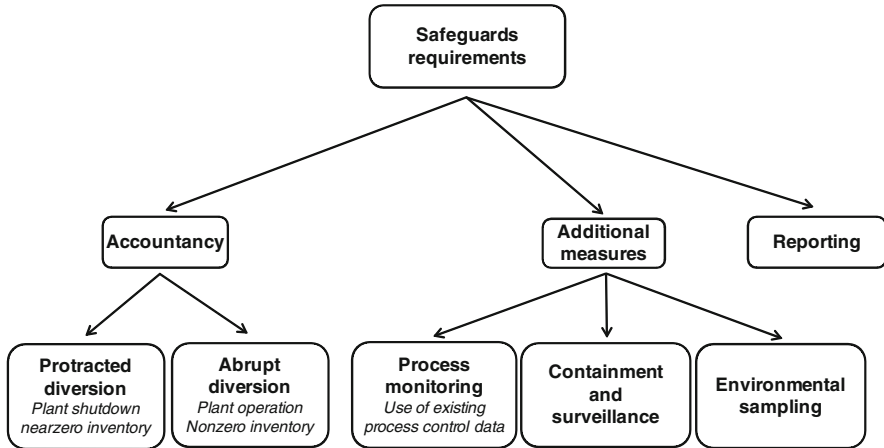

2.3.1 Safeguards Requirements

High-level safeguards requirements, whether domestic or international, can be generalized as shown in  Fig. 12. In addition to that shown in  Fig. 12, additional protocol (AP) can be considered a supplementary requirement imposed by the IAEA for those countries that are signatories. While safeguards terminology is often inconsistent between governing agencies, the concepts represented by the high-level requirements of  Fig. 12 are not. Requirements not shown in  Fig. 12 do exist, but those that are shown dictate a significant portion of the safeguards design.

Accountancy

Primary accountancy is usually based on destructive assay (DA) rather than nondestructive assay (NDA), due to the smaller measurement error. DA requires the collection of samples and transfer to an analytical laboratory; whereas, NDA can be conducted in-place often without collecting a sample. NDA is used principally for verification in conjunction with DA, by the IAEA. NDA may also be used for criticality control by the operator, but this is not a safeguards activity. NDA techniques are thoroughly described in the Passive Nondestructive Assay (PANDA) manual (<http://www.lanl.gov/orgs/n/nl/panda/index.shtml>). A discussion of both NDA and DA can be found in Ottmar 2010.

Abrupt Diversion This represents the theft or diversion of material during a short period of time. As such, its timely detection is paramount. Inventories used to detect abrupt diversion are

■ **Figure 12**
Example safeguards requirements

usually performed during plant operation due to their short interval. Both domestic and international agencies have a quantitative requirement or goal for abrupt diversion measurement performance, often referred to as the (1) standard deviation for MUF ($\sigma\text{-MUF}$ or σ_{MUF}), (2) standard deviation in the inventory difference ($\sigma\text{-ID}$ or σ_{ID}), or standard error in the inventory difference (SEID).

Protracted Diversion This represents the theft or diversion of material during a long period of time. Inventories used to detect protracted diversion are often performed during annual plant shutdown and cleanout.

Additional Measures

While the contribution of additional measures to safeguards justifies their use in and of themselves, they are often supplemental when accountancy requirements or goals cannot be completely satisfied.

Process Monitoring Process monitoring as part of additional measures refers to the use of the operator's process control data. This data is often limited due to its proprietary nature, and for the most part cannot be authenticated. It can include, tank levels, tank transfers, temperatures, and non-SNM chemical compositions such as acid.

Containment and Surveillance Containment and surveillance refer to the tracking of objects and personnel. For example, this can be by way of cameras, or more quantitatively with bar codes on individual items.

Environmental Sampling Environmental sampling as part of traditional safeguards is concerned with sampling to determine if operations have been conducted as declared. For example, surface swipes within a LEU enrichment facility are analyzed to determine if HEU is present. With the additional protocol, similar sampling may be extended to search for clandestine facilities.

Additional Protocol

As of October 2008, 127 states and other parties had received Board Approval for additional protocols (APs) to their IAEA Safeguards Agreements, for the Agency's application of strengthened safeguards. These APs are described in "Model Protocol Additional to the Agreement(s) between state(s) and the IAEA for the Application of Safeguards," INFCIRC/540 (Corrected) (IAEA 1972). AP grants the IAEA complementary inspection authority beyond that given by the traditional safeguards agreements. The AP expands inspection authority particularly in the area of undeclared activities, for which the IAEA is given expanded rights of access to information and sites. Implementation of the AP allows IAEA collection of environmental samples at locations beyond declared locations when deemed necessary by the Agency.

2.3.2 Safeguards by Design

Safeguards by Design (SBD) is defined as the incorporation of safeguards design early in the design phase of a new nuclear facility in order to avoid the need to redesign the process and/or facility at a later date, or retrofit the completed facility. The safeguards design itself should be based on best practices, lessons learned, and advanced concepts. Integration of the safeguards design with process and facility design will allow design trade-offs that maximize safeguards effectiveness based on overall capital and operating cost.

In its most simple form, SBD implies safeguards requirements of the governing agencies are considered early in the overall design effort. More specifically, the sequencing of safeguards design activities are dictated by high-level requirements of the facility owner. ➤ [Table 20](#) provides a high-level example of sequencing the facility and process design with the safeguards design (DeMuth et al. 2009).

Conceptual Design

Primary Objective: Initial Capital Cost Estimate The initial capital cost estimate is primarily dictated by the amount of steel and concrete required for construction. As such, the necessary design features developed for conceptual design are those that significantly affect the facility foot print (area). Conceptual design is usually conducted by way of Trade-Studies that are used to analyze alternatives.

1. Determine regulatory and product requirements.
2. Determine the category and attractiveness of nuclear material. This impacts the physical protection, and material control and accountancy requirements. Document functional requirements based on nuclear material categories and attractiveness, where the functional requirements define the purpose of relevant systems and components.
3. Determine MBAs and outline on process flow sheets.
4. Plan for accountancy of nuclear material by destructive analysis and verification by nondestructive analysis measurements. Identify equipment and instruments that meet measurement requirement needs. Select key measurement points (KMPs).
 - (a) DA accountancy is important during conceptual design because it dictates the sample locations and consequent number of samples. The number of samples is then directly related to the size of analytical laboratory.
 - (b) NDA monitoring is important during conceptual design because instrumentation is typically colocated with production equipment in process cells. Process cells require

■ **Table 20**
Safeguards by design (SBD) example activities

Design phase	Process and facility design activities	Safeguards design activity
Conceptual	Define requirements Process design Equipment list Plant layout Initial capital cost estimate Conceptual design report	Define goals/requirements Determination of SNM attractiveness and category MBA designation Identify SNM measurements (DA & NDA) Laboratory layout (domestic and international) Personnel access control Identify technology development needs Prepare a conceptual safeguards design report

Final	Complete equipment design Detailed design report Regulatory approval	Detailed instrument and equipment design Reporting and data integration Requirements validation Final overall design with integrated safeguards Update the preliminary safeguards design report for the final safeguards design report

more concrete and steel than the remainder of the facility. Accurate sizing of the process cells is required for an accurate initial cost estimate.

5. Determine DA measurement throughput for both domestic (SSAC) and international (IAEA) needs, and size laboratories for each. Additionally, determine office space needs for IAEA inspectors.
6. Identify personnel access control concepts.
7. Identify long-lead time technology development needs.
8. Write and issue a Conceptual Safeguards Design Report.

Preliminary Design

Primary Objective: Performance Baseline A primary objective for preliminary design is preparation of the performance baseline, an event-driven schedule with defined accomplishment criteria for each event leading to facility operation. The performance baseline results from a near-complete, although not necessarily detailed design. Since the safeguards conceptual design is focused on those aspects that affect facility capital cost, preliminary design should be used to complete the full safeguards design with enough detail to create the performance baseline.

1. The process monitoring plan can be completed during this design phase following completion of the process and facility I&C design. The process monitoring design makes use of the process and facility I&C design, and must therefore await its completion.
2. Containment and surveillance features are prepared during this phase. This affects safety and security, and allows for more efficient material processing if designed well.
3. The accountancy performance is estimated following completion of the process and facility I&C design. The accountancy performance is characterized by way of the sigma-ID. This is the cumulative measurement error for the inventory difference at one standard deviation. This design is primarily dependent on DA.
4. The accountancy monitoring/verification design is prepared following completion of the process and facility I&C design. This design is primarily dependent on NDA, which is adequate for validation of accountancy DA, in most cases. Redundant but independent DA samples are required for limited verification.
5. Incorporate data authentication and protection into the preliminary design. This dictates wiring and security issues.
6. Update the conceptual design and issue the preliminary design, which should address all safeguard and security issues.

Final Design

Primary Objectives: Regulatory Approval and Construction Readiness Regulatory and customer approval is a primary objective for the final design. Paramount in gaining regulatory approval is validation that the safeguards design meets regulatory requirements. Another primary objective for final design is readiness for construction. Readiness for construction implies all aspects of the design must be fully complete.

1. Detailed instrumentation and equipment design is conducted during this phase.
2. Review reporting and data integration systems.
3. Update with any recent technology advances. This is dependent on the completed safeguards system design.
4. Validate that safeguards requirements are fully met as required for regulatory approval.
5. Update safeguards design if needed based on requirements validation.
6. Update the preliminary design documents for the final safeguards design report.

2.4 Unattended Monitoring

The IAEA relies heavily on the use of Unattended Monitoring Systems (UMS) to provide continuous monitoring at declared nuclear facilities around the world as part of its treaty-based mandate to ensure that nuclear material in these facilities is not being diverted from peaceful uses. Currently, over 100 UMS exist worldwide, with an average of ten new systems installed per year. The primary overall goal for these systems is to never lose safeguards-significant data under even the most challenging infrastructure and operational environments. The stringent data loss goal demand that these systems have high reliability through fault tolerant designs for both hardware and software and the success of these systems, has led to a growing reliance on UMS. Also of concern is the more practical operational side of the hardware and software used by the IAEA in multiple platforms, the interplay among worldwide vendors, the flexibility for upgrades and enhancements, the ease of implementation and configuration, and the training aspects. This

section introduces the current UMS as deployed by the IAEA, as well as the goals, benefits, challenges, and financial drivers. For any organization meeting new challenges in a rapidly evolving technology environment, it must be remembered that these technologies are always in flux as the next generation is designed, tested, and implemented. Nevertheless, the basic principles do not change.

2.4.1 Background

The concept of UMS is new neither in concept nor in implementation. The first example is the use of film cameras to monitor spent-fuel ponds in reactors. In the 1970s, the IAEA relied on twin Minolta film cameras for this monitoring effort. The cameras had a fixed interval of 20 min based on the operational time for moving a spent fuel cask, and required regular film cassette changes. The effort to review these images was quite problematic. Black and white images of a spent fuel pond with very little activity and no way to advance rapidly to images of interest challenged the most astute viewer to maintain attention through the entire review process.

With the advent of integrated circuitry and computers, this field has seen a revolution in capability. One of the first implementations of a modern distributed UMS took place at the Darlington CANDU reactor in Canada in the late 1980s. A Los Alamos National Laboratory (LANL)-developed system was installed to monitor the discharge of spent fuel from this online reactor. Even today this system continues to operate with high reliability. The only recent upgrade was made to the computer data collection system because the old PCs were obsolete, thus making them difficult to repair or support new devices such as data storage.

2.4.2 Definition of an Unattended Monitoring System (UMS)

An UMS comprises a single or multiple set of sensors designed to maintain CoK about the content and location of all nuclear material of interest in a facility 24 hours a day and 365 days a year. The concept of CoK can take many forms, from simply tracking spent fuel bundles or assemblies to performing a quantitative analysis on cans of MOX fuel. The intent is that the system can provide the necessary assurance for the IAEA to draw rapid, comprehensive, and definitive conclusions that nuclear material is not being diverted from peaceful use. This intent directly relates to two specific IAEA criteria and two scenarios: goal quantity and conversion times; and abrupt and protracted diversion.

As an example, the IAEA considers 8 kg of plutonium and 25 kg of HEU to be goal quantities that indicate quantities of interest to a diverter and, therefore, detection goals for the IAEA safeguards system. Conversion times are the estimated times for a diverter to convert these quantities into a nuclear weapon. These conversion times are based on the form of the material. The two high-level diversion scenarios consider the complete diversion of a goal quantity in a short time (abrupt) versus a series of small diversions that lead to a goal quantity over a long time (protracted). Taken in combination, all of these factors lead to the basis for the detection sensitivity of the IAEA safeguards system and the periods in which definitive safeguards conclusions must be drawn. The IAEA defines the word “remotely” (see item 4 below) as data going from a computer server in a monitored facility to some remote location. This transfer could go to an inspector data review room, an IAEA field office (such as Toronto or Tokyo), or the headquarters in Vienna.

Basically, a UMS

1. Is a system that automatically monitors the flow of nuclear materials 24 hours a day, 365 days a year, without the need for human interaction
2. May use a variety of sensors, such as radiation, pressure, temperature, flow, vibration, optical, and electromagnetic fields to collect qualitative or quantitative data
3. Is permanently installed in a nuclear facility
4. Is computer-based for data retrieval either on site or remotely
5. Has all of its components in tamper-indicating enclosures

Regarding 5, the IAEA must be able to independently verify its conclusions regarding the nuclear material in a facility. At the same time, the IAEA must consider that every state is a potential adversary. As such, there is always the potential threat that a state might try to alter the data being collected by the IAEA. The IAEA takes several steps to prevent an adversary from succeeding and to ensure that the data is authentic. One step is to design all enclosures so that the IAEA can detect tampering. The IAEA cannot prevent tampering; it can only detect it. Specific examples of tamper-indicating enclosures are presented in this document.

2.4.3 Why Does the IAEA Use UMS?

Before UMS was used, the routine inspection approach was periodic, relying on inspectors to visit nuclear facilities at a specified frequency, perform specific activities, and draw timely conclusions based on the data collected. This approach had many problems. Because it was periodic, the information collected at a facility by an inspector was no longer current once the inspector finished. This approach also meant that a significant effort could be required to reestablish this information across the inventory during the next inspection. Requiring a physical presence to carry out inspections also meant that the operator had to support every inspector's visit with personnel resources and interrupt activities to allow an inspector access. This process placed a heavy burden on both the IAEA and the facility operator. Some facilities, such as reprocessing, on-load reactors, and hot cells, precluded inspector presence because of health and safety concerns. Even in the case where inspectors could have complete access, it was not economically feasible for a facility that operated continuously, or for the IAEA, to provide around-the-clock safeguards using inspectors and the facilities' support staff. In fact, it was the design of fully automated facilities that actually drove the advancement into modern unattended safeguards as the only rational solution to the problem.

2.4.4 Benefits of UMS

1. Provides the highest level of safeguards assurance through continuous monitoring of activities in nuclear facilities
2. Minimizes the impact on the facility operator by allowing uninterrupted facility operation
3. Minimizes the impact on the IAEA by reducing inspector visits and inspection resources (including the high cost of worldwide travel)
4. Reduces radiation exposure to personnel and can operate in radiation areas too dangerous for humans

2.4.5 Key to Maintaining a Balanced Approach in IAEA Safeguards

The process of applying international safeguards to the entire fuel cycle encompasses the balanced nature of the approach and, particularly, the negotiations between the facility operator and the IAEA. The IAEA must be able to draw independent conclusions to fulfill its mission as a neutral arbiter of compliance with the Nonproliferation Treaty (NPT). Although it is true that certain principles must be maintained, such as independent verification, it does not imply that the means of gaining information to reach this verification cannot be flexible.

This balanced approach is possible because of the foresight of those who wrote the key provisions of Information Circular (INFCIRC)/153 as follows:

INFCIRC/153 – The structure and content of agreements between the agency and states in connection with the NPT

- PART I, Para 4, The Agreement should provide that safeguards shall be implemented in a manner designed:
 - To avoid hampering the economic and technological development of the state . . . in the field of peaceful nuclear activities, including international exchange of nuclear materials
 - To avoid undue interference in the state's peaceful nuclear activities, and in particular in the operation of facilities
 - To be consistent with prudent management practices required for the economic and safe conduct of nuclear activities

This instruction to the IAEA stressed the need to be expeditious in implementing safeguards. It also gave the state and the facility operator, who has the deepest knowledge of the facility, the right to negotiate efficient safeguards, while the IAEA maintained its right to independent verification. Any state can learn from this example in its own domestic compliance policies.

2.4.6 Major Cost Drivers in the Department of Safeguards

One of the primary selling points for UMS is cost-effective safeguards, which would include not only cost-effective safeguards at facilities, but also a reduced burden on IAEA resources. A 2004 financial plan shows the following average breakdown of costs in the department:

- Staff = 68%
- Other direct costs = 13%
- Travel = 10%
- Laboratory = 5%
- Shared costs = 3%

With the exception of travel, very little can be done to reduce the costs in these areas. If technology could be used to replace some portion of an inspector's effort without sacrificing independent verification, it is logical that the travel required for the scheduled periodic worldwide inspections could be dramatically reduced. The intent of the current push is to spread the use of UMS to appropriate facilities around the world as fast as possible.

Worldwide Deployment of UMS

The push to deploy UMS started in the late 1980s and has rapidly advanced, along with technological leaps in the capability and reliability of hardware, firmware, and software. From 2000 to

2004, the IAEA installed an average of ten new systems per year. In August 2004, statistics on these systems were as follows:

- 90 Systems installed (~115 in 2005)
 - 79 Radiation-based
 - 5 Thermohydraulic-based
 - 6 Process monitoring-based
- 44 Facilities
- 22 Countries
 - SGOA, 30 systems (SE Asia)
 - SGOB, 40 systems (North and South America, Africa, India, Pakistan, Iran)
 - SGOA, 20 systems (Europe, Kazakhstan, Ukraine)

The abbreviations SGOA, SGOB, and SGOA indicate the Department of Safeguards Operations Division that has specific geographical areas defined to implement their safeguards mission. The increase of nearly 25 systems in a little over 1 year primarily reflects the UMS installations in the Japanese Rokkasho Reprocessing Facility. For the IAEA to draw timely safeguards conclusions, this complex, high-throughput facility represents the greatest challenge to date. In 2004, 18 UMS were planned to allow the IAEA to draw independent verification.

2.4.7 Primary Goals of UMS

The commitment to implement UMS around the world is a daunting task. The consequences of failure are both technical (the need to reestablish the knowledge of content and location of the nuclear material at a facility and the complexity and cost in doing so) and political (the state impacted by a UMS failure will rightfully complain to the IAEA about the additional costs it will face because of a failure of IAEA equipment). These consequences, in turn, can raise questions about the IAEA's competence in accomplishing its mission (it should be noted that some installed systems are "joint use" by the state Inspectorate and the IAEA and therefore are jointly specified – the state often has equal responsibility and also often funds the development and installation). Therefore, the UMS unit established two primary goals in order of priority: no loss of safeguards-significant data and assurance that the data is authentic.

The key in the first goal is "safeguards significant." It is not possible to ensure that all components work all the time. Instead, the emphasis is on providing fault-tolerant systems that can continue to meet the needs of the IAEA in maintaining knowledge of the nuclear material in a facility in spite of some equipment failures. Therefore, by using systems that are designed to be robust and reliable while eliminating or minimizing single points of failure through redundancy, components can fail without jeopardizing the IAEA's mission.

Authentication of data is a tremendous challenge. Because the IAEA must assume that every state could be a potential adversary, it goes to great lengths to protect its data from the point of origin in the sensor through data analysis. Nevertheless, data authentication is of secondary importance to data loss. Authentication must not jeopardize the reliability of the data collection scheme.

2.4.8 Method of Obtaining Primary Goals

Considering the primary goal, "No loss of safeguards significant data," some key approaches include the use of high reliability and/or redundant critical components and/or reduced reliance

on low reliability components. High reliability components can be a great challenge in the UMS area primarily due to the low unit volume for some key components. Specialty components such as the data generators are only made by small vendors, so reliability is always tested to assure performance. The current design philosophy at the IAEA strives to use as many high-volume, commercial, off-the-shelf (COTS) products as possible, which helps not only with reliability but also with costs. Fortunately, many high-reliability components are available commercially, including sensors, batteries, cables, software, air conditioners, uninterruptible power supplies, industrial PCs and servers, operating software, connectors, encryption and wireless hardware and software, and cabinets.

Using independent redundant components to monitor the same event is another primary design approach to prevent the loss of data. Defense in depth by layering both the sensor and data collection systems is another fault-tolerant approach. Some approaches include the use of signal splitters. The sensor could be a gas-filled tube for neutron detection, which has demonstrated reliability over many decades (unlike the data generator, which may not be so reliable), and has its signal split and sent to two different data generators. Therefore, a single sensor can be used in conjunction with two data generators (radiation data generators can support multiple sensors) to ensure robust data collection.

The use of an uninterruptible power supply (UPS) to ensure uninterrupted data collection even after a loss of supply is a clear application to UMS. It is even more crucial considering that the infrastructure in many countries around the world is such that loss of power of varying duration is a routine event. It is the practice of the IAEA to negotiate with the facility to obtain Class 2 power from the facility (Class 1 supports the facility's safety system. Because of its importance, nothing else is added that might risk its integrity). This system is their backup power, and obtaining power for IAEA systems from it helps ensure reliability for the IAEA system. Besides a main UPS deployed in an electronics rack, the same defense in depth is applied where other critical components, such as data generators, have battery backup internally.

Using multilayer security is the second goal, and it reflects all the activities that the IAEA performs to secure its data. These activities include mechanical approaches, such as secured housings that hold sensors and all other associated equipment used to collect data, such as electronics cabinets, cabling, and junction boxes. The activities also include electronic approaches, such as authentication and encryption.

The primary objective for any UMS is to collect safeguards information reliably without an inspector's presence, on a continuous basis, and to

- Verify flow and inventory of nuclear materials
- Minimize intrusiveness on the operator
- Reduce IAEA and operator manpower requirements
- Decrease radiation exposure to the IAEA inspector and facility operator
- Standardize hardware and software for the IAEA to minimize maintenance and training

When beginning the design of a UMS, the following design considerations are investigated for each application:

- Cost benefit: A cost benefit analysis is made, comparing inspector days in the field with and without a UMS.
- Reliability and stability: Have the UMS components demonstrated a reliability of at least 150 months mean time between failures (MTBF) for the requested application? Can the components stably perform within the available infrastructure?

- Meet operation's user requirements: Can the UMS meet the performance and functionality required by the operation division that will use the data from the UMS?
- Operator-provided equipment: Is there operator equipment that could be used jointly by the IAEA and the operator while maintaining the independent verification capability required by the IAEA?
- Authentication requirements: Can the UMS be secured to assure the IAEA that the data is authentic?
- Early involvement of the agency in the planning stages: allows integration of facility-specific safeguards features into final plant designs, attaining the most cost-effective design before the facility is constructed, and thus avoiding the high cost and restrictions associated with facility retrofits.

Authentication

Authentication is defined as all measures taken to ensure that the safeguards measurement systems collect and provide authentic data. This broader category also includes encryption. For the classical application of electronic authentication and encryption on cryptographic modules, the IAEA follows FIPS-140 (Federal Information Processing Standard-140). This standard specifies the security requirements for a cryptographic module used within a security system protecting sensitive information in computer and telecommunication systems. Because of the nature of its work, the IAEA must monitor activities by leaving its equipment in facilities in states that are potential adversaries; this action represents a great challenge for UMS authentication.

Some examples of the steps taken by the IAEA to ensure that its data are authentic include the following security methods:

- Software controlled: IAEA software is not accessible by states, nor are systems shipped with hard drives in them. These actions eliminate opportunities for a state to examine the software during the process of shipment, customs clearance, and receipt at a facility.
- Tamper-indicating enclosures: Includes all external housings and shipping containers.
- Containment/surveillance (C/S) on detector head and electronics: Containment devices, such as seals and surveillance, as with optical sensors, can be used to protect any enclosure (seals at any time and surveillance during operation).
- Visual inspection of components and cables: Because the IAEA cannot prevent tampering, it is critical that inspections identify potential tampering. Currently, this identification is limited to visual techniques; however, many other techniques are applicable.
- Efficiency check with normalization source: It is common practice to use an IAEA source that is stored at a facility under IAEA seal to check the operational response of equipment that the IAEA will use for any measurements.
- Supervision of maintenance: In cases where the IAEA must use local companies to perform maintenance or repair on IAEA equipment, all such work is done under the supervision of the IAEA.
- Cross-correlation with other SG measures: As difficult as authentication can be for the IAEA, the use of multiple sensors on time correlated activities increases the difficulty for an adversary to compromise such a system.
- Use of unique data signature on all digital data: The IAEA maintains a cryptographic standard for all digital data and communications. Currently, this standard requires 128-bit encryption algorithms.

- Encrypted data transmission between cabinets and for remote monitoring: Data encryption is used both on site and off site for all data (special consideration for each state is also given for off-site data, as appropriate).
- Uninterrupted power supplies (UPS): Maintaining power is not only key for uninterrupted data collection, but for data protection as well. A layered approach is used.

Tamper-Indicating Features

Tamper-indicating features address all detection mechanisms, both electrical and mechanical. Although not separately categorized, various design features are used to minimize or eliminate access points by an adversary. At the most basic hardware level, the IAEA uses simple mechanical approaches to eliminate easy tamper routes. Consider the standard 19-in. Rittal industrial rack and enclosure that are used to house IAEA instrumentation. ➤ [Figure 13a–c](#) shows details of this enclosure.

➤ [Figure 13a](#) shows the application of an IAEA tamper-indicating metal seal that is applied to the locking mechanism for the cabinet. ➤ [Figure 13b](#) shows the locking mechanism in the open configuration; this mechanism moves full-length door pins so that the edges of the door cannot be pried open. ➤ [Figure 13c](#) shows the use of internal hinges (because external hinge pins are readily removed). The standard UN blue used on all IAEA equipment is applied using a powder process to make touchup of tampering more challenging.

The concept of “protected enclosure” reaches out to sensors, as well. ➤ [Figure 14](#) shows a picture of the entrance gate monitor used to measure fresh MOX fuel prior to entry into the reactor core. The application of the standard IAEA metal seal to detect attempts to access the upper portion of the neutron tube electronics can be seen. This neutron collar uses coincidence counting to assay the plutonium content of each assembly. ➤ [Figure 15](#) shows the IAEA tamper-indicating conduit used to protect unauthenticated signal cabling that connects

■ **Figure 13**
Cabinet close-ups

■ Figure 14
Entrance gate monitor (ENGM) detector

■ Figure 15
Tamper-indicating conduit

sensors to the electronic equipment in the IAEA instrument enclosures. This attempt to protect the cabling is problematic. Some facilities can have kilometers of cabling, including many portions that must go through wall penetrations that cannot be accessed. The addition of this stainless-steel bellows-type conduit is expensive and must be visually inspected periodically by an inspector to detect tampering. This requirement is very impractical because some areas cannot be accessed due to operational and radiation constraints, let alone the task of examining the conduit in a thorough-enough manner to actually detect tampering. This area clearly needs to apply new technical means to either authenticate all cabling or detect electronic tampering.

■ **Figure 16**
AP-10

Security Solution: Virtual Private Network (VPN)

The Virtual Private Network (VPN) transmits data both between cabinets and remotely from a facility through various available mediums such as internet, satellite, public switched telephone network (PSTN), and digital subscriber line (DSL).

One device that has been used at the IAEA is made by NetScreen. Specifically, models 5XP and 5XT have been installed. These products meet the FIPS 140 Level 2 standards used by the IAEA. They are small and relatively inexpensive, at less than US \$1,000 each. Expert installation is not required, and they can be used for wire or wireless applications.

Wireless Solution

A particularly costly activity in any nuclear facility is the installation of cabling. Installing tamper-indicating conduit further increases this cost. In addition, the IAEA often must install monitoring equipment on movable platforms. Taking a wireless transmission approach is quite attractive for these reasons. The IAEA recently installed a wireless system using the Alvarion AP-10 indoor wireless hub (~US \$1,000 and shown in ▶ [Fig. 16](#)) and the SA-10 station adaptor (~US \$500 and shown in ▶ [Fig. 17](#)) for the end-user computer. This system operates on 10BASE-T Ethernet using RJ-45 connectors with data rates up to 3 Mbps and a range up to 150 m (500 ft.).

Software Standards The IAEA has gone through a learning process in terms of the software it uses in UMS. Of particular note is that, in the past, the IAEA accepted custom software from each developer for both collection and review functions. This technique significantly complicated training, upgrades, field support, installation, and debugging. As a result, the IAEA has now defined single standards for collect-and-review software. However, this transition is an ongoing process because the IAEA does not have the resources for a major program to upgrade all systems to these new standards. On average, it takes at least 2-years for any worldwide software upgrades to be completed. This approach is based solely on the standard 2-year maintenance replacement cycle required for all batteries.

■ **Figure 17**
SA-10

It should also be pointed out that there are always unique one-of-a-kind systems that do not warrant the time and effort to migrate such unique limited-use systems to the standard software platform. Collect Software is the automated software application used by the IAEA in a local cabinet's computer system to collect data from sensors at the facility being monitored. This technique could be a large distributed sensor system or one that is very small (on the order of just a few sensors). The primary function is the polling of data from data generators. A data generator is the first electronic device that receives the sensors' input and, if required, digitizes the signal.

The IAEA's current data collection standard is called multi-instrument collect (MIC). MIC was designed by LANL under the auspices of the US Support Program. This application has the following functions:

- Data collection (can support ~40 data generators)
- Startup service (automatically starts up during the PC's start-up routine)
- File transfer service (can provide automatic file transfer to an archive)
- Delete files (can automatically clear data storage space as desired)
- Binary files to text (can convert error code to readable text)
- Debug tool (a self-diagnostic tool to discover/resolve problems)
- Tracker (transmission of state of health)
- File copy routine (can provide automatic copies of data as desired)
- Display instrument messages (allows user to view messages from polled instruments)

Review Software is used by IAEA inspectors to analyze and draw conclusions on the data collected at a facility. In general, this software is used in an attended mode. That is, it takes an inspector to use this software for the analysis effort. It is also important to note that, in general, the IAEA does not perform real-time data analysis; the IAEA's inspection methodology is based on drawing timely, but periodic, conclusions based on the type of nuclear material, its form, its quantity, and the estimated time for conversion into a weapon.

The IAEA's current data collection standard is called Integrated Review Software (IRS). IRS was designed by LANL for the Rokkasho Spent Fuel Storage Facility and was funded by the Japanese Nuclear Material Control Center (NMCC) (Abhold et al. 1998). It was further developed to integrate INCC for the Japanese Plutonium Fuel Production Facility (PFPP), with funding provided by the Japan Nuclear Fuel Cycle (JNC) Development Institute. Further enhancements have been made under the auspices of US Support Program because this software has been rolled out worldwide. This application has the following functions:

- Allows for review of data outside of active area. Inspectors are encouraged to minimize their time in a radiation area. Therefore, the IRS software is usually on a PC in an office area controlled by the IAEA.
- Provides event screening by threshold settings. A sort on events detected by a sensor can be screened first using threshold settings to eliminate events that are not of safeguards significance.
- Provides graphical display. This plots the sensors' events against time for a visual display.
- Provides data analysis. This capability uses algorithms to assess events.
- Provides campaign management. This capability allows for data partition in line with the operator's declaration of activities.
- Marks assays by time correlation. This capability allows for specific selection of an event based on time.
- Transfers marked data to software for analysis. This capability allows the use of more sophisticated analysis algorithms in other modules to assess the events.

This modular piece of software allows for any vendor to add capability to its suite of analysis tools. The current suite of review tools includes

- RAD: radiation review (graphical plot of radiation signals against time)
- DVR: digital video review (display of video images against time)
- PR: position review (display of global positioning system (GPS) data on a two-dimensional map)
- ISO: plutonium isotopic review (quantitative analysis of isotopic composition)
- OP: operator review (operator's declaration of events/activities)
- IR: integrated review (comparison engine that uses defined limits to match the operator's declaration against the IAEA data)

An example of IR in association with the RAD, INCC, and OP modules is shown in  Fig. 18.

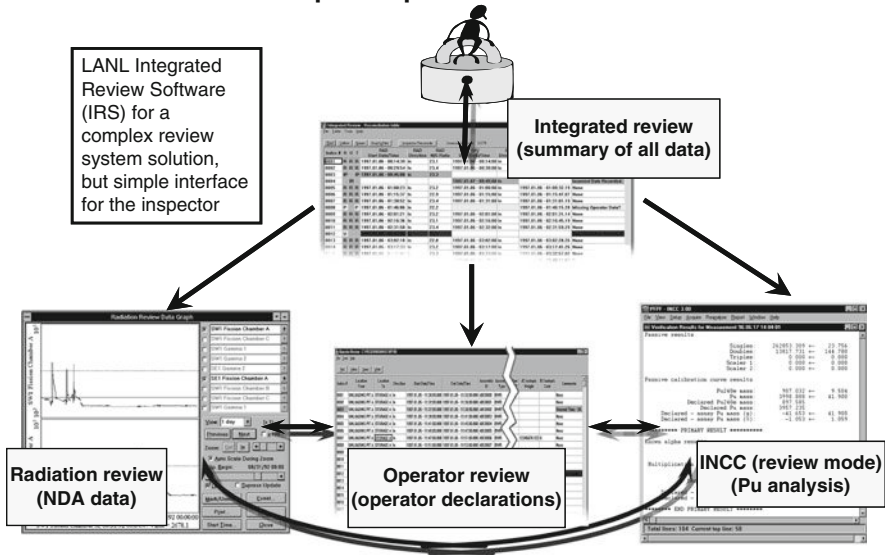

Hardware Standards

A similar learning process has occurred with hardware. Originally, entire UMS cabinets were designed by vendors. However, it quickly became clear that these specialty vendors needed to focus only on safeguards-unique hardware, whereas the remaining components would be COTS units. This approach would give the IAEA the best combination of dedicated devices and cost-effective commercial components, providing maximum flexibility by using a building block approach to UMS.

System Components

Computers One of the least reliable components used in a UMS is the computer. A standard model is impossible to maintain because the technology changes so rapidly that having two PCs

IAEA assistance: inspector point of view

■ Figure 18
Integrated Review Software (IRS)

with the same name and model number may not mean that the internal components remain the same; therefore, reliability always remains an issue. The IAEA has used configurations to ensure higher reliability. This method is based on the following basic approaches: minimize or eliminate moving parts (by using passive cooling and solid state drives), use redundant components “redundant array of independent disks” (RAID, multiple independent cooling fans, or a fail-over box that starts up a second PC), and use an independent watchdog that can restart a PC.

A fault-tolerant system should be able to run without a “collect” PC. One of the approaches used by the IAEA is the LANL-designed intelligent local operating node (ILON). This device can maintain certain critical functions that allow a distributed sensor network to continue to collect data without the collect PC. In addition, these instruments collect data even during total failure of both the collect computer and the IILON. However, certain critical functions, such as triggering, can be disabled without the IILON. This particular device is undergoing an upgrade to meet the IAEA’s Ethernet standards and to use strong authentication. It has the following characteristics and functions:

- Open topology and cabling: This approach allows maximum versatility for facility upgrades that require additional monitoring sensors that were not planned at the time of installation due to a new facility capability or new IAEA requirements. The newly upgraded IILON is Ethernet compatible.
- Instrument or collect function.
- Time synchronization: This approach can keep all of the data generators on the same clock setting.

- **Triggering (direct and indirect):** This critical function allows sensors to be combined to obtain the highest level of safeguards assurance. One example is a radiation sensor triggering a camera.
- **Authentication:** The current ILON has weak 32-bit wrapper authentication; the upgrade brings this to 128-bit authentication.
- **Watchdog:** If a data generator fails to check into the ILON, it can send a hard reset command.
- **Functions independent of collect computer:** It operates at the same independent level as a data generator using batteries as necessary.
- **Narrow bandwidth:** The current ILON has a limited bandwidth of 78 kb/s because it was not intended for digital images; the upgrade brings this speed up to 100 MB/s.

Surveillance Data Generator The Digital Camera Module 14 (DCM-14) was designed by Dr. Neumann GmbH under the auspices of the German Support Program. The module is commonly combined with a charge-coupled device (CCD) camera. The DCM-14 also has a rotating buffer memory for up to eight images. This capability plays a key role when triggering is used for safeguards applications. The camera is set at a regular “heartbeat,” where an image is taken at a designated frequency. As an untriggered image, this new image is placed in the rotating buffer as the new #1 image, and the previous images rotate through the buffer, with the last image, old #8, being deleted. When a trigger takes place, such as from a radiation sensor, the DCM-14 dumps the rotating buffer to the permanent data storage as permanent images. It then goes into a triggered mode with the subsequent post-trigger images at some set interval that will also be dumped to permanent data storage. In this way, a complete cycle of images is available to fully define the triggering event.

The DCM-14 has the following capabilities:

- Digital image
- Scene change detection
- Image compression
- Image/data authentication
- Image/data encryption (triple DES algorithm)
- Power management (minimization mode when on battery power)
- Battery backup (~2–3 days, depending on image frequency)
- External triggers
- On-board 100-day data storage (in removable flash cards)
- State of health

The module can store up to 100 days of images, which allows a safeguards inspector on a 90-day inspection cycle to recover all images, if the collect computer has failed, by removing the flash cards. The internal battery is another fault-tolerant approach because the main cabinet has a “smart” UPS that extends the maximum life to the data generator by shutting down the collect computer; the UPS batteries are dedicated to the data generators. If the UPS’s life is exceeded, the data generators’ internal batteries further extend the life of the module. All of these layers of power are intended to carry the IAEA systems through the majority of power outages without a loss of data.

Radiation Data Generators These data generators follow the same functionality as that seen with the surveillance generator; the difference is the capability to support radiation sensors and transmit triggers. The two primary radiation data generators are the LANL designed MiniGRAND

(miniature gamma-ray and neutron detector) developed under the auspices of the US Support Program, and the BOT Engineering-designed standalone autonomous data acquisition module (ADAM) developed under the auspices of the Canadian Support Program. Both radiation data generators are undergoing upgrades.

The MiniGRAND supports three pulse channels and two current channels, allowing a broad assortment of radiation sensors to be attached. The Standalone ADAM data generator supports eight pulse channels; however, an adaptor is under development to allow current-based sensors, as well.

Dedicated Simple Systems

VXI-Based Flow Monitor (VIFM) In contrast to the modular units mentioned previously, the IAEA has had a complete UMS developed by a single vendor. One example is the VXI-based flow monitor (VIFM), which was designed in the last decade by BOT Engineering, under the auspices of the Canadian Support Program, specifically to monitor spent-fuel bundles from CANDU reactors. The primary specification established by the IAEA required the use of the industrial VXI architecture, whereas the manufacturer was free to design the rest of the system. This unit is used to monitor core discharges from the reactor face (core discharge monitor-CDM), and bundles (bundle counter-BC) as they are moved into the spent fuel pond. It has proven to be very reliable, using paired ADAM data generators, which provide full data generator backup, and up to eight SOLGEL batteries, which provide up to 90 days of operation without power supply. The main problem with the unit is the custom design of nearly all components, including the collect computer. Upgrades have been costly and lengthy. This experience helped the IAEA focus on using COTS where it is most logical.

The VIFM is a qualitative system that can count items but cannot assay nuclear material quantities. ➤ *Figure 19* shows a typical spectrum from the CDM sensors for a CANDU 600. In this display, we show counts along the ordinate axis (traditional y -axis) and time along the abscissa axis (traditional x -axis). The neutron signal is represented in white and the gamma in black. An algorithm is applied that can count bundle movements using this peak structure. The algorithm is designed to detect off-normal responses. To understand the radiation profile shown in ➤ *Fig. 19*, a short review of CANDU reactor operations is in order. This reactor uses natural uranium for fuel and heavy water for the moderation necessary to sustain a nuclear reaction. The fuel channels are aligned horizontally in the reactor. In this on-load power reactor (the category of power reactors that can be refueled during operation), approximately 15–23 bundles per full power day are replaced on a daily basis to refuel the reactor. Each spent fuel bundle is tracked because it will contain plutonium once the fission process has occurred. Therefore, the CDM detectors are located only on the reactor face from which spent fuel will be removed. Thus, the IAEA must be able to conclusively count and maintain surveillance on the nearly 3,000 spent bundles removed from the reactor each year.

The process of removing and replacing fuel bundles follows a specific sequence. Two fuel-handling machines are aligned on the same fuel channel from opposite faces of the reactor. One fuel-handling machine has four pairs of fresh fuel bundles (total: eight) loaded in its rotating cylinders (much as the barrel on a revolver-type handgun) for insertion into the reactor. The other fuel-handling machine is empty and is ready to receive the spent fuel bundles that are removed. When the neutron (white) spectrum of ➤ *Fig. 19* is considered, the first peak represents the removal of the channel plug from the reactor face where the spent fuel is removed. The second peak represents the removal of the radiation shield plug, now allowing direct access

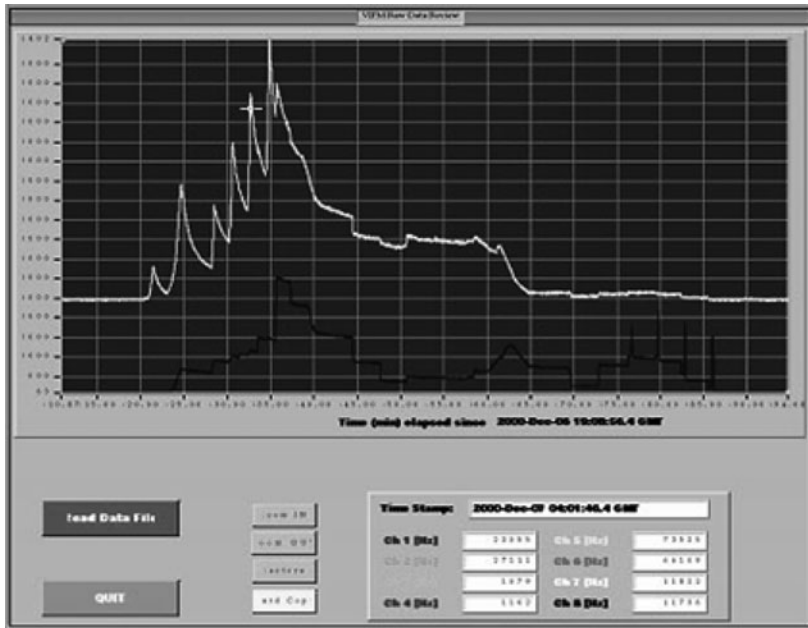

Figure 19
Core discharge monitor (CDM)

to the fuel. The next four peaks represent the removal of four pairs of spent fuel bundles, representing eight bundles from the reactor.

Figure 20 represents the bundle counter. This counter uses three solid-state gamma ray detectors located above the tray mechanism that transfers the spent fuel bundles from the reactor hall to the spent fuel storage pond. The response from these three detectors is represented by the sequential response graphs. A fourth sensor is located at a point where it can detect the transfer of the two bundles into the spent fuel pond and is indicated by the last trace. The first three sensors are used to verify the transfer of the two bundles from the reactor core face onto the transfer tray. These sensors are located longitudinally along the axis of the tray transfer mechanism, with the first two sensors above the final resting position of the second bundle and the third above the final resting position of the first bundle. The forward location of the first two sensors allows them to view the spacing between the two bundles, which is evident by the dip in response on the graphs of the peaks (see Fig. 20).

The response from the third sensor that is located toward the rear of the transfer tray shows only the first bundle; therefore, this sensor never sees this gap, as evidenced by the lack of a response dip. The specific locations of these three sensors were chosen to detect all possible scenarios of diverting bundles from the tray.

The VIFM system, as is true for most UMS, uses counting algorithms to aid the inspector in drawing conclusions from the data collected by these automated systems. In the normal first screen display, the total counts of bundles from the CDM and BC systems are displayed. Under conditions of normal operation, the two bundle counts must match. In this case, the inspector can consider his or her inspection of the data as complete, and looking at the detailed response would be unnecessary, as shown in Figs. 19 and 20. A mismatch in count would

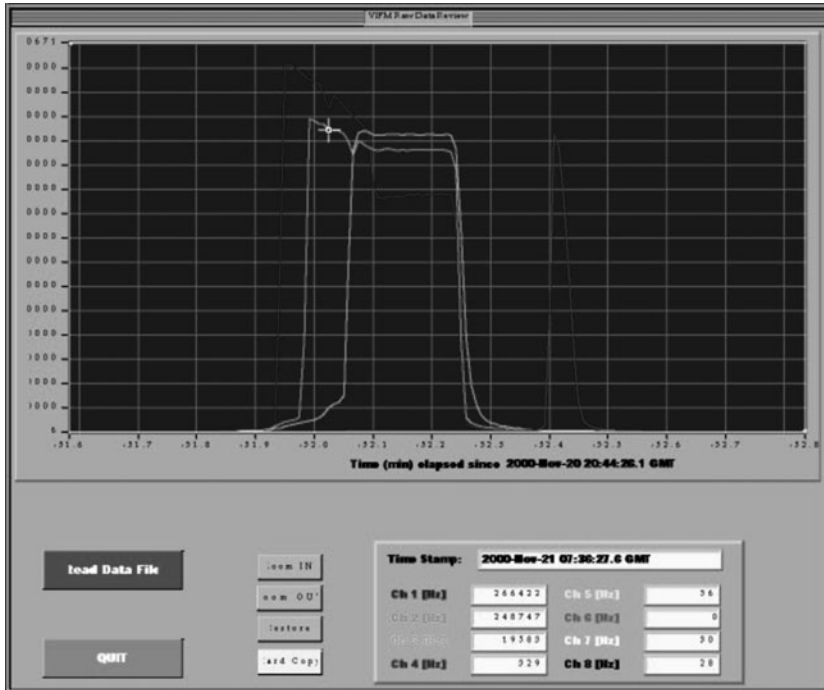

Figure 20
Bundle counter

indicate an anomalous condition. It would then be up to the inspector to determine the cause of this discrepancy. Under a condition that requires detailed investigation, the inspector can then “drill down” to a lower-level screen in the software to see the response peaks for each event. A mismatch would not immediately cause the inspector to suspect potential diversion. In fact, discrepancies are not that uncommon because problems may occur during operations at a facility. As part of the operator’s obligation to the IAEA, an operator declaration of activities for the period covered by the inspection is made. In this declaration, the IAEA inspector would most likely find mention of some difficulties during operations that may be detected by the UMS.

Advanced Thermohydraulic Power Monitor (ATPM) Although the majority of UMS use radiation sensors for safeguards on nuclear facilities, the IAEA deploys a wide range of sensors. One nonradiation sensor system is the ATPM. This system was designed specifically to meet the safeguards challenges associated with plutonium production in research reactor fuel. Unlike commercial power reactors that operate at full power in a fixed-core configuration for extended periods of time as part of a state’s base power grid, research reactors typically operate for short (2–3-week) periods at varying power levels and can have the flexibility to change the core configuration. In addition, spent fuel is routinely replaced in commercial power reactors on a routine basis (typically every 12–14 months in LWRs and daily in on-load reactors such as the CANDU), allowing for direct monitoring and measurement. Because of the periodic nature of operation in research reactors, a single core loading of fuel lasts for many years.

The challenge to the IAEA is how to determine plutonium production in the fuel in the core accurately throughout the lifetime of a research reactor. Because the IAEA has access to the detailed design of each facility (through the design information verification process), knowledge of power can be used to calculate plutonium production in the core of the reactor. This methodology is the basis for the ATPM approach.

➤ *Figure 21* shows a schematic representation of the ATPM system design. The data collection side of the system is located in the radioactive cold portion of the facility. On the “Hot Area” portion of the schematic, two redundant sets of sensors are mounted on the hot and cold sides of the primary core cooling loop. Each set contains a resistive-type temperature sensor (T) and an ultrasonic flow monitor (F). The output from these sensors provides a velocity measurement on the cooling loop’s water and the temperature drop as heat is removed from the loop. The data from these sensors, in combination with the required reactor design information, are used to calculate reactor power output. This calculation is plotted against the unit’s internal clock. In addition to being used as a direct comparison with the operator’s declaration on reactor operations, this information can be used with predictive reactor operation codes, such as ORIGEN, to calculate plutonium production.

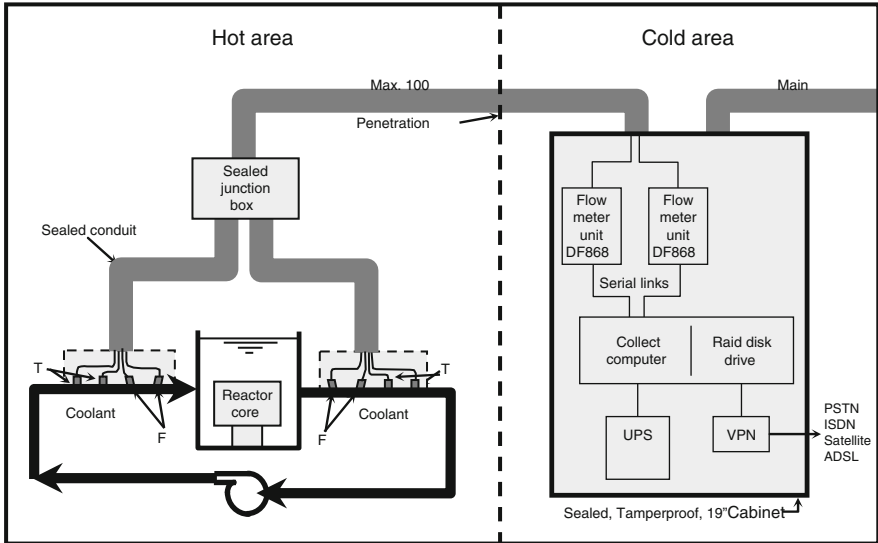

➤ *Figure 22* shows an IAEA engineer installing an ultrasonic flow sensor on the primary core cooling pipe. The long frame that is strapped onto this cooling pipe (the IAEA makes every attempt to apply its sensors in a manner that minimizes interference in operations and safety) is used to secure the ultrasonic sensors at the required angle for this specific pipe diameter. The engineer has one sensor in his hand and is securing it on the frame. A matching sensor is installed at the far end of the frame (not visible in this image). Note the two threaded rods that are mounted perpendicular to the frame and extend away from the cooling pipe. The first is located immediately adjacent to the engineer’s left hand. The second is in the center of the frame. A third rod is on the other end, not visible in this picture. This photo shows the difficult work environment often faced by the UMS staff.

➤ *Figure 23* shows the tamper-indicating cover applied to the sensor frame shown in

➤ *Fig. 23*. Nuts have been tightened on the threaded rods securing the cover. Tamper-indicating wire has been pulled through the holes in each threaded rod and tied off at the center rod, awaiting the application of a metal seal by the IAEA inspector.

➤ *Figure 24* shows the primary computer screen display when an inspector or UMS staff member opens the sealed cabinet door. In the lower left-hand corner, note the power versus time display that indicates that the system is functioning. Above that display are current read-outs from the sensors and the power calculation. At the upper right is a state-of-health button with the following legend: green (current status) = all sensors are functioning; yellow = loss of one sensor, conclusions can still be drawn using the backup sensor; red = loss of both sensors, conclusions are in jeopardy. The remaining buttons serve many functions for the inspector, such as viewing the graphs for each sensor, data for specific periods, and data downloads. Other buttons are used for UMS staff to set up the system, make diagnostic checks, and fulfill other requirements.

Dedicated Complex Systems The previous systems were defined as “simple” systems solely from the perspective of the nuclear material they were designed to safeguard. Both the VIFM and the ATPM were designed to provide safeguards on an item facility. In an item facility, all nuclear materials are permanently sealed within a container that has no access point and structurally never changes during the entire time at the facility. Nuclear fuel contained in fuel rods that are mounted in assemblies fits this definition. In a bulk facility, material can be accessed directly

■ Figure 21
Advanced thermohydraulic power monitor (ATPM) system diagram

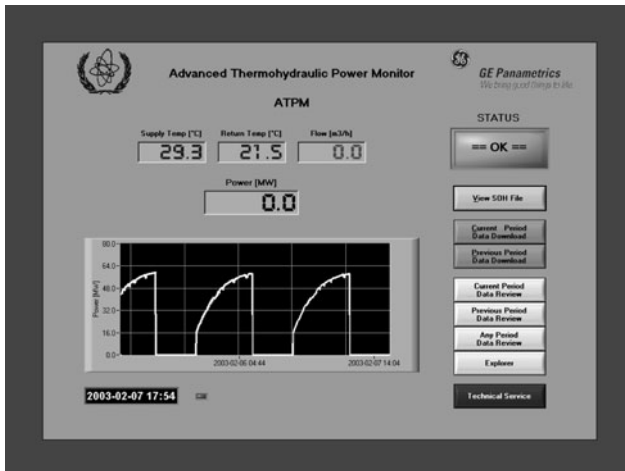

■ Figure 22
Flow sensor installation

and could change form. Examples include gases, powders, solutions, and metals. Many of these forms are found in enrichment, reprocessing, and fuel fabrication facilities. Access to bulk materials present a much greater safeguards challenge for the IAEA as small portions of material can be diverted.

One of the greatest facility challenges is safeguarding a reprocessing facility. The plutonium–uranium reduction extraction (PUREX) process is one example. At this facility, nuclear material

■ Figure 23
Tamper cover installed

■ Figure 24
ATPM main screen

progresses through the following different forms: feed material (spent fuel, which contains irradiated nuclear material with actinides and fission products); processed material (input liquids, separated liquids, undissolved solids, and low-level and high-level liquid and solid wastes); and product material (separated oxides and MOXs). High radiation levels dictate that most of these activities be controlled remotely. Good safety and business practices demand that such facilities be fully automated. This is the case at the Japanese Rokkasho Reprocessing Plant (RRP).

► Figure 25 shows a picture of the Improved Plutonium Canister Assay System (iPCAS). This dedicated quantitative system is fully integrated into the operational flow of the facility. It

■ **Figure 25**
Improved Plutonium Canister Assay System (iPCAS) side view

is owned by the Japanese safeguards authority and used by the IAEA. It was designed by LANL and represents 1 of 10 systems from LANL that are deployed throughout the flow stream at the RRP. iPCAS was designed to measure precisely three cans totaling 36 kg (18 kg of plutonium and 18 kg of uranium) (Abhold and Baker 2000) of MOX product ($(\text{Pu}/\text{U})\text{O}_2$) from the reprocessing activities that provides the feed material for a fuel fabrication facility currently under construction.

One unique aspect of this neutron coincidence and gamma isotopic counting system is the use of unmoderated ^3He tubes to correct for moisture content. The inner unmoderated and outer moderated (high-density polypropylene polyethylene) neutron tubes can be seen in ▶ [Fig. 26](#), which shows a top view into the iPCAS counter. ▶ [Figure 27](#) shows the three gamma spectroscopy units and the associated electro-coolers for the intrinsic germanium detectors, the location of which can be seen in ▶ [Fig. 25](#). This spacing along the vertical axis of the iPCAS allows each gamma detector to view one can and determine the isotopics. Combining the isotopic measurement with the neutron measurement allows for an accurate quantitative determination of plutonium in each can.

Pre-Field Installation Testing With the primary focus on reliability, the UMS Unit spends considerable time assembling and testing complete field-configured systems at the IAEA in Vienna, in the Safeguards Equipment Support Facility (SESF). Although not always possible, the goal is to test all systems for 90 days before installation in the field to ensure that all infant mortality and configuration issues have been addressed. The testing protocols include the full range

■ Figure 26
iPCAS top view

■ Figure 27
Isotopic system

of expected field conditions, with one exception: testing of the sensors to matching radiation fields. It is not practical to create duplicate radiation environments nor required because radiation sensors are very robust and reliable. Testing with smaller sources either at the SESF or at the IAEA's Seibersdorf Analytical Laboratory, where stronger sources are available, is sufficient to guarantee performance in the field. The IAEA's experience has been that these sensors, if defective, are defective upon delivery. Therefore, these simple tests are sufficient to ensure reliable performance.

To test these units fully without the actual radiation field present, the IAEA UMS Unit has developed a dedicated signal generator that can duplicate the exact response peak, allowing full testing of the counting algorithms in these instruments. The importance of the focus on laboratory testing of these generators before they are installed in the field becomes clear when considering that the cost of travel alone averages approximately US \$5,000 per trip. Whether simple or complex problems surface in the field, repair trips are expensive. Because of the distances traveled and the unique nature of the equipment, even simple trips require that a technician or engineer carry sufficient replacement parts and tools to deal with all contingencies; this excess baggage adds considerably to the expense of traveling.

2.4.9 Conclusion

Over the last two decades, the IAEA has successfully developed and deployed UMS, automating what was once a periodic inspection effort by inspectors. The success of these systems is based on effective design methodologies that emphasize reliability through fault-tolerant designs, by taking a component building block approach to ensure maximum flexibility in meeting the needs at the diverse and complex facilities that comprise the nuclear fuel cycle. This approach has been accomplished in a cost-effective manner that benefits both the IAEA and the facility operator. As the use of nuclear power continues to expand across the world, UMS are leading a revolution in safeguards capability so that the IAEA can continue to meet its treaty-based obligations, which ensure the peaceful use of nuclear technologies.

2.5 Process Monitoring

The main goal of nuclear materials accounting (NMA) is to confirm within measurement error uncertainty the quantity of SNM in all declared locations. Because the absolute value of measurement error uncertainty increases as throughput increases, in spite of monumental and successful efforts to improve the uncertainty of measurements over the years, modern large scale facilities are unlikely to meet the quantitative safeguards goals by NMA alone. NMA involves material balance (MB) closures, which require estimates of SNM inventories throughout the facility. Traditionally, these inventories were estimated after extensive shutdown and cleanout measures to move material into measurable locations. The procedures to accomplish these inventories are time consuming and are conducted only on an annual basis, during what has become known as "physical inventory taking" (PIT), where, in international safeguards, "physical inventory verification" (PIV) is conducted.

In international safeguards, an annual PIT is not sufficient, partly because the IAEA's timeliness goal for detection of the removal of a goal quantity is 30 days. Since the 1980s, the concept of near-real-time accounting (NRTA) has been pursued, where an "in-process inventory" or

Interim Inventory taking is implemented to measure and/or estimate the facility inventory without shutdown and flush-out. The verification of this inventory by the international safeguards regime has become known as the interim inventory verification (IIV). Typically, IIVs have been conducted on a 30-day basis to meet the timeliness goals of international safeguards. But the large throughputs of modern facilities and propagated uncertainties of measurement make even the relatively short 30-day detection goal difficult to meet. Therefore, modern applications in large facilities are moving to shorter intervals, making the same in-process inventories and referring to the procedures as special inventory verifications (SIVs). Particularly when SIVs include partial SNM assays such as bulk volume combined with SNM concentration estimates to estimate SNM amounts rather than direct measurement of SNM, the distinction between SIVs and some forms of process monitoring (PM) becomes blurred.

PM has become a tool of international safeguards. It provides additional assurances of proper facility operations and increases confidence in IIV procedures. For example, PM helps guarantee continuity of information on process solutions as they move through the plant, helping to ensure that materials are not moved to clandestine locations.

The same constraints exist in process facilities in the United States. Within the DOE complex, the local implementation of DOE rules have typically required monthly PIV's in bulk handling facilities. Under these conditions, the facilities lose a large percentage of operating time during a month. In addition, in drawing safeguards conclusions, such monthly PIV's do not reflect normal operating conditions of the facility and so are arguably less effective than more frequent accounting. Therefore, there has been a push to implement PM even if it includes a combination of full measurements, partial measurements, and estimates of the SNM. Although quantitative metrics are lacking, many believe that the combination of PM and less frequent PIV's is highly effective (Burr et al. 2003a, b). The reduced frequency of PIV's is an added bonus for the facility.

Regulated by the NRC, US domestic industry requirements have been established for timely (depends on facility category) detection of a loss of a "formula quantity" (5 kg HEU and 2 kg Pu). NRC regulations specifically mention "process monitoring" as a method to meet the requirements, but leave its specification to the facility operator. Those facilities operating under these rules have also implemented PM.

PM can be defined in terms of measures to ensure "timely information on the location and movement of nuclear materials." That same definition on timely information also applies to measures for process control and can also be applied to meet the requirements of safety and criticality control. Therefore, there is an overlap of instrumentation needed to meet the goals of all three important plant functions. In all three cases there may be measures and evaluations that do not make use of traditional MBs and NMA but instead evaluate related process measurements.

In the modern safeguards applications NMA is rarely meant to be the only safeguards component. PM can increase safeguards effectiveness of NMA when viewed as a tool to enhance the accuracy of NRTA, either by indirect or direct support of inventory measurements, or when viewed as a type of data consistency monitoring (DCM). Used for DCM, PM can provide assurance that the facility is operating as declared and that IIV procedures are appropriate for the conditions. In PM, bulk volumes, masses, and temperatures are tracked. In circumstances where samples are analyzed or on-line assays are available, SNM quantities can be estimated on the basis of mixing and transfer calculations to support NRTA. In other PM examples, mass quantities might be computed using gross neutron counting and/or gross weight and confirmatory attribute measurements.

As an aside, concerning jargon, which is often important for the IAEA because operators are hesitant to release certain kinds of data, the catch-all term “data consistency monitoring” might be preferred to “process monitoring” for two reasons. First, plant operators have reserved the latter to encompass information that might be proprietary. Second, the term “monitoring” is also applied to safeguards-specific surveillance systems such as certain cameras, TIDs, and radiation detectors. DCM would in that case refer to the acquisition and evaluation of any type of safeguards-relevant data, including traditional NMA data. We, instead, continue to use the term PM as described in the previous paragraph, with DCM being one type of PM to be discussed here.

Operation as declared, and procedures supporting various NMA activities, when viewed in the continuous evaluation of PM, can generate typical “reference signatures.” The term “reference signature” describes, for example, the sub-events in a tank’s operational cycle such as filling, homogenizing, sampling, and shipping. In other plant components it can describe signals from related and connected equipment.

The definition of PM must include some mention of the difference between domestic and international applications. Domestic applications are directed at the detection of loss or unauthorized removal of material at the sub-national level. Therefore, the regulatory bodies require implementation at the facility level, typically by an organizational unit that is independent of the organization responsible for control and processing of the materials. Typically, the national regulatory organization approves the procedures within the licensing process and only monitors that the facility operating plan is properly implemented. On the international level, the concern is for diversion at the national level, where the facility operator and the national regulatory organization are in collusion for the diversion. Therefore, the authority cannot be sure of the accuracy of the data reported. Thus the accuracy of data supplied must be guaranteed through verification and authentication measures that guarantee the accuracy.

2.5.1 Key Elements

There are four key elements in any process monitoring system: sensors, data acquisition, data storage, and evaluation. These elements are not unique to safeguards. The minimum data set necessary for process monitoring is difficult to define because it is defined by the scope application itself. The earliest efforts were limited by the instrument technology itself and the extent of computer technology available. The earliest efforts preceded concerns such as technology and export control, and concerns over propriety information. They were very ambitious in the scope, but limited in technology. More recent efforts have been implemented with technology that makes large amounts of information available, but depending on the safeguards end users, whether they are facility personnel or regulatory agencies, there has developed a reluctance to provide information to support very robust applications. But if process monitoring is to grow in applications for safeguards purposes, particularly for international safeguards, a careful evaluation of what is needed and can be supplied is necessary.

Sensors and Data

Sensors Safeguards inspectors might install their own sensors, or, more likely, share those used by the operators. Pressure and temperature sensors are commonly used. The case for installation of more sophisticated sensors has to be accepted by the operators. In recent times, this has led to rather limited success for international inspectors because of proprietary concerns.

■ Figure 28
Rack of six modern pneumacator instruments

Data Acquisition Modern data acquisition equipment can collect data at rates far in excess of what is required. It is therefore possible to collect data at one rate, while exporting at a slower rate. For instance data collected every 0.1s can be filtered with every tenth point output (i.e., at a rate of 1/s). Its standard deviation can be estimated and “state-of-health” tests can be applied. A major issue is the design of this so-called “pre-processing” stage. ➤ [Figure 28](#) shows a rack of six modern pneumacator instruments.

Data Storage and the Estimation of Indirect Measurements

Each sensor outputs one or more variables every time period, so that at the end of say, every day, one could imagine all the data would be stored in a 2D table with each variable in a separate column and each time instance in a separate row. So called Real-Time Databases or Data Historians

are available commercially to handle such data. They gather, store, archive, and process operational data from sensors and control systems. They also provide tools needed to manipulate and distribute the data, turning it into meaningful information that can be processed.

Mass, volume, and other variables might be estimated from each time instance of the raw data. These estimates are then accommodated in extra fields (i.e., columns) that can be added to the real-time database. Mass/volume estimation is based on calibration equations obtained, empirically, for each vessel. A certain amount of uncertainty is associated with these estimates and this uncertainty might “drift” with time (De Ridder et al. 2004; Binner et al. 2008). Key vessels are regularly recalibrated because of this. However, other vessels are likely to be monitored, so there is a possibility that re-verification might become an issue (Howell 2009).

Evaluation

Large, modern, industrial complexes have extensive, state-of-the-art digital control systems (DCSs) that enable operators to observe the performance of their plants. The primary role for DCS data is to inform the operators in real-time. This is achieved largely through displays of trends and schematics. Most of the information is processed visually, and far less is processed quantitatively. Although major software vendors do provide products to evaluate data, quantitatively, commercial pressures tend to mean that these products are necessarily targeted for relatively wide application areas, like the petrochemicals industries. There are considerable costs in developing and maintaining custom software during the lifetime of a plant, and hence the incentives to purchase tried, broadly-applicable and well-supported software are clear.

Materials balance issues are not special to reprocessing plants. Similar tasks for data reconciliation or gross error detection are performed in other chemical industries (Rosenberg et al. 1987), and commercial software is available to support these activities. However, the focus is on steady state mass balances based on flow meter measurements. Nuclear facilities operate very differently. In particular, they can have a rather unique blend of batch and continuous operations. Therefore, custom developed software is the only option.

2.5.2 Role of Models and Simulation

There are at least two roles for modeling and simulation in process monitoring: models are sometimes an integral part of the detection, isolation, and diagnostic tools (Howell 1994; Howell and Scothern 1995, 2000; Scothern and Howell 1997; Garcia and Yoo 2005); simulations are often used to assess the performance of these tools (Burr and Wangen 1996; Howell and Scothern 1998; Burr et al. 2003a, b). Clearly the former cannot be tested with their own models, although in practice these models are usually simplified for reasons of both computational necessity and for ease of reasoning (Howell 1994). One of the most extensive reprocessing plant simulations developed for safeguards purposes was FACSIM (Li 1996). A product storage area simulation of Howell and Scothern (1995) was also quite extensive, in that it modeled thermodynamic effects. Although these simulations are less detailed than those used for design purposes, they are somewhat different in that they are dynamic (i.e., they model variations with time). They can, however, exploit the more detailed models primarily by extracting reduced models (Cobb et al. 1980; Walford et al. 1983).

Experience has shown that results obtained from simulation-based performance evaluations have to be viewed with considerable caution. There are at least three reasons for this: the physical

models are rarely comprehensive resulting in so-called “systematic errors”; models of operational activities are rarely comprehensive, so that the data tends to look more sanitized than it should be; data acquisition effects are rarely incorporated. For instance, Binner et al. (2008) describe the types of systematic errors that still plague tank volume measurement. Simulation-based performance evaluations are therefore more likely to be appropriate for comparisons rather than for making any absolute conclusions.

2.5.3 Strategy for Reprocessing Plants

The RRP is the first, and to date the only facility where safeguards process monitoring was considered for implementation early in the overall design phase (Johnson et al. 1997; Ehinger et al. 2004; Johnson 2005). And it is the first facility where it was considered for areas other than just the solution processing area. All applications prior to the RRP were limited to what can be considered to be “solution monitoring,” where the data collected and evaluated was limited to process vessels in the main process line. In the case of the RRP, process monitoring was included in the design and it included data from cameras and radiation sensors monitoring movement of items and packages from the receipt of the spent fuel, through the pool storage area and mechanical processing. Specialized equipment was designed and installed to monitor the movement of materials through the MOX conversion area and the packages of MOX powder through to the product storage area. And the data from specialized NDA equipment was included for quantitative measurements at key locations.

The complete list of systems deployed at RRP for IAEA use is as follows:

- Integrated Spent Fuel Verification System (ISVS)
- Integrated Head-end Verification System (IHVS)
- Solution Measurement and Monitoring System (SMMS)
- Independent Jug Passage Detectors (IJPD)
- Automatic Sample Authentication System (ASAS)
- Waste Crate Assay System (WCAS A&B)
- Waste Drum Assay System (WDAS)
- Vitrified Canister Assay System (VCAS)
- Plutonium Inventory Measurement System (PIMS)
- Temporary Canister Verification System (TCVS)
- Improved Plutonium Canister Assay System (iPCAS)
- Directional Canister Passage Detector (DCPD)
- Uranium Bottle Verification System (UBVS)
- Uranium Storage C/S System (USCS)

From the above list, the SMMS represents the extension of the previous solution monitoring efforts. There was an extensive dialog between the IAEA, facility operator JNFL, and the Japanese regulatory authority to select the vessels and associated instruments that would be made available. There was also consideration of proprietary information on the part of the operator and their agreement with the plant designer, in this case COGEMA, that influenced the decisions.

The SMMS had to meet the needs of process monitoring as well as verification at flow key measurement points (FKMPs) and inventory key measurement points (IKMPs). In the end, the

deciding factor was to select all vessels that potentially contained more than one gram of plutonium based on vessel capacity and expected concentration. In one sense this was adequate since it included all tank-like vessels in the main process line, from the dissolver to the plutonium conversion facility. The final decisions allowed for monitoring of tank to tank transfers of solutions in the process that contain 98% of the plutonium in the facility under normal operations. But it excluded measurements of some processing equipment within important solvent extraction and concentrator systems.

The RRP represents a significant step forward in application of process monitoring over previous applications in the monitoring, beyond the solution processing area of the facility. But in the solution monitoring area, the application was again limited to level, density and temperature measurements, and evaluation of solution transfers between vessels. There were a few additional sensors, principally gross neutron detectors deployed along the pulsed columns of the solvent extraction systems that were also included. These were included on the basis of their value in estimation of column inventory for NRTA. The deployment of these sensors and the algorithms for calculation were based on a research project conducted by the Japanese.

The RRP system extends the concepts of process monitoring to areas where items and product packages are handled. Much of this was driven by the need to verify measurements at FKMPs. Additional equipment was also added to track movement of materials.

From the above list, the ISVS consists of a camera, and pairs of gross neutron and gross gamma monitors positioned at the point where spent fuel assemblies unloaded from shipping casks, move into the spent fuel storage pool. The pairs of detectors are spaced so that the timing of the signals between the sensors provides direction of movement, to verify receipt of fuel.

The integrated head end verification also combines gross neutron sensors with cameras. Comparison of the timing of signals again provides information of movement of spent fuel assemblies from the pool through the head end to the shear. And the cameras supplement the information. A second set of detectors associated with the system monitors movement of hulls containers.

The IJPD, with software for analysis of the signals, and the Automated Sample Authentication system, track sample bottles from the laboratory to the sampling stations and return.

The PIMMS is a complex system to measure the inventory of plutonium at a number of locations in the conversion process. Sequential measurements can track material as it moves through the process. The DCPDs combine neutron detectors and cameras to track the movement of filled MOX storage containers from the process, to the measurement station (IPCAS) and on to storage.

2.5.4 Operational Evaluation Systems

Currently, a number of evaluation systems are either fully operational, undergoing field trials, or in the process of commissioning. Here we attempt to deal with them in terms of their roots.

IAEA TAMES Root

Tank Monitoring and Evaluation Systems (TAMES) have been implemented at Tokai (TRP) in Japan. Safeguards at the TRP evolved after the Tokai Advanced Safeguards Experiments (TASTEX) of the late 1970s. One of the recommendations following TASTEX was to implement Process Monitoring in future facilities, and it was this recommendation that spurred related

developments at the US Barnwell plant, and later the US Integrated Engineering Test (IET) facility at Oak Ridge National Laboratory.

A rudimentary process monitoring system was implemented in the IET and in the plutonium nitrate storage area in Tokai which became operational by the early 1980s. But Tokai was an older generation facility with typically pneumatic measurement equipment. The solution monitoring installation for the IAEA included dedicated differential pressure measurement. However, the equipment was expensive, and consequently the installation included a pneumatic multiplexer to allow a single device to step through the measurements. Only level measurements were available in the three original product tanks, while density and temperature signals were also available in the four newer product tanks. The use of pneumatic multiplexers meant that simultaneous measurements of all vessels were not available, as had been done at Barnwell and the IET. Interpretation of data had to consider time delays between related measurements. A similar system was eventually implemented at the plutonium conversion demonstration facility (PCDF) in Japan. This facility received plutonium product solutions from the TRP and was based on a 50/50 mixture of uranium and plutonium. These installations were limited to level, density, and temperature measurements only, and they used the pneumatic scanner which precluded collection of time correlated data from all vessels.

Currently, TAMES-PCDF and TAMES-TRP are the only solution monitoring systems that are premised on mass balance data. TAMES-PCDF (Sirajov and Wang 2008) evaluates data pertaining to four tanks placed in series, which link a facility where concentrated plutonium nitrate solution is stored, to a MOX conversion plant. There are two input streams, the first contains plutonium nitrate and the second contains uranium nitrate, and one output stream used to fill small dishes, batch-wise for processing. The volume, density, and temperature of the solution, contained in each tank, are monitored. The quantity and assay of the plutonium nitrate solution input to the first tank is known. The uranium nitrate solution is input directly into the third tank. All transfers are carried out as batches. The evaluation draws on temperature measurements to confirm that a particular batch input to the third tank contains plutonium, as opposed to uranium. Knowledge of the plutonium concentration enables the evaluation system to propagate plutonium concentrations forwards from input to output. Density estimates derived from concentrations thus propagated can then be compared with densities measured.

This evaluation system has probably the most sophisticated preprocessing algorithms of any of the systems, mainly because of the complexities involved in filling the small dishes. In addition, the system is able to verify that “Operation is as Declared” by looking at more than just internal flows. To do this, it seeks to detect then explain all features that are observable in the data.

Euratom’s System 7 Root

Euratom installed System 7 in La Hague during the early 1990s. At that time, it was the only system to be actively used to monitor solutions in a large commercial reprocessing plant. This system has since formed the basis for Ispra’s (EU Joint Research Center) DAI software and also for the IAEA’s SMES at RRP. Although the later products are clearly not identical, they have evolved from the same root and still have many of the same attributes, so the original specification (Dekens et al. 1995) is still of key importance here. At that time, System 7’s main published objectives were as follows:

Euratom:A. To produce a log of safeguards related events for each measurement point

Euratom:B. To verify the plant inventory accessible to measurements in a timely manner

- Euratom:C. To verify in a near-real-time the flows at KMPs and other strategic plant locations
- Euratom:D. To analyze the plant parameters and to identify safeguards related events
- Euratom:E. To evaluate the equipment cycle characteristics and to establish their conformity with expected equipment behavior
- Euratom:F. To perform a flow consistency check and a flow follow-up at strategic locations of the reprocessing plant
- Euratom:G. To identify the non standard plant operations, which might give rise to safeguards related concerns

There is considerable overlap with the IAEA objectives. It appears that the system mainly sought to verify operations at the KMPs. Presumably the original intention was to monitor the bulk contents for inventory taking purposes only. The system focused on accountancy tanks and their adjacent feed/receipt tanks. In particular, the system sought to eliminate the recognized diversion scenario, in which the input accountancy tank (the IAT) is filled at the same time that it is emptied enabling more solution to be processed than “declared.” Another important system feature was that evaluations were based on reference signatures. This was hardly surprising, because operation of the IAT was largely automatic, so that its measurement histories repeated themselves cyclically and looked something like that shown in Fig. 29. This tightly prescribed operation could be represented by a reference signature.

The system has since been extended to analyze data from facilities, which handle “dry” materials like powder (Janssens-Maenhout and Dechamp 2004).

PIMMS

The FissTrack[®]: PIMS provides a full-time unattended monitoring function for the Co-Denitration Facility at THORP in the UK, ensuring CoK of in-process materials and providing assurances that the plant process is operating as declared.

Figure 29
Measurement histories

The PIMS is a distributed total neutron counting system jointly used by JNFL, IAEA, and JSGO to meet a number of requirements. The sharing of such instrumentation and data reduces the costs associated with such safeguards equipment to both the operator and the safeguards authorities. The system is based on total neutron counting techniques to determine the overall count rate at each neutron detector and mathematically deconvolutes the responses from each detector to determine the number of neutrons emitted from each plant item (vessels, glove-boxes, etc.), using a knowledge of the response of each detector to each plant area determined during commissioning.

The calculated neutron emission is then converted into an equivalent mass of plutonium using known or declared material characteristics (plutonium and uranium isotopic composition, chemical compositions, etc.). This enables a determination of the distribution of material throughout the plant to be made. A vulnerability assessment of the techniques and system design has been performed on behalf of the IAEA with the system design reviewed to address specific areas of concern.

The ability to monitor the whole of the processing plant simultaneously and the rapid update time of the system (approximately 30 s) permits near real-time tracking of process material to be performed.

2.6 Environmental Sampling

The use of trace analysis of uranium and plutonium for safeguards purposes was first developed within national safeguards programs. In the United States, a large program was developed that included many US national laboratories and private companies that specialized in forensic analysis. Other countries and international organizations, such as the UK, France, Russia, and the European Commission developed similar methods within its safeguards work.

The IAEA started a development program called “93 + 2” in the mid-1990s that included an evaluation of environmental samples as part of the IAEA’s international safeguards work (Hooper 1997; Kuhn 1995; Kuhn et al. 2001). This environmental sampling started as a complement to traditional safeguards and was driven mainly by a need for better verification of the correctness and completeness in state declarations of nuclear material handling. The use of environmental sampling, together with the implementation of the additional protocol that gives the IAEA more access for this sampling, has enhanced the IAEA’s ability to verify the declarations made.

In the startup of the IAEA environmental program, field trials were made on different types of samples taken around nuclear facilities from vegetation, soil, sediments, water, dust, etc. Tests were also made collecting larger amounts of dust in air samplers in an attempt to cover wider areas. Later, the sampling focused more on dust samples collected on cotton swipes taken in the nuclear facilities or at locations suspected of clandestine nuclear material handling. A special case is the use of cellulose swipes that were developed for sampling small amounts of materials on the surfaces inside hot cells. A closer sampling at the facilities under verification significantly improves the possibility to detect materials and also increases the relevance of the sample results.

The IAEA has established a capacity for analyzing environmental dust samples at its own laboratories in Seibersdorf, Austria. However, these facilities cannot manage the full amount of samples collected by IAEA inspectors around facilities. A network of analytical laboratories (NWL) in IAEA member states makes the main bulk of sample analysis in support to the

IAEA's safeguards efforts. These laboratories are situated in many countries, including the USA, UK, France, Russia, Finland, Japan, Australia, and the European Commission. In addition, new countries adding laboratories to the NWAL include South Korea, Brazil and China.

Apart from the IAEA's work, environmental sampling is also carried out by national and international safeguards organizations, like the European Commission's work within the Euratom treaty and the Argentinean–Brazilian collaboration within the safeguards organization ABACC.

2.6.1 Basic Principles of Environmental Sampling

In most handling or processing of nuclear material there is a small but detectable release of fine particulate material or aerosols containing uranium and/or plutonium materials. The released particles are highly mobile and can be found in many locations at a nuclear facility. These particles are representative of the original material, and their composition provides specific information about the source. The fact that it is difficult to clean up and remove the released particles is what makes environmental sampling so efficient. Samples taken at a facility that has been operated over a long period provide an insight into the entire history of the operation.

The analysis of the samples can be treated either as a bulk sample, where the average plutonium and uranium isotopic and elemental concentration are determined, or an isotopic analysis on individual particles. The bulk measurements have the main advantage of being able to detect and analyze very small amounts of plutonium mixed with a larger amount of matrix materials (Vogt et al. 2001). Bulk can also detect small amounts of nonnatural uranium isotopes such as ^{233}U and ^{236}U . However, the bulk measurements have a fundamental limitation in the uranium measurements, as there is a background component of natural uranium from the swipe material and from the dust matrix. In addition, there is a small background component from the chemical separation work. However, the background problem is less of a limitation on samples richer in materials.

The individual particle analysis does not have the background problems of the bulk measurements and can give precise isotopic information on individual particles. In addition, particle analysis can be used to map relationships in isotopic ratios on populations of particles specific to a nuclear activity. An example is irradiated nuclear fuel, where there is a rapid increase of ^{236}U and ^{240}Pu and a decrease of ^{234}U with increased burn-up (decreased ^{235}U abundance) (Fischer and Wiese 1983). The consistency from the isotopic measurements can be compared with declared irradiation that can be modeled with the ^{236}U , ^{240}Pu , ^{234}U versus ^{235}U abundance. Another typical application for particle analysis is samples taken from enrichment plants (Bush et al. 2001). The particles isotopic signature is typically plotted with the ^{234}U versus ^{235}U , and ^{236}U versus ^{235}U . The $^{234}\text{U}/^{235}\text{U}$ and the $^{236}\text{U}/^{235}\text{U}$ relationship are dependent on the layout of the enrichment facility and on the feed material used.

► **Figures 30 and 31** show an example of materials produced in three different enrichment plants (A, B, and C), with the plotted $^{234}\text{U}/^{235}\text{U}$ and $^{236}\text{U}/^{235}\text{U}$ relationship. As shown in ► **Fig. 1**, the observed $^{234}\text{U}/^{235}\text{U}$ ratio shows that small variations typically stay within a range of 0.005–0.012. As shown in ► **Fig. 2**, the $^{236}\text{U}/^{235}\text{U}$ changes significantly for the three different facilities, depending on the feed material used. Facilities A and B have little or no ^{236}U in the feed material; however, facility B does exhibit a ^{236}U background possibly from prior feed that did contain ^{236}U .

■ Figure 30

The relationship of ^{234}U versus ^{235}U in three samples (A, B, and C) from different facilities

■ Figure 31

The relationship of ^{236}U versus ^{235}U for the same samples as in [Fig. 3](#)

2.6.2 Sampling Methods

The main sampling methods used today are sampling in hot cells using specially designed cellulose swipes that can be handled with the hot-cell manipulators or the more common cotton swipes for sampling dust at nuclear facilities. [Figure 32](#) shows a typical sample kit for dust sampling using cotton swipes. The kit contains a set of swipes, gloves, labels, a report form with instructions, and zip bags for the swipes used in the sampling.

■ **Figure 32**
Sample kit for dust sampling using cotton swipes

The sampling locations differ for the type of facility that is inspected. Typical sampling locations can be tube connections for UF_6 at enrichment facilities or ventilation ducts, changing rooms, etc.

2.6.3 Bulk Measurements of Dust Samples

For the bulk method, it is common to dissolve the swipe together with the sample material and to make a chemical separation to obtain pure fractions of the elements of interest, mainly uranium and plutonium. Dissolution can be performed directly on the swipe or after ashing the swipe in a furnace. Dissolution is made using an oxidizing acid such as nitric acid. Separation of the elements normally is made using traditional methods of ion exchange resins.

To determine the assay of uranium and plutonium, a spike is added for isotope dilution mass spectrometry (IDMS) measurements. Typically, high-purity ^{233}U spikes are used for uranium and ^{244}Pu or ^{242}Pu spikes are used for plutonium. Commonly, one spiked fraction and one unspiked fraction are prepared for the uranium which improves the isotopic measurements of the isotopes. The plutonium fraction is often so small that only a spiked fraction is prepared. The isotopic measurements are typically made by either thermal ionization mass spectrometry (TIMS) or multi collector-inductive coupled mass spectrometry (MC-ICPMS).

2.6.4 Particle Measurements of Dust Samples

The particle analysis can be split into two tasks. The first task is to find the particles of interest in a matrix of other materials. This task is followed by precise and accurate analysis of the individual particles. High demands are set on the analysis techniques to obtain reliable information and not to overlook any undeclared activities. Both tasks are a challenge. To find a single man-made uranium particle in a matrix of hundreds of millions of other particles is a typical “needle-in-the-haystack” problem. To perform isotopic analysis of both the major and minor isotopes on particles, often not having more than sub-pg amounts of material, is also a challenge. The precision of the isotopic analysis is limited mainly by counting statistics because of the very small amounts of materials at hand. Two methods are routinely used: fission track/TIMS (FT/TIMS) and magnetic sector secondary ion mass spectrometry (SIMS).

FT/TIMS

FT/TIMS is a two-step method. The location of the particle is made by using polycarbonate fission track detectors, followed by the precise and accurate isotopic measurements using TIMS. The particles are removed from the swipe either by ultrasonification of the swipe in a suspension (typically heptane), or by ashing the swipe in a furnace (Baude et al. 2001; Lee et al. 2007). The material is then mixed with flexible collodium and spread out and dried on a set of polycarbonate plates and placed in a capsule to prepare it for irradiation. After neutron radiation of the plates, the collodium film containing the particles is removed and the polycarbonate plates are treated in a bath of sodium hydroxide for chemical etching to visualize the star-shaped damages (fission tracks) caused by the induced fission in uranium or plutonium particles. The collodium film containing the sample material is then replaced on the plates so that the location of the uranium and plutonium particles in the film can be determined. At the location of the particles, a small piece of the collodium film is removed from under a microscope and placed on a rhenium filament to prepare it for the final TIMS analysis.

The fission-track method has been proven to be very effective for finding single particles in a large amount of other material. The TIMS measurements are very reliable and can provide highly precise and accurate measurements on both uranium and plutonium particles. TIMS analysis does not have any significant baseline or background problem, and it does not have the SIMS hydride interference problem of $^{235}\text{U}^1\text{H}$ overlapping the ^{236}U . The main limitation is that the method is both costly and very time consuming because it involves many processing steps; it requires the availability of a suitable neutron source, and requires each particle to be loaded on individual filaments for the TIMS analysis. Another common limitation compared to SIMS is lower ion yields in the TIMS measurements.

Secondary Ion Mass Spectrometry (SIMS)

The SIMS technique combines the search of particles and the final measurement within one instrument (Tamborini et al. 1998). Before the samples are measured, the particles must be removed from the swipe and placed on a substrate, typically pyrolytical graphite planchets. The particles and their dispersion on the sample planchet can be removed by the ultrasonification of pieces or of the entire sample swipe, thus releasing the particle into a suspension. The suspension is deposited and dried on a sample planchet. An alternative method is to use the vacuum impactor technique, which pulls particles from the sample swipe with a vacuum suction and sprays them directly on a sample planchet (Esaka et al. 2004).

One of the fundamental strengths of the SIMS is its ability to perform automatic particle screening measurements very quickly in isotopic imaging mode on deposits containing millions of particles, to find those of interest (Simons et al. 1998; Nittler and Alexander 2003). These measurements provide the exact particle location and a first estimate of the enrichment. The final isotopic measurement on an individual particle is made with a focused primary microbeam.

Compared with FT/TIMS, the SIMS technique is fast and requires smaller laboratory facilities and fewer staff resources for a given sample throughput. The technique can also provide the enrichment distribution of thousands of uranium particles from the screening measurements.

A main limitation to the SIMS measurements, which to date have been performed almost solely using small-geometry SIMS (SG-SIMS) instruments (typically the Cameca F-series), is the presence of isobaric background interferences that can significantly reduce the accuracy of the isotopic measurements. It has been demonstrated that background problems in SG-SIMS measurements can be reduced, or in some cases even eliminated, by improving the sample preparation. Improving sample preparation can be effective for some samples, but are problematic if the uranium particle itself includes interfering elements (Esaka et al. 2007).

An alternative to SG-SIMS is provided by large-geometry SIMS (LG-SIMS) instruments, which were developed in response to a demand in geosciences and cosmochemistry, for high mass resolution at a high transmission (see ► Fig. 33). As with the SG-SIMS, these instruments are based on a double focusing mass spectrometer, but with the implementation of a large-radius magnetic sector and improved secondary ion optics. It has been demonstrated that these

► Figure 33

Large geometry secondary ion mass spectrometry (LG-SIMS) (Cameca 1280) at the Nordic NORDSIM Laboratory

instruments have a superior quality of the isotopic measurements, and allow for faster screening measurements without any noticeable drawback compared with SG-SIMS instruments (Ranebo et al. 2009). Due to the availability of multi ion counting systems for the LG-SIMS, there is also an improvement in the detection efficiency.

2.7 Forensics

Since the beginning of the 1990s, more than 1,000 cases of illicit trafficking involving radioactive or nuclear material have been recorded in the IAEA illicit trafficking database. Most of the reported seizures refer to radioactive sources, such as ^{137}Cs , ^{192}Ir , ^{60}Co , and ^{90}Sr , which pose a radiological hazard due to their high activity. The seized samples of nuclear material were generally of higher mass, yet of lower activity as compared with medical or industrial radionuclide sources. However, the radiotoxicity of the alpha-emitting nuclides typically encountered in nuclear material is significantly higher than that of beta or gamma emitters usually applied in medical sources. As such, nuclear materials represent a considerable hazard if the material is handled in an inappropriate way and particularly if considered in a terrorist context. The use of nuclear material in a radiological dispersal device therefore is a matter of serious concern.

The reported seizures of nuclear material prove that, despite the strict control of national or international safeguard authorities, nuclear material can be diverted or stolen. These seizures lead to the conclusion that the implementation of treaties, agreements, or conventions on safeguards and physical protection has not been fully achieved, or that they suffer from gaps. Closing these gaps and improving the control of nuclear material at the sites where theft or diversion occurred are therefore of prime importance; however, this requires the identification of the origin of the seized nuclear material.

As a result of illicit trafficking, nuclear material has become a part of the forensic investigations and a new discipline, nuclear forensic science, was developed. The nuclear forensics methodology developed for the nuclear security area also may be applied to source attribution in a much broader range of applications:

- In *proliferation* issues the investigation of particles of HEU found in Iran provided insights into Iran's clandestine nuclear program. The comparison of the uranium isotopic pattern with material obtained from Pakistan showed that the scenario was consistent with the available evidence (Bokhari 2005).
- The measurement of chemical impurities is increasingly applied in *nuclear safeguards*. Particularly, samples of uranium are analyzed to establish relations between different samples and to check consistency of the impurity pattern with the declared processes.
- Also, *environmental samples* can be subject to nuclear forensic investigations. As demonstrated by Ray et al. (2002), particles found on the seabed and occasionally on the beaches of Dounreay could be attributed to the materials testing reactor at Dounreay.

2.7.1 Methodology

Nuclear forensic investigations must be considered as part of a comprehensive set of measures for detection, interception, categorization, and characterization of illicitly trafficked nuclear

material. As mentioned previously, nuclear forensic analysis may result in important conclusions on the origin of the material and thus provide the most essential contribution to the prevention of future diversions from the same source. Therefore, it is crucial to ensure the integrity and authenticity of the collected evidence throughout the entire process. This requires a close collaboration between the various actors on the scene: law enforcement, radioprotection services, forensics experts, and nuclear measurement experts. The International Technical Working Group (ITWG) on combating nuclear smuggling has developed a model action plan (MAP) for handling cases of seized nuclear material (Fig. 34). This action plan lays out the elements that are needed in the instance that illicit nuclear material is uncovered (e.g., incident response, crime scene analysis, collection of evidence, transportation to a nuclear facility, subsequent laboratory analysis, and then development of the case) (Janssens et al. 2001; IAEA Nuclear Security Series No. 6, 2007; Smith et al. 2008). The MAP clearly needs to be adapted to the regulatory, logistical, and technical specifics in each country. Many states have implemented the concept of the MAP and have developed a dedicated handbook summarizing the responsibilities and processes relevant in response to illicit trafficking of nuclear material.

For each seized sample, a specific analytical strategy must be developed, considering the particular conditions of the seizure, the very nature of the material and of its packing, and other evidence. The analytical strategy is based on a step-by-step approach, where experimental

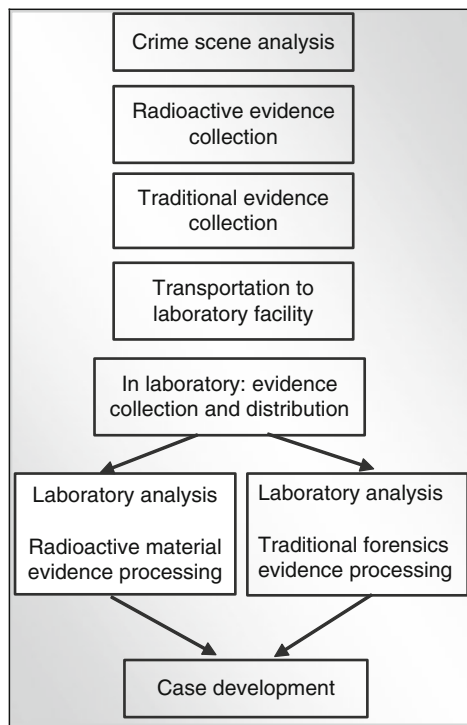

Figure 34

The model action plan (MAP) as developed by the nuclear smuggling International Technical Working Group (ITWG) provides guidance on incident response

results are compared with information on nuclear material of known origin contained in a relational database if available. Based on the actual findings, the next step is defined and performed. Beyond the actual analytical work in the laboratory, the actions to be taken at the incident site (place of seizure of the material), the legal and law enforcement aspects, and the question of data interpretation must be considered. The complexity of these issues, and the fact that illicit trafficking of nuclear material is a border-crossing problem, call for international collaboration and coordinated measures.

2.7.2 Characteristic Parameters in Nuclear Forensic Investigations

Nuclear forensics is a methodology that reveals information inherent to nuclear material. Nuclear material has either been subjected to technological processing or is entirely of anthropogenic origin. Consequently, nuclear material carries “toolmarks” or “fingerprints” of the process to which it was subjected. Uranium fuels are examples of the first category, whereas plutonium belongs to the second category. Both elements contain fissile isotopes, substantiating the broad interest in the history, origin, and intended use of these materials.

Nuclear forensic investigations start after material has been seized and categorized as “nuclear material.” These investigations are performed to answer specific questions on the nature of the material and its origin, such as the intended use, the mode of production, the plant and production batch, the last legal owner, and the smuggling route. The investigations may comprise conventional forensic tests applied to radioactive material, the morphology of the material, the structure of the material components, the composition of traces in the material and its packing, and the isotopic composition of the nuclear material itself and of minor constituents. Consequently, a suite of analytical techniques, specifically adapted to the needs of radioactive material, is required. Most of the analytical techniques used are normally applied for accountancy and safeguards measurements or for the characterization of nuclear fuel. However, specific measurement protocols may apply (Mayer et al. 2005; Tandon et al. 2008).

Controlling the radiological hazard is of paramount importance at all stages of the investigation. Furthermore, attention should be given to preserving classical forensic evidence. In the nuclear analytical laboratory, the material is first subjected to visual inspection which may reveal useful information on the material itself (e.g., physical form, geometry, and primary packing) and provides the starting point for further analysis. This process may be complemented by imaging techniques: specifically, optical microscopy for examination of the sample at high magnification.

If the analyzed material contains fuel pellets, their dimensions (height, diameter, and the size of a possible central hole) and mass are measured. These so-called macroscopic parameters, together with the ^{235}U enrichment are characteristic and often reveal the reactor type for which the pellets are intended. Other characteristic parameters are shown in  [Table 21](#) and are discussed in more detail in the following section.

Isotopic Patterns of Uranium and Plutonium

The isotopic composition of uranium and plutonium allows us to draw conclusions on the reactor type in which the material has been irradiated, as well as on the intended use of material. Depending on the enrichment of the main isotope (i.e., ^{235}U or ^{239}Pu), the material can be categorized as weapons grade, reactor grade, or fuel grade (Smith et al. 2008). In the case of

■ **Table 21**

Parameters of interest for nuclear forensic analysis

Parameter	Elements of interest	Information
Major elements	Uranium and plutonium	Intended use, production reactor (plutonium)
Minor/trace elements	Metallic impurities, gadolinium, oxygen, lead, thorium, etc.	Age, geolocation (uranium), production process, reactor type
Macrostructure	Pellet dimensions	Intended use/reactor type
Microstructure	Particle size and form grain size	Production process

plutonium, its isotopic composition may also reveal the reactor type, using the so-called isotope correlation technique. The isotope correlation technique was used in safeguards in 1970s for two reasons: to verify the consistency of the isotopic analyses performed at the reprocessing plants and to deduce the amount of specific isotopes by measuring other isotopes and using established correlations.

The isotope correlation shown in [Fig. 35](#) is based on the following principle: The neutron capture cross-sections of the individual plutonium isotopes vary as a function of neutron energy. As a consequence, the buildup of plutonium isotopes is different in reactors with different neutron energy spectra. In addition, the initial enrichment of ^{235}U varies in different reactors. These two parameters then are reflected in the isotopic composition of plutonium (Wallenius et al. 2000). To demonstrate the feasibility of the correlation, a sample seized in the context of a criminal investigation has been added in [Fig. 35](#). The sample seems to originate from an LWR having initial ^{235}U enrichment close to 3.5%, which was later confirmed (Wallenius et al. 2007) ([Fig. 35](#)).

The minor isotopes of uranium, ^{234}U and ^{236}U , carry information about the irradiation history, enrichment process, and geological origin of the material. First, the presence of small amounts of ^{236}U indicates a contamination with recycled uranium, which thus points at reprocessing activities. Second, different enrichment processes may result in slight differences in the ^{234}U abundance. Last, variations in ^{236}U as well as in ^{234}U abundances have been recorded in natural uranium, which may help to locate the mine that is the source of the uranium (Richter et al. 1999; Keegan et al. 2008). The isotope abundances of ^{234}U and ^{236}U may also help to verify coherence between different samples and consistency with declared operations.

Minor Constituents and Trace Elements

Uranium and plutonium materials contain variable amounts of minor constituents from different “origins.” These materials arise from processes such as production, companion elements in uranium ores, and radioactive decay.

Age Determination of nuclear materials uses the radioactive decay of these elements. If a complete separation of the daughter products is assumed during the production process (e.g., during chemical purification of the material), the “age” of the material (i.e., the time that has elapsed between the last chemical treatment of the material and today) can be determined by quantifying the amounts of parent and daughter nuclides. Age determination of plutonium classically is

Figure 35

Plutonium isotope correlation for different types of reactors. “WAK” denotes seized material, which can be attributed to an light-water-reactor (LWR)

being performed by gamma spectrometry using the $^{241}\text{Pu}/^{241}\text{Am}$ parent/daughter ratio. However, in a few cases it has been noticed that the americium separation has not been complete, and thus the age from this parent/daughter may give a wrong answer. Using the uranium daughters of ^{238}Pu , ^{239}Pu , and ^{240}Pu offers a consistency check because these three parent/daughter relations should result in the same age, provided that the separation of uranium was complete during processing of the material (Wallenius et al. 2000; Nygren et al. 2007). Residual amounts of uranium isotopes lead to biased results in the plutonium age determination. The degree of the bias is dependent on the plutonium composition (weapons-grade or reactor-grade), as well as on the parent/daughter relationship (Mayer et al. 2001).

Age determination of uranium is more complicated because (1) uranium has only two possible candidates of parent/daughter ratios, namely $^{234}\text{U}/^{230}\text{Th}$ and $^{235}\text{U}/^{231}\text{Pa}$, and (2) the half-lives of uranium parent isotopes are much longer compared with the plutonium parents. Therefore, only tiny amounts of daughter nuclides grow in with time (Morgenstern et al. 2002; Wallenius et al. 2002a; Varga and Suranyi 2007).

Another interesting aspect in the age determination, especially in the safeguards context, is the question of the age of particles. Age determination of plutonium particles has been demonstrated (Wallenius et al. 2002). Age determination of uranium particles proves to be much more challenging, as already stated. Even if the ^{234}U is the lower abundant isotope in uranium materials, due to the 1,000-fold-shorter half-life, the parent daughter ratio $^{234}\text{U}/^{230}\text{Th}$ is more favorable for the age determination of uranium as compared with the $^{235}\text{U}/^{231}\text{Pa}$ ratio. The particles of interest in swipe samples from enrichment plants typically are only $1\ \mu\text{m}$ in diameter. Based on this assumption, we can calculate the detection limit for the age determination as a function of the age of the particles and the ^{235}U enrichment. If we assume further a detection efficiency of 0.5% and a dark noise of 2 cpm with 3 min measurement time in the secondary ion

■ Figure 36

The number of ^{230}Th atoms contained in a uranium oxide particle (with an assumed number of 10^{10} atoms of uranium per particle) depends on the age of the particle and on the ^{235}U enrichment. The detection limit of a typical SIMS instrument is marked with a fragmentary line and is about 1,500 atoms of ^{230}Th

mass spectrometer, we see from ► Fig. 36 that age determination can be successfully performed only for “old” particles of HEU.

Metallic Impurities Metallic impurities are present in nuclear material samples at varying concentration levels. In starting materials (e.g., uranium ore), the impurities may have the character of accompanying elements and are present in relatively high concentrations. In intermediate products (e.g., yellow cake), the concentration of most of the chemical impurities has been drastically reduced. After this reduction, toward the final product, a further decrease of impurities is minute if at all. ► Figure 37 shows metallic impurities in natural uranium compounds of different origins. Five samples from the same origin can be recognized clearly through their identical pattern of metallic impurities (Wallenius et al. 2002b; Keegan et al. 2008).

Although metallic impurities can be used for identifying coherences between samples or batches of material, the systematics behind the impurity patterns are not well understood because the metallic impurities may be carried into the material at different stages of the process. For example, the concentration of some impurities may vary as a function of exposure time to the container material or the storage tank as they are leached from the surface of the walls. In sample analysis, the concentration of such elements appears to be fluctuating randomly.

The drawback of using impurities is that cross-contamination (e.g., from environment) must be prevented. In addition, the level of impurities within a production plant may vary with time, thus requiring continuous input from the production plants, as well as updating of the database. In general, the use of common elements as indicators should be avoided. Another solution to this dilemma could be to look at ratios of chemical elements instead of looking at

Figure 37

Selected metallic impurities in intermediate natural uranium products. Samples 1–5 are apparently of the same origin

the absolute concentrations of impurities. Although the absolute concentration of the impurities may change, the ratio of certain elements will vary only within narrow limits. This variation applies in particular for elements of similar chemical behavior (e.g., the rare earth elements) (Wallenius et al. 2002; Keegan et al. 2008).

Stable Isotopes In the field of food science and geochemistry, the analysis of stable isotopes (e.g., ^1H , ^2H , ^{12}C , ^{13}C , ^{16}O , and ^{18}O) has been successfully applied for a few decades. The principle of the use of stable isotopes is very straightforward: The stable isotope compositions of elements, which are part of a substance, are a function of the origin and history of that substance. That is, two substances that are chemically the same may have different stable isotope compositions if either their origin and/or history differ. This methodology was also introduced recently to nuclear forensics.

The application of oxygen isotope ratio measurements for geo-location purposes was demonstrated several years ago (Pajo et al. 2000). A correlation between the geographic location of the production site of uranium oxide samples and the variation in the $n(^{18}\text{O})/n(^{16}\text{O})$ ratio could be established. Moreover, it could be shown that the method is also applicable to individual particles (i.e., the oxygen isotope ratios established by “bulk” measurements using TIMS could be reproduced on individual particles using SIMS) (Pajo et al. 2001). This type of information certainly does not identify a specific plant, but it provides a parameter for attributing the material to a region. This parameter can be used, for instance, to distinguish between imported and domestic materials.

Another parameter that has been widely used in geochemistry and in environmental sciences is the isotopic composition of lead. Lead isotopes may be primordial (natural lead), or they may be produced through the decay of uranium isotopes. The small variations in the isotopic composition of natural lead have been used to locate the origin of some fuel additives (mainly consisting of tetra-ethyl lead). The adaptation of this methodology for nuclear safeguards and nuclear forensics purposes has been studied (Svedkauskaite-LeGore et al. 2007; Keegan et al.

■ Figure 38

Lead isotope ratios observed in yellow cake samples from different mines, adapted from Svedkauskaite-LeGore et al. (2007). Combined uncertainties, U_c (with $k = 2$) on the ratios $n(^{207}\text{Pb})/n(^{206}\text{Pb})$ and $n(^{208}\text{Pb})/n(^{206}\text{Pb})$ are between 0.0002 and 0.00008, and are thus too small to be visualized on the graph

2008). It could be shown that the lead isotopic composition of yellow cake provides useful information to distinguish between natural uranium materials of different origins (see 🔍 Fig. 38). Because lead is omnipresent in our environment, special care must be taken when performing the chemical separation of the lead from the uranium samples in order not to introduce any natural lead from dust particles or chemical reagents and thus bias the results.

Anionic Impurities Aqueous processing of nuclear material is encountered at many stages in the nuclear fuel cycle. In these processes, mineral acids are frequently used. They leave anionic impurities (e.g., Cl^- , F^- , SO_4^{2-} , and NO_3^-) in the material behind, together with those anions that were initially present in the starting material. It has been demonstrated that, depending on the type of ore from which the uranium was extracted and the type of process applied as well as the associated chemical reagents used, the isotopic patterns generated in the yellow cake are significantly different (Badaut et al. 2006). These patterns provide additional information for distinguishing materials from different origins, or if appropriate reference data are available, for relating a given material to a specific facility. For data evaluation, the pattern of anionic species is more informative than the actual concentration values (see 🔍 Figs. 39 and 🔍 40).

Microstructure

The microstructural properties of nuclear materials are another important parameter. The particle and grain size distributions and the surface structure of the particles are material characteristics that reflect the production process of the material. Therefore, these data allow the

■ Figure 39

Anionic impurities determined in yellow cake samples from a German mine by ion chromatography

direct comparison of samples, enabling conclusions on coherence between samples. For example, ► Fig. 41 shows a comparison of four UF_4 samples. The particles are shaped and sized very differently; thus, they can be distinguished clearly from each other, indicating different origins of the four samples in question.

2.7.3 Data Interpretation and Attribution

The main challenges in nuclear forensics are the identification of characteristic parameters and the availability of reference information. Based on the reliable measurements of well-chosen parameters, clues on the origin of the material can be obtained. Information obtained by nuclear forensic analyses from an unknown nuclear material can basically be divided into two groups: endogenic and exogenic. Endogenic information is to be understood as being self-explaining, and only some model calculations might be required to help data interpretation. The isotopic compositions of uranium and plutonium and the age are good examples of endogenic information. These compositions provide immediately important features regarding the material (in this case, about its intended use and production date, and additionally for plutonium, the reactor type where the material was produced).

In contrast, exogenic information must be compared with data from known samples. The availability of “reference information” or comparison samples is essential for the interpretation

■ Figure 40

Anionic impurities determined in yellow cake samples from a Gabonese mine by ion chromatography

of data such as chemical impurities or the isotopic composition of minor constituents. This type of information includes all geolocation and production parameters (i.e., impurities, lead isotopic composition, $^{18}\text{O}/^{16}\text{O}$ ratio, and microstructure). Known data can be either compiled and systematized in form of a relational database, where data (e.g., from fuel manufacturers) is collected, or it can be a collection of analytical results of known samples (Dolgov et al. 1997, 1999; Schubert et al. 1998).

A major challenge in data interpretation is the accessibility of reference data. Measured data on reactor-grade nuclear material, which is essentially produced for power reactors, are available with the fuel manufacturers. Note that certain data (e.g., chemical impurities) might be commercially sensitive, and therefore their accessibility might be limited. Detailed information on weapons-grade material (HEU and low burn-up plutonium) is clearly subject to confidentiality for national security reasons, and data are not shared.

Source attribution is generally done by comparing measurement results to data contained in a database applying the “exclusion principle.” The results of the first measurements on the unknown material (e.g., pellet dimensions and isotopic composition) are used for a query. All nonmatching records (database entries from known materials) are rejected, and the matching records are compared with each other to identify parameters to be analyzed next. Thus,

■ Figure 41
Comparison of the microstructure of four different UF_4 samples

the database query also serves for analytical guidance, streamlining the laboratory work and rendering the measurement effort more efficient. Based on the subsequent measurement data, another query is performed in the database, and further records are rejected. This process then results in records where all search parameters match within the stated tolerances. Ideally, the search results point to a single production location.

2.7.4 Conclusions

Nuclear forensics is highly relevant in the areas of nonproliferation and of nuclear security, and it is also increasingly used for investigative nuclear safeguards and environmental studies. Forensics provides support (e.g., to law enforcement authorities) in combating illicit trafficking and dealing with criminal environmental issues. Characteristic parameters of nuclear material, such as isotopic composition, chemical impurities, age of the material, and microstructure, provide clues to the origin and the intended use of the material. A wide variety of analytical techniques, specifically adapted for measuring nuclear material from various scientific disciplines, is used for the investigations. The availability of up-to-date references on nuclear material is essential to identify the origin or to exclude certain origins. Continued development activities and strengthened international cooperation is the key to perfecting nuclear forensics. Nuclear

forensics provides sustainability in combating illicit trafficking of nuclear material and thus in preventing nuclear terrorism.

2.8 Statistics for Accountancy

In the context of international nuclear nonproliferation agreements and domestic safeguards requirements, declared facilities that process and/or store SNM are required to perform periodic NMA measurements. In traditional safeguards, a key function of periodic NMA measurements is to confirm the presence of SNM in accountability vessels to within relatively small measurement error. Containment and surveillance (C/S) are used as a complementary measure to confirm the absence of undeclared flows that could divert SNM for possible illicit use. NMA, C/S, and related topics involve statistical methods that are described here.

International safeguards face several issues that are distinct from domestic safeguards. In the IAEA context, the entire facility could be involved in a diversion plan; therefore, for example, safeguards components such as gates, vaults, and guards are irrelevant. In domestic safeguards, no credible basis for concern exists that the entire facility might attempt a diversion; therefore, these same components are highly relevant. The commensurate distinctions between IAEA and domestic safeguards do not concern us here; however, for example, the IAEA's need to monitor for possible data falsification and the role of C/S in reducing required verification measurements lead to statistical issues that are described.

2.8.1 Background

The inventory difference (ID) for SNM at time t is defined as,

$$ID_t = BI_t + R_t - EI_t - S_t, \quad (3)$$

where BI is the beginning physical inventory, R is the receipts, EI is the ending physical inventory, and S the shipments, and all terms include measurement error. Equation (3) is similar to (2).

If we know all terms in (3), and the measurement uncertainty associated with each measurement system, we apply statistical rules involving the variance of a sum (propagation of variance, or POV) to estimate the measurement error standard deviation of the ID, or σ_{ID} . Note that (3) is a sum of many terms, some of which have negative signs.

An example ID sequence is plotted in  Fig. 42. The alarm limits are at $0 \pm 2\hat{\sigma}_{ID}$ (where $\hat{\sigma}_{ID}$ is the estimate of σ_{ID}). A good estimate of σ_{ID} is usually all that is required for statistical evaluation of an ID because of the central limit effect, whereby sums of approximately 10 or more random variables (all measurement errors are random at some stage, even the so-called “systematic” errors) will have approximately a Gaussian distribution. If no material loss is assumed, the ID has an approximate $N(0, \sigma_{ID})$ distribution (denoted $ID \sim N(0, \sigma_{ID})$), where $N(\mu, \sigma)$ is the normal distribution with mean μ and standard deviation σ . Therefore, to test for SNM loss, the ID can be compared to $k\hat{\sigma}_{ID}$, where k is 2–3, depending on the desired false alarm probability.

NMA to confirm declared facility operation involves periodically comparing the latest ID to a predefined goal. To check for abrupt loss, the null hypothesis, $H_0: ID_{true} = 0$, is tested versus the alternative $H_A: ID_{true} > ISQ$, where SQ is the significant quantity of interest, such as

■ **Figure 42**
Data for process status

8-kg of plutonium (IAEA SQ). To check for trends in a sequence of IDs, which could indicate small protracted loss, the n -by- n measurement error covariance matrix Σ_{ID} is used (see [▶ Sect. 2.8.5](#)).

The magnitude of σ_{ID} determines what SNM loss L would lead to an alarm with high probability. For example, if testing is performed only for SNM loss (not gain) with a false alarm probability of $\alpha = 0.05$, the alarm probability $1 - \beta$ is 0.95 for $L = 3.3\sigma_{ID}$ (and $1 - \beta > 0.95$ if $L > 3.3\sigma_{ID}$). Usually the safeguards goals include a goal that $1 - \beta$ is at least 0.95 if $L \geq SQ$, which is accomplished if and only if $\sigma_{ID} \leq SQ/3.3$. If $\sigma_{ID} > SQ/3.3$, then either measurement errors should be reduced to achieve $\sigma_{ID} \leq SQ/3.3$ (if feasible) or additional measures such as enhanced C/S are required.

Statistical science includes methods to summarize and describe large data sets, and methods to infer population parameters using samples. Such inference is inductive reasoning using probability models to describe how population data are generated and is sometimes referred to as “the inverse problem.” That is, given observations (data) from a population, the goal is to infer various properties of the population(s).

Statistical hypothesis testing receives considerable attention in NMA, partly because of the appeal of quantified, objective testing. Speed and Culpin (1986) focused on NMA, but NMA is only one component of safeguards. C/S is another key component. In addition, in all cases, IAEA must “trust, but verify” by making random confirmatory (qualitative and/or quantitative) measurements of the operator’s declared measurements; consequently, the IAEA’s measurement

error is even larger than the operator's measurement error, making the quantified portions of the safeguards conclusions even less capable.

The most important statistical concept involved in evaluating ID sequences is variability. Measured values (e.g., inventory differences and shipper-receiver differences) are often compared with their nominal values, and decisions must be made whether they are within the estimated variability due to measurement error (Jaech 1973; Bowen and Bennett 1988; Venables and Ripley 1999) (🔍 Fig. 42).

2.8.2 Measurement Error Models

All assay measurements involve multiple errors that can have different relative contributions in different contexts. Therefore, measurement error modeling is a complex topic that is briefly discussed here to describe some of the models that are commonly used in NMA.

The terms “random” and “systematic” errors are qualitative terms until we specify a particular measurement system and associated error model. Generally, random errors are unique to each measurement, whereas a systematic error affects two or more measurements (Neuilly 1999; Aigner et al. 2002; Burr et al. 2003a, b). Sometimes the term “long-term systematic error” is contrasted to “short-term systematic error” (“long-term” implying that all measurements in the campaign share a common systematic error and “short-term” implying that two or more measurements in the time period share that error, but not all do).

An example error model is,

$$M = T(1 + S_{\text{item}} + S_{\text{inst}} + R), \quad (4)$$

where M is the measured mass, T is the true mass, S_{item} is the item-specific systematic error (bias), S_{inst} is the measurement-instrument-specific systematic error (bias), and R is the random error. All errors are random at some stage, which we denote as $S_{\text{inst}} \sim N(0, \sigma_{S_{\text{inst}}})$, for example, and $N(\mu, \sigma)$ is the normal distribution with mean μ and standard deviation σ .

It is often assumed that a new S_{inst} is generated if and only if the instrument is recalibrated, leading to new estimates of calibration parameters. Therefore, $\sigma_{S_{\text{inst}}}$ can be estimated by using calibration data and commensurate results for uncertainties in estimated parameters or by using measurement control (MC) data on standards. Replicate measurements on the same item allow us to estimate the standard deviation σ_R of R . It is always challenging to estimate $\sigma_{S_{\text{inst}}}$. In fact, because S_{item} varies from item to item, we would model it as random error, at least for the purposes of POV for ID evaluation. However, items having the same characteristics tend to have similar biases, so it is preferred to model S_{item} as being random within a class of items.

To some extent, how well the relevant properties of the standards match those of the items has always been an issue. This issue is becoming increasingly important in the United States. DOE complex because of the need to measure scrap, waste, and residues, which can have highly variable material composition. Often S_{item} can be included with R . The implication is that either S_{item} is negligible compared with R or auxiliary methods must be included to measure selected items as part of the MC program and thereby have data to support per-item estimates of systematic error. For example, we might be characterizing a nondestructive (NDA) neutron assay method using (4), but with $S_{\text{item}} + R$ redefined to be R .

If we use a “gold standard” assay method (with negligible S_{item}) such as calorimetry to occasionally remeasure an item, we can redefine σ_R appropriately, and use such item remeasurements to estimate σ_R . Some facilities maintain a remeasurement database that provides selected data for this purpose. As an important aside, it is necessary to separately estimate σ_S and σ_R to estimate $\sigma_{S_{\text{inst}}}$. After estimating $\sigma_{S_{\text{inst}}}$, it is usually acceptable to replace σ_R with

$$\sigma_{R_{\text{effective}}} = \sqrt{\sigma_R^2 + \sigma_S^2}.$$

In addition to remeasurement results, calibration data are useful for developing measurement error models by applying the results of statistical function fitting (such as regression and least squares fitting of response to predictors). Assay methods are often calibrated on items having accurately known SNM amounts; however, the material form of the calibration items might not match the form of test items in all respects, such as density, impurity effects, and source distribution. Therefore, statistical issues are often involved in designing experiments to assess the impact of mismatch between calibration standards and test items and to develop assay methods that measure and correct for mismatches.

2.8.3 Propagation of Variance

A common way to estimate the variance of a sum of measurements is to apply (2) and assume that two measurements have nonzero covariance if and only if they are in the same measurement group and made during the same calibration period. Other models such as additive error models are available (Taylor and Kuyatt 1994). The variance of a sum of two measured items using (4) (with $S_{\text{item}} + R$ redefined to be R) can be written as (Taylor and Kuyatt 1994)

$$\sigma_{M_1+M_2}^2 = \text{var}(T_1(1 + S_1 + R_1) + T_2(1 + S_2 + R_2)).$$

Because $S_1 = S_1$ during the same calibration period, it follows that

$$\sigma_{M_1+M_2}^2 = (T_1 + T_2)^2 \sigma_S^2 + (T_1^2 + T_2^2) \sigma_R^2. \quad (5)$$

Equation (5) follows either by applying the statistical principle that the variance of a sum of random variables is the sum of all variances plus the sum of all covariances, or by substituting the measurement error model (5) into the $M_1 + M_2$ expression and carefully interpreting terms as just shown. It is then straightforward to derive a useful formula for a given strata with SNM total T as shown by,

$$\sigma_T^2 = T^2 (\sigma_R^2/n + \sigma_S^2), \quad (6)$$

where $\sigma_R^2 (\sigma_S^2)$ is the sum of all random (systematic) error variances and n is the number of items in the strata. Or, more correctly,

$$\sigma_T^2 = T^2 (\sigma_R^2/n + \sigma_S^2) + (n-1)(S_T)^2 (\sigma_R)^2, \quad (7)$$

where

$$S_T^2 = \sum_{i=1}^n (T_i - \bar{T})^2 / (n-1).$$

Equation (7) differs from (6) only in the term $\sigma_R^2 = \sum_{i=1}^n (T_i - \bar{T})^2$, which is assumed to be zero in (6) “stream-average” assumption. Also, if there are recalibrations of all measurements on the same schedule (unlikely, but used for illustration here), with a total of n_{cal} recalibrations, then (6) is modified as,

$$\sigma_T^2 = T^2 (\sigma_R^2/n + \sigma_S^2/n_{\text{cal}}), \quad (8)$$

where again we use the stream average assumption. Generally, instruments will be recalibrated on different schedules, so no simple formulas are available. However, it is often useful to bind the correct solution by assuming two extreme cases: recalibrate each instrument after each measurement (effectively converting all errors to random errors) or never recalibrate. In the simplest case, we apply (6) to each strata. Sometimes we must also allow for nonzero covariance among terms in BI, EI, and R and among terms in EI and S or R and S (Burr et al. 1997).

2.8.4 Sequential or Trend Testing

In  Fig. 43, apparent losses on periods 12, 48, and 82 are followed by apparent gains in successive periods. Even if the three pairs of large values are removed, a large negative correlation remains between successive IDs  Fig. 44). This is consistent with a gaseous diffusion facility where large SNM (uranium, in this case) inventories are present, where a large inventory loss (or gain) for period “1” is followed by a large inventory gain (or loss) for period “2,” if there are no actual losses. Therefore, the inventory measurement error is a large contributor to σ_{ID} and leads to negative serial correlation.

 Figure 43
Monthly IDs

■ Figure 44

Same as  Fig. 43 except monthly IDs are plotted as $ID(t + 1)$ versus $ID(t)$

A typical performance measure for the NMA system of a declared facility is the magnitude of σ_{ID} . Note that because throughput usually increases for longer balance periods, a facility often can use more frequent balance closures (such as weekly rather than monthly) to reduce σ_{ID} . However, this will not improve the detection of protracted loss, and because facilities must monitor for abrupt and protracted loss, either sequential testing or at least monitoring IDs for trends is often used (Burr et al. 2003a, b).

Sequential tests include those for abrupt and protracted loss, and the best sequential test depends on the exact loss scenario. Therefore, in practice it is common to use a sequential test that performs well (although perhaps not as well as the best test for the given scenario) for a wide range of scenarios.

A large abrupt loss leads to a single large ID, and a large protracted loss leads to multiple large IDs. First, it is assumed that the random vector of IDs observed through the n th period $x = \{x_1, x_2, \dots, x_n\}$ is approximately normally distributed with mean μ_n and $n \times n$ covariance matrix Σ_{ID} . If no material loss occurs, then $\mu_n = 0$. The covariance matrix, Σ_{ID} , contains the variances of each ID along the diagonal, and the off-diagonal entries are the covariances.

We are concerned with tests for the null hypothesis $NH: \mu_n = 0$ versus an alternative hypothesis: $AH: \mu \neq 0$ with $\sum_{i=1}^n \mu_i > 0$.

The best test (the most power to detect loss for a given false alarm rate, in the sense of the Neyman Pearson lemma), depends on the exact form of the alternative hypothesis. We cannot

assume to know the exact form of the alternative hypothesis, or a test would be unnecessary (Avenhaus and Jaech 1981). Therefore, many tests have been proposed, with each test designed to do well for certain forms of the alternative hypothesis. Many tests are assembled to study their performance over a range of loss scenarios and covariance matrices. In practice, a facility would implement one or a few of these tests, depending on individual circumstances. If the false-alarm probability for any one test is denoted α , then α is the probability that the test alarms one or more times during the n balance periods when the null hypothesis of zero loss is true.

2.8.5 ID Test

The ID test is the same as a one-at-a-time Shewhart test, except that a serial correlation exists among successive IDs (Avenhaus and Jaech, 1981; Burr et al. 1995).

This test alarms if $x_i \geq h_i \sqrt{\sigma_i}$ for at least one i in $1, 2, \dots, n$, where $h = \{h_1, h_2, \dots, h_n\}$ is selected so that,

$$P(x_i \geq h_i \sqrt{\sigma_i}) \leq \alpha \quad \text{for at least one } i \text{ in } 1, 2, \dots, n.$$

Many methods can be used to select h . One method is to fix $h_i = h$ for all i and select this threshold via simulation. Analytical methods are also available but are complicated to compute because Σ_{ID} is not a diagonal matrix in general. Until Σ_{ID} is known, which in practice does not occur until the entire MUF (MUF is another name for the ID) sequence is observed, it is impossible to determine h to achieve the overall false-alarm rate of α .

2.8.6 SITMUF Test

The SITMUF test is the standardized, independently transformed MUF test (Picard 1987; Burr et al. 1995). This test is based on the unique linear transform of x to y that preserves the time ordering implied in x , and with the components of the transformed y being independent, approximately normally distributed random variables with variance 1.

To transform the original MUF sequence x to an independent sequence $y = \{y_1, y_2, \dots, y_n\}$, a well-known linear algebra method (Cholesky decomposition) is used. We assume that the measurement error covariance matrix of x , Σ , is estimated using variance propagation of all key measurements.

It is helpful to consider the y sequence as arising from calculating $y_t = x_t - E(x_t | x_{t-1}, \dots, x_1)$, where $E(x_t | x_{t-1}, \dots, x_1)$ is the expected (i.e., average) value of x_t given all previous x values, and then standardizing so that the variance, $\sigma_{y_t}^2 = 1$ for all balance periods t . The transformed vector, y , has mean μ_y that depends on the mean μ_n of x . Under the NH, $\mu_y = \mathbf{0}$. Under the AH, $\mu_y \neq \mathbf{0}$. The test alarms if $y_i \geq h_i$ for at least one i in $1, 2, \dots, n$, where $h = \{h_1, h_2, \dots, h_n\}$ is selected so that $P(y_i \geq h_i \text{ for at least one } i \text{ in } 1, 2, \dots, n) \leq \alpha$ for at least one i in $1, 2, \dots, n$ when $\mu_n = \mathbf{0}$.

Because the y_i are mutually independent, we have $h = z(1 - \alpha)^{1/n}$, where $h = z(1 - \alpha)^{1/n}$ is the $(1 - \alpha)$ quantile of the standard normal distribution. To explicitly show the time-order interpretation of the transformed vector, y , the transformation of the component x_i to y_i is written as $y_t = (x_t - E(x_t | x_{t-1}, \dots, x_1)) / \bar{\sigma}_i = (x_t - \sigma_{i-1}^T \Sigma_{i-1}^{-1} x_{i-1}) / \bar{\sigma}_i$, where $\bar{\sigma}_i = \sigma_i$, and where

we decompose Σ_i as

$$\Sigma_i = \begin{pmatrix} \Sigma_{i-1} \sigma_{i-1} \\ \sigma_{i-1}^T \sigma_{i,i} \end{pmatrix}.$$

These two expressions for y_t arise from a standard result for the multivariate normal distribution. The $\mathbf{y} = \{y_1, y_2, \dots, y_n\}$ sequence is referred to as the standard innovation sequence or the MUF residuals, and testing for loss in this sequence is the same as testing for loss in a sequence of independent normal random variables having mean zero and variance 1. However, because of the transformation from \mathbf{x} to \mathbf{y} , any true loss will also be transformed.

Picard (1987) has shown that a numerically stable and convenient way to calculate the SITMUF sequence from the MUF sequence is to apply the Cholesky decomposition of Σ as follows. For $\Sigma = \mathbf{C}\mathbf{C}^T$, where $\mathbf{C} = c_{ij}$ is the lower-triangular Cholesky factor, it can be shown that $\mathbf{y} = \mathbf{C}^{-1}\mathbf{x}$. The Cholesky decomposition is available in many standard linear algebra libraries, such as LinPack.

Other common tests in safeguards that consider more than one period at a time include cumulative MUF (CUMUF) and GEMUF (a likelihood ratio that is equivalent to the Mahalanobis distance from $\mathbf{0}$ at each time period).

Page's Test Applied to the SITMUF Sequence

An effective sequential test that is often used in nuclear safeguards and elsewhere is Page's test applied to the SITMUF sequence, y (Picard 1987; Burr et al. 1995). Picard (1987) examined other sequential tests and found that Page's test applied to the SITMUF sequence is competitive for a wide range of diversion scenarios. Other safeguards studies also evaluated sequential tests for safeguards and for anomaly detection in time series, such as a sequence of MUF values (Speed and Culpin 1986).

Page's test can be applied to any sequence, but its properties (e.g., average run length) are most easily studied if the sequence is independent. It is therefore common to apply Page's test to the SITMUF sequence. Page's test is similar to the CUMUF test but restarts the sum at 0 if the sum is negative. The motive for this restart mechanism is to achieve a compromise between the MUF statistic and the CUMUF statistic. Page's statistic applied to the SITMUF sequence, y , is defined as,

$$P_i(\mathbf{y}) = \text{maximum}(P_{i-1}(\mathbf{y}) + y_i - k, 0).$$

The test alarms if $P_i(\mathbf{y}) \geq h_i$ for some $i = 1, 2, \dots, n$, where the h_i are selected to give the desired false-alarm probability, α . The parameter k is a control parameter intended to give the user some control over the size loss that the test is well suited to detect. Generally, smaller values of k are best for detecting small protracted losses, and larger values of k are best for detecting abrupt losses. If we specify that we want good detection probability for a loss of 1σ , then $k = \sigma/2$ should be chosen. Because the y sequence is standardized to zero mean and variance is equal to 1, we choose $k = 1/2$.

2.8.7 Verifying Declarations

Verification measurements of items that are randomly selected from various strata (usually available inventory) at the time of physical inventory (PI) are compared to their book values. In

a processing area that measures each input “batch” and each output “batch,” there could be snapshots in time when the in-process batch is difficult to measure. Assume that we have input items that will change material form while in process, possibly distributing some SNM in glove boxes, pipes, furnaces, uncalibrated tanks, etc. In situations with non-negligible amounts of SNM in difficult-to-measure forms (“holdup”), “data-driven” rules could determine when a process area cleanout is required during PI.

“Data-driven” rules to determine when a process cleanout and PI are required include (1) σ_{CID} increases to its allowed upper limit (currently 2% of cumulative throughput since the previous cleanout); (2) the ID exceeds two or three times σ_{CID} ; (3) the ID exceeds (by a negotiated amount) what can be expected to be recovered from process cleanout; and (4) it has been more than a negotiated time (e.g., 5 years) since the previous cleanout.

Generally, facilities fall into two groups: (1) facilities that rely on activities during PI to get material into measurable form and (2) facilities that evaluate IDs in NRTA. Those of Type 1 probably need to continue to do periodic PIs and the associated verification or confirmation measurements of statistical samples of items in various strata. The LANL Plutonium Facility is of Type 2, provided in some cases that we assume that material control is adequate to allow certain shortcuts in assay methods. For example, the input material to one process is plutonium metal. This metal is weighed, and the weight is multiplied by a historical plutonium purity factor to estimate the plutonium mass. Strictly speaking, this is not a safeguards measurement because the plutonium is not directly measured (but a gross attribute gamma measurement is used to confirm the presence of plutonium). If a credible substitution scenario exists that material control procedures failed to detect, the input would be overestimated. Fortunately, the plutonium in the final product is assayed, so there is a loss detection capability. We believe it is acceptable to treat the input plutonium measurement as though it were a true plutonium assay, compare it with the assay of the plutonium output, and track the ID of each batch as well as the CID. And generally, many facilities could be granted certain shortcuts in assay methods, provided that material control procedures were adequate. When feasible, it is clearly preferred to have complete assay methods for all SNM streams.

In summary, for facilities that do batch tracking or some type of NRTA, it is possible to argue that the PI is required only when a “data-driven” rule as described comes into effect (Burr et al. 2001).

2.8.8 Other Purposes of the PI

Because it is desirable to reduce the PI frequency when feasible, it is important to recognize all of the purposes of the PI under current DOE practices. The purposes of the PI are as follows: for some facilities, the PI is the mechanism that allows IDs to be computed; and for all facilities, the PI provides a convenient time for auditors to ensure that the accounting system captures the true picture of SNM in the facility (the audit role to detect data falsification).

Suppose we measure all inputs and outputs for the MBA and do not rely on the PI to compute IDs. How will auditors know that the accounting system captures the true picture of SNM in the facility? In the case of international safeguards as performed by the IAEA, the effort to detect or deter data falsification is substantial because the IAEA must protect against the entire facility or state falsifying data. Generally, the threat of widespread data falsification is thought to be less in the context of domestic safeguards. Nevertheless, the MC&A approaches (such as the “difference statistic” D , which measures the average difference between operator

and inspector measurements) that have been in use for many years by the IAEA do provide a logical framework for evaluating verification measurements.

This chapter focuses on domestic safeguards; therefore, verifying facility declarations is not typically as high a priority as it is in international safeguards. Nevertheless, modern domestic safeguards approaches recognize that if IDs are evaluated frequently, the real goal of the PI is not to check for loss but to audit the facility's accounting records for accuracy. Therefore, verification measurements to verify book values of SNM items are required in domestic safeguards, much in the same way that the IAEA's difference statistic is used in international safeguards.

The IAEA's difference statistic D for a given stratum (e.g., inputs) is defined as the average difference between operator (o) and inspector (i) measurements for n items, multiplied by the number of items in the strata, N . That is,

$$D = N \sum_{i=1}^n (o_i - i_i) / n.$$

The IAEA's estimate of the ID is the operator's ID minus D . For example, consider a simple case with one input (x_1) and one output (x_2) measurement by the operator that are both verified by the IAEA (y_1 and y_2 , respectively). Then $ID - D = (x_1 - x_2) - \{(x_1 - y_1) + (x_2 - y_2)\} = (y_1 - y_2)$, which is the IAEA's ID. Usually, the IAEA or the domestic safeguards auditor verifies a small random sample from some or all strata (inputs, outputs, and inventory). In the case of the IAEA, the average difference in each strata is multiplied by Picard (1988) provides variance calculations (and the IAEA maintains several technical manuals regarding D) for several situations to estimate σ_D^2 and $\sigma_{ID-D}^2 = \sigma_D^2 - \sigma_{ID}^2$ (not obvious but true).

2.8.9 Sampling

Statistical sampling is used in several ways in safeguards. One of the most commonly used is attributes sampling, in which each measured item is either acceptable or not acceptable. Typically, in attributes sampling, a random sample n containers of SNM from a population of N containers is selected, and the population, N , is unacceptable if one of more defects is found in a sample of size n . This process is called "zero-acceptance" sampling, which refers to the fact that the only "acceptable" number of defects in the sample is zero.

The usual zero-acceptance sampling procedure is to specify the minimal detectable percent defective (p) and the detection probability ($1 - \beta$) (confidence level), then calculate sample size n and randomly select n items. Perform attributes tests on each selected item. The required sample size is approximated by: $n = N(1 - \beta/pN) = N(1 - \beta/D)$, where $D = pN =$ the minimal number of detectable defects.

Often, container tags and seals in a C/S program can reduce the required number of samples (Olinger et al. 2002). Properly sealed items can either be simply omitted from the list of possible items to measure, or inspection of the tag and seal constitutes a "measurement."

2.8.10 Difficulties with ID Evaluation

Issues that complicate ID evaluation include (1) the impact of holdup on σ_{ID} ; (2) serial correlation in successive IDs; (3) poorly characterized measurement quality leading to poor estimates

of σ_{ID} , and (4) time delays in measurement results. Issue 2 was addressed in the section on sequential testing. Issue 3 can be addressed by using a measurement control program that is designed to reflect accurately how measurements are actually performed. An example of Issue 4 is destructive analysis (DA) elsewhere, destructive assay of grab samples required to assay plutonium. Often, many days are required for DA lab results, so the ID cannot be computed in a timely manner, perhaps not until many days after a balance period closure. Typically, estimated values based on previous or target concentration values are allowed, but note that this introduces vulnerability unless plutonium presence is at least confirmed using rapid, low-accuracy confirmatory measurements. Generally, real facilities face processing challenges, and the impact of safeguards to operations needs to be as minor as possible. Ideally, safeguards measures are not viewed as pure overhead but can add value by forcing the operator thoroughly to understand and control the process.

We now consider Issue 1 by evaluating the impact of changing material holdup (poorly measured or unmeasured inventory) on ID evaluation. Changing holdup from period to period leads to larger-than-POV-based estimates of σ_{ID} .

Let $\Delta H = \text{Holdup}_i - \text{Holdup}_{i+1}$ be the change in holdup from balance period i to $i + 1$. The key point is that if holdup is changing (ΔH is nonzero), then instead of estimating the true loss, the ID estimates ΔH . Note that because of measurement error, the IDs vary randomly around ΔH . This error adds uncertainty to the ID equation that must be considered but is often difficult to quantify. Fortunately, NDA measurements are often very effective at estimating changes in holdup and sometimes effective in estimating holdup itself; thus, NDA measurements play a key role in holdup and ID evaluation.

2.8.11 Solution Monitoring

Solution monitoring (SM) is a form of process monitoring (see [Sect. 2.5](#)) that can be considered to provide a C/S capability. Experience to date has shown that SM is a challenging but useful safeguards measure that contributes to both NMA and C/S. Part of the challenge involves choosing effective evaluations of SM data that avoid data indigestion, enable anomaly detection and/or resolution, and do not burden the operator or the inspector with too many investigations.

Potential benefits of SM include improved abrupt loss detection while controlling for multiple tests, anomaly resolution, measurement error model validation, and data authentication. Data authentication results from the many internal consistency checks that arise when relating level, density, and temperature readings; these checks make it very difficult to alter data without being detected.

SM is the nearly continuous monitoring of solutions in all key process tanks. Typically, the level (L) and density (D) of the solution in a tank is obtained by measuring the differences in pressures that are required to bubble air through dip tubes located at various points in the tank. Temperature (T) is obtained via thermocouples. The (L, D, T) data are collected frequently, perhaps every few seconds or even less. At this stage, the data can be analyzed to check their validity, filtered, and perhaps compressed before they are uploaded to some form of real-time database. Various data storage and/or change-detection rules determine how frequently these measurements are archived (Miller and Howell 1999). The various time histories are then combined with tank calibrations to estimate their associated volume and mass histories. All of these histories can then be evaluated by so-called solution monitoring evaluation systems.

Burr et al. (1997) considered the effect of analyzing frequent IDs over small MBAs (individual tanks in this case) and concluded that in the worst-case protracted diversion scenario, less-frequent IDs over a single MBA, actually lead to higher detection probability. The proof used the Neyman Pearson lemma from classical statistics and assumed that the diversion was optimally (from the diverter's view) allocated. This worst-case loss vector is proportional to the sum of the rows of the variance-covariance matrix Σ_{ID} .

SM involves tanks and frequent balance closures (each transfer and wait mode in the example that follows). If the worst-case diversion occurred, it is straightforward to prove that the optimal strategy is to compare the total input to tank 1 with the total output from tank 15. This would be classical ID accounting, not SM as we have defined it. However, frequent balance closures around each transfer and wait mode will have very high detection probability against abrupt loss and nearly as high of a detection probability against the worst-case loss as an annual ID comparing tank 1 input with tank 15 output.

SM cannot improve protracted loss detection against this worst-case loss vector; however, it dramatically improves loss detection against other protracted loss vectors and against any abrupt loss (Burr et al. 2003a, b).

In addition, the bias corrections that become available via SM data could possibly reduce the volume measurement error, thereby leading to improved loss detection against even the worst-case loss vector. Shipments and receipts between tanks will have many paired comparisons; each of these should agree with the propagated total measurement error, or the error models must be refined.

Any statistically detectable diversion would have to be concealed by replacing the lost mass with a proper density solution. The adversary would have to work hard to conceal the diversion (and would probably be discovered at the time that plutonium was measured offline because of out-of-specification chemical species). The same type of calculations would apply if we use an in-tank plutonium concentration measurement, in which case the adversary would have no way to conceal a statistically detectable diversion.

2.8.12 Conclusions

This overview of statistical methods for nonproliferation at declared facilities included (1) POV of algebraic combinations such as products and sums of random variables, such as $\text{mass(uranium)} = \Sigma (\text{volume} \times \text{concentration})$; (2) measurement error modeling; (3) sequential testing to support NRTA; (4) specialty topics such as holdup and NDA of heterogeneous material; and (5) other specialty topics such as process and solution monitoring.

At declared facilities, the key statistical concept is variability and the main tool for ID evaluation is σ_{ID} . Statistical methods are used to estimate measurement uncertainties of individual assay methods and to combine these via the ID equation to estimate σ_{ID} . A numerical example is given in [▶ Sect. 2.9](#). In the broader nonproliferation context, monitoring for undeclared activities involves many statistical issues.

2.9 Accountancy for Abrupt Diversion

An example is given of validating a safeguards design for detection of abrupt diversion, based on a simplified PUREX-type MBA as shown in [▶ Fig. 45](#). The objective here is to solve

■ **Figure 45**
Example reprocessing material balance area (MBA)

for the inventory period at which the σ_{ID} equals the IAEA goal for the interim inventory. Greater inventory periods will then exceed the IAEA goal. A simplified statistical approach is used.

Sigma for the inventory difference (σ_{ID}), or in other words the overall measurement error at one standard deviation, is derived from the material balance of (9) to obtain (10), where t_0 is beginning time for the inventory period and t_{inv} the end.

$$M_{\text{inventory difference}} = M_{\text{receipts}} + (M_{\text{process}, t_0} - M_{\text{process}, t_{inv}}) - M_{\text{shipped}}, \quad (9)$$

$$\sigma_{ID}^2 = \sigma_{\text{receipts}}^2 + \sigma_{\text{process}, t_0}^2 + \sigma_{\text{process}, t_{inv}}^2 + \sigma_{\text{shipped}}^2. \quad (10)$$

If an approximation is made that the mass of each receipt measurement is equal, the mass of each shipment measurement is equal, and the mass of similar process measurements is equal, then (11) and (12) can be used to represent random (σ_r) and systematic errors (σ_s). As shown in (11) and (12), “ M ” represents the total mass measured during the inventory period, “ n ” the number of measurements made during the inventory period, and “ ε ” the percent or fractional measurement error at one standard deviation.

$$\sigma_r^2 = \sum_{i=1}^{n_r} \left(\frac{M}{n_r} \varepsilon_{r,i} \right)^2,$$

$$\varepsilon_1 = \varepsilon_2 = \dots = \varepsilon_n,$$

$$\sigma_r^2 = \frac{1}{n_r} (M \varepsilon_r)^2, \quad (11)$$

$$\sigma_s = \sum_{i=1}^{n_s} \frac{M}{n_s} \varepsilon_{s,i},$$

$$\sigma_s = M \varepsilon_s. \quad (12)$$

If it is also assumed that the mass of process holdup at the beginning of the inventory period t_0 is approximately equal to the end of the inventory period t_{inv} , then (10) through (12) can be combined to yield (13). This approximation represents steady-state operation. As shown in (13), “ x ” represents the fraction of process holdup in tanks, $(1 - x)$ the fraction in “other” process

equipment, such as solvent extraction equipment, precipitation equipment, etc.

$$M_{\text{process}, t_0} \approx M_{\text{process}, t_{\text{inv}}},$$

$$\begin{aligned} \sigma_{\text{ID}}^2 = & M_{\text{receipts}}^2 \left(\frac{\varepsilon_{r,\text{receipts}}^2}{n_{r,\text{receipts}}} + \varepsilon_{s,\text{receipts}}^2 \right) \\ & + 2M_{\text{process}}^2 \left[x^2 \left(\frac{\varepsilon_{r,\text{process,tanks}}^2}{n_{r,\text{process,tanks}}} \right) + (1-x)^2 \left(\frac{\varepsilon_{r,\text{process,other}}^2}{n_{r,\text{process,other}}} \right) + \varepsilon_{s,\text{process}}^2 \right] \\ & + M_{\text{shipped}}^2 \left(\frac{\varepsilon_{r,\text{shipped}}^2}{n_{r,\text{shipped}}} + \varepsilon_{s,\text{shipped}}^2 \right). \end{aligned} \quad (13)$$

If it is further assumed that the mass of receipts is approximately equal to that of shipments, then (13) can be further simplified as (14). Once again, this approximation represents steady-state operation.

$$M_{\text{receipts}} \approx M_{\text{shipped}},$$

$$\begin{aligned} \sigma_{\text{ID}}^2 = & M_{\text{receipts}}^2 \left[\left(\frac{\varepsilon_{r,\text{receipt}}^2}{n_{r,\text{receipt}}} + \varepsilon_{s,\text{receipt}}^2 \right) \right] + \left(\frac{\varepsilon_{r,\text{shipped}}^2}{n_{r,\text{shipped}}} + \varepsilon_{s,\text{shipped}}^2 \right) \\ & + 2M_{\text{process}}^2 \left[x^2 \left(\frac{\varepsilon_{r,\text{process,tanks}}^2}{n_{r,\text{process,tanks}}} \right) + (1-x)^2 \left(\frac{\varepsilon_{r,\text{process,other}}^2}{n_{r,\text{process,other}}} \right) + \varepsilon_{s,\text{process}}^2 \right]. \end{aligned} \quad (14)$$

Receipts, process and product measurements each consist of a bulk and concentration measurement. In the case of the tanks, bulk measurement consists of tank volume. In the case of oxides, bulk measurement consists of mass.

$$\sigma_{\text{measurement}}^2 = \sigma_{\text{bulk}}^2 + \sigma_{\text{concentration}}^2,$$

$$\sigma_b = \sigma_{\text{bulk}},$$

$$\sigma_c = \sigma_{\text{concentration}}.$$

Covariance applies to systematic errors for which they approximately cancel when the same or a similar instrument is used. An example of this is concentration measurement for receipts and shipments. The oxide is dissolved and then the plutonium concentration is determined with an instrument similar to that used for the receipt inventory tank. This also applies to the beginning and end process holdup measurements.

$$\sigma_{s,\text{receipts},c} = 0,$$

$$\sigma_{s,\text{receipts},c} = 0,$$

$$\sigma_{s,\text{process}} = 0.$$

Equation (15) reflects the incorporation of bulk and concentration measurement error, plus the elimination of systematic error for receipt and shipment concentration, and the elimination of

systematic error for all process holdup measurements.

$$\begin{aligned} \sigma_{ID}^2 = & M_{\text{receipts}}^2 \left[\left(\frac{1}{n_{r,\text{receipts}}} \right) (\varepsilon_{r,\text{receipts},b}^2 + \varepsilon_{r,\text{receipts},c}^2) + \varepsilon_{s,\text{receipts},b}^2 \right] \\ & + M_{\text{receipts}}^2 \left[\left(\frac{1}{n_{r,\text{shipped}}} \right) (\varepsilon_{r,\text{shipped},b}^2 + \varepsilon_{r,\text{shipped},c}^2) + \varepsilon_{s,\text{shipped},b}^2 \right] \\ & + 2M_{\text{process}}^2 \left[x^2 \left(\frac{\varepsilon_{r,\text{process,tanks}}^2}{n_{r,\text{process,tanks}}} \right) + (1-x)^2 \left(\frac{\varepsilon_{r,\text{process,other}}^2}{n_{r,\text{process,other}}} \right) \right]. \end{aligned} \quad (15)$$

As previously mentioned, the objective for this example is to solve for the inventory period at which the σ_{ID} equals the IAEA goal for interim inventory. For this reasons, the number of measurements are expressed in terms of the inventory period, t_{inv} .

$$\begin{aligned} n_{r,\text{receipts}} &= \left(\frac{M_{\text{receipts},1 \text{ year}}}{t_{1 \text{ year}}} \right) \left(\frac{t_{\text{inv}}}{M_{\text{receipts},\text{inv}}} \right), \\ n_{r,\text{shipped}} &= \left(\frac{M_{\text{shipped},1 \text{ year}}}{t_{1 \text{ year}}} \right) \left(\frac{t_{\text{inv}}}{M_{\text{shipped},\text{inv}}} \right) \approx \left(\frac{M_{\text{receipts},1 \text{ year}}}{t_{1 \text{ year}}} \right) \left(\frac{t_{\text{inv}}}{M_{\text{shipped},\text{inv}}} \right), \\ M_{\text{receipts}} &= \left(\frac{M_{\text{receipts},1 \text{ year}}}{t_{1 \text{ year}}} \right) t_{\text{inv}}. \end{aligned}$$

Based on an 800-MTHM/year reprocessing facility (1% plutonium in spent fuel), operation of 250-days/year, with a process holdup equal to 10% of the annual throughput, (16) is produced from (15). The number of receipt measurements is based on 55 kg-Pu/measurement (inventory tank), and that for shipment is based on 5 kg-Pu/measurement (product can). The number of tanks within the process is assumed to be eight of equal inventory, and unique pieces of process equipment are six of equal inventory. These numbers are oversimplifications for the sake of example.

$$M_{\text{receipts},1 \text{ year}} \approx M_{\text{shipped},1 \text{ year}} \approx \left(\frac{0.01 \text{ MT-Pu}}{\text{MTHM}} \right) \left(\frac{1,000 \text{ kg}}{\text{MT}} \right) \left(\frac{800 \text{ MTHM}}{\text{year}} \right),$$

$$t_{1 \text{ year}} = 250 \text{ days/year},$$

$$M_{\text{receipts},\text{inv}} \approx 55 \text{ kg Pu},$$

$$M_{\text{shipped},\text{inv}} \approx 5 \text{ kg Pu},$$

$$n_{r,\text{process,tanks}} = 4,$$

$$n_{r,\text{process,other}} = 3,$$

$$M_{\text{process}} = 0.1(M_{\text{receipts},1 \text{ year}}),$$

$$x = 0.9,$$

$$n_{r,\text{receipts}} = \frac{8,000 \text{ kg-Pu/year}}{250 \text{ day/year}} \left(\frac{t_{\text{inv}}}{55 \text{ kg Pu}} \right) = \left(\frac{800}{1,375} \right) t_{\text{inv}},$$

$$\begin{aligned}
 n_{r,\text{shipped}} &= \left(\frac{8,000 \text{ kg-Pu/year}}{250 \text{ day/year}} \right) \left(\frac{t_{\text{inv}}}{5 \text{ kg Pu}} \right) = \left(\frac{800}{125} \right) t_{\text{inv}}, \\
 M_{\text{receipts}} &= \left(\frac{M_{\text{receipts,1 year}}}{t_{1\text{year}}} \right) t_{\text{inv}} = \left(\frac{8,000 \text{ kg-Pu/year}}{250 \text{ day/year}} \right) t_{\text{inv}} = 32t_{\text{inv}}, \\
 M_{\text{process}} &= 0.1(M_{\text{receipts,1 year}}) = 800 \text{ kg-Pu/year}, \\
 \sigma_{\text{ID}}^2 &= (32t_{\text{inv}})^2 \left\{ \left[\frac{1,375}{800} \left(\frac{1}{t_{\text{inv}}} \right) \right] (\varepsilon_{r,\text{receipts},b}^2 + \varepsilon_{r,\text{receipts},c}^2) + \varepsilon_{s,\text{receipts},b}^2 \right\} \\
 &+ (32t_{\text{inv}})^2 \left\{ \left[\frac{125}{800} \left(\frac{1}{t_{\text{inv}}} \right) \right] (\varepsilon_{r,\text{shipped},b}^2 + \varepsilon_{r,\text{shipped},c}^2) + \varepsilon_{s,\text{shipped},b}^2 \right\} \\
 &+ 2(800 \text{ kg Pu})^2 \left[(0.9)^2 \left(\frac{\varepsilon_{r,\text{process,tanks}}^2}{8} \right) + (1 - 0.9)^2 \left(\frac{\varepsilon_{r,\text{processed,other}}^2}{6} \right) \right]. \quad (16)
 \end{aligned}$$

Rearranging (16) to solve for t_{inv} yields,

$$\begin{aligned}
 1,024 (\varepsilon_{s,\text{receipts},b}^2 + \varepsilon_{s,\text{shipped},b}^2) t_{\text{inv}}^2 &+ [1,760 (\varepsilon_{r,\text{receipts},b}^2 + \varepsilon_{r,\text{receipts},c}^2)] t_{\text{inv}} \\
 &+ [160 (\varepsilon_{r,\text{shipped},b}^2 + \varepsilon_{r,\text{shipped},c}^2)] t_{\text{inv}} + 129,600 (\varepsilon_{r,\text{process,tanks}}^2) \\
 &+ 2,133 (\varepsilon_{r,\text{process,other}}^2) - \sigma_{\text{ID}}^2 = 0. \quad (17)
 \end{aligned}$$

And finally, the following typical measurement errors (fractional standard deviation) have been approximated for existing PUREX reprocessing facilities. The measurement errors for process equipment are chosen only for the example, and may not represent actual operations.

$$\begin{aligned}
 \varepsilon_{r,\text{receipts},b} &= 0.003, \\
 \varepsilon_{r,\text{receipts},c} &= 0.003, \\
 \varepsilon_{s,\text{receipts},b} &= 0.003, \\
 \varepsilon_{r,\text{shipped},b} &= 0.0005, \\
 \varepsilon_{r,\text{shipped},c} &= 0.002, \\
 \varepsilon_{s,\text{shipped},b} &= 0.0005, \\
 \varepsilon_{r,\text{process,tank}}^2 &= \varepsilon_{r,\text{process,tank},b}^2 + \varepsilon_{r,\text{process,tank},c}^2 = (1.5\varepsilon_{r,\text{receipts},b})^2 + \varepsilon_{r,\text{receipts},c}^2 = 0.000029, \\
 \varepsilon_{r,\text{process,other}}^2 &= \varepsilon_{r,\text{process,tank},b}^2 + \varepsilon_{r,\text{process,tank},c}^2 = (0.01)^2 + (0.01)^2 = 0.0002.
 \end{aligned}$$

The IAEA goal for interim inventory requires that $3.3 \sigma_{\text{ID}}$ is less than or equal to a significant quantity of SNM (8 kg Pu). The 3.3 factor represents high confidence of detection, and the goal can then be rewritten as:

$$3.3\sigma_{\text{ID}} \leq 8 \text{ kg Pu}. \quad (18)$$

Equation (17) is a quadratic in t_{inv} where the solution is given by (19). There are two roots to the equation, -15 and 12, with 12-days being the “real” solution. Therefore, for this example, to satisfy the IAEA goal, the interim inventory period must be 12-days or less.

$$t_{\text{inv}} = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} = \frac{-0.032 \pm \sqrt{0.0639}}{0.019} = (-15 \text{ and } 12). \quad (19)$$

Acknowledgments
